Acknowledgments

The authors gratefully acknowledge the assistance of the following individuals and organizations whose contributions made publication of this textbook possible:

**St. Louis, Missouri:** Catherine F. Castner, RN, BSN; Sandra E. Decker; John H. Niemeyer, MD; John D. Brooks, CCP; Elizabeth White
The Missouri Baptist Health Care Foundation

**Cleveland, Ohio:** Michelle Haywood; Luci Mitchin; Tess Parry; Kristin Purdy; Gina Ventre
Cleveland Clinic

**Stanford, California:** Sam Suleman; V. Mohan Reddy, MD; Frandics Chan, MD; and Norman Silverman MD, for their expertise and contributions

**Birmingham, Alabama:** Dr. David McGiffin for his expertise and contributions
Ms. Peggy Holmes for her expert editorial assistance
Preface to Fourth Edition

The fourth edition of Cardiac Surgery has been prepared without contributions from two of the authors of the third edition, Drs. Robert B. Karp and Donald B. Doty. Dr. Karp was fatally injured in an automobile accident in 2006. Dr. Doty retired from the practice of cardiothoracic surgery in 2004. We are extremely grateful to both of them for their outstanding contributions, many of which remain in the fourth edition. We are equally pleased to welcome as a contributor to the fourth edition, Dr. James K. Kirklin, son of Dr. John W. Kirklin, co-author with Sir Brian Barratt-Boyes of the first two editions of Cardiac Surgery.

Except for Dr. Frank Hanley, we received our cardiothoracic surgical education at the University of Alabama Medical Center under the tutelage of John Kirklin, and we were privileged to serve as faculty members in the Department of Surgery at the University of Alabama at Birmingham School of Medicine during his tenure as chair of the department and director of the Division of Cardiothoracic Surgery. James Kirklin currently serves as director of that division.

We have all, including Dr. Hanley, been profoundly influenced by the teachings of John Kirklin, and by his intellect, vision, and clinical skills. His commitment to improving the quality of cardiac surgery through rigorous clinical and laboratory investigations and providing superb clinical care and disciplined training of young surgeons was truly exemplary. Although our interactions with Sir Brian Barratt-Boyes were less frequent and less intense, he possessed these same attributes and was an inspiration to us as well. In the last year of his life, he was engaged in updating the echocardiographic and structural valve deterioration data of the entire Green Lane Hospital experience of aortic allografts, with the intent of transmitting these data for analysis by one of us (EHB).

The systematic approach to cardiac surgery developed and promulgated by these two pioneering surgeons, who both died between publication of the third and this fourth edition of Cardiac Surgery, has been a major fixture in our professional careers. The decision to author the third and now fourth editions of Cardiac Surgery was in large part influenced by our desire to perpetuate their philosophical approach to this discipline. Thus, the general format of the three previous editions has been maintained.

All chapters present in the third edition have been revised. They have been rearranged so that every chapter relating to surgical treatment of congenital heart disease (except for Chapter 29, “Congenital Heart Disease in the Adult”) has been placed in Volume 2. Each chapter was rewritten with input from at least two of the four authors. Chapter 4 (“Anesthesia for Cardiovascular Surgery”) was revised by Drs. Colleen G. Koch and Chandra Ramamoorthy. The content, and in some instances the titles, of several chapters have been altered to reflect current knowledge and practice. As an example, the chapter “Heart Failure” in the third edition has been expanded into three chapters in the fourth edition: “Cardiomyopathy,” “Cardiac Transplantation,” and “Mechanical Circulatory Support.” New illustrations and new echocardiographic, computed tomographic, and magnetic resonance images have been added to reflect important advances in the diagnosis and management of congenital and acquired diseases of the heart and great vessels.

We recognize the potential limitation of four authors writing separate portions of this textbook. This challenge was met, in part at least, by dual authorship of each chapter, and by author meetings and correspondence. It was also met by a process of universal review. Specifically, as with the third edition, Dr. Blackstone was designated as the final arbiter. After completion of the revision of each chapter by the primary author, copyedited material was forwarded to Dr. Blackstone in Cleveland, where he and his assistant, Tess Muharsky Parry, reviewed, edited, reorganized, questioned, and adjudicated the entire content of each chapter. It is our hope that this intensive process has improved the accuracy and comprehensiveness of each chapter.

As in the previous editions, Part I of Volume 1 discusses basic concepts of cardiac surgery: anatomy, support techniques, myocardial management, anesthesia, postoperative care, and methodology for generating new knowledge from previous experience. These core chapters are applicable to the broad audience of medical professionals who care for patients with cardiac disease. The remaining chapters of Volume 1 (Parts II to V) discuss specific acquired diseases of the heart and great vessels, and congenital heart disease in adults. This edition has retained, in these later sections and in all of the chapters in Volume 2, presentation of “Indications for Operation” at the end of each chapter, because the indications are the derivatives of comparison of various outcomes (results) of alternative forms of treatments, including no treatment (natural history).

The abbreviation UAB has been retained, and is used to identify data and illustrations from the University of Alabama at Birmingham; similarly, GLH identifies those from Green Lane Hospital in Auckland, New Zealand. The bibliographic references are again designated using the first letter of the surname of the first author and a number (e.g., L4), rather than simply a number. This convention is simple and convenient, and allows the reader to easily locate a given author’s publication among the alphabetically arranged references. The abbreviation CL is used throughout to denote 70% confidence limits around the point estimate. The reasons for presenting 70% rather than 95% or 50% confidence limits are presented in Chapter 6.

The fourth edition is written at a time of great change for the specialty of cardiac surgery. Percutaneous catheter-based interventions are being increasingly used to treat patients with
coronary arteriosclerotic heart disease, aortic valve stenosis, mitral valve regurgitation, hypertrophic obstructive cardiomyopathy, diseases of the thoracic aorta, and congenital cardiac lesions such as patent ductus arteriosus, coarctation of the aorta, atrial and ventricular septal defects, and pulmonary valvar stenosis and regurgitation. Less invasive techniques are rapidly being incorporated into cardiac surgical practice for many conditions that continue to require open surgical repair. These advances must be acknowledged and embraced if cardiac surgery is to thrive in the future.

It is our hope that this textbook will be of value to cardiac surgeons who care for patients with congenital and acquired heart disease and with disorders of major blood vessels in the chest, as well as to cardiologists and interventional cardiologists who treat children and adults with these conditions, anesthesiologists, intensivists, pulmonologists, imaging specialists, cardiovascular nurses, trainees in all of these disciplines, and others.

CORONARY ARTERIAL SUPPLY TO SPECIALIZED AREAS OF THE HEART 23

Dimensions of Normal Cardiac and Great Artery Pathways 25
DIMENSIONS OF THE PATHWAY 25
NORMALIZATION OF PATHWAY DIMENSIONS 26

STANDARDIZATION OF DIMENSIONS 26
DIMENSIONS OF THE PULMONARY ARTERIES 29
RELATING DIMENSIONS TO OUTCOME 29

Dimensions of Normal Ventricles 29
Terminology and Classification of Heart Disease 30
SITUS OF THE THORACIC VISCERA AND ATRIA 30
SITUS OF THE VENTRICLES 31
COMPLETENESS OF THE VENTRICLES 31
DOMINANCE OF THE VENTRICLES 31
CARDIAC CONNECTIONS 31
CARDIAC AND ARTERIAL POSITIONS 32
ATRIOVENTRICULAR FLOW PATHWAYS 32
DEFECTS AND ABNORMALITIES 32
CONVENTIONAL DIAGNOSES 32
SYMBOLIC CONVENTION OF VAN PRAAGH 33

Appendixes
1A: Morphogenesis 33
1B: Normal Pathway Dimensions from Autopsy Specimens 33
1C: Normal Pathway Dimensions from Cineangiography 36
1D: Normal Pathway Dimensions from Two-Dimensional Echocardiography 39
1E: Comparison of Pathway Dimensions from Different Measurement Modalities 46
1F: Comparison of Methods for Normalizing the Dimensions of Pulmonary Arteries 48
1G: Normal Ventricular Volume, Masses, and Dimensions from Different Measurement Modalities 49
1H: Illustrative Models of Congenital Heart Disease 61
This chapter describes normal cardiac and great artery anatomy and dimensions, as well as the terminology usually employed.

**CARDIAC CHAMBERS AND MAJOR VESSELS**

Accurate diagnosis of congenital heart defects depends in part on identifying cardiac chambers and major vessels by their morphology, regardless of their spatial positions (Fig. 1-1).

**Right Atrium**

The right atrium (Fig. 1-2) is the heart chamber that normally receives systemic venous drainage from inferior and superior venae cavae. It also normally receives the major portion of coronary venous drainage from the coronary sinus. Morphologic characteristics important for identifying the right atrium are presence of the limbus of the fossa ovalis, which surrounds the valve of the fossa ovalis (septum primum) superiorly, anteriorly, and posteriorly; a wide-based, blunt-ended, right-sided atrial appendage (auricle); eustachian valve at the orifice of the inferior vena cava and thebesian valve at the orifice of the coronary sinus; and crista terminalis, which separates trabeculated from nontrabeculated (venous) portions of the atrium (Fig. 1-3).

The normal structures are sometimes expressed in an excessive or unusual manner. These are not themselves functionally important abnormalities but are usually associated with cardiac malformations. Thus, the eustachian and thebesian valves may be sufficiently prominent to appear to divide the right atrium into two parts, a common finding in tricuspid atresia. The right atrial appendage may be juxtaposed leftward, and the left atrial appendage is less frequently juxtaposed rightward. Juxtaposition of the atrial appendages is usually associated with cardiac malformations.

Radiologically, the definitive morphologic features of the right atrium may be difficult to recognize. Occasionally, the atrial septum is seen well enough in angiographic profile to delineate the limbus of the fossa ovalis, and sometimes the right atrial appendage is outlined sufficiently to differentiate its shape from that of the left atrial appendage. The fact that the hepatic portion of the inferior vena cava usually drains into the right atrium often makes it possible to determine the location of the right atrium by passage of a catheter from the inferior vena cava to the heart. Cardiovascular magnetic resonance imaging (MRI) and three-dimensional (3D) echocardiographic computed tomography are increasingly able to identify even complex morphologic features of this and other cardiac chambers and their connections.

**Left Atrium**

The left atrium (Fig. 1-4) is the cardiac chamber that normally receives pulmonary venous drainage from the four pulmonary veins. Its septal surface is characterized by the flap valve of the fossa ovalis (septum primum), in contrast to the limbus of the fossa ovalis present on the right atrioseptal surface. The left atrial appendage (auricle) is long and narrow, in contrast to bluntness of the right atrial appendage, and is the best indicator that the atrium is morphologically a left atrium. There is no crista terminalis at the base of the left atrial appendage, the only trabeculated structure in the left atrium.

In general, at cardiac catheterization, the location of the left atrium is determined by exclusion after identifying the position of the right atrium as described earlier. With normal pulmonary venous connection, the left atrium may

---

**Figure 1-1** Surface anatomy of heart. Left atrial appendage is long and narrow, whereas right atrial appendage is short and blunt. Aorta originates posterior and to the right of the pulmonary trunk at the base of the heart, but is anterior and to the right by the pericardial reflection (not shown). Right ventricle occupies most of anterior aspect of heart, with left ventricle forming the apex and posterior aspects.
**Figure 1-2** Interior of normal right atrium, viewed from right side at operation. Key: AA, Atrial appendage; AnMV, position of mitral valve anulus on other side of septum, indicated by dotted line; AnTV, anulus of tricuspid valve, indicated by dotted line; ASCTV, anteroseptal commissure of tricuspid valve; CS, coronary sinus orifice; CT, crista terminalis (inside of sulcus terminalis); EuV, eustachian valve; FO, fossa ovalis (sometimes called septum primum); IVC, inferior vena cava orifice; LFO, limbus of fossa ovalis (C-shaped, extending anteriorly and posteriorly to enclose fossa ovalis); SLTV, septal leaflet of tricuspid valve; SVC, superior vena cava orifice; ThV, thebesian valve; TT, tendon of Todaro; X, muscular portion of atrioventricular septum; Z, membranous portion of atrioventricular septum.

**Figure 1-3** Interior of right atrium, oriented as at operation. Right atrium receives superior and inferior venae cavae. Its trabeculated portion is separated from its smooth portion by the crista terminalis. Fossa ovalis is located in center of atrial septum, surrounded on its superior, anterior, and posterior aspects by the limbus. Coronary sinus is positioned inferiorly. Coronary sinus, along with tendon of Todaro and anulus of septal leaflet of tricuspid valve, form the boundaries of triangle of Koch. Atrioventricular node and proximal portions of bundle of His, portions of the specialized conduction system, lie within the triangle of Koch. Right coronary artery lies in atrioventricular groove, the anatomic point of separation of right atrium and right ventricle.
be well opacified after a right ventricular or pulmonary artery injection.

Right Ventricle

Topographically, the right ventricle has a large sinus portion that surrounds and supports a tricuspid atrioventricular (AV) valve (inlet portion) and includes the apex and a smaller infundibulum (outlet portion) that supports a semilunar valve. The inlet and outlet valves of the right ventricle are thus widely separated. The entire sinus portion of the right ventricle and most of the infundibulum (both free wall and septum) are coarsely trabeculated.

The septal surface of the right ventricle is divided into an inlet portion, a trabecular portion (sometimes called the apical trabecular portion), and an outlet portion (Fig. 1-5). Alternatively, the septal surface of the right ventricle may be divided into posterior (basal), middle, apical (anterior), and infundibular (conal) portions (Fig. 1-6). The inlet portion of the ventricular septum surrounds and supports the tricuspid valve. The trabecular portion is that portion with the coarse trabecular pattern typical of the right ventricle (see Fig. 1-6). The outlet portion of the right ventricular aspect of the ventricular septum is smooth but complex and has three components. The largest is the infundibular (conal) septum, which separates the pulmonary from the aortic and tricuspid valves. Only part of the infundibular septum is interventricular (see Fig. 1-5), and in some malformations (e.g., double outlet right ventricle), none of it may be. It must be emphasized that the most distal cephalad portion of the infundibular septum is not, strictly speaking, part of the ventricular septum, because in the normal heart, the pulmonary valve arises from the apex of a cone of muscle and does not have a septal attachment.

A second part of the outlet portion of the septum is the anterior (superior) extension, or division, of the trabecula septomarginalis (septal band). A third small, very anterior portion is a narrow extension superior to the trabecular septum. Laterally to the right, the infundibular septum imperceptibly merges with the free right ventricular wall immediately beyond its attachment to the membranous septum; at that point, it can be called the parietal extension of the infundibular septum (Fig. 1-7). The parietal band lies anterior to the right aortic sinus (see Fig. 1-7), partially overlying that portion of the free wall of the right ventricle termed the ventriculo-infundibular fold. Many surgeons call the infundibular septum and the parietal band the crista supraventricularis. Medially and to the left, the infundibular septum merges with the trabecular portion of the septum between the limbs of the particularly prominent smooth, Y-shaped muscle bundle called the trabecula septomarginalis (Fig. 1-8). The trabecula septomarginalis extends apically to become continuous with the moderator band, a prominent trabeculation running from septum to free wall.

1The phrase inlet septum is in some ways undesirable because the term has developmental implications, and the large inlet septum on the right ventricular side is not duplicated on the left side. Use of the term trabecular to describe a portion of the sinus septum is also undesirable in some ways because part of the infundibular septum is also trabeculated (see Fig. 1-5).
Figure 1-5  Interior of normal right ventricle, particularly trabecular and outlet portions, oriented as at operation. Infundibular (conal) septum separates pulmonary valve from tricuspid valve, and only its rightward portion and inferior part of its central portion form part of the interventricular septum (see also Fig. 1-6). Entire outlet portion of septum of infundibulum is composed of the septal extension of infundibular septum, anterior limb of trabecula septomarginalis (septal band), and in front of that, a heavily trabeculated portion of septum. Key: AL, Anterior (superior) limb of TSM; AP, anterior papillary muscle; InfS, infundibular (conal) septum; MB, moderator band; MS, position of membranous septum; PE, parietal extension of infundibular septum (parietal band); PL, posterior limb of TSM, giving origin to medial papillary muscle; SE, septal extension of infundibular septum; TS, trabeculated portion of septum, part of which lies in infundibulum and remainder in sinus portion of ventricle; TSM, trabecula septomarginalis (septal band); VIF, ventriculoinfundibular fold.

Figure 1-6  Right ventricular side of septum after right atrium, right ventricle, and pulmonary trunk have been exposed by removing their anterior walls and rightward portion of aorta and parietal band (or parietal extension of infundibular septum). Entire right ventricular septum is displayed, together with relationship of infundibular septum to aortic root. In this heart, infundibular septum is less prominent than in some. Dashed line defines atroventricular portion of membranous septum. Dotted lines define arbitrary division of sinus septum into posterior (beneath septal tricuspid leaflet), middle, and apical portions. Specimen corresponds to a right anterior oblique projection in cineangiography. Key: A, Left anterior division septal band; Ao, aorta; CoS, coronary sinus; FO, fossa ovalis; IS, cut end of infundibular septum; NC, noncoronary aortic sinus; P, right posterior division of septal band; PT, pulmonary trunk; R, right coronary aortic sinus; SLTV, septal tricuspid leaflet; TSM, trabecula septomarginalis (septal band).
The junction between outlet and sinus (trabecular) portions of the right ventricle is clearly demarcated only along the lower margin of the outlet portion of the septum. The incomplete muscular ridge formed by the outlet septum (here, specifically, the infundibular septum) and the parietal band, together with the septal and moderator bands, forms a natural line of division between the posteroinferior sinus portion and the anterosuperior outlet portion of the ventricle. \(^2\) It is in this area that ventricular septal defects (VSDs) most commonly occur; the morphology of this area gives the name “junctional,” or “conoventricular,” to these defects.

The papillary muscle arrangement supporting the three leaflets of the tricuspid valve is different from that of the mitral valve in the left ventricle. In the case of the tricuspid valve, in addition to a single large anterior papillary muscle attached to the anterior free wall that fuses with the moderator band, there are multiple smaller posterior papillary muscles attached partly to the posterior (inferior) free wall and partly to the septum, and a group of small septal papillary muscles. The lowermost of these small septal muscles attaches posterior to the trabecula septomarginalis (see Fig. 1-5) and the uppermost, called the *medial (conal) papillary muscle* (muscle of Lancisi or muscle of Luschka), to the posterior limb of the septal band (Fig. 1-9).

**Left Ventricle**

The left ventricle consists of a larger sinus portion, which supports a bicuspid AV valve and includes the apex, and a much smaller outlet (outflow) portion beneath a semilunar...
valve. The inlet and outlet valves of the left ventricle lie juxtaposed within its base, and inflow and outflow portions are separated by the anterior mitral leaflet\textsuperscript{2} (Fig. 1-10).

The entire free wall of the left ventricle and apical half to two thirds of the septum are trabeculated (Fig. 1-11; see also Fig. 1-10), but the trabeculations are characteristically fine compared with those in the right ventricle.\textsuperscript{3}\textsuperscript{1} The septal surface of the left ventricle may be considered to have a sinus portion, most of which is trabeculated, and a smooth outlet (outflow) portion (see Fig. 1-11). The part of the sinus portion of the septum immediately beneath the mitral valve may be termed the \textit{inlet septum}, and the rest of the sinus portion, the \textit{trabecular septum} (Fig. 1-12). The outlet (outflow) portion lies in front and to the right of the anterior mitral leaflet, corresponding to the inlet portion on the right ventricular side of the septum, and includes the AV septum (Fig. 1-13). In contrast to the right ventricular side, where the septal tricuspid leaflet is the only valvar attachment to the septum, on the left ventricular side, the rightward half of the anterior mitral valve leaflet attaches to the septum posteriorly, and the right and part of the noncoronary aortic cusps attach to it anteriorly (see Fig. 1-12). The leftward half of the anterior mitral leaflet is in fibrous continuity with the aortic valve in an area termed the \textit{aortic–mitral anulus} (Fig. 1-14; see also Figs. 1-12 and 1-13). The anteriorly placed right ventricular infundibular (conal) septum lies opposite the aortic valve (Fig. 1-15). It may occasionally be displaced into the left ventricular outflow beneath the aortic valve; occasionally, muscle may also extend between the aortic and mitral valves, forming a true infundibulum to the left ventricle (see Fig. 1-10). The papillary muscles are called \textit{anterolateral} (or simply \textit{anterior}) and \textit{posteromedial} (posterior). No papillary muscles attach to the left side of the ventricular septum.

Myoarchitecture of the Ventricles

The adult ventricular mass is made up of a three-dimensional network of myocardial cells.\textsuperscript{33} This network is highly structured and arranged in layers in which the myocardial cells have a preferred orientation. In all hearts, the ventricular wall is arranged in three layers: superficial (subepicardial), middle, and deep (subendocardial). Superficial and deep layers are present in both right and left ventricles, whereas the middle layer is only present in the left ventricle. The superficial and deep layers are anchored at the ventricular orifices to fibrous structures of the central fibrous skeleton of the heart. This

\[\text{\textsuperscript{1}In this text, cusps of atrioventricular valves are termed leaflets, although current anatomy texts use the term cusp for both semilunar and atrioventricular valves.}\]
Figure 1-10  Interior of left ventricle after anterior ventricular and aortic walls have been excised, leaving obtuse margin, posterior free wall, and septum intact. Specimen is oriented anatomically. Posterior (mural) mitral valve leaflet lies against posterior free wall, whereas anterior mitral leaflet hinges in part from fibrous subaortic curtain and in part from septum and separates outflow portion of ventricle from remaining sinus portion. Arrow indicates direction of left ventricular outflow. Papillary muscles and chordae tendineae support mitral valve. Key: APM, Anterior papillary muscle; ALMV, anterior leaflet of mitral valve; PLMV, posterior leaflet of mitral valve; PPM, posterior papillary muscle; S, septal surface.

Figure 1-11  Interior of left ventricle after the free wall, including mitral valve apparatus, has been displaced to observer’s right and away from the septal surface by a fish-mouth incision into the left ventricle and aorta to demonstrate sinus and outlet portions of the septum. Key: ALMV, Anterior leaflet of mitral valve; MS, membranous septum; NC, noncoronary aortic cusp; O, outlet septum; R, right coronary aortic leaflet; S, sinus septum.
Figure 1-12  Interior of normal left ventricle, viewed from a slightly different perspective than in Fig. 1-11 to demonstrate inlet, outlet, trabecular, and membranous portions of septum. Key: ALPM, Anterolateral papillary muscle; AoM, aortic-mitral anulus (continuity); InS, inlet septum; MS, membranous septum; OS, outlet septum; PMPM, posteroomedial papillary muscle; TS, trabecular septum.

Figure 1-13  Ventricular septum from its left ventricular side, displaying relationship between its outflow portion and aortic and mitral valves. Pins protrude along line of attachment of tricuspid septal leaflet to right ventricular side of septum. Septal tissue inferior to this and dashed line correspond to right ventricular inflow, and septal tissue superior to it corresponds to atrioventricular septum. Arrow indicates a nodulus Arantii. (In this specimen, also shown in Fig. 1-11, right coronary artery ostium is located eccentrically near right noncoronary commissure.) Key: ALMV, Anterior leaflet of mitral valve; AV, atrioventricular septum (muscular portion); L, left aortic cusp; MS, membranous septum, with AV portion superior to dashed line and interventricular portion inferior to it; NC, noncoronary aortic cusp; R, right aortic cusp.
Figure 1-14  Interior of left ventricle, lateral view. Trabecular and outflow portions of ventricular septum are demonstrated. Inflow portion is beneath and behind mitral valve. Anterior leaflet of mitral valve is in fibrous continuity with aortic valve. Passageway below aortic valve, bounded by outflow portion of ventricular septum and anterior leaflet of mitral valve, is called the left ventricular outflow tract. Mitral valve is supported by two papillary muscles, anterior and posterior, arising from free wall of left ventricle.

Figure 1-15  Transverse section of heart at level of medial papillary muscle of tricuspid valve, showing curvature of septum that results in right ventricular infundibulum lying superior and anterior to aortic valve. Curvature of papillary muscles of the mitral valve is also shown. (Specimen is from a 9-month-old infant with a patent ductus arteriosus and pulmonary hypertension.) Key: AV, Aortic valve; LV, left ventricle; MV, mitral valve; P, posterior division of trabecula septomarginalis (septal band) and medial papillary muscle; PB, parietal band (parietal extension of infundibular septum); PV, pulmonary valve; RV, right ventricle; TV, tricuspid valve; VS, ventricular septum.
suggests that myocardial contraction plays an active role in cardiac valve function. The middle layer, unique to the left ventricle, shows a circumferential pattern. No planes of fibrous septation are present between the three layers. Instead, the distinction between one layer and the next is made by a change in muscle fiber direction. This is particularly evident in the ventricular septum, where the superficial layer of the right ventricle invaginates at the interventricular sulcus to form a thin muscular layer that forms the right side of the ventricular septum, covering the circumferentially arranged muscle fibers of the middle layer of the left ventricle. There are age-related changes in direction of the muscle fibers in the superficial layer. With advancing fetal and infant age, muscle fiber arrangement progresses from a horizontal to an oblique orientation. This change is especially evident in the right ventricle and probably reflects the changing pressure gradient between right and left ventricles.

The anatomy of the muscular subpulmonary infundibulum was studied by Merrick and colleagues. They point out a freestanding sleeve of myocardium supporting the pulmonary valve that is separate from the underlying anatomic ventricular septum, and Van Praagh argues that this subsemilunar infundibulum “belongs” to the great arteries, not the ventricles. It may be identified by changing directions of myocardial muscle fibers, referred to by surgeons as “layers” of the septum. This anatomic feature makes possible the safe separation of the pulmonary trunk from the right ventricular outflow tract for use as a valve substitute (autograft).

**Great Arteries**

The aorta is the great artery arising from the base of the heart that normally gives rise to the systemic and coronary arteries. Identity of the aorta is established by recognizing it as the vessel of origin of the brachiocephalic arteries, which never arise from the pulmonary artery. It is not so definitively the vessel of origin of the coronary arteries; occasionally one, or rarely both, coronary arteries may arise from the pulmonary artery. (Appendix 1A).

The pulmonary trunk (main pulmonary artery) is the great artery that normally gives rise to the pulmonary arterial system. The pulmonary trunk characteristically has no brachiocephalic vessels arising from it. At angiography, differentiation between pulmonary trunk and aorta may require careful study, as the brachiocephalic vessels may opacify with the pulmonary trunk by filling through a patent ductus arteriosus. The pulmonary valve is normally anterior, and the aortic valve posterior and to the right, in individuals with visceral and atrial situs solitus.

**ATRIAL SEPTUM**

See “Right Atrium” and “Left Atrium.”

**VENTRICULAR SEPTUM**

The right and left ventricular septal surfaces are asymmetric, related mainly to presence of an infundibulum in the right ventricle only (although Van Praagh and colleagues argue that a small portion of the subsemilunar conus lies just beneath the right aortic valve cusp) [see Appendix 1A]. In addition, higher pressure in the left ventricle makes the sinus septal surface concave on the left side and convex on the right (see Fig. 1-15), a feature accentuated during ventricular systole. The axes of the right and left ventricular outflow tracts differ. That of the right ventricle is almost vertically oriented, whereas that of the left ventricle angles sharply to the right (Fig. 1-16), a feature profiled cineangiographically in the left anterior oblique (LAO) view and in the parasternal long axis view by two-dimensional (2D) echocardiography.

**Muscular Septum**

See “Right Ventricle” and “Left Ventricle.”

**Membranous Septum**

The membranous septum (pars membranacea) is the fibrous part of the cardiac septum separating the left ventricular outflow tract from, in part, the right ventricle and, in part, the right atrium. The line of division between these components is determined by attachment of the tricuspid valve anulus to the septum (see Fig. 1-12). On the right ventricular side of this attachment is the interventricular component. On the right atrial side, it forms the membranous portion of the AV septum.

**Atrioventricular Septum**

The AV septum is the portion of the cardiac septum that lies between the right atrium and left ventricle. It consists of a superior membranous portion and an inferior muscular portion. The AV septum is apparent because the septal attachment of the tricuspid valve is more apical than the septal
attachment of the anterior leaflet of the mitral valve (Fig. 1-17). Viewed from the left ventricular side, the muscular component forms part of the outlet septum (see Fig. 1-13). The AV node lies in the atrial septum adjacent to the junction between membranous and muscular portions of the AV septum, and the bundle of His passes toward the right trigone between these two components (Fig. 1-18).

CONDUCTION SYSTEM

The following description is based on studies of hearts without congenital defects. Abnormalities of the conduction system are associated with certain congenital cardiac malformations and determined primarily by the alignment between atrial and ventricular septal structures and the pattern of ventricular architecture (see Chapters 55 and 56).

Sinus Node

The sinus (sinoatrial) node is located along the anterolateral aspect of the junction between the superior vena cava and the right atrial appendage (Fig. 1-19). In rare cases, it extends medially across the crest of the caval–atrial junction. The node is superficial, lying just beneath the epicardial surface in the sulcus terminalis, and is approximately $15 \times 5 \times 1.5$ mm. It is pierced by the relatively large sinus node artery. (For details of the blood supply, see “Coronary Arteries”.)

Internodal Pathways

The spread of activation between sinus node and AV node occurs preferentially through the muscle bundles delimited by orifices of the right atrium (Fig. 1-19). Considerable histologic and electrophysiologic investigation has been carried out to determine whether pathways of specialized conduction tissue exist within these broad muscle bundles and connect the sinoatrial (SA) and AV nodes. Investigators have not found discrete internodal tracts composed of homogeneous cells or fibers, although some have identified Purkinje-like cells in the major muscle bundles of adult hearts. Controversy continues as to whether these pale cells seen in the atrial myocardium are Purkinje-type cells and whether they form preferential conduction pathways.

Atrioventricular Node

The AV node lies directly on the right atrial side of the central fibrous body (right trigone) in the muscular portion of the AV septum, just anterosuperior to the ostium of the coronary sinus. At times, its posterior margin has been found to lie directly against the coronary sinus ostium. It has a flattened oblong shape and an average dimension in adults of $1 \times 3 \times 6$ mm. Its left surface lies against the mitral anulus. Viewed from the right atrium, the AV node can be localized within a triangle—described by Koch (Fig. 1-20)—formed by the tricuspid anulus, tendon of Todaro (continuation of the...
Figure 1-18  Diagram of right heart, aortic root, and conduction tissue at approximately 65-degree right anterior oblique projection. Plane of mitral valve attachment (dashed line) corresponds to atrial edge of muscular atrioventricular septum and inferior edge of membranous septum, but differs from plane of tricuspid valve (solid line). Muscular portion of atrioventricular septum is frequently smaller than depicted. Key: Ao, Ascending aorta; AVN, atrioventricular node extending into bundle of His and right bundle branch; AVS, muscular atrioventricular septum; CS, coronary sinus; FO, fossa ovalis; IVC, inferior vena cava; M, moderator band; MS, membranous septum, crossed by attachment of tricuspid valve; MV, mitral valve anulus; RC, right coronary artery; S, portion of trabecula septomarginalis (septal band); SVC, superior vena cava; TV, tricuspid valve. (Modified from McAlpine.)

Chapter 1  Anatomy, Dimensions, and Terminology

Bundle of His and Bundle Branches

The common AV bundle (bundle of His) is a direct continuation of the AV node. The bundle passes through the rightward part of the right trigone of the central fibrous body to reach the posteroinferior margin of the membranous ventricular septum. This area is just inferior to the commissure between the tricuspid valve’s septal and anterior leaflets (see Fig. 1-19, B). Its diameter in the region of the central fibrous body is about 1 mm. The bundle courses along the posteroinferior border of the membranous septum and crest of the muscular ventricular septum, giving off fibers that form the left bundle branch. This branching occurs beneath the commissure between the right and noncoronary cusps in close proximity to the aortic valve, over a distance of 6.5 to 20 mm, after which the remaining fibers form the right bundle branch (Fig. 1-21). The bundle of His lies on the left side of the ventricular septal crest in about 75% to 80% of human hearts and on the right side of the crest in the remainder. In the latter situation, the His bundle connects to the left bundle by a relatively narrow stem.

The left bundle branch fans out over the left ventricular septal surface, gradually forming two or three main radiations. It is not uncommon for the anterior and posterior subdivisions to be accompanied by a central, third radiation that originates from the His bundle or from both of the former subdivisions. The anterior radiation travels toward the base of the anterolateral papillary muscle of the left ventricle. The wider posterior subdivision courses toward the base of the posteromedial papillary muscle. Multiple peripheral anastomoses occur among the subdivisions of the left bundle branch system as it distributes to the left ventricle.

The right bundle branch originates from the bundle of His in the region of the anteroinferior margin of the membranous septum and courses along the right ventricular septal surface, passing just below the medial papillary muscle and along the inferior margin of the septal band and the moderator band to the base of the anterior papillary muscle. The fibers then fan out to supply the walls of the right ventricle. Proximally, the right bundle averages about 1 mm in diameter. It is usually subendocardial in its proximal portion, intramyocardial in its middle portion, and again subendocardial near the base of the anterior papillary muscle. VSDs associated with malalignment of portions of the ventricular septum affect these relationships to some extent.

Cardiac Valves

The interrelationships among the heart valves in normally formed hearts are remarkably uniform. The aortic valve occupies a central position, wedged between the mitral and tricuspid valves, whereas the pulmonary valve is situated anterior, superior, and slightly to the left of the aortic valve. The anuli of the mitral and tricuspid valves merge with each other and with the membranous septum to form the fibrous skeleton of the heart. The core of the skeleton is the central fibrous body, with its two extensions, the right
Cardiac conduction system. **A**, Sinus node is located on anterolateral aspect of junction between superior vena cava and right atrial appendage. Internodal pathways are not well defined anatomically and are presented here as proposed pathways. Atrioventricular (AV) node lies in triangle of Koch. Right and left bundle branches spread out on subendocardial surfaces of right and left aspects of ventricular septum. **B**, This section of the heart, taken more posterior than that shown in **A**, demonstrates location of AV node in triangle of Koch, bounded by coronary sinus, anulus of tricuspid valve septal leaflet, and tendon of Todaro. The common AV bundle (bundle of His) continues from AV node to penetrate central fibrous body and reach posteroinferior margin of membranous septum. Left bundle branch spreads over left ventricular aspect of ventricular septum. Right bundle branch continues on right ventricular surface of ventricular septum into moderator band.
and left fibrous trigones. The right fibrous trigone forms a dense junction between the mitral and tricuspid anuli, the left ventricular-aortic junction below the noncoronary cusp, and the membranous septum. The trigone is pierced by the bundle of His. The left fibrous trigone, situated more anteriorly and to the left, lies between the left ventricular-aortic junction and the mitral anulus. The tendon of the infundibulum is a fibrous band joining the more superiorly placed pulmonary valve to the central cardiac skeleton. The tendon of Todaro also joins the central fibrous body (see “Atrioventricular Node”).

By virtue of similarities in morphology and function, the heart valves naturally fall into two groups: AV (mitral and tricuspid) valves and semilunar (aortic and pulmonary) valves.
Mitral Valve

The AV valve of the left ventricle, the mitral valve, is bicuspid, with an anterior (aortic, or septal) leaflet and a posterior (mural, or ventricular) leaflet (Fig. 1-23). Tissue that could be called commissural leaflets is usually present at the commissures between these two leaflets. The combined area of the two mitral leaflets is twice that of the mitral orifice, resulting in a large area of coaptation.\(^{3,4,17}\) When this large area is lost because of malalignment of the leaflets, undue stress is placed on the chordae tendineae, and they may rupture. Although there has been some controversy as to the definition of commissural areas, particularly in regard to clefts in the posterior leaflet, Silver and colleagues describe chordae tendineae that define the limits of the septal (anterior) and posterior leaflets.\(^{1,2}\)

Rusted and colleagues found the depth of commissures in the normal mitral valve averaged 0.7 to 0.8 cm and never exceeded 1.3 cm in the 50 hearts they studied.\(^5\)

The larger anterior (septal, aortic, anteromedial) leaflet is roughly triangular in shape, with the base of the triangle inserting on about one third of the anulus. It has a relatively smooth free margin with few or no indentations. A distinct ridge separates the region of closure (rough zone) from the remaining leaflet (clear zone).\(^1\) The clear zone is devoid of direct chordal insertions. The anterior leaflet is in fibrous continuity with the aortic valve through the aortic–mitral anulus and forms a boundary of the left ventricular outflow tract.\(^{11}\) This region of continuity occupies about one fourth of the mitral anulus and corresponds to the region beneath half the left coronary cusp and half the noncoronary cusp of the aortic valve. The limits of this attachment are demarcated by the right and left fibrous trigones (Fig. 1-24). The commissure between the left and noncoronary sinuses of the aortic valve is located directly over the middle of the anterior leaflet of the mitral valve (Fig. 1-25; see also Fig. 1-24). These points do not correspond to the commissures of the mitral valve (see Fig. 1-4). The AV node and bundle of His are at risk of surgical damage adjacent to the right trigone.

The smaller posterior (mural, ventricular, posterolateral) leaflet inserts into about two thirds of the anulus and typically has a scalloped appearance. Ranganathan and colleagues found the posterior leaflet to be divided into three segments in 46 of the 50 normal mitral valves they studied.\(^1\) The posterior leaflet has rough and clear zones corresponding to those of the anterior leaflet, as well as a basal zone close to the anulus, which receives chordae directly from left ventricular trabeculae.\(^1,2,11\)

The mitral valve leaflets may be described using a segmental classification. The valve leaflets are segmented into six sections, A1 to A3 for the anterior and P1 to P3 for the posterior (see Fig. 1-25, C). Sections A1 and P1 represent the anterolateral sections, A2 and P2 the middle sections, and A3 and P3 the posteromedial sections. This segmental classification has been useful in describing morphology observed at operation,\(^4,10\) multiplane 2D transesophageal echocardiography,\(^9,14\) and 3D echocardiography.\(^5,4\)

The majority of chordae tendineae to the mitral valve originate from the two large papillary muscles of the left ventricle: anterolateral and posteromedial. Each leaflet receives chordae from both papillary muscles, and the majority insert on the free leaflet edge.\(^5\) Papillary muscles are often thought of as fingerlike structures protruding into the left ventricular cavity from the ventricular wall, possibly because these muscles are frequently visualized in two dimensions by angiography or echocardiography. Actually, the papillary muscles have a
somewhat crescent shape that conforms to the curvature of the free wall of the left ventricle. This is reasonable because the papillary muscles and chordae tendineae are derived embryologically by undermining of the left ventricular myocardium.

Victor and Nayak examined 100 normal human hearts at autopsy, evaluating and characterizing the papillary muscles and arrangement of the chordae. The anterolateral papillary muscle is attached by chordae tendineae to the left half of the anterior and posterior mitral leaflets (as viewed by a surgeon through the usual right-side approach to the mitral valve), whereas the postero-medial papillary muscle is attached by chordae tendineae to the right-sided half of both anterior and posterior leaflets. Papillary muscles are considered an anterolateral “group” and a postero-medial “group” because there is often more than a single papillary muscle “belly.” There are patterns of mostly single or two muscle bellies, but occasionally three, four, or even five bellies are observed. When there are three muscle bellies, the papillary muscle supporting the chordae to the commissure arises separately from the ventricular wall. Commisural chordae are shorter than the others and usually originate from the highest tip of the papillary muscle. Victor and Nayak also described variations of the chordal attachments. There are usually 4 to 12 chordae originating from each papillary muscle group (range, 2 to 22). Chordal branching results in a number of chordae inserting to the mitral valve leaflet, ranging from 12 to 80.

Acar and colleagues proposed a clinical morphologic classification of the papillary muscles. A single undivided papillary muscle is referred to as type I. Type II refers to papillary muscles cleaved in a sagittal plane into two heads that separately support the anterior and posterior leaflets of the mitral valve. Type III papillary muscles are cleaved in a coronal plane, forming an individual head that supports the commissural chordae. Type IV refers to papillary muscles divided into multiple heads, with a separate papillary muscle originating as a separate muscular band close to the mitral anulus, which supports short chordae to the commissure.

Tandler defined three orders of chordae. Those of the first order insert on the free margin of the leaflet, those of the second order insert a few to several millimeters back from the free edge, and those of the third order insert at the base of the leaflet (applicable only to the posterior leaflet).
region. The leaflets and chordae tendineae are thinner than those of the mitral valve. Its orientation is nearly vertical. The anterior (anterosuperior) leaflet is the largest of the three leaflets and may have notches creating subdivisions. Silver and colleagues found a notch close to the anteroseptal commissure in 47 of the 50 anterior leaflets they examined. This notch was occasionally as deep as a commissure, but could be differentiated from a true commissure by the type of chordal attachments. The chordae attaching to this leaflet arise from anterior and medial papillary muscles. The anterior papillary muscle is the larger of the two, its base arising from the right ventricular free wall and trabecula septomarginalis.

The posterior (inferior) leaflet is usually the smallest and is commonly scalloped. Its chordae originate from the posterior and anterior papillary muscles. It is attached wholly to the ventricular free wall. The septal leaflet is usually slightly larger than the posterior leaflet. Its chordae arise from the posterior and septal papillary muscles. Most of this leaflet and its chordae attach to the membranous and muscular portions of the ventricular septum, although part may attach to the posterior wall or the right ventricle. The transition between the attachments to the posterior wall and septum is associated with a fold in the leaflet.

Lam and colleagues reclassified chordae into rough zone (including strut chordae), cleft, basal, and commissural chordae. These investigators suggest that this classification provides a clear definition of mitral valve leaflets and should be useful in studying mitral valve function.

The design of the mitral valve offers the largest possible orifice during the diastolic phase of ventricular filling and limits the slightest obstruction to flow at low pressures in the left atrium and left ventricle. The valve opens as the anterior leaflet swings anteriorly from the posterior leaflet. Orifice dimensions are enhanced by flexion of the anterior leaflet (see Fig. 1-25, B). During systole, the mitral valve closes under the full load of left ventricular contraction. The anterior leaflet straightens and extends toward the posterior leaflet. The posterior leaflet functions like a shelf to stop the movement of the anterior leaflet as the leaflets appose.

Tricuspid Valve

The tricuspid valve, the AV valve of the right ventricle, has three leaflets: anterior, posterior, and septal (Fig. 1-26). Its orifice is roughly triangular and larger than the mitral orifice. The anulus is relatively indistinct, especially in the septal region. The leaflets and chordae tendineae are thinner than those of the mitral valve. Its orientation is nearly vertical.

The anterior (anterosuperior) leaflet is the largest of the three leaflets and may have notches creating subdivisions. Silver and colleagues found a notch close to the anteroseptal commissure in 47 of the 50 anterior leaflets they examined. This notch was occasionally as deep as a commissure, but could be differentiated from a true commissure by the type of chordal attachments. The chordae attaching to this leaflet arise from anterior and medial papillary muscles. The anterior papillary muscle is the larger of the two, its base arising from the right ventricular free wall and trabecula septomarginalis.

The posterior (inferior) leaflet is usually the smallest and is commonly scalloped. Its chordae originate from the posterior and anterior papillary muscles. It is attached wholly to the ventricular free wall.

The septal leaflet is usually slightly larger than the posterior leaflet. Its chordae arise from the posterior and septal papillary muscles. Most of this leaflet and its chordae attach to the membranous and muscular portions of the ventricular septum, although part may attach to the posterior wall of the right ventricle. The transition between the attachments to the posterior wall and septum is associated with a fold in the leaflet.
The walls of the sinuses are considerably thinner than the wall of the aorta proper, an important consideration when designing proximal aortotomies.

The crown-shaped anulus, fibrous trigones, aortic cusps, aortic sinuses, and sinutubular junction share a dynamic coordinated action to provide unidirectional transmission of large volumes of blood pumped intermittently through the channel while maintaining laminar flow, minimal resistance, optimal coronary artery flow, and least damage to blood elements during widely variable and frequently changing conditions.

The origins of the coronary arteries are the basis of a nomenclature for the sinuses and cusps. The ostia of the right and left coronary arteries identify the right and left sinuses and cusps. The sinus and cusp without an associated coronary artery are termed noncoronary. Several other nomenclatures for the cusps and sinuses have been described (see Morphology in Chapter 52).

Aortic Valve

The aortic valve is normally tricuspid and composed of delicate cusps and sinuses of Valsalva. These components form three cuplike structures that constitute the entire valve mechanism; the valve is in fibrous continuity with the anterior leaflet of the mitral valve and the membranous septum (see Fig. 1-25).

The free edge of each cusp is of tougher consistency than the remainder of the cusp. At the midpoint of each free edge is a fibrous nodulus Arantii. On either side of each nodulus is an extremely thin, crescent-shaped portion of the cusp termed the lunula (see Fig. 1-13). The lunulae are occasionally fenestrated near the commissures. These regions form the area of coaptation during valve closure.

The aortic sinuses (sinuses of Valsalva) are dilated pockets of the aortic root that form the outer component of the three cuplike closing structures of the aortic valve (see Fig. 1-25). The coronary arteries arise from two of the aortic sinuses. The walls of the sinuses are considerably thinner than the wall of the aorta proper, an important consideration when designing proximal aortotomies.

The pulmonary valve structure is similar to that of the aortic valve. The pulmonary valve normally has three cusps, with a nodule at the midpoint of each free edge, and lunulae and thin, crescent-shaped coaptive surfaces on both sides of the nodules. The pocket behind each cusp is the sinus. Major differences from the aortic valve are (1) lighter construction of pulmonary valve cusps, (2) normal absence of coronary artery origins, and (3) normal lack of fibrous continuity with the anterior tricuspid valve leaflet. Pulmonary valve cusps are supported entirely by freestanding musculature, having no direct relationship with the ventricular septum. The pulmonary valve is lifted away from the ventricular septum by the subpulmonary infundibulum. The first septal branch of the left anterior descending coronary artery pierces the
ventricular septum below the shortest part of the subpulmonary infundibulum. The artery is protected by the subpulmonary infundibulum.

Pulmonary valve cusps have been described by several terminologies, usually named by their relationships to the aortic valve: right, left, and anterior (nonseptal). Kerr and Goss found that a commissure of the pulmonary valve was adjacent to a commissure of the aortic valve in 199 of 200 specimens they studied. These investigators suggested that the cusps of each arterial valve should be termed right adjacent, left adjacent, and opposite (or, as suggested by Anderson, right facing, left facing, and nonfacing) in relationship to the adjacent commissure of each valve.

CORONARY ARTERIES

From an anatomic point of view, the coronary artery system divides naturally into two distributions, left and right. From the standpoint of the surgeon, the coronary artery system is divided into four parts: the left main coronary artery, the left anterior descending coronary artery and its branches, the left circumflex coronary artery and its branches, and the right coronary artery and its branches. The branches of each of the last three vessels must also be familiar to the surgeon.

The major coronary arteries form a circle and a loop about the heart (Fig. 1-27). The circle is formed by the right coronary and left circumflex arteries and is displayed in the left anterior oblique (LAO) projection. The loop is formed by the left anterior descending and posterior descending arteries and is demonstrated in the right anterior oblique (RAO) projection. Circulation is right dominant. Right coronary artery, which forms the right component of circle, is visualized. B, Left coronary injection in LAO projection. Note that this is a left dominant circulation. Left circumflex artery, which forms the left component of circle, is visualized. C, Left coronary injection in RAO projection. Left dominant circulation allows demonstration of both components of the loop: left anterior descending and posterior descending arteries. Key: AV, Atrioventricular node artery; CX, left circumflex artery; LAD, left anterior descending artery; LM, left marginal artery; PD, posterior descending artery; RC, right coronary artery; RPL, right posterolateral artery.
serves the left side of the heart to a greater extent than it does the right side in terms of the number and volume of vessel segments involved.\textsuperscript{21} A right dominant artery does not necessarily supply branches to the inferior surface of the left ventricle, however, because it may terminate only as the posterior descending artery. Blood supply to the anterior portion of the left ventricle comes from the diagonal branches of this portion of the loop, the left anterior descending coronary artery. That to the lateral part of the anterior portion comes from the first branches of both the left anterior descending and circumflex arteries. The ventricular septum receives its blood supply from the loop that encircles it, formed by the left anterior descending coronary artery in front and the posterior descending artery behind.

Variability in the origin of the posterior descending artery is expressed by the term dominance. A right dominant coronary circulation is one in which the posterior descending coronary artery is a terminal branch of the right coronary artery. A left dominant circulation, which occurs in about 10\% to 15\% of hearts, is one in which the posterior descending coronary artery is a branch, usually the last one, of the left circumflex coronary artery. Left dominance occurs more frequently in males than in females. This distinction as to whether the right or left coronary supplies the posterior descending artery is important in evaluating patients with coronary artery disease and in planning coronary artery bypass grafting.

The following is a general description of coronary artery anatomy in normal hearts.\textsuperscript{81,86,87,88,92,93,95,108} As with the conduction system, some congenital cardiac malformations are associated with abnormalities of the coronary arteries. The nomenclature is based on the U.S. National Heart, Lung, and Blood Institute’s Proposal and Manual of Operations for Collaborative Studies in Coronary Artery Surgery\textsuperscript{109} (Fig. 1-28) and the American Heart Association’s coronary artery disease reporting system.\textsuperscript{110} Both systems include rules for defining the various segments of the major coronary arteries. Fig. 1-29 is also supplied to provide a more dimensional representation of the coronary arteries on the surface of the heart and should be studied along with the brief descriptions that follow.

Left Main Coronary Artery

The left main coronary artery extends from the ostium in the left sinus of Valsalva to its bifurcation into the left anterior descending and left circumflex branches. Its usual length is 10 to 20 mm, with a range of 0 to 40 mm. It normally courses between the pulmonary trunk and the left atrial appendage to reach the left AV groove. Occasionally, additional vessels originate from the left main coronary artery and course parallel to the diagonal branches of the left anterior descending branch.\textsuperscript{111} Such an additional artery (formerly called a ramus intermedius) is termed the first diagonal branch of the left anterior descending artery. Rarely (in 1\% of persons), the left main coronary artery is absent, the left anterior descending and left circumflex coronary arteries originating directly from the aorta via separate ostia.

Left Anterior Descending Coronary Artery

Beginning as a continuation of the left main coronary artery, the left anterior descending coronary artery courses along the anterior interventricular sulcus to the apex of the heart. Part of it may be buried in muscle. In most cases, this artery extends around the apex into the posterior interventricular sulcus, supplying the apical portion of both right and left ventricles.\textsuperscript{112} This vessel supplies branches to the right ventricular free wall (usually small), septum, and left ventricular free wall. One or more branches to the right ventricle connect with infundibular branches from the proximal right coronary artery. This important route for collateral flow is the loop of Vieussens. The septal arteries arise almost perpendicularly
Figure 1-29  Coronary arteries. A, Left coronary artery. Left main coronary artery originates from aorta and divides to form left anterior descending and left circumflex coronary arteries. Branches of left anterior descending artery on surface of heart are termed diagonal arteries, whereas those coursing into the ventricular septum are called septal arteries. Branches of left circumflex artery on posterior wall of left ventricular surface are termed obtuse marginal arteries. A large artery originating near the left main coronary bifurcation and supplying the obtuse margin between the diagonal branches of left anterior descending and circumflex marginal branches was formerly called an intermediate branch or ramus intermedius. B, Right coronary artery, right dominant pattern. Right coronary artery originates from aorta and courses in the atrioventricular (AV) groove. Branches of right coronary artery supplying blood to right ventricle are called right ventricular branches, except for the nearly constant and often large branch at the acute margin of the heart, termed the acute marginal artery. Right coronary artery divides at the crux of the heart into right posterior descending branch, which courses over posterior aspect of ventricular septum, and right posterolateral segment artery, which continues in the AV groove, providing branches to posterior wall of left ventricle. Arterial branches to the specialized conduction system frequently arise from right coronary artery. Sinoatrial node branch originates from proximal portion of right coronary artery. AV node branch originates from the U-bend in posterior lateral segment of right coronary artery.
from the left anterior descending coronary artery, a characteristic sometimes helpful in angiographic identification of the anterior descending artery. A variable number of diagonal arteries course obliquely between the anterior descending and left circumflex arteries and supply the left ventricular free wall anteriorly and laterally.

Variations in the left anterior descending artery are infrequent, although in about 4% of hearts, it exists as two parallel vessels of about equal size. It may terminate before the apex or extend as far as the posterior AV groove.

**Left Circumflex Coronary Artery**

The left circumflex coronary artery originates at about a 90-degree angle, with its initial few centimeters lying medial to the base of the left atrial appendage. The sinus node artery occasionally originates from the first few millimeters of the left circumflex artery. Rarely, the circumflex artery terminates before the obtuse margin. A large branch originating from the proximal left circumflex artery and coursing around the left atrium near the AV groove is termed the atrial circumflex artery. The ventricular branches of the circumflex artery, the obtuse marginal arteries, supply the obtuse margin of the heart and may be embedded in muscle. Often their position can then be identified at operation by the altered color (reddish or light tan) of the overlying thin muscle layer compared with that of the remainder of the ventricular wall. Those branches supplying the inferior surface of the left ventricle in a heart with a left dominant system (or in one with a co-dominant system in which the right coronary artery gives rise only to a posterior descending artery) are termed left posterolateral (marginal) arteries. In hearts with a left dominant system, the left circumflex coronary artery gives rise to the posterior descending artery at or usually before the crux. Variations in the origin and length of the left circumflex artery, and in the number and size of its marginal branches, are common.

**Right Coronary Artery**

The right coronary artery is usually a single large artery and courses down the right AV groove. Branches supplying the anterior right ventricular free wall exit from the AV sulcus in a looping fashion because of the depth of the right coronary artery in the sulcus. In this same area, the anterior right atrial artery arises, and this branch often gives origin to the sinus node artery. More distally, a lateral right atrial artery usually arises (this artery is frequently severed when an oblique atriotomy is made). In the region of the acute margin of the heart, a relatively constant long branch of the right coronary artery arises, the acute marginal artery, which courses most of the way to the apex of the heart. The right coronary artery in most hearts crosses the crux, where it takes a characteristic deep U-turn, giving off the atrioventricular node artery at the apex of the turn. The right coronary artery then terminates by bifurcating into the right posterior descending coronary artery and the right posterolateral segment artery. The posterior descending coronary artery descends in the posterior interventricular sulcus for a variable distance, giving rise to septal, right ventricular, and left ventricular branches. Variations in its anatomy are numerous, and it frequently arises before the crux. The right posterolateral segment of the right coronary artery gives origin to marginal branches to the inferior surface of the left ventricle in most hearts with a right dominant system.

Variations in the right coronary artery are common. It may have a dual origin from the right sinus of Valsalva. In about 10% of hearts, it bifurcates within a few millimeters of the aortic ostium, forming two diverging trunks of equal size. In half the cases, the artery supplying the right ventricular infundibulum arises separately from the aortic sinus and is then termed the conus artery. The sinoatrial node (sinus node) artery originates from the second or third centimeter of the right coronary artery in many hearts (see “Coronary Arterial Supply to Specialized Areas of the Heart”). The acute marginal artery crosses the diaphragmatic surface of the right ventricle in 10% to 20% of hearts and reaches the anterior aspect of the diaphragmatic portion of the ventricular septum, to which it gives branches.

**Coronary Arterial Supply to Specialized Areas of the Heart**

The predominant blood supply to the ventricular septum is from the left anterior descending coronary artery via four to six large septal arteries 70 to 80 mm in length. In contrast, the septal arteries from the posterior descending coronary artery (except for the AV node artery) are rarely more than 15 mm in length (Fig. 1-30). They supply only a small zone of the ventricular septum near the posterior interventricular sulcus and in the region of the AV node. The septal arteries from the posterior descending artery may, however, serve as an important source of collateral circulation. Until their final terminations, the septal arteries from both anterior and posterior descending arteries course along the right ventricular side of the septum, where pressure is lower than on the left side. In 10% of hearts with a left dominant circulation, the entire blood supply is from the left coronary artery.

The sinus node artery is a single artery in 89% and double in 11% of hearts. Its origin is from the right coronary artery in 55% to 65% of cases and from the left circumflex or left main coronary artery in the remainder. When it arises from the right coronary artery, it courses posteriorly and superiorly over the anterior wall of the right atrium beneath the right atrial appendage and courses obliquely between the anterior descending and left circumflex arteries and supplies the right atrial appendage. The sinus node artery occasionally originates from the proximal left circumflex artery, it courses over the left atrial appendage. The Kugel artery anastomoses with branches of the sinus node artery. The AV node artery courses superiorly and anteriorly from the left circumflex artery, it courses posteriorly and superiorly from the first few millimeters of the left circumflex artery. The AV node artery (except for the AV node artery) is rarely more than 15 mm in length (Fig. 1-30). They supply only a small zone of the ventricular septum near the posterior interventricular sulcus and in the region of the AV node. The AV node artery may penetrate the interatrial septum in its course to the superior vena cava. It then encircles the cava clockwise or counterclockwise, or bifurcates and encircles it in both directions. If the sinus node artery arises from the left circumflex artery, it courses over the left atrial wall, variably penetrates the interatrial septum, and ascends to the base of the superior vena cava, encircling that vessel as when it originates from the right coronary artery.

The AV node artery arises from the characteristic U-turn of the right coronary artery as it crosses the crux of the heart. The AV node is usually supplied by the dominant coronary artery. The AV node artery courses superiorly and anteriorly and terminates with a distinctive angulation. An important accessory blood supply to the AV node is the Kugel artery, which originates from the proximal segment of either the right coronary artery or the left circumflex artery and courses through the interatrial septum to the crux of the heart to anastomose with the AV node artery. In the atrial septum, Kugel artery anastomoses with branches of the sinus node artery. Kugel artery is the source of blood supply to the AV node in 40% of normal hearts.
Figure 1-30  Blood supply of ventricular septum. Most of the septum is supplied by left anterior descending coronary artery via large septal arteries. Septal arteries from posterior descending artery are relatively small. In this right dominant circulation, note origin of the atrioventricular (AV) node artery from the characteristic U-turn of right coronary artery. (Modified from James and Burch.)

Figure 1-31  Origin and distribution of sinus node artery. Sinus node artery may arise from right coronary artery and encircle base of superior vena cava in (A) a clockwise direction or (B) a counterclockwise direction, or it may (C) bifurcate and encircle it in both directions. It may also arise from (D) the left circumflex artery and encircle the base of the superior vena cava as in A, B, or C. (Modified from Lewis and colleagues.)
**Dimensions of Normal Cardiac and Great Artery Pathways**

Cardiac and great artery pathways with normal dimensions accommodate blood flow at rest and during exercise and stress, with little or no pressure drop across the pathway. Sluysmans and Colan have hypothesized that optimal size of cardiovascular structures is such as to mimic hemodynamic cost of providing blood flow across the physiologic range of cardiac output. The body does this by optimizing the relationship between vessel radius and flow rate. To achieve minimum work requires minimizing viscous energy (shear stress related to inverse radius) and inertial energy related to pulsatile flow, which is directly related to radius (Fig. 1-32). Sluysmans and Colan show that this optimization of energy is related to body surface area (BSA) over a wide range of sizes of mammals, including humans. For valve and blood vessel area, this relationship is linear with BSA; for diameter of vessels, this relationship is to the square root of BSA (BSA^{0.5}).

Although the theoretical relationship tolerates vessel dimensions over a substantial range, in some patients being considered for cardiac surgery, dimensions are so small as to preclude a satisfactory outcome. Therefore, prediction of outcome based on dimensions of a pathway becomes important. A major problem in predicting outcome in a patient simply from subjective evaluation of the size of a structure is that this evaluation may be grossly inaccurate because of unconscious comparison of the size of the structure in question with that of a neighboring unusually large structure. Prediction of outcome simply from subjective evaluation is also affected by the preformed bias of the observer, as well as by inexperience. Therefore, measurements and their relationship to outcome are required for reproducible, accurate predictions, and decisions must be made regarding the methods for expressing the dimensions.

**Dimensions of the Pathway**

The measured dimension is usually expressed as diameter of the pathway. Occasionally a circular shape is assumed, and the dimension is transformed to cross-sectional area. Under some circumstances, cross-sectional area can be measured directly. In other circumstances, an elliptical shape is assumed, and major and minor axes are measured and area calculated with an equation that applies to ellipses. Use of observed (measured) dimensions generally requires their being related to normal dimensions, which vary with body size and age (allometric growth). Normal dimensions may also vary according to imaging modality, image...
projection (e.g., anteroposterior vs. lateral), phase of the cardiac cycle, method of fixation in the case of specimens, and other factors. These must be specifically controlled in making the measurements.

Dimensions have been measured in autopsy specimens and by cineangiography (in which dimensions must be corrected for magnification), echocardiography (M-mode, 2D, 3D, cineangiography), and in a few instances MRI. However, normal values are not available in each of these modalities, so dimensions have to be related to available normal values, even if from another modality.

Echocardiography has evolved as the most commonly used modality for measuring these dimensions. Pathway dimensions have been determined by echocardiography at nearly all ages of life, from fetal to age 90. Hornberger and colleagues established dimensions by high-resolution 2D echocardiography for the fetal aortic arch in 92 fetuses aged 16 to 38 weeks gestation to facilitate diagnosis of left heart and aortic abnormalities, particularly coarctation. Skelton and colleagues followed changes in cardiac dimensions of preterm infants during the first month of life, suggesting there are differences from term infants, with preterm babies showing mild left ventricular dysfunction.

Pathway dimensions for hearts from birth to about 20 years have been determined by M-mode and 2D echocardiography. Daubeney and colleagues prospective study aimed at developing equations relating cardiac dimensions to body area over the range of 0.1 to 2.0 m² is particularly useful. A number of studies in adults use 2D echocardiography (transthoracic or transesophageal) with pathway dimensions measured directly or derived from Doppler ultrasound measurements and the continuity equation. The age range is often wide, but there are populations studied at mean age 23, 28, 33, 45, and 53 years. Swinne and colleagues called attention to age-associated changes in left ventricular outflow tract geometry observed in normal subjects, mostly after age 70. These changes consist of a more acute septo-aortic angle or septal bulge that is not associated with left ventricular outflow tract obstruction. These may represent degenerative changes associated with aging.

Normalization of Pathway Dimensions

Pathway dimensions may be used without any normalization to body size or age. Some cardiologists who work exclusively with adult patients express aortic size simply in centimeters. This method is not recommended, not only for the obvious reason that it is unacceptable when the population being considered consists of patients who range from very young to very old, but also because it takes no account of differences between adults of differing size.

Normalization may be based on age, height, weight, or BSA. Normalization to body size generally is termed indexing. Normalization may also be to another structure, such as the size of the descending aorta at the diaphragm. Normalization to another body structure generally is termed a ratio. The preference is for normalization to BSA of the patient, but this is often done by dividing the value of the dimension by the BSA, expressing it as “per square meter BSA.” This preference presumes a strictly linear relation between the dimension and BSA, which may be inaccurate. If a structure’s area is measured, the relationship to BSA is probably accurate. If instead a diameter of a structure is normalized this way, it will be inaccurate. What must be achieved is normalization that is constant across body size from smallest neonate to adult.

Indexed cross-sectional area and diameter of mitral and tricuspid valves, left ventricular–aortic junction (aortic valve “anulus”), right ventricular infundibulum, and right ventricular–pulmonary trunk junction (pulmonary valve “anulus”) in normal individuals are summarized in Table 1-1 according to the modality in which the dimension was measured. Those for the pulmonary trunk, right and left pulmonary arteries, and descending thoracic aorta at the diaphragm are summarized in Table 1-2. Values for the diameter of the upper descending thoracic aorta on both sides of the ductus arteriosus are also available. These tables are not intended as a source of normalized dimensions in patients, but rather as a reference and guide to the appendixes to this chapter, which contain specific regression equations and nomograms for calculating mean normal values and their standard deviations for use in patients.

Standardization of Dimensions

Values of dimensions are made useful by standardizing them to body size. They are expressed as deviation from their mean normal value for body size in terms of number of standard deviations from the mean. Standardization takes into account the fact that values in normal individuals of the same size vary. The mathematical framework for standardization of dimensions is the normal distribution domain because of its mathematical flexibility and tractability. This framework may require transformation of the dimension scale of the variable under consideration to comply with assumptions of the normal distribution.

A less desirable alternative is standardization according to percentiles (the 50th percentile is the median). This method is commonly used in relating body weight or height to age. Although percentiles are easily expressed, the method has the major disadvantage that the relationships cannot be reduced to equations. This increases the difficulty of relating dimensional data to outcome.

Once in the normal distribution domain, any given value for a dimension can be expressed in terms of the number of standard deviations of the given value from the mean value of that dimension in normal individuals. This is the z value, or z score (Fig. 1-33). The transformation to a dimensionless z value is as follows:

\[
z = \frac{\text{Observed dimension} - \text{Mean normal dimension}}{\text{Standard deviation around mean normal dimension}}
\]

where (1) is the observed dimension or its appropriate transformation in scale in the patient who is of a known size (BSA), and (2) and (3) refer to corresponding values in normal individuals of the same BSA as the patient, obtained from regression analysis and equations.

Appendix 1B includes dimensions (obtained at autopsy) of various cardiac and pulmonary artery pathways in normal individuals. In Appendix 1C, the dimensions were obtained at in vivo cineangiography, and in Appendix 1D at in vivo 2D echocardiography. Appendix 1E compares pathway dimensions in normal individuals from different measurement modalities. Additional reliable information is contained in other sources (e.g., Roman et al. R3).

*Normalization is in terms of BSA.
Key: 2D, Two-dimensional; BSA, body surface area; RPA, right pulmonary artery.
dimensions to the percentage of a population of normal individuals
with that specific dimension or a smaller one. Exact percentage on
vertical axis, related by dashed lines to the patient’s z value, is the
percentile of normal individuals with the corresponding z value. A
patient with a specific z value has the dimension of the correspond-
ing percentile of the normal population.

Dimensions of the Pulmonary Arteries

Indexing and standardizing the dimensions of the pulmonary
arteries present special problems because of the multiplicity of
methods that have been used. They have been important in
considering treatment for patients with tetralogy of Fallot and
pulmonary stenosis, tetralogy of Fallot with pulmonary
atresia, and conditions for which the Fontan operation is
performed.

Among the different methods for expressing dimensions of the
pulmonary arteries are the McGoon ratio, the sum of the diameters of the prebranching portions of the right and left pulmonary arteries, pulmonary artery area index (PAAI), cross-sectional area index (Nakata index), and z value. The z value is the preferred method. It should be applied to more distal portions of the pulmonary arteries as well.

To facilitate transformation of already published dimensions of the pulmonary arteries in patients with congenital heart disease to a different normalization, relationships between the values obtained by these various methods are shown in Appendix 1F.

Relating Dimensions to Outcome

The goal is an equation expressing the continuously variable
relationship between normalized dimensions of the patient and
some outcome event (e.g., death, freedom from reoperation, postrepair $P_{RV/LV}$, cardiac index). Obtaining the equation may require detailed studies and complex analyses, but once obtained, the equation is made easy to use by expressing it in a nomogram. This process is the basis of many of the depictions in the subsequent chapters.

As is already evident from Appendix 1B, 1C, and 1D, the normalization used in relating dimensions to outcome can be to measurements made at autopsy or at cineangiography, 2D echocardiography, MRI, or other imaging method. Although in theory it may seem proper to normalize

measurements made on cineangiography, for example, using
normalizing equations based on cineangiographic measurements, this is in fact unnecessary. If the same method of normalizing the patient’s dimensions is used in predicting outcome as was used in previous studies that determined the relationship between dimensions and outcome, this suffices. For example, in normalizing measurements of the dimensions of the tricuspid valve made at cineangiography, one might like to use equations based on cineangiographic measurements. Unfortunately, an insufficient number of measurements is made at cineangiography in normal individuals to generate equations for indexing or standardizing tricuspid measurements by this modality.

Equations for standardization of tricuspid measurements using measurements obtained by 2D echocardiography are available, as are measurements made at autopsy. Based on these practical considerations, normalization to autopsy or echocardiographic measurements may be used for standardizing tricuspid dimensions to a z value, even though these measurements are made by cineangiography (see Appendix 1E). Thus the nomograms shown in Appendix 1D or the actual equations described in tables in Appendixes 1B through 1D may be used. However, once a disparate standardization of a dimension is related to outcome, the user of that relationship must make that identical standardization. This is analogous to the use of a ruler. Rulers may be subdivided into inches or centimeters, but once a scale is chosen, it must be used consistently.

DIMENSIONS OF NORMAL VENTRICLES

Normal ventricular volumes, masses, and dimensions—assuming normal myocardial contractility and loading conditions—can accommodate normal blood flow at rest and during exercise. Sometimes the dimensions of the left or right ventricle are smaller or larger than those of the other, leading to problems in simply judging the normality of the size and its relationship to outcome, for the same reasons as in the case of pathway dimensions.

Accurate and precise ventricular diameters, volumes, and masses are difficult to obtain, because ventricles may have unusual shapes. Nevertheless, a number of useful studies have been done that use M-mode and 2D directed M-mode echocardiography to determine left ventricular volume and mass and to relate these dimensions to body size over the life course of humans. Particularly interesting is de Simone and colleagues’ study of left ventricular mass in overweight children and adults. They found that height is the best means of normalizing left ventricular mass. Normalization of ventricles to body size has also been challenged for obese subjects by Whalley and colleagues. BSA is highly sensitive to weight, less so to height. Whalley and colleagues support normalizing to fat-free mass, but requirement of specialized equipment is a barrier to its widespread use. Their view is not shared by all. Vasan and colleagues provide “cut” limits for range of normal values (90th and 95th percentiles) for ventricular mass and thickness and atrial and ventricular dimensions derived from nearly 5000 subjects in the Framingham Heart Study. Bull and colleagues proposed making surgical decisions based on the size (in terms of $z$ values) of the AV valve guarding the entrance to the ventricle, rather than on the size of the ventricle itself.
The \( z \) value method (standardization) can be used to describe patients’ ventricular volumes and masses, although this general body of knowledge is not yet well developed, in part because of methodological problems. The \( z \) value method can also be used for diameters. Table 1-3 gives the mean values for normal individuals of various body sizes, as an approximation and for guidance rather than for use in calculating patient-specific \( z \) values. Appendix Fig. 1G-1 presents the information in a form from which patient-specific \( z \) values can be calculated.

**TERMINOLOGY AND CLASSIFICATION OF HEART DISEASE**

Understanding the morphology of heart disease is fundamental to its surgical treatment. Morphology could be described fully using any one of a number of systems of terminology and classification. However, appropriate and accurate terminology and classification are important because they greatly facilitate understanding and teaching of cardiac morphology, diagnosis, and surgical treatment. Also, they determine the method of categorization of cases, a procedure essential to the study of groups of patients.

The system of terminology and classification used here evolved over many years, to a considerable extent in response to clinical, and particularly surgical, needs. It was based originally on the teaching of Edwards and his pupil, Becu. It has been profoundly influenced and modified on numerous occasions by the work of Van Praagh, has benefited through the years from the work of Van Mierop and of Lev and Bharati, and has embraced many of the concepts of Anderson and Becker.\(^{A12,B6}\)

Following the ideas of Lev, terminology based on the somewhat shifting sands of embryology has been avoided as much as possible. Any terms that have embryologic implications are used only because they have become conventional. This is not to deny the importance of the science of embryology, but rather to emphasize the importance of precise description of morphology (see Appendix 1A). Complete description of a cardiac anomaly includes the anatomic variables listed in Box 1-1.\(^{B6,R11,R6,E7,S14,V10}\)

Nomenclature and classification schemes are essential for accurate data reporting and establishment of databases. A continuing worldwide effort of surgeons, cardiologists, morphologists, perfusionists, pathologists, and government officials has resulted in the International Pediatric and Congenital Cardiac Code (IPCCC).\(^{S5}\) The framework of this effort will serve as a guideline for future efforts at classification of cardiac morphology. These efforts have not as yet embraced a true ontology of congenital heart disease that, at least in theory, could integrate with a cardiovascular Gene Ontology to couple phenotype with genotype.

### Situs of the Thoracic Viscera and Atria

The possible situs of the thoracic viscera and atria are (1) situs solitus, or usual situs, (2) situs inversus, and (3) situs ambiguous. **Situs solitus** means that the right/left relationships of the asymmetric viscera and the atria are usual. That is, the right (eparterial) and left (hyparterial) mainstem bronchi are normally positioned, the right atrium is to the right of the left atrium, and the left atrium is to the left. **Situs inversus** indicates that the right/left relationships are the opposite of usual. In chemical language, these are isomers. With rare exceptions, atrial and thoracic visceral situs are the same (concordant). **Situs ambiguous** is the absence of lateralization in the thoracic organs and atrial chambers.\(^{V3,V4}\) in the latter case, this condition is termed atrial isomerism (see Chapter

</table>

\(^{a}\)Normalization is in terms of BSA.

Key: 2D, Two-dimensional; BSA, body surface area.
In asplenia and polysplenia, the usually asymmetric structures tend to be symmetric. In both, in contrast to normal, the length of the right and left mainstem bronchi is the same, as is the relation of each bronchus to its pulmonary artery and the configuration of the artery. Persons with asplenia tend to have bilateral right-sidedness and right atrial isomerism, a condition identified by finding the right-type configuration of mainstem bronchi and its pulmonary artery on both left and right sides (the bronchus is relatively short and posterior and superior to the pulmonary artery, which bifurcates into an upper and lower trunk). Patients with polysplenia tend to have bilateral left-sidedness and left atrial isomerism, with the left-type configuration of the mainstem bronchi and its pulmonary artery on both sides (the bronchus is anterior and inferior to the pulmonary artery, which gives off individual branches rather than a discrete trunk to the upper lobe).

A determination of situs can sometimes be made by study of the plain chest radiograph. When there is situs ambiguous, a common atrium is often present, and only the morphology of the atrial appendages indicates whether there is right or left atrial isomerism (see Chapter 58). Complex forms of congenital heart disease tend to occur in patients with atrial isomerism, although in rare cases the heart is normal.

Situs of the Ventricles

In situs solitus, ventricles are said to have normal (usual, concordant) situs when the morphologically right ventricle is anterior and to the right of the morphologically left ventricle, which is posterior and to the left. Van Praagh’s term, D-loop, may be used to describe this ventricular situs or isomer, as may his term right-handedness, also used by Anderson. D-loop indicates that the sinus portion of the morphologically right ventricle is to the right vis-à-vis that of the left. In hearts with D-loop (as described by Van Praagh), direction of blood flow in the right ventricle is from right to left through the right-sided tricuspid valve and inflow (sinus) portion to the usually left-sided outflow portion (infundibulum). D-loop or right-handedness can also be defined as existing when the palmar surface of the right hand can be placed on the septal surface of the right ventricle such that the thumb is in the inlet (tricuspid valve), the wrist is in the apical trabecular component, and the fingers are in the outlet (pulmonary valve).

In situs solitus, ventricles are said to be inverted when the morphologically right ventricle is more or less posterior and to the left of the morphologically left ventricle; Van Praagh’s term, L-loop, applies here, as does the term left-handedness. In L-loop, the sinus (inlet) portion of the morphologically right ventricle is to the left vis-à-vis that of left ventricle; that is, internal organization is opposite of that in D-loop, and direction of blood flow is from the left-sided tricuspid valve to the right-sided infundibulum. L-loop, or left-handedness, can also be defined as existing when the palmar surface of the left hand can be placed on the septal surface of the right ventricle such that the thumb is in the inlet, the wrist is in the apical trabecular component, and the fingers are in the outlet. L.M. Barger (UAB; personal communication) suggested that looking through the right ventricle’s AV valve toward its apex, in D-loop the septal structures are to the left, and in L-loop they are to the right.

In atrial situs inversus, L-loop is the normal (usual, concordant) situs and D-loop is the inverted situs. The definitions of loop, or handedness, are independent of atrial or visceral situs and are thus the same as just described. Because there are two possible ventricular situses (D-loop and L-loop) in both atrial situs solitus and atrial situs inversus, there are four basic hearts, an idea expressed many years ago by Stanger, Edwards, and colleagues (see Appendix 1H). When thoracic and atrial situs are ambiguous, only ventricular situs can be described, and its relationship to thoracic and atrial situs is “ambiguous.”

Completeness of the Ventricles

Both the right and left ventricle may be considered to have inlet, sinus, and outlet portions when complete. Either ventricle may be incomplete (or rudimentary). For example, the inlet portion of the right ventricle is absent in hearts with tricuspid atresia.

Dominance of the Ventricles

Normally, the size of the two ventricles is similar and can be said to be balanced. In many kinds of cardiac conditions, one ventricle is larger, or dominant, and the smaller one can be severely hypoplastic. The dominance may be mild, moderate, or severe. Generally, a ventricle is said to be dominant only when the other ventricle is too small to maintain adequate pulmonary or systemic blood flow.

Cardiac Connections

Information about cardiac connections is fundamental in describing any malformed heart and requires elucidation at both AV and ventriculoarterial levels. The AV connection may be concordant (right atrium connects to right ventricle;
left atrium connects to left ventricle), discordant (right atrium connects to left ventricle; left atrium connects to right ventricle), univentricular (atria connect to only one ventricle; see Chapter 56 for more details of this subset), or ambiguous (situs ambiguous of atria). When an AV valve is straddling, it is considered to be connected to the ventricle into which more than 50% of the valve orifice faces. As Bharati and colleagues have pointed out, it is pertinent to distinguish between straddling of the valve anulus across the septum and of the chordal attachments into an inappropriate ventricle.88 Milo and colleagues suggested that the term overriding be used when referring to the anulus, and straddling when referring to chordal attachments.56

The ventriculoarterial connection may be discordant (left ventricle connects wholly or nearly so to aorta; right ventricle to pulmonary artery) or discordant (right ventricle connects to aorta, left ventricle to pulmonary artery, commonly called transposition of the great arteries). As with AV connections, when a semilunar valve is overriding a VSD, it is considered to be connected to the ventricle from which more than 50% of the valve area arises. The connection may also be double outlet (great arteries arise wholly or for the most part from one ventricle).

The ventriculoarterial connection may be considered single outlet when there is a common arterial trunk (truncus arteriosus communis) or only a single artery, usually the aorta, connected to a ventricle. In the latter case, there is usually pulmonary atresia, and categorization as single outlet ventriculoarterial connection, although morphologically precise, considerably complicates the presentation of information in many types of congenital heart disease. Alternatively, the ventriculoarterial connections can be termed concordant, discordant, or double outlet by identifying the connection, although atretic, of the pulmonary artery to a ventricle. Even when there is a ventriculopulmonary artery discontinuity, this is often possible. For example, when the morphology is typical for tetralogy of Fallot, except that there is only a single ventricular outlet because of pulmonary atresia, the condition is called tetralogy of Fallot with pulmonary atresia (see Chapter 38).

Cardiac and Arterial Positions

Normally, the cardiac apex points to the left, a situation called levocardia. The term dextrocardia applies when the cardiac apex points to the right, and mesocardia when it is in the midline. There is merit to using the term dextroversion to denote dextrocardia with situs solitus of the viscera and atria, and levoversion to denote levocardia with situs inversus. Dextroversion and levoversion alter the geometry and position of all cardiac chambers. Thus, the position of the heart is important surgically, but it is not a basic abnormality, as is D- or L-loop. The left atrium is generally to the left and the right atrium to the right in situs solitus, and vice versa in situs inversus.

Position of the ventricles is determined primarily but not exclusively by the ventricular situs (loop or handedness). The morphologically right ventricle is usually anterior and to the right in D-loop, and the left ventricle posterior and to the left. Generally, with L-loop (inverted ventricles), the morphologically left ventricle is anterior and to the right, and the morphologically right ventricle is posterior and to the left. However, the ventricles may be side by side or directly anteroposterior to each other, with either ventricle in either position. Ventricles may also be in a superoinferior (over and under) position; this occurs most commonly with L-loop but can occur with D-loop. This and probably other positional anomalies are most clearly seen by echocardiographic and angiographic study and may be entirely overlooked by autopsy studies. Positional interrelations are not basic pathologic entities, but rotational anomalies producing variations of the four basic hearts.

The possible positions of the origins of the great arteries are nearly infinite around the 360 degrees of a circle but may be simplified as (1) normal, with aorta to the right (in visceroatrial situs solitus) or left (in inversus) and somewhat posterior to the pulmonary artery; (2) aorta anterior to the pulmonary artery, either directly or somewhat to the right (D-malposition); (3) aorta to the left of the pulmonary artery (L-malposition); and (4) aorta posterior to the pulmonary artery. Normally, the great arteries tend to cross rather than run parallel. In contrast, when the great arteries are malposed, their first portions are usually parallel.

As indicated, these are all positional arterial abnormalities and are not basic parts of a malformation. However, certain probabilities exist. For example, the inflow portion of the right ventricle is usually on the side of the aortic origin.

Atrioventricular Flow Pathways

In normal hearts, AV flow pathways are more or less parallel. In cases of crisscross AV flow pathways, they cross over each other. The term crisscross hearts was introduced by Ando and colleagues416 and Anderson and colleagues418 in 1974, but the condition had been described earlier by Lev and Rowlatt in 1961.57

The word crisscross has led to confusion and controversy. One point of view is that in some abnormal hearts, the pathways cross when viewed on cineangiography. Another point of view is that this is an illusion.414 In any event, crisscross has no implications with regard to internal ventricular architecture or AV connections. The crisscross of the flow pathways is produced by positional abnormalities of the ventricles (often a superior/inferior position). Hypoplasia of the inflow or sinus of the right ventricle often contributes to crisscross. In most cases of crisscross, there is ventriculoarterial discordant connections and either discordant ventriculoarterial connections or double outlet right ventricle.

Defects and Abnormalities

Defects involving cardiac septa, chambers, and valves occur as more or less isolated anomalies, but are more common when connection and rotational anomalies exist. Such defects must be described separately for each heart, along with segmental situs, connections, and positions of the heart. Possible defects include VSD, atrial septal defect, AV septal defect, anomalous systemic and pulmonary venous connections, congenital valvar and subvalvar lesions, straddling AV valves, and abnormalities of septal morphology, including infundibular (conal) development.

Conventional Diagnoses

As a summarizing convenience, certain old and widely used phrases that are in themselves not anatomically specific but well understood by surgeons continue to be useful. In each
instance, morphology denoted by a given phrase must be defined, in part because others may use the same phrase (e.g., transposition of the great arteries) differently. Such phrases include AV canal (see Chapter 34), tetralogy of Fallot (see Chapter 38), Taussig-Bing heart (see Chapter 53), complete transposition of the great arteries (see Chapter 53), double outlet ventricle (see Chapters 53 and 54), corrected transposition of the great arteries (see Chapter 55), isolated ventricular inversion (see Chapter 55), and anatomically corrected malposition of the great arteries (see Chapter 57). In the interest of readability, the text does not use quotation marks for these phrases; once defined they are used primarily for convenience.

Symbolic Convention of Van Praagh

Van Praagh’s symbolic convention for the heart—for example, S,D,D heart—is widely used and a convenient and concise way of expressing certain anatomic features and relations. The first symbol refers to situs (isomerism) of thoracic viscera and atria (S for solitus, I for inversus). The second symbol indicates situs (isomerism) of the ventricles in terms of D-loop and L-loop (see “Situs of the Ventrices”). When taken with the first symbol, it is of fundamental significance in designating which of the four basic hearts, or isomeric combinations, is present. The third symbol refers to position of the aortic origin (D for right-sided, L for left-sided).

1A Morphogenesis

Kirklin and Barratt-Boyes were reluctant to use terms with developmental implications, but our understanding of developmental events that lead on the one hand to normal anatomy and on the other to morphologic abnormalities has greatly expanded in recent years. It is now well understood that certain anomalies of the aorta can be traced to abnormalities of fetal remodeling of the embryonic aortic arches. Abnormalities of the aorta in bicuspid aortic valve appear traceable to neural crest cells that migrate late in heart development. Van Praagh and colleagues present a unifying developmental theory for a large number of congenital heart anomalies, including transposition of the great arteries, double outlet ventricles, tetralogy of Fallot, and VSD. These anomalies have in common variable remodeling (resorption) of the embryonic subarterial conus, particularly that under the developing aortic valve. Insights such as this give rise to the idea, for example, that tetralogy of Fallot is fundamentally a monolesion from a developmental perspective.

Discoveries about the genetic basis for a number of cardiac abnormalities are also on the rise. How this knowledge will be instrumental in advancing cardiac surgery in particular and cardiothoracic medicine in general is uncertain at this time.

1B Normal Pathway Dimensions from Autopsy Specimens

Rowlatt and colleagues provided extensive information about the dimensions (measured as circumference) of cardiac valves in formalin-fixed autopsy specimens from apparently normal children. Because usually it is the diameter that is measured by echocardiography, angiography, and in the operating room, circumferences have been transformed to diameter, assuming that valve orifices are perfectly circular and using the equation:

\[
\text{Diameter} = \frac{\text{Circumference}}{\pi}
\]

These dimensions can also be expressed in terms of cross-sectional area, using for the transformation the equation:

\[
\text{Area} = \pi \left(\frac{\text{Diameter}}{2}\right)^2
\]

Krovetz and Westaby and colleagues also made measurements from adult autopsy specimens that are compatible with those of Rowlatt and colleagues. These investigators added the information that as adults age, the aortic orifice gradually enlarges. Eckner and colleagues measured
pressure-fixed autopsy specimens and found dimensions similar to but slightly larger than those of Rowlett and colleagues.\(^{31}\) Scholz and colleagues also present extensive information on cardiac dimensions obtained in autopsy specimens.\(^{30}\) Their findings and equations are generally similar to those of Rowlett and colleagues, except they find that valve dimensions are best normalized to age and gender of the individual (rather than to body surface area [BSA]). These investigators believe that the predicted values from their regression equations are applicable to either fresh or fixed specimens and compare well with systolic anular dimensions obtained by imaging techniques in living subjects.

Most of the information in this book relating dimensions in patients to those obtained at autopsy uses equations derived from the work of Rowlett and colleagues\(^{34}\) to compute the mean normal value and standard deviation based on the patient’s BSA. This group expressed dimensions as circumference and BSA as cm\(^2\). For use in this text, these have been transformed into diameter (assuming the cross-section was a perfect circle) and m\(^2\). Diameters of cardiac valves for normal individuals are summarized in Table 1B-1.

Capps and colleagues\(^{52}\) analyzed 6801 fresh autopsied hearts for valve cryopreservation over the range of 0.18 to 3.55 m\(^2\) BSA. Mean indexed aortic valve area \((n = 4636)\) was 2.02 ± 0.52 cm\(^2\) · m\(^{-2}\). Mean diameters of each valve within ranges of BSA are given in Table 1B-2. Regression equations useful for predicting mean normal aortic and pulmonary valve diameters are given for males, females, and overall in Table 1B-3. This analysis ignores increase in valve size due to aging, which, though normal, may be considered a degenerative process.

Modified from Capps and colleagues.\(^{21}\)

\(^{1}\)General form of equation: predicted diameter = exp(intercept + slope · Ln(BSA)), where exp is the base of the natural logarithms (Ln).

Key: AVD, Aortic valve anulus diameter; BSA, body surface area; PVD, pulmonary valve anulus diameter; SD, standard deviation.
Normal Pathway Dimensions from Cineangiography

Using cineangiograms made in both anteroposterior and lateral projections in 42 normal children, Bini and colleagues measured cardiac and great artery dimensions at peak systole and in diastole (Bini M, Naftel DC, Blackstone EM: unpublished study, 1984). Median patient age was 12 months, range 2 days to 16 years; 25% were 2 months of age or younger, and 25% were 67 months of age or older; 24 were males and 18 were females. Consideration of adoption was usually the indication for study. Structures measured included midportion of the right ventricular infundibulum and junction of the right ventricle and pulmonary artery (“anulus”); distal end of the pulmonary trunk; origin, midportion, and immediately prebranching portion of the right pulmonary artery; origin and immediately prebranching portion of the left pulmonary artery; and aorta immediately downstream to the aortic valve, immediately before the takeoff of the brachiocephalic artery, and immediately above the diaphragm. By dividing the measured internal diameter of the cardiac catheter in the same frame by the known internal diameter of the catheter, a correction factor was calculated and used to correct the measured value for magnification.

To account for increased scatter of dimension data as body surface area (BSA) increased, logarithmic transformations were made of both dimension and body size. Individual regression equations (derived only when the number of observations was >10) were developed for each location and individually for systole and diastole in the anteroposterior and lateral projections. Mean normal diameter and standard deviation according to BSA were derived from these equations. A similar analysis of cineangiographic measurements was made earlier by Sievers and colleagues. Both groups, working without knowledge of the other, found logarithmic transformation to best express the relations. Information for the equations is presented in Tables 1C-1 and 1C-2. The equations may be used to calculate the mean normal dimensions and standard deviations of the right ventricular outflow tract and pulmonary arteries for a specific BSA, for use in determining the z value of the dimension of a structure in a patient.

Dimensions of a part of the left ventricular tract and aorta were also determined by the Bini and Sievers groups (Bini M, Naftel DC, Blackstone EH: unpublished study, 1984) (see Tables 1C-1 and 1C-2). Clarkson and Brandt made measurements of the aorta in cineangiograms of normal infants and young children, similar to those of Bini and colleagues.

Most of the information in this book relating patient dimensions to z values based on cineangiographic measurements uses regression equations derived from measurements made by Bini and colleagues, which are similar to those made by Sievers and colleagues (see Tables 1C-1 and 1C-2). Unfortunately, they did not measure the tricuspid valve. These equations are used to calculate normal mean values and standard deviations according to the patient’s BSA; then the equation given in “Standardization of Dimensions” (see text) is used to calculate the z value. These equations and nomograms are for diameter. Some prefer to express the dimensions of the pulmonary arteries as cross-sectional area. Because of the logarithmic transformation used in the Bini and Sievers analyses, the z value for cross-sectional area is the same as that for diameter.

aNormal structure size (diameter or cross-sectional area) is calculated as $\text{Ln(size[diameter or cross-sectional area])} = \text{scale factor} + \text{exponent} \cdot \text{Ln(BSA)}$, where body surface area (BSA) is expressed as square meters. Size can then be obtained by exponential transformation (e taken to the power of the logarithm). If diameter is used, coefficients are as shown in the table. If cross-sectional area is used, a circular lumen is assumed and the coefficients modified by multiplying the scale factor by 2 and subtracting 0.2415645 from the value obtained [Ln($\pi$) − 2Ln(2)], by multiplying the exponent by 2, and by multiplying the standard deviation by 2. In all instances, $P < .0001$.

The z value (number of standard deviations a structure is above or below normal size) is calculated from the observed size as the logarithm of the observed size minus the calculated logarithm of normal size, divided by the standard deviation. Because the analysis uses the logarithmic transformation, z obtained using diameters is identical to one using cross-sectional area. All logarithms are natural logarithms.

b(Systolic + diastolic diameters)/2.

Normal Pathway Dimensions from Two-Dimensional Echocardiography

Dimensions obtained by two-dimensional (2D) echocardiography are sometimes measured and expressed as length of anulus (without a commitment as to the shape of the orifice), sometimes as the shortest axis (anteroposterior) and the longest axis (lateral), and sometimes as cross-sectional area measured directly on the 2D echocardiographic image, without an assumption as to shape. Sometimes both the smallest and largest dimensions in a cardiac cycle are measured and expressed.

Daubeney and colleagues\textsuperscript{1,2} have provided a comprehensive catalog of cardiac structural dimensions by 2D echocardiography in normal infants and children. Definition of each dimension and the 2D echocardiographic view in which it was measured are given in Table 1D-1. For the most part, a regression equation was developed using BSA in the logarithmic transformation domain. The regression equation is:

$$\text{Ln}[\text{Mean normal diameter (mm)}] = \text{Intercept} + \text{Slope} \cdot \text{Ln}(\text{BSA})$$

where \textit{mean normal diameter} is specific for BSA, BSA is expressed in square meters, and \text{Ln} is the natural logarithm. Values for the intercept and slope, as well as for the standard deviations (root mean square error), are presented in Table 1D-2. Values are the largest ones during the cardiac cycle, nearly always at end-diastole. The \text{z} value equation (see “Standardization of Dimensions” in text) can then be used to calculate the \text{z} value. More simply, a nomogram (Fig. 1D-1) may be used.

King and colleagues measured dimensions of mitral and tricuspid valves by 2D echocardiography.\textsuperscript{5} Based on these data, regression equations were developed for mean normal diameter (logarithmic transformation) and BSA (logarithmic transformation) as shown in Table 1D-3. A digital nomogram is presented in Table 1D-4.

Habbal and Somerville measured dimensions of the left ventricular–aortic junction (aortic “anulus”) in normal children by 2D echocardiography.\textsuperscript{1,1} Their regression equation relating mean normal value to BSA is:

Based on data from King and colleagues. From Daubeney and colleagues.

The form of the equation is Ln(mean normal value of structure) = intercept + slope · Ln[BSA], where Ln is the natural logarithm and BSA is body surface area (m²). The structures are expressed in cm or cm². Value of z can be calculated as z = [Ln(measured structure) − Ln(mean normal value)]/SD. Key: A-P, Anteroposterior; Lat, lateral; SD, standard deviation (root mean square error).

Based on data from King and colleagues. Measured in parasternal long-axis projection. Measured in four-chamber view. Key: SD, Standard deviation.

Mean normal value = 17.20[1 − exp(−2.486 · BSA)] + 0.4663 · BSA

where Ln is the natural logarithm and exp is e, the base of the natural logarithms. The standard deviation is 0.09717 and was obtained in the log-log domain to stabilize variability. Therefore, as in the case of Bini and colleagues' analysis of cineangiographic data and Daubeney and colleagues' analysis of 2D echocardiography, the z value for cross-sectional area in a given patient is the same as for diameter, because of the logarithmic transformations used.

Using 2D echocardiography in children, Snider and colleagues measured cross-sectional dimensions of the right pulmonary artery and pulmonary trunk. The regression equation is:

\[ \text{Mean normal diameter (mm) = Intercept + Slope} \cdot \sqrt{\text{BSA}} \]

where BSA is expressed in square meters. Values for the intercept and slope are given in Table 1D-5. Because insufficient numeric data are presented to permit derivation of the standard deviation for the mean normal diameter, z values cannot be derived from this analysis.
Figure 1D-1 Nomograms expressing measured diameter of the indicated structure (isobars) in an individual of a given body surface area (horizontal axis) as a z value (vertical axis). Mean normal values and standard deviations used in equations to calculate z values were obtained from Daubeney and colleagues (see Table 1D-2). A, Tricuspid valve. B, Right ventricular–pulmonic junction (pulmonary valve).

Comparison of Pathway Dimensions from Different Measurement Modalities

Comparisons between Cineangiographic Dimensions and Those Obtained at Autopsy

The relationship of measurements obtained by imaging techniques to those obtained from autopsy specimens is arguable, but as was expressed earlier, this is not critical in studies relating dimensions to outcome when the $z$ value is used. Differences relating to measurement modalities are nonetheless interesting.

Dimensions obtained from autopsy data are probably the most complete and reliable dimensions available. Even among postmortem direct measurements of dimensions, however, differences exist. As stated earlier, Scholz and colleagues found that dimensions are similar in both fresh and fixed specimens (except that when pressure fixation is used, the tricuspid valve and right heart dimensions are somewhat larger) and that dimensions in autopsy specimens from normal children are similar to those obtained by imaging techniques. However, Alboliras and colleagues obtained data indicating that autopsy measurements should be multiplied by 1.04 to be comparable to cineangiographic measurements. Bull and colleagues derived a multiplication factor of 1.4 for this purpose.

A comparison of the carefully performed cineangiographic measurements of Sievers and colleagues with those of Rowlatt and colleagues indicates that normal dimensions for the left ventricular–aortic junction were about 40% larger cineangiographically than at autopsy (Fig. 1E-1). A similar comparison of the dimensions of the right ventricular–pulmonary artery junction indicated that in subjects of less than about 1 m² body surface area (BSA), cineangiographic measurements were about 17% larger, and that in larger subjects, cineangiographic measurements were 33% larger (Fig. 1E-2).

Sepehri and colleagues found that in diseased states in children, dimensions of the left ventricular–aortic junction obtained at autopsy were similar to those obtained from cineangiography, whereas those of the mitral valve obtained by cineangiography were approximately 16% larger than those obtained at autopsy. These same investigators, using a perfusion fixation technique, found the tricuspid valve to be about 50% larger by cineangiography and the pulmonary valve about 14% larger, thereby confirming the statements of Scholz and colleagues.

Comparisons between Two-Dimensional Echocardiographic Dimensions and Those Obtained at Autopsy

An informal comparison between the echocardiographic measurements of the mitral valve by King and colleagues and those obtained at autopsy by Rowlatt and colleagues suggests that in subjects who have less than about 0.5 m² BSA, the echocardiographic dimensions are about 33% larger (Fig. 1E-3). A similar comparison between the echocardiographic dimensions obtained by Riggs and colleagues and those obtained in autopsy specimens by the Rowlatt group indicates that dimensions were similar in small subjects, but the echocardiographically determined dimensions were about 20% larger in patients with BSAs greater than 1 m².

Other Comparisons

Formal comparisons of dimensions of cardiac structures in normal subjects obtained by angiography and echocardiography are missing. However, N.C. Nanda (personal communication, 1989) believes that in diseased states, echocardiographic dimensions are slightly larger than angiographic ones, probably because different bordering structures are used to define the dimension in these two different imaging techniques.

It is particularly difficult to compare dimensions derived from all three modalities. However, a comparison made for the tricuspid valve suggests that there is considerable difference in dimensions obtained using different measurement modalities (Fig. 1E-4).
**Figure 1E-1** Relation between diameter of left ventricular–aortic junction (aortic “anulus”) and body surface area, according to whether measurements were made in fixed autopsy specimens (Rowlatt and colleagues\(^\text{R4}\)) or by cineangiography (Sievers and colleagues\(^\text{S15}\)). Solid lines represent continuous point estimates of the relations, and dashed lines enclose 70% confidence interval.

**Figure 1E-2** Relation between diameter of right ventricular–pulmonary artery junction (pulmonary “anulus”) and body surface area, according to whether measurements were made on fixed autopsy specimens (Rowlatt and colleagues\(^\text{R4}\)) or by cineangiography (Sievers and colleagues\(^\text{S15}\) and Bini M, Naftel DC, Blackstone EH: Unpublished study, 1984). Meanings of depictions are as described for Fig. 1E-1.

**Figure 1E-3** Relation between diameter of mitral valve orifice and body surface area, according to whether measurements were made in fixed autopsy specimens (Rowlatt and colleagues\(^\text{R4}\)) measuring circumference or by echocardiography (King and colleagues\(^\text{K5}\) measuring major and minor axes; Riggs and colleagues\(^\text{R2}\) measuring area directly). Meanings of depictions are as described for Fig. 1E-1. Key: AP, Anteroposterior.

**Figure 1E-4** Relation between diameter of tricuspid valve and body surface area, according to whether measurements were made in fixed autopsy specimens (Rowlatt and colleagues\(^\text{R4}\)), by cineangio- graphy (Alboliras and colleagues,\(^\text{A6}\) Bull and colleagues\(^\text{B13}\)), or by echocardiography (King and colleagues\(^\text{K5}\)). Meanings of depictions are as described for Fig. 1E-1.
Four data sets were used to derive the interrelationships among three methods of expressing the dimensions of the right and left pulmonary arteries: (1) 35 normal children among the 42 studied by Bini and colleagues (see Appendix 1C), (2) 168 patients who had undergone repair of tetralogy of Fallot with pulmonary stenosis, whose cineangiograms were made before any surgical procedure, \(^{31}\) (3) 215 patients with tetralogy of Fallot and pulmonary atresia, \(^{31}\) and (4) 106 patients who had undergone the Fontan operation. \(^{33}\)

Comparisons are expressed in Figs. 1F-1, 1F-2, and 1F-3.

**Figure 1F-1** Relation between McGoon ratio and \(z\) value for summed diameters of right and left pulmonary arteries just before the takeoff of their first branch. **A**, Analysis of all patients as a single group. Symbols represent an individual patient’s values, solid line represents the continuous point estimate of the relation, and dashed lines enclose 70% confidence interval. The regression equation is:

\[
\text{McGoon ratio} = 2.355 \cdot \exp(0.1356 \cdot z)
\]

where \(\exp\) is \(e\), the base of the natural logarithms. **B**, Individual analysis of each of the four groups. No confidence limits are displayed. Key: \(P\), Pulmonary; \(PS\), pulmonary stenosis; TF, tetralogy of Fallot.

**Figure 1F-2** Relation between cross-sectional area index (mm\(^2\) \(\cdot\) m\(^{-2}\)), the so-called Nakata index, and \(z\) value for summed diameters of the right and left pulmonary arteries just before takeoff of their first branch. **A**, Analysis of all patients as a single group. Meanings of depictions are as described for Fig. 1F-1. The regression equation is:

\[
\text{CSA index} = 288.6 \cdot \exp(0.1856 \cdot z)
\]

where \(\exp\) is \(e\), the base of the natural logarithms. **B**, Individual analysis of each of the four groups. No confidence limits are displayed.
Figure 1F-3 Relation between McGoon ratio and cross-sectional area index (mm$^2 \cdot$ m$^{-2}$). A, Analysis of all patients as a single group. Meanings of depictions are as described for Fig. 1F-1. The regression equation is:

McGoon ratio = 0.07332 \cdot CSA index + 0.599

B, Individual analysis of each of the four groups. No confidence limits are displayed. Key: CSA, Cross-sectional area; P, pulmonary; PS, pulmonary stenosis; TF, tetralogy of Fallot.

1G Normal Ventricular Volume, Masses, and Dimensions from Different Measurement Modalities

Right and left ventricular dimensions and area, left ventricular wall thickness and mass, and septal thickness were measured by echocardiography (Table 1G-1). Regression equations are presented in Table 1G-2. Fig. 1G-1 shows the information presented in pairs of figures.

In addition to the measurements of Daubeney and colleagues, the relation between right ventricular end-diastolic volume (RVEDV) and body surface area (BSA) was presented by Graham and colleagues, Thilenius and Arcilla, Nakazawa and colleagues, and Lange and colleagues. Graham’s equation and its use for $z$ values is:

$$\ln(\text{mean normal RVEDV, mL}) = 4.162 + 1.340 \cdot \ln(\text{BSA, m}^2)$$

and:

$$z = \frac{\ln(\text{observed RVEDV}) - \ln(\text{normal RVEDV})}{0.2710}$$

where 0.2710 is the standard deviation and $\ln$ is the natural logarithm.

The relation between right ventricular end-systolic volume (RVESV) and BSA was presented by Graham and colleagues, Thilenius and Arcilla, and Lange and colleagues. Graham’s equation and its use for $z$ values is:

$$\ln(\text{mean normal RVESV, mL}) = 3.692 + 1.284 \cdot \ln(\text{BSA, m}^2)$$

and:

$$z = \frac{\ln(\text{observed RVESV}) - \ln(\text{normal RVESV})}{0.3211}$$

Mean normal value for right ventricular infundibular wall thickness from Rowlatt and colleagues is 2.962 ± 0.779 mm and:

$$z = \frac{\text{Observed wall thickness} - 2.962}{0.779}$$

Mean normal value for right ventricular wall thickness in the area of the tricuspid valve is 3.117 ± 1.55 mm and:

$$z = \frac{\text{Observed wall thickness} - 3.117}{1.55}$$

The relation between heart weight and BSA was studied by Kitzman and colleagues, Scholz and colleagues, and Rowlatt and colleagues (Table 1G-3). The regression equation in all cases is:

Section I  Hypothermic Circulatory Arrest

HISTORICAL NOTE

In 1950, Bigelow and colleagues, in their publications on experimental hypothermia produced by surface cooling, introduced the concept that whole-body hypothermia might be useful in cardiac surgery. They subsequently reported cooling dogs to 20°C by surface cooling, with recovery after 15 minutes of circulatory arrest. In 1951, Boerema and colleagues reported experimental studies indicating that when animals were cooled by a femoral-femoral shunt through a cooling coil, up to 15 minutes of circulatory arrest (produced by inflow stasis) were tolerated without apparent ill effect. Using surface cooling, Lewis and Taufic reported successful repair of an atrial septal defect in a 5-year-old girl in 1953, and in the same year, Swan and colleagues reported successful results in a series of patients treated using the same technique. In 1958, Sealy and colleagues reported successful clinical cases in which hypothermia was combined with cardiopulmonary bypass (CPB). In 1959, Drew and colleagues reported experimental studies in which CPB (using the subject’s own lungs as the oxygenator) was used to cool and rewarm the subject, and operations were done during circulatory arrest at 15°C. In 1960, Guiot and colleagues and Weiss and colleagues reported use of hypothermia and circulatory arrest for cardiac surgery in humans. In 1961, Kirklin and colleagues at Mayo Clinic reported results of operation with hypothermic
tem perature is substantially lower than nasopharyngeal hypothermia is produced by surface cooling, internal tem perature of the organism during the arrest period. Conveniently, according to this equation, the reaction rate increases by two to three times for an increase in temperature of 10°C. Chemists use the symbol Q10 for this multiple.

At physiologic temperatures, biochemical systems operate only on the upswing of the curve. Thus—particularly when the range of temperatures is relatively small—this relationship finds numeric expression in the van’t Hoff law, which relates the logarithm of a chemical reaction rate directly to temperature. Conveniently, according to this equation, the reaction rate increases by two to three times for an increase in temperature of 10°C. Chemists use the symbol $Q_{10}$ for this multiple.

Because oxygen uptake is the expression of all oxidative reactions, both direct and indirect, the logarithm of $V_{O_2}$ might be expected to be directly proportional to temperature. In general, this appears to be so. Whether the observed decline in $V_{O_2}$ during clinical hypothermia can be accounted for entirely on this physicochemical basis is doubtful, however (see “Oxygen Consumption during Hypothermia in Tissue Slices and Isolated Organs” later in this section).
Box 2-1  Kinetics of Oxygen Consumption

The relationship of oxygen consumption \( (V_{O_2}) \) to perfusion flow rate \( (Q) \) and temperature \( (T) \) is not linear; that is, a unit increase in \( Q \) or \( T \) does not increment \( V_{O_2} \) a constant amount. A number of formal mathematical models (see Box 6-5 in Chapter 6) have been proposed that relate, in particular, metabolic activity and \( T \) based on fundamental thermodynamics. These models provide a good starting point for examining \( V_{O_2} \) data for other empirical relations, such as with blood flow.

**Arrhenius Equation**
The Arrhenius equation relates reaction rate \( k \) to temperature \( T \), the universal gas constant \( R \), activation energy \( E_a \), and a constant related to molecular collision as:

\[
k = A e^{\frac{E_a}{RT}}
\]

where \( e \) is the base of the natural logarithms. If logarithms are taken of both sides of this equation, one obtains the following:

\[
\ln[k] = \ln[A] - \frac{E_a}{RT}
\]

Constants \( A \), \( R \), and \( E_a \) are coalesced \((a, b)\) to obtain a log-inverse equation:

\[
\ln[k] = a - \frac{b}{T}
\]

Therefore, one can examine the correlation of the logarithm of oxygen consumption and inverse temperature to see if the data are consistent with this relation.

**van’t Hoff Law \((Q_{10})\)**
Another relation is expressed in the van’t Hoff law, which is generally formulated in terms of change in metabolic rate \( (k) \) per 10°C change in temperature \( (Q_{10}) \):

\[
Q_{10} = \left( \frac{k_1}{k_2} \right)^{\frac{10}{T_1 - T_2}}
\]

If \( T_1 - T_2 = 10^\circ \), then \( Q_{10} \) is simply the ratio of \( k_1 \) to \( k_2 \) (metabolic rates at each temperature). This relation can be derived from the parameter \( b \) in the Arrhenius equation.

**Hyperbolic Equation**
Metabolic rate (reflected in \( V_{O_2} \)) and \( Q \) should be independent until blood flow becomes limiting. This suggests a hyperbolic relation between the two variables:

\[
\frac{1}{V_{O_2}} = \frac{1}{c + \frac{d}{Q}}
\]

where \( c \) is the asymptotic (limit of \( V_{O_2} \) value of \( V_{O_2} \) as \( Q \) becomes large (metabolic rate independent of flow).

**Empirical Relations**
Actual data may be better characterized by (1) a linear relation (rare), (2) a log-linear (exponential) relation, (3) a log-log relation, (4) an inverse-log relation, or a more complex relation. Many of these models can be fitted to data using linear regression (see Box 6-5 in Chapter 6) by logarithmic or inverse transformations of scale. Others require iterative nonlinear optimization methods to obtain parametric estimates (see Box 6-14 in Chapter 6).

---

**Total Body Oxygen Consumption after Surface Cooling**

When hypothermia is induced by cooling the surface of anesthetized humans or experimental animals, cooling is rather uniform throughout the body, and temperatures of internal organs and regions differ by less than 2°C.\(^{C18}\) Therefore, values for whole-body \( V_{O_2} \) at various body temperatures are probably useful, and the relative magnitude of reduction can be assumed to be similar throughout the body.

Good data in this area are available from the animal experiments of Bigelow and colleagues, Ross, and Penrod.\(^{R31,R12,R22}\) Data for surface cooling in humans are sparse, although Harris estimated \( Q_{10} \) to lie between 1.9 and 4.2 in 10 surface-cooled infants.\(^{H17}\) The experimental data were reanalyzed using (1) a linear equation, (2) the Arrhenius equation, and (3) the van’t Hoff law. The van’t Hoff law best fits this combined set of data (Fig. 2-1) and is considered the most appropriate model for this purpose.\(^{R31,R12,R22}\) This model also best fits the relation between temperature and cerebral oxygen consumption during CPB in humans.\(^{C37}\)

Kent and Peirce studied \( V_{O_2} \) in experimental animals during hypothermia produced by combined surface and core cooling.\(^{K4}\) Their data are similar to those obtained from surface cooling alone.

**Oxygen Consumption during Hypothermia in Tissue Slices and Isolated Organs**

Data from the studies described could lead to an underestimation of true oxygen demand, because only areas in which perfusion of the microcirculation continues can participate in oxygen consumption (tissue and cellular stores of oxygen being trivial). In theory at least, a considerable part of the reduction in oxygen consumption from surface cooling could be from shutting down the microcirculation of portions of the body or from arteriovenous shunting. New technologies, particularly magnetic resonance imaging (MRI), may resolve some of these questions.\(^{N14,S7}\)

Studies of tissue slices at various temperatures show that oxygen consumption is in fact reduced by hypothermia.\(^{F12,F29,F31}\) These studies and those of isolated organs suggest that \( Q_{10} \), although differing from tissue to tissue, is on average about 2 (for references and a table of \( Q_{10} \) values, see Harris and colleagues).\(^{H18}\) Measurement of human whole-body \( V_{O_2} \) before and after heating, rather than cooling, indicates a \( Q_{10} \) in this range (=1.9).\(^{S11}\) Vasodilatation caused by heating presumably ensures access of oxygen to the tissues, and this \( Q_{10} \) probably represents true tissue oxygen requirement. A \( Q_{10} \) greater than 1.9 associated with cooling may therefore indicate that oxygen delivery has been compromised by inadequate flow rate. Fuhrman and colleagues have spent many years investigating this possibility. They showed that, in general, there was a close agreement between resting \( V_{O_2} \) at 37°C and tissue slice respiration.\(^{F31,M9}\) However, rats cooled by immersion to 18°C exhibited a 33% lower \( V_{O_2} \) than would be expected from studies of tissue slice respiration at this temperature.\(^{F12}\) The discrepancy was not accounted for either by inhomogeneities in whole-body temperature or by known changes in \( Q_{10} \) exhibited by some tissues (in part related to altered function at reduced temperatures). The precise mechanism remains unknown. It could be due to arteriovenous shunting or to shutting down of perfusion to
species differences in tissue respiration, suboptimal conditions for tissue respiration in the studies with tissue slices, or increased \( \text{VO}_2 \) during whole-body perfusion caused, for example, by catecholamine release.

A striking and important fact from whole-body, tissue, and organ studies is that \( \text{VO}_2 \) is not reduced to near zero at temperatures close to 0°C. Metabolic activity is therefore continuing, and the time limits of safe circulatory arrest must be finite. Furthermore, this continuing metabolic activity causes a tendency for organs and systems to rewarm during some areas of the body. Microvascular physiologists have referred to the latter as a decrease in effective capillary density. This may result not only from reduced cardiac output and vasoconstriction but also from changes in blood viscosity, geometry, and compliance of red blood cells, plasma “skimming,” and clumping of formed blood elements.

Some studies of tissue slices and isolated perfused organs show a relative reduction of oxygen consumption at any degree of hypothermia that is greater than in those of the body as a whole (Table 2-1). This may be related to known

---

**Figure 2-1** Temperature and oxygen consumption. (Note reversal of temperature scale from normothermia on the left to hypothermia on the right.) A, Figure contains two depictions. One is a group of symbols representing data points relating measured whole-body oxygen consumption (\( \text{VO}_2 \)) to body temperature in dogs made hypothermic by surface cooling. (Crosses are data points from Ross; circles from Bigelow and colleagues; squares from Penrod.) From these, a regression equation, the second depiction, was derived, showing the van’t Hoff relation between \( \text{VO}_2 \) and temperature (Appendix Equation 2A-1). Solid line (representing the point estimates) and dashed lines (70% confidence band) are nomograms of the equation. Slope indicates a \( Q_{10} \) of 2.7. B, Nomogram of the same equation, with oxygen consumption expressed as percentage of control value at 37°C.
the arrest period. Donald and Kerr showed in dog brains cooled to 1°C to 2°C that an increase in temperature occurred during a 30-minute period of circulatory arrest and that this was in part related to the gradient between brain and room temperature and in part to continuing metabolic activity in the brain.

**OTHER PHENOMENA DURING HYPOTERMIA AND CIRCULATORY ARREST**

**No-Reflow Phenomenon**

It is only a hypothesis that a numeric relationship exists between V\textsubscript{O\textsubscript{2}} and safe circulatory arrest time at any given temperature. In fact, existence of a necessary and close relationship between the two over a wide range of temperatures would be surprising in view of other phenomena that occur during circulatory arrest. One of these is regional vascular occlusion in the brain and probably in all organs and tissues, leading to the no-reflow phenomenon. This is an obstructive lesion of the microcirculation that prevents local reperfusion and leads to additional damage after the general circulation of blood has been reestablished.

The no-reflow phenomenon could theoretically damage the brain after hypothermic circulatory arrest. However, Norwood and colleagues have shown experimentally that this phenomenon develops as a result of severe hypoxia or anoxia, not because of circulatory arrest per se. They have also shown that hypothermia to 20°C prevents the no-reflow phenomenon from 90 minutes of anoxia produced by continuing perfusion at an arterial Pa\textsubscript{O\textsubscript{2}} of about 10 mmHg. Thus, this phenomenon may represent, at least in part, hypoxic endothelial cell injury, with altered expression of endothelial relaxing and constricting factors. In experimental studies, hypoxia followed by reoxygenation results in an almost twofold increase in release by endothelial cells of endothelin-1, the most powerful vasoconstrictor yet identified. Other experimental studies have shown that this response can be blunted when ischemia is induced under hypothermic conditions, so hypoxia may promote a procoagulant response in endothelial cells that can result in intravascular microthrombosis. Edema, as well as neutrophil and platelet plugging, may also contribute to the impaired perfusion that occurs following ischemia, despite what appears to be adequate restoration of blood flow.

**Changes in Plasma Volume**

Chen and colleagues demonstrated progressive hemoconcentration and decrease in plasma volume during surface cooling of infants to 25°C, an observation supporting their own and previous experimental studies. This may represent sequestration of plasma in portions of the vascular bed and plasma leakage into the interstitial fluid compartment.

**DAMAGING EFFECTS OF CIRCULATORY ARREST DURING HYPOTERMIA**

It is generally agreed that the brain has the shortest safe circulatory arrest time of any organ or region of the body, although occasionally the kidney seems to be damaged by a period of circulatory arrest when the brain is not. Although other organs and regions can be severely damaged by long periods of circulatory arrest, their safe arrest times are generally longer than that of the brain.

**Brain Function and Structure: Risk Factors for Damage**

The possibly damaging effects of circulatory arrest on the brain, as well as the risk factors related to it in patients undergoing cardiac operations during hypothermic circulatory arrest, are incompletely understood. The conduct of cooling and rewarming by CPB and the damaging effects of CPB itself likely contribute to or interact with the injury produced by circulatory arrest per se.

Duration of total arrest of cerebral blood flow is clearly a determinant of the amount of brain damage, but the safe duration of circulatory arrest to the brain (the duration within which irreversible structural or functional damage does not occur) is affected by a few known risk factors and no doubt by other risk factors that are as yet poorly understood. Furthermore, in patients undergoing cardiac surgery, brain damage that occurs in the setting of hypothermic circulatory arrest is rarely diffuse. In adults, it is usually manifested by specific intellectual or motor deficits, whereas in neonates, infants, and small children it is more likely to be manifested by seizures or choreoathetoid movements. This may be related to the phenomenon of selective neuronal vulnerability, a heightened sensitivity of specific neuron groups to ischemic injury. This sensitivity has been correlated with the concentration of specific membrane receptors whose density in

specific areas varies with age. Concentration of these receptors is transiently high in the basal ganglia in the neonatal period, which may relate to the appearance of choreoathetosis as a result of ischemic injury in the very young.

Risk factors for irreversible structural and functional brain damage from circulatory arrest, in addition to duration of the arrest, include mean and regional brain temperature during circulatory arrest, rate of cooling and rewarmin, cerebral blood flow and distribution during cooling, arterial blood pressure during cooling and reperfusion, electrical activity before arrest, biochemical milieu and catecholamine levels during cooling and circulatory arrest, absence of pharmacologic interventions before and after cessation of cerebral blood flow, and total management of reperfusion.

Temperature and Duration
Most clinical studies of the relationship of temperature to safety of a given circulatory arrest time are flawed by lack of information about the temperature of the brain itself and by the variety of sites of measurement of temperature ( tympanic membrane, nasopharynx, rectum, midesophagus, bladder, extremity skin) used to estimate safety. There is little consistent correlation between some of these sites, although temperature of the tympanic membrane and nasopharynx most closely resembles mean temperature of the brain. For this reason, these sites should be used whenever possible.

Animal experiments and clinical experiences indicate that when the brain is cooled to 15°C to 20°C, circulatory arrest of 30 minutes or less is tolerated without development of evident structural or functional damage. During such a period, adenosine triphosphate (ATP) concentrations decline to 35% of initial values but return rapidly to normal during reperfusion. Evidence that circulatory arrest of 45 minutes at these temperatures is safe is less secure.

Considerable information supports the inference that circulatory arrest of 60 minutes or more at temperatures of 15°C to 18°C is associated with irreversible structural or functional damage, although it may be tolerated without evident damage by some subjects under some circumstances. In experimental studies by Folkerth and colleagues and Fisk and colleagues, histologic evidence of anoxic brain damage was found in all animals subjected to hypothermic circulatory arrest for 45 to 60 minutes, although some animals survived without evident functional abnormality. Half (2 of 4) of the animals studied by Kramer and colleagues showed no recovery of ATP when subjected to 60 minutes of hypothermic circulatory arrest.

Some clinical studies have found few problems associated with 60 minutes or more of hypothermic circulatory arrest. Particularly striking is the experience of Coselli and colleagues, who found no clinical evidence of brain damage attributed to hypothermic circulatory arrest (mean nasopharyngeal temperature 16.9°C; range, 10.1°C-24.1°C) in 56 patients with arrest times ranging from 14 to 109 minutes (median 36 minutes). Comprehensive neuropsychometric studies were not undertaken. Hemiparesis or hemiplegia attributed to cerebral edema developed in 3 of 51 surviving patients (6%; CL 3%-11%). In contrast, Gega and colleagues, in a subsequent study of 394 patients undergoing aortic arch replacement, reported 8 strokes (13%; CL 8.6%-18%) among 61 patients in whom the duration of hypothermic circulatory arrest exceeded 40 minutes. Only 10 strokes (3.3%; CL 2.3%-4.3%) occurred among the remaining 333 patients with shorter intervals of circulatory arrest.

Temporary neurologic dysfunction (postoperative confusion, agitation, delirium, obtundation, or transient parkinsonism without localizing signs) can occur in up to 20% of survivors of operations on the thoracic aorta in which hypothermic circulatory arrest is used. Incremental risk factors associated with developing this complication are duration of hypothermic circulatory arrest and increasing patient age. Prevalence of temporary neurologic dysfunction increases substantially among patients in whom duration of circulatory arrest exceeds 60 minutes (Fig. 2-2). Although postoperative delirium is not permanent, it can be an important complication. Among a group of patients undergoing pulmonary thromboendarterectomy, circulatory arrest times of greater than 50 minutes were a powerful risk factor for its occurrence.

Some evidence supports the concept that continuous perfusion of the brain for 60 or more minutes at low temperature also produces neurolologic sequelae in a few patients (see “Evidence of Gross Neurologic Damage”). However, cold (10°C-15°C) continuous perfusion of brains already at 15°C resulted in no intellectual or other deficit in trained rhesus monkeys.

Characteristics of the Cooling Process
Uneven cooling of the brain is probably a risk factor for brain damage, although evidence is largely indirect. Almond and colleagues conducted experiments in dogs undergoing hypothermic circulatory arrest for 30 minutes. Results were interpreted to indicate structural and functional brain damage when cooling by CPB was done with the perfusate 20°C colder than the patient. These investigators believed that this did not occur when the blood was only 4°C to 6°C cooler than the subject. However, the damage might have been related to the short period of cooling required with the very cold blood, producing uneven brain cooling, as suggested by the work of Zingg and Kantor. The longer period of cooling required with the blood only 4°C to 6°C colder than the subject probably produced more uniform cooling. In their patients, Stewart and colleagues noted a considerably higher
prevalence of major neurologic events after circulatory arrest when core cooling by CPB alone was used, compared with surface cooling first to 28°C, followed by core cooling (Table 2-2). A reasonable presumption is that the more rapid core cooling resulted in uneven cooling of the brain. In another study in neonates and infants, rapid core cooling was associated with more evidence of neurologic deficits after hypothermic circulatory arrest than more prolonged core cooling. Again, a reasonable presumption is that prolonged core cooling results in more uniform cooling of the brain.

Cerebral Blood Flow during Cooling and Rewarming

The relationship of cerebral blood flow during cooling (before establishing hypothermic circulatory arrest) to safety of the arrest period has received little investigation. The earlier literature suggested that reduced arterial blood pressure during CPB without circulatory arrest contributes to postoperative neurologic dysfunction, presumably because the hypotension resulted in reduced cerebral blood flow but this possibility now appears less certain (see “Cerebral Blood Flow” under Distribution of Blood Flow in Section II).

More recently, when cerebral blood flow was measured during operations involving hypothermic circulatory arrest in children, Grecley and colleagues observed that patients with increased oxygen extraction before circulatory arrest may be particularly vulnerable to cerebral injury. In a subsequent study, they demonstrated that during cooling, a parallel reduction in cerebral oxygen consumption and cerebral blood flow occurred. However, in three of four patients who were subsequently found to have sustained neurologic injury, oxygen extraction before the period of circulatory arrest was increased, suggesting that cerebral blood flow during this period was inadequate to sustain metabolic requirements. Other studies in children have confirmed the observation that cerebral blood flow generally decreases with temperature during cooling, and that coupling with cerebral metabolism is maintained even at low temperatures when ventilation is managed according to the alpha-stat strategy.

Information is available about the magnitude and effect of cerebral blood flow during rewarming. Experimental studies have found that cerebral blood flow is reduced during rewarming after circulatory arrest (Fig. 2-3). With or without circulatory arrest, this phenomenon occurs in humans during cardiac surgery and may affect outcome. In infants, cerebral blood flow is reduced during rewarming immediately after hypothermic circulatory arrest and after achieving normothermia. Based on measurements of jugular venous oxygen saturation, oxygen delivery appears to be adequate during this period of reduced flow. In a study of 255 adult patients undergoing elective coronary artery bypass grafting (CABG) with or without associated cardiac valve replacement, Croughwell and colleagues observed a decline in postoperative cognitive function in 38%. The severity of decline was related to greater arteriovenous oxygen content difference between radial artery and jugular venous blood (CavO2) during rewarming. This increase in oxygen extraction was associated with a low jugular venous oxygen saturation and low cerebral blood flow.

Biochemical Milieu

Only incomplete information is available in the area of biochemical milieu. It is uncertain whether some variables are actual risk factors or surrogates for the real risk factor. Arterial blood pH and PCO2 during cooling may have important direct effects on brain tissue at the beginning of the period of circulatory arrest, and thereby on outcome, but they also influence cerebral blood flow, and perhaps its distribution, during cooling (see Controlled Variables in Section II). Any effect they may have on neurologic outcome, which is uncertain, could be through either mechanism.

Brunberg and colleagues and Anderson and colleagues suggested that increased tissue glucose, such as is usually present at the beginning of the arrest period, may lead to excessive glycolysis and acidosis during the arrest period, possibly resulting in tissue damage from lactic acid accumulation. This possibility makes it imprudent to

Data from Stewart and colleagues.511

*Excludes seizures followed by uneventful convalescence.

*Repair of ventricular septal defect, tetralogy of Fallot, transposition of the great arteries, and atrioventricular septal defects. Mean temperature ± standard deviation during arrest for both groups was 19.7 ± 1.7°C.

![Figure 2-3 Cerebral blood flow (mL · 100 g⁻¹ · min⁻¹) in gerbils after induction of and recovery from hypothermia by surface cooling. Along the horizontal axis is rectal temperature. Break between 37°C and 18°C represents 48 minutes of circulatory arrest (total bilateral carotid artery occlusion) at 18°C (arrest group) or continuing hypothermic perfusion (no arrest group). Note that cerebral blood flow was lower during rewarming in those animals that had total cessation of cerebral blood flow for 48 minutes. (From Kirklin.110)*
use glucose solutions for priming the pump-oxygenator and for intravenous infusion when a period of circulatory arrest is contemplated.

Based on the work of Choi and of Olney and colleagues, evidence has accumulated indicating that the neuroexcitatory amino acids—particularly glutamate, the major transmitter mediating synaptic excitation in the mammalian central nervous system—have potent neurotoxic activity during conditions of depleted cellular energy (e.g., hypoxia, ischemia) when the synaptic reuptake of these amino acids, a highly energy-dependent process, is compromised.\textsuperscript{17,66} Resulting overaccumulation of glutamate leads to excessive excitation of the glutamate receptors, leading to an increase in intracellular calcium and eventual neuronal cell injury and death. This process has been observed in experimental animals after 2 hours of circulatory arrest.\textsuperscript{85} Neuronal necrosis is selective and corresponds closely to distribution of excitatory amino acid receptors.\textsuperscript{84} The hippocampus, cerebellum, and basal ganglia, which have high concentrations of glutamate receptors, are characteristically most vulnerable to this injury, implying excitation as an underlying mechanism.\textsuperscript{84,85}

Apoptosis, or programmed cell death, has been demonstrated experimentally in the neocortex of piglets following hypothermic circulatory arrest for 90 minutes at 19°C.\textsuperscript{13,14} Damaged neurons were observed between 8 and 72 hours after reperfusion. Caspase 3 and caspase 8, the principal cysteine proteases involved in apoptosis, were substantially elevated in these animals compared to control animals (no CPB or CPB without circulatory arrest). ATP levels were similar to those of control animals. Glutamate excitotoxicity secondary to hypothermic circulatory arrest has been shown to mediate neuronal apoptosis as well as necrosis.\textsuperscript{79}

Fessatidis and colleagues' experimental studies using histopathologic techniques demonstrated that the cerebellum is the most vulnerable area of the brain to prolonged periods (>70 minutes) of hypothermic (15°C) circulatory arrest.\textsuperscript{10,11}

Electroencephalogram Before Arrest

Electroencephalographic (EEG) criteria for safe circulatory arrest are conflicting. In a study by Coselli and colleagues, the longest recorded durations of safe circulatory arrest in adults were in situations in which a full formal EEG had recorded \textit{electrocerebral silence} (no electrical activity of cerebral origin at maximal gain, 2 \textmu V \cdot mm\textsuperscript{-1}) for 3 minutes before the arrest.\textsuperscript{30} Mean nasopharyngeal temperature at this point was 16.9°C (range, 10.1°C-23.1°C).

In a subsequent study by Stecker and colleagues of 109 adult patients undergoing hypothermic circulatory arrest, electrocerebral silence was achieved at a mean nasopharyngeal temperature of 17.8°C (range, 12.5°C-27.2°C).\textsuperscript{28} Using a standardized protocol, this required cooling for a mean of 27.5 minutes (range, 12-50 minutes). Distinctions of times to cool to various EEG events are shown in Fig. 2-4. The time to cool to electrocerebral silence was prolonged by high hemoglobin concentration, low arterial partial pressure of carbon dioxide, and slow cooling rates. Only 60% of patients demonstrated electrocerebral silence by either a nasopharyngeal temperature of 18°C or a cooling time of 30 minutes. Although cooling to an end point such as electrocerebral silence provides a more reproducible effect of hypothermia on the nervous system than cooling to a specific temperature (e.g., 12.5°C, which was sufficient to produce electrocerebral silence in all patients in this study), the optimal temperature for circulatory arrest could not be determined.\textsuperscript{28}

Others have found that in infants and children cooled to a nasopharyngeal temperature of 18.5°C, the EEG was characterized by continuous phasic activity.\textsuperscript{28,13,10,11} During cooling, however, there was a gradual disappearance of fast components and an increase in slow components. Occasionally, repetitive rapid discharges occurred. Such reports indicate that when circulatory arrest is established, electrocerebral silence develops after an interval that is inversely related to nasopharyngeal temperature at the beginning of the arrest period.\textsuperscript{10,11} However, Reilly and colleagues reported persistent EEG activity during circulatory arrest, perhaps reflecting activity in the white matter and cerebellum.\textsuperscript{11} This is of interest because of the occasional postoperative occurrence of choreoathetoid movements in humans and high-stepping gaits in experimental animals. These abnormalities may be due in part to uneven brain cooling secondary to regional differences in flow.

When CPB is resumed after circulatory arrest in infants, EEG activity is absent initially and then gradually returns as rewarming proceeds.\textsuperscript{25} In general, after 20 to 30 minutes of rewarming, the EEG has returned approximately to its control condition.\textsuperscript{25} This latent period between resumption of whole-body perfusion for rewarming and time of return of reasonably normal EEG activity is believed by Weiss and colleagues to be related to the important metabolic (oxygen) debt that develops during the arrest period.\textsuperscript{11} This in turn is influenced by brain temperature during arrest and by duration of the arrest. They observed that when circulatory arrest lasted less than 40 minutes, EEG activity always reappeared within less than 20 minutes, whereas longer periods of circulatory arrest were followed by longer and more varied latent periods.\textsuperscript{11}

In adults, Stecker and colleagues observed that lower nasopharyngeal temperatures at the time of circulatory arrest resulted in a slower return to continuous activity.\textsuperscript{29} Prolonged time to recovery of continuous EEG activity and higher temperature at which the EEG first became continuous were associated with increased risk of neurologic injury. Patients who sustained postoperative neurologic injury also had a longer period of circulatory arrest (52 ± 21 minutes) than patients who did not (37 ± 12 minutes) (\textit{P} = .006).

\textbf{Patient Age}

Although it has been stated that very young patients suffer less brain damage than older patients from hypothermic circulatory arrest, there is little factual support for this concept. Relative to the general population, cognitive, language, and motor performances are importantly reduced at age 4 years in infants younger than 3 months in whom circulatory arrest has been used.\textsuperscript{14} In a randomized trial of 171 neonates with D-transposition of the great arteries who had open repair using either hypothermic circulatory arrest or low-flow CPB, the circulatory arrest group at age 4 years had lower motor scores and more speech abnormalities (\textit{P} = .03). They also performed worse on tests of fine motor and visuospatial skills.\textsuperscript{14} At 8 years, the circulatory arrest group performed worse on tests of motor function (\textit{P} = .003), speech apraxia (\textit{P} = .01), visual motor tracking (\textit{P} = .01), and phonologic awareness (\textit{P} = .0003) than children in whom low-flow CPB was used.\textsuperscript{12} In adults in whom circulatory arrest is used, increasing age is an important predictor of both stroke and
Temporary neurologic dysfunction is a marker for long-term functional neurologic deficit.\textsuperscript{E14,E15}

**Effects of Brain Damage**

**Choreoathetosis** has occurred early postoperatively in infants and children undergoing hypothermic circulatory arrest.\textsuperscript{B20,B58,C21,S31} When it occurs, it usually develops 2 to 6 days postoperatively. As time passes, the movements usually lessen in severity. If mild, they disappear completely, but if severe, they or hypotonia may persist. Brunberg and colleagues found no correlation between circulatory arrest time or depth of cooling (between 16°C and 20°C) and development of choreoathetosis.\textsuperscript{B58} These reports suggest that this specific complication occurs in 1\% to 12\% of patients and that its residual effects are permanent in some. When choreoathetosis occurs, it is often in the setting of prolonged circulatory arrest.\textsuperscript{S31}

Choreoathetosis has been observed in infants and children subjected to hypothermic CPB without circulatory arrest.\textsuperscript{D8}

**Figure 2-4** Distribution of nasopharyngeal temperatures at which various electroencephalogram (EEG) landmarks occur. A, Appearance of periodic complexes. B, Appearance of burst suppression. C, Electrocerebral silence. Examples of typical EEG patterns during cooling are also shown: D, Precooling. E, Appearance of periodic complexes. F, Appearance of burst suppression. G, Electrocerebral silence. Each of the EEG samples represents four channels recorded from the left hemisphere. (From Stecker and colleagues.\textsuperscript{S28})

**Figure 2-5** Relationship of interval (seconds) from beginning of circulatory arrest to appearance of electroencephalographic quiescence, and nasopharyngeal temperature at time of circulatory arrest. (Note reversal of temperature scale.) (Redrawn from Harden and colleagues.\textsuperscript{H13})
There are suggestions that this complication can result from perfusion of the brain with very cold blood for a prolonged period at relatively high flows.18,20 This is the basis for the recommendation that arterial temperature not be reduced to less than 15°C.

The cause of choreoathetosis is unclear. Deep hypothermia per se may cause neurologic injury. Egerton and colleagues reported that continuous hypothermic perfusion at 10°C to 12°C produced moderate or severe brain damage, including choreoathetosis, in 10 of 16 patients (63%; CL 46%-77%).19 Air or particulate embolization to the brain may be a contributing factor. When circulatory arrest is used, choreoathetosis may be related to uneven brain cooling, leading to continued metabolic activity in the white matter and cerebellum (as reported by Reilly and colleagues21), and possibly to uneven brain reperfusion related to vascular changes associated with the no-reflow phenomenon. The latter finding lends support to the rationale for using hemodilution during cooling, because absence of red cells in the perfusion used just before circulatory arrest to the brain eliminates the no-reflow phenomenon.22 Use of the alpha-stat strategy of acid-base balance has also been implicated as a causative factor.18

Seizures have occurred in the early postoperative period in 5% to 10% of patients undergoing hypothermic circulatory arrest.23,24,25,26,27 Because seizures are usually transient and followed by uneventful convalescence, they have not been considered major neurologic events. However, in an analysis from the Boston Circulatory Arrest Study involving 171 children with D-transposition of the great arteries, transient postoperative clinical and EEG seizures were associated with worse neurodevelopmental outcomes at ages 1 and 2.5 years, as well as neurologic and MRI-detected abnormalities at age 1 year.28 At age 4 years, occurrence of perioperative seizures was associated with lower IQ scores \( (P = .01) \) and increased risk of neurologic abnormalities (odds ratio 8.4, \( P = .05)\).29

In a more recent prospective study of 178 neonates and infants less than age 6 months undergoing CPB with or without hypothermic circulatory arrest for a variety of congenital heart defects, including hypoplastic left heart syndrome and other forms of single ventricle, EEG-recorded seizures occurred in 20 patients (11.2%, CL 8.8%-14.2%).30 Patients with duration of circulatory arrest of more than 40 minutes had more seizures (14 of 58, 24%; CL 18%-31%) than those with a duration of 40 minutes or less (4 of 59, 6.8%; CL 3.5%-12%; \( P = .04 \)). Occurrence of seizures among patients with a duration of circulatory arrest of 40 minutes or less was similar among those in whom circulatory arrest was not used \( (P = .58)\).

The comments concerning possible causes of choreoathetosis are applicable to seizures. However, it is well known that infants are highly susceptible to seizures from other causes, such as disturbances of thermoregulation and fluid balance, as well as from metabolic disorders, especially those related to glucose and calcium, and many of these factors may be operative in these patients.

Severe gross evidence of brain damage occurs uncommonly after hypothermic circulatory arrest in infants and children, including coma either dating from surgery or developing some hours later, followed by lasting impairment or death. In a study by Stewart and colleagues, 3 (1.4%; CL 0.6%-2.7%) such instances occurred among 218 young patients undergoing repair of the common types of congenital heart disease with hypothermic circulatory arrest; 5 other patients developed choreoathetosis.31 All these events occurred in the group of patients in whom core cooling alone was used. None occurred in patients in whom the duration of circulatory arrest was less than 45 minutes, and the probability of developing major neurologic events increased as circulatory arrest time increased beyond this (Fig. 2-6).

Focal neurologic damage resulting in serious neurologic impairment (stroke) occurs in adult patients following hypothermic circulatory arrest. Ergin and colleagues demonstrated that this form of injury is related to older age \( (P < .0001) \) particularly beyond 60 years, presence of clot or atheroma in the aortic arch \( (P < .0001) \), as well as longer duration of hypothermic circulatory arrest \( (P < .0001)\).32 In the series of adult patients reported by Gega and colleagues in whom hypothermic circulatory arrest was used as the sole means of brain preservation, prevalence of stroke was 13.1% (8 of 61; CL 8.6%-19.1%) among patients in whom the duration of circulatory arrest exceeded 40 minutes.33 Computed tomographic (CT) scans demonstrated that 62% of these strokes were embolic in origin and 38% were related to hypoperfusion.

**Postoperative Intellectual Capacity**

The effect of hypothermic circulatory arrest on late postoperative intellectual capacity and behavior in infants and children has been difficult to study. Problems in testing infants preoperatively so that each may serve as his or her own control contribute to the difficulty. Associated congenital developmental disorders, possible adverse effects before operation of severe congenital heart disease, and effects of other perioperative events complicate interpretation of the data.

Results of psychomotor testing in 146 children undergoing cardiac surgery during hypothermic circulatory arrest early in the experience with this technique, obtained by combining the three largest reported series, are summarized in Table 2-3.34,35 Late postoperatively, 23 of the 146 (16%; CL 13%-19%) had an IQ of 80 or less, more than 1 standard deviation below the test mean. In approximately half these patients, preoperative events were considered likely to account for the low scores. In the remainder, an occasional child

![](https://i.imgur.com/3Q3Q3Q.png)
suffered an adverse perioperative event, but the low scores were unexplained in nine (6.2%; CL 4.1%-9.0%) patients.

Wells and colleagues obtained data on intellectual and psychological development in children that caused them to question the idea that 60 minutes of circulatory arrest at 18°C is safe.\textsuperscript{W12} They found that verbal ($P = .06$), quantitative ($P = .07$), and general cognitive ($P = .003$) IQ scores of patients with an arrest time of 50 minutes or more were lower late postoperatively than those of patients with an arrest time of less than 50 minutes.

The first randomized clinical trial comparing prevalence of brain injury after corrective heart surgery in infants with D-transposition of the great arteries using deep hypothermia, predominantly with circulatory arrest or low-flow CPB, was conducted at Boston Children’s Hospital.\textsuperscript{N8} This study demonstrated that infants in whom circulatory arrest was used had a higher prevalence of neurologic abnormalities and poorer mental function at age 1 year, and poorer expressive language and motor development at age 2.5 years. Follow-up studies of the same cohort at age 4 years showed that use of circulatory arrest is associated with worse motor coordination and planning but not with lower IQ or worse overall neurologic status.\textsuperscript{R14} However, neither IQ nor overall neurologic status was correlated with duration of circulatory arrest. In the cohort as a whole, cognitive, language, and motor performance were reduced relative to the general population.\textsuperscript{R14}

In summary, there is increasing evidence that intervals of hypothermic circulatory arrest of 40 minutes or more are associated with brain injury in infants, children, and adults. Early experience at the Mayo Clinic suggested that 45 minutes was the maximum safe duration even when nasopharyngeal temperature was reduced to 20°C.\textsuperscript{K11}

### Spinal Cord Function

The spinal cord is less susceptible to ischemic injury than the brain, as evidenced by absence of sensory or motor deficits of the trunk or the upper and lower extremities of infants, children, and adults who have been subjected to intervals of hypothermic circulatory arrest of up to 60 minutes. Hypothermia also provides important protection of the spinal cord during ischemic intervals produced by aortic clamping. In a clinical study of hypothermic CPB and circulatory arrest (mean interval of arrest, 38 minutes; range, 8-62 minutes) for operations on the descending thoracic and thoracoabdominal aorta in 161 patients, prevalence of paraplegia or paresis (severe injury resulting from spinal cord ischemia) remained constant and less than 3.5% for ischemic (but hypothermic) intervals of up to 138 minutes\textsuperscript{K20} (Fig. 2-7).

### Renal Function and Structure

#### Experimental Studies

At normothermia, at least in rats, 20 minutes of circulatory arrest to the kidney produces no histochemical evidence of cell death, whereas 30 minutes produces extensive cell death in the distal portion of the proximal convoluted tubules, with scattered areas of cell death being seen at 25 minutes.\textsuperscript{V15} Vogt and Farber identified progressive accumulation of lactic acid during ischemia as a causative factor, and rapid decrease of ATP to 20% of control values as an indicator of impending renal death.\textsuperscript{V18}

Hypothermia prolongs the safe circulatory arrest time for the dog kidney. Ninety minutes of circulatory arrest after surface cooling to 18°C to 20°C produces no late morphologic changes in the kidney,\textsuperscript{R16} but precise relationships among temperature, duration of circulatory arrest, and morphologic and functional renal damage are not clear. Gowing and Dexter suggest that minimal morphologic changes evolve in the rat kidney after 60 minutes of circulatory arrest at 21°C.\textsuperscript{S22} It is apparent, however, that at any temperature, the safe circulatory arrest time for the kidney is longer than it is

Key: CL, 70% confidence limits; IQ, intelligence quotient.
for the brain and shorter than it is for the liver. In addition, a scattered loss of cells through cell death probably results in no detectable loss of renal function, whereas this may not be true in the brain.

As with other organs, the question of damaging effects of hypothermia per se is not fully resolved. Ward found fewer morphologic and functional derangements of the kidney after 90 minutes of circulatory arrest at 15°C than at either lower or higher temperatures.\textsuperscript{58} This suggests that temperatures less than 15°C may damage the kidney.

Studies in Humans
Important oliguria beginning about 12 hours postoperatively occasionally complicates recovery of infants operated on with hypothermic circulatory arrest for less than 60 minutes. Venugopal and colleagues reported 4 deaths (3%; CL 2%-6%) from renal failure among 130 patients operated on with surface-induced hypothermic circulatory arrest.\textsuperscript{510} Among patients who died, renal failure was the mode of death in 14%.

The primary cause of the renal failure appears to be low cardiac output after operation. However, in at least some cases, severe oliguria develops when the hemodynamic state of the patient appears to be adequate. In view of the finding in experimental studies that morphologic and functional damage to the kidney does not occur after 60 minutes of circulatory arrest at temperatures of 18°C to 20°C (Fig. 2-8), damaging effects from CPB must be implicated. In part, this may be the result of low cardiac output preceding and following the interval of circulatory arrest. In part, it may be due to damage to the kidneys by free hemoglobin and circulating toxins that appear during CPB (see Section II). Free hemoglobin has been found in the renal tubules of some of these patients at autopsy.

In 161 adult patients undergoing resection of the distal aortic arch and descending thoracic and thoracoabdominal aorta in whom hypothermic circulatory arrest was used (mean nasopharyngeal temperature, 14.5°C; mean interval, 38 minutes; longest interval, 62 minutes), prevalence of postoperative renal failure requiring dialysis among 157 operative survivors was 2.6% (4 patients; CL 1.3%-4.6%).\textsuperscript{320} Among the subgroup of 18 operative survivors who had evidence of renal dysfunction preoperatively (serum creatinine level > 1.5 mg · dL\textsuperscript{-1}), none developed renal failure that required dialysis.

Liver Function
Studies in dogs suggest that complete hepatic circulatory arrest for 45 minutes or more at 37°C is followed by serious functional derangements.\textsuperscript{20,82} The normothermic liver of humans resumes normal function after its complete isolation from the circulation for 35 to 40 minutes.\textsuperscript{514} With hypothermia (20°C-22°C), 60 minutes of circulatory arrest does not produce structural or functional abnormalities in the liver.\textsuperscript{R16}

SAFE DURATION OF CIRCULATORY ARREST

The preceding information does not allow formulation of a table or an equation relating safe duration of circulatory arrest to various temperatures based on rigorously derived rules. Knowledge of biological systems in general indicates that if adequate information were available, relationships should be expressed as probability of no functional or structural damage (i.e., probability of safe circulatory arrest) at a given temperature, rather than as an absolute value.

Fig. 2-9, A shows three curves relating probability of safe circulatory arrest to arrest time at nasopharyngeal temperatures of 37°C, 28°C, and 18°C. These estimates are based on available information, but because of lack of data they have not been rigorously derived. To emphasize that each curve would have a degree of uncertainty even if considerable data were available, the 70% confidence limits around the continuous point estimate for 18°C are shown in Fig. 2-9, B. The preceding pages indicate that histologic changes in the central nervous system, without functional abnormalities, are the most sensitive indicators of lack of complete safety of the arrest period used. The portrayal at 18°C of essentially complete safety of 30 minutes of circulatory arrest is consistent with all available information. The portrayal of essentially complete safety of arrest of 45 minutes for at least 70% of subjects is also consistent with the facts, and the damage produced within this period is likely to be structural and without permanent functional sequela. Most patients will have some structural evidence of damage from 60 minutes of arrest, but only about 10% to 20% will have evident functional damage, and in many of them the manifestations will be transient. It remains a vexing clinical problem that the probability of the safe period of circulatory arrest varies widely, especially because state-of-the-art medicine is not yet capable of defining specific patient genetic or phenotypic profiles that

![Figure 2-8](image-url) Freehand nomogram for the kidney of the relation between probability of safe total circulatory arrest and duration of circulatory arrest at two temperatures. Normothermic relationship is based on the work of Vogt and Farber\textsuperscript{915} and the hypothermic one on data presented in the text.
CPB for cardiac surgery is conceptually simple, and equipment is available to accomplish it with relative ease. Most or all of the patient’s systemic blood, which normally returns to the right atrium, is diverted into a device in which oxygen is supplied to the blood and carbon dioxide is removed. The newly arterialized blood is pumped from the device into the aorta. Among the complexities of CPB are that blood does not naturally (1) circulate through nonendothelially lined channels, (2) contain gaseous and particulate emboli, and (3) experience nonphysiologic shear stresses. Also, the body is unaccustomed to absence of any appreciable pulmonary blood flow and to presence of only minimally pulsatile aortic pressure. In addition to CPB, the patient undergoing cardiac surgery experiences all of the stress responses characteristic of major surgical procedures and trauma.

What is truly remarkable is that most patients survive operation and CPB and convalesce in a reasonably normal manner. For a time, however, almost every patient retains a few demonstrable stigmata from the procedure; some have major morbidity, and a few die of their response to CPB. Prevalence of these unfavorable outcomes in a group of patients is in part determined by identifiable risk factors, but determinants of their occurrence and severity in an individual patient remain incompletely defined.

When essentially all systemic venous blood returns to the pump-oxygenator instead of to the heart, the situation is termed **total cardiopulmonary bypass**. When some systemic venous blood returns to the right atrium and right ventricle and is pumped into the lungs, then passes back into the left atrium and is pumped by the left ventricle into the aorta, the situation is termed **partial cardiopulmonary bypass**. Partial CPB has long been known to be better tolerated than complete CPB. Reasons for this have not been clearly defined, but continuation of at least some pulmonary blood flow is a likely explanation. The remainder of this section is concerned with total CPB.

**HISTORICAL NOTE**

The historical aspects of CPB for cardiac surgery are not easily described, because it is almost impossible to determine who first conceived the idea of diverting the circulation of a patient to an oxygenator outside the body and pumping it back to the arterial system to allow surgery to be performed on or within the heart. References to extracorporeal gas exchange in blood go back to the last part of the 19th century. For example, Frey and Gruber worked with an oxygenator in 1885. Subsequently, scores of laboratory studies with oxygenators and pumps were reported. However, serious consideration of pump-oxygenators for cardiac surgery had to await development of modern anesthesia, modern surgical methods, and scientific developments such as discovery and use of heparin and manufacture of biocompatible plastic materials.

Without doubt, John Gibbon, with his pioneering experimental work at Massachusetts General Hospital in Boston in the late 1930s, was a major contributor to development of CPB and its advancement to the stage of successful clinical

---

**Figure 2-9** Probability of safe (absence of structural or functional damage) circulatory arrest according to duration. **A**, Estimate at nasopharyngeal temperatures of 37°C, 28°C, and 18°C. **B**, Estimate at 18°C, with dashed lines representing 70% confidence limits. Number of experiments in the literature concerning 40 minutes of circulatory arrest at 18°C nasopharyngeal temperature is estimated at 20 as a basis for calculating these confidence limits. Note that at 30 minutes a safe arrest is highly likely and that at 45 minutes it is probable. Other data suggest that at 45 minutes, damage will probably be only structural and without evident functional sequelae.

...
application. Gibbon’s work was interrupted by World War II, but when he came to Jefferson Medical College in Philadelphia after military service, he resumed work with CPB, its pathophysiology, and the equipment required for it. Most of the medical and surgical world took little note of his work, considering it unlikely to lead to any useful purpose, but Gibbon persevered. In 1953, he performed the first successful operation in which the patient was totally supported by CPB when he repaired an atrial septal defect in a young woman using a pump-oxygenator. Unfortunately, his subsequent four patients died of a variety of problems, and he became discouraged with the method (Gibbon JH Jr: personal communication, 1955).

Meanwhile, a few others began to work with pump-oxygenators for CPB during the late 1940s. Among them were Clarence Dennis and his colleagues at the University of Minnesota. His laboratory studies led him to make what may have been the first attempt to use a pump-oxygenator for clinical cardiac surgery in 1951. Dennis and Richard Varco operated on a patient thought to have an atrial septal defect. These surgeons believed they had done a satisfactory repair, but the patient died. Autopsy showed that the lesion was in fact a partial atrioventricular septal defect, and misinterpretation of the anatomy was a major factor in the patient’s death. In Stockholm, Viking Bjork and Åke Senning also worked with CPB during the late 1940s and early 1950s. In related efforts, Clarence Crafoord was an early user of this method for removal of an atrial myxoma.

After Dennis’s unsuccessful effort, C. Walton Lillehei and his colleagues at the University of Minnesota began working in the laboratory with controlled cross-circulation, using another intact subject as the “oxygenator.” Their experimental studies led them to adopt the now discarded “azygos flow principle,” which presumed that only low perfusion flow rates were needed. In March 1954, they began a spectacular series of operations in 45 children with congenital heart disease using “controlled cross-circulation” with the mother or father as the oxygenator. A 53-year follow-up of the 28 hospital survivors documented only 8 late deaths, and of the remaining 20 survivors, none was limited by cardiac conditions. Although this particular technique was soon abandoned, the work of Lillehei and colleagues brought into being the modern era of open intracardiac surgery.

Experimental work at the Mayo Clinic with pump-oxygenators began in the early 1950s under the direction of John Kirklin. This led to the first use of CPB with a pump-oxygenator at the Mayo Clinic on March 22, 1955, when a ventricular septal defect was successfully repaired, and subsequently to the world’s first published series of intracardiac operations performed with use of CPB and a pump-oxygenator. These procedures were performed using the Mayo-Gibbon pump-oxygenator, which was designed and constructed in the engineering shops of the Mayo Clinic. Use of a pump-oxygenator for CPB during cardiac surgery expanded rapidly, and today the method is used many times a day in hospitals in almost every country in the world.

UNIQUENESS OF CARDIOPULMONARY BYPASS

The patient whose arterial blood flow is temporarily provided by means of a pump-oxygenator is in an abnormal state that affects most if not all physiologic processes. Throughout evolution, blood has passed only through channels lined with endothelial cells, but during CPB, it is passed across noneendothelial foreign surfaces. As a result, and perhaps because of other factors, virtually all humoral and cellular components of the inflammatory response are acutely activated, and probably some of the more slowly reactive specific immune responses are activated as well, at least initially. The general stress response seen after surgery and trauma also occurs to a major degree.

During total CPB, a number of physiologic variables are under direct external control, in contrast to the situation in intact humans. These include total systemic blood flow (“cardiac” output); input pressure waveform; systemic venous pressure; pulmonary venous pressure; hematocrit and chemical composition of the initial perfusate; arterial oxygen, carbon dioxide, and nitrogen levels; and temperature of the perfusate and patient.

Another group of variables is determined in part by the externally controlled variables but in large part by the patient. These include systemic vascular resistance, total body oxygen consumption (Vo2), mixed venous oxygen levels (Pvo2), lactic acidemia and pH, regional and organ blood flow, and organ function.

A third group of largely uncontrolled variables includes, to a greater or lesser degree, all components of the process of inflammation, incited in large part by the organism recognizing the foreign surfaces across which blood passes as “nonself.” These features make the patient who has undergone CPB a unique organism, at least for a few days. Recognition of this, as well as a detailed knowledge of the post-CPB state, is necessary for delivery of optimal postoperative care (see Chapter 5).

CONTROLLED VARIABLES

Arterial Output to the Patient

Arterial output (outflow) from the pump-oxygenator to the subject is achieved by generating a large pressure gradient by a pump. The most commonly used type of arterial pump is the roller pump (originally used by DeBakey for blood transfusion). It generates a relatively nonpulsatile flow and is simple, reliable, and relatively inexpensive. In clinical use, roller pumps are generally set to be nearly occlusive. When they are occlusive, trauma to the formed elements in blood is increased; when they are too nonocclusive, they are unable to maintain the same rate of flow against the wide range of resistances (pressure differentials of 30-300 mmHg) offered by arterial cannulae and the patient’s systemic vascular resistance. The tubing passing through the roller pump head is most often Tygon, a special nontoxic surgical grade of polyvinyl chloride. During hypothermia, Tygon tubing decreases in elasticity and filling volume, so stroke volume of the pump is slightly decreased. Silicone rubber tubing does not have this disadvantage and may be used in the roller pump head when hypothermia is required. Volume output of the roller pump head is controlled by creation of a pressure drop over 1 minute.
pump is more certain to be that predicted when output resistance is high than when a high negative pressure is generated on the input side. When generated negative pressure on the input side exceeds about 200 mmHg, volume output of the roller pump becomes less predictable.

The controlled vortex (centrifugal) pump is also commonly used for cardiac surgery and for closed-chest support of patients in whom both arterial and venous cannulation are accomplished centrally or peripherally (termed cardiopulmonary support [CPS]). Flow generated by a controlled vortex pump varies with changes in resistance to flow into and out of the pump. When pressure in the output line reaches about 500 mmHg, both outflow from and inflow into the pump become zero. When pressure in the inflow line decreases to about −500 mmHg, both inflow and outflow become zero. Therefore, in contrast to the roller pump, revolutions per minute (rpm) of the controlled vortex pump cannot be used to estimate flow. Instead, a flow meter must be placed on the arterial (output) or venous (input) line. However, if the arterial line becomes completely occluded, either intentionally or by accident, flow immediately ceases, but pressure in the arterial line will rise no higher than 500 mmHg, and it is unlikely that the tubing will rupture or a junction connector will give way. Blood trauma is similar in controlled vortex and roller pumps. Although air can be entrapped within the controlled vortex pump, it, like the roller pump, can transmit air bubbles from the venous to the arterial lines. (However, air entrapped in a vortex pump breaks down into microbubbles that eventually pass out of the pump; a roller pump will pump gross air presented to it.)

Venous Input from the Patient

The venous input (inflow) into the pump-oxygenter from the patient is achieved by a negative pressure gradient from patient to machine. The negative pressure required to move blood from the patient to the pump-oxygenter is considerably less than the pressure required to move blood from the pump-oxygenter to the patient, because of the different characteristics of the venous and arterial systems of the patient and to some extent of the venous and arterial cannulae.

Sufficient negative pressure for venous input into the pump-oxygenter can be generated by:

- Creating a controlled vacuum within a venous reservoir
- Using a siphon system in which gravity creates the negative pressure
- Using a controlled vortex pump to create the negative pressure within the venous line from the patient

Vacuum-Assisted Venous Return

The ideal method for creating negative pressure for venous input into the pump-oxygenter is by a regulated and monitored vacuum pressure system coupled to the venous reservoir. The patient and machine can be at or near the same vertical level from the operating room floor, the negative pressure does not rise above the controlled level if the cannula becomes occluded, and the amount of negative pressure can be varied as needed. Most importantly, the two pressures (i.e., output pressure to the patient and input pressure from the patient) are uncoupled and can be varied independently with an arterial roller pump. If a controlled vortex pump is used, the vacuum pressure in the venous system will reduce the outflow pressure of the nonocclusive vortex pump, thus requiring higher rpm to achieve a constant flow.

Use of a hard-shelled venous reservoir in currently available oxygenators and a vacuum regulator connected to wall suction set at −40 to −60 cm H2O has allowed vacuum-assisted venous return (VAVR) to become widely accepted. VAVR permits use of smaller venous cannulae, smaller reservoirs, considerably shorter tubing, and low priming volume. It is of considerable value for cardiac operations performed in infants and through small incisions in children and adults (see Special Situations and Controversies in Section III). In a study by Banbury and colleagues at Cleveland Clinic, VAVR was found to reduce priming volume from 2.0 ± 0.4 L to 1.4 ± 0.4 L (P < .0001), increase hematocrit both on bypass and immediately postbypass (P < .0001), and reduce use of blood products both intraoperatively and postoperatively from 39% of patients to 19% (P = .002).

Siphon (Gravity) Drainage

A common method of generating the negative pressure gradient is through siphonage. Disadvantages of this approach include an imposed difference in the levels of patient and pump-oxygenter, the relatively narrow range of negative pressures that can be generated in the operating room by its use, and its interruption by large boluses of air in the venous line. Most importantly, the need for a reservoir increases the filling (priming) volume of the pump-oxygenter. It is, however, simple, reliable, effective, and inexpensive.

Venous Pumping

The controlled vortex pump permits direct pumping from the patient’s venous system and is more effective and safer than a roller pump. The potentially large pressure gradient between the tip of the venous cannula and right atrium or venae cavae must be controlled in some way to prevent “fluttering” of their walls around the end of the cannulae. One way of accomplishing this is to use small venous cannulae to impose a considerable resistance between the pump and tip of the cannula, rather than between the tip of the cannula and the patient’s venous system. This is fortuitously advantageous in percutaneous peripheral cannulation, because an 18F or 20F venous cannula of some length can be easily passed into the venous system of a normal-sized adult and provides adequate venous drainage. It also facilitates minimally invasive cardiac surgery. By contrast, 28F to 32F catheters are required when gravity drainage is used.

Gas Exchange

The device for gas exchange, the oxygenator, is a highly important component of pump-oxygenators. Not only does it regulate tension of gases in the arterial blood emerging from the pump-oxygenator, it is also the largest area of foreign surface blood comes into contact with, and therefore probably the component of the pump-oxygenator where the most blood damage occurs. This contact occurs in the boundary layer of the blood, which is made very large in the oxygenator to facilitate gas exchange. Only a small proportion of the formed and unformed blood elements comes into contact with tubing and pump surfaces.

Gas exchange occurs directly across the blood/gas interface in bubble oxygenators, rotating disk and cylinder
oxygenators, and stationary vertical screen oxygenators used in the past. It occurs across a multitude of tiny pores in so-called membrane oxygenators of the hollow-fiber, microporous polypropylene and other types, in which there are still blood/gas interfaces. However, damage to the blood is less in these types of oxygenators than in bubble oxygenators. Only in the true silicone rubber membrane oxygenator of the type devised by Kolobow and colleagues, or the tightly woven microporous polymethylpentene membrane currently used for extended extracorporeal membrane oxygenation, is there no blood/gas interface. This allows CPB to be used for more than 24 hours with reasonable safety.

Because of their efficiency, hollow-fiber and true membrane oxygenators do not depend on minute ventilation (gas flow) to the oxygenator for CO₂ regulation under most circumstances. Rather, the ventilating gas flow rate and composition are regulated independently. This allows precise regulation of arterial Po₂ and PCO₂.

**Arterial Oxygen Levels**

With present-day oxygenators, maintaining PaO₂ at about 250 mmHg is easily accomplished. Higher PaO₂ is unnecessary and theoretically subjects patients to the risk of oxygen toxicity and bubble formation. PaO₂ lower than about 85 mmHg results in a declining arterial oxygen content (CaO₂) (according to the oxygen dissociation curve of blood) and a corresponding reduction of tissue and mixed venous oxygen levels. Shepard demonstrated that when arterial oxygen saturation (SaO₂) fell below 65% in dogs undergoing normothermic CPB, Vo₂ fell, indicating hypoxic cell damage.

PaO₂ is related to temperature of the patient, which is related to Vo₂ (see Fig. 2-1), blood flow rate (Q), performance of the oxygenator, and, in a complex fashion, to ventilating gas flow rate and composition (see “Gas Exchange,” earlier). Reducing the patient’s body temperature reduces Vo₂ and increases P⁰₂, resulting in increased PaO₂. During rewarming by perfusion from the pump-oxygenator, the increasing Vo₂ and the metabolic debt that has accumulated result in relatively low P⁰₂. **(Fig. 2-10).** This period, then, places maximal demands on the oxygen transfer capacity of the oxygenator.

**Arterial Carbon Dioxide Pressure**

Arterial carbon dioxide pressure (PaCO₂) is controllable during CPB by varying the ratio between gas flow rate into the oxygenator (V, or ventilation · min⁻¹) and Q through the oxygenator. This is facilitated by use of microporous or true membrane oxygenators, because V is not the force driving blood through the oxygenator, as is the case in bubble oxygenators, and PaO₂ is well maintained over a wide range of V. Inline P⁰₂ and pH meters facilitate control of PaCO₂ and pH.

Some clinical perfusions for cardiac surgery are performed at normothermia (=37°C) and others at various levels of hypothermia: mild (30°C-35°C), moderate (25°C-30°C), or deep (<25°C). Therefore, it is necessary to consider the strategy for controlling PaCO₂ and, indirectly, pH. The alpha-stat strategy is based on (1) using the pH measured at 37°C and uncorrected for the temperature of the patient’s blood, and (2) maintaining this level at pH 7.4. That is, the ventilation of the oxygenator is maintained at the level appropriate for a body temperature of 37°C, no matter how low the temperature. This hyperventilation during hypothermia results in a decrease in PaCO₂ and an increase in pH when the values for these are corrected for the temperature of the patient’s blood. Swan and Reeves and Rahn and colleagues have all emphasized that at low temperatures, neutrality exists at a higher pH than at normothermia, because of the change of the dissociation constant of water with temperature. The alpha-stat strategy results in optimal function of a number of important enzyme systems, including lactate dehydrogenase, phosphofructokinase, and sodium-potassium ATPase.

In contrast, the pH-stat strategy strives for the same values of pH and PaCO₂, corrected to the temperature of the patient’s blood, during hypothermia as at normothermia. This represents a state of respiratory acidosis and hypercapnia. Cerebral blood flow usually increases under these circumstances. This may be considered advantageous in some situations, but so-called luxury perfusion may expose the brain to a larger number of microemboli than would otherwise be the case, and therefore could be disadvantageous.

At a cellular enzyme level, the alpha-stat strategy may be preferable, but which is preferable in clinical cardiac surgery in neonates, children, and adults is the subject of continued investigation and debate. The alpha-stat strategy results in a lower PaCO₂, which may adversely affect cerebral blood flow. This may be of particular importance for patients with cyanotic congenital heart disease (e.g., tetralogy of Fallot with pulmonary atresia) for whom low PaCO₂ may result in pulmonary vasodilatation in addition to cerebral vasocostriction. Thus, there can be a steal of blood from the cerebral to the pulmonary vascular bed. Several studies in infants suggest that pH-stat management results in superior neurologic outcome during deep hypothermic CPB.
and hypothermic circulatory arrest.\textsuperscript{B13,K14,P11} The pH-stat technique may depress cardiac function.\textsuperscript{B10} However, at least in dogs, regional distribution of blood flow during normothermic and hypothermic full-flow CPB is similar with the alpha-stat and pH-stat strategies.\textsuperscript{B45}

A recent review of 16 best-evidence published papers concluded that better results were achieved with the alpha-stat technique in adult patients and with the pH-stat technique in pediatric patients.\textsuperscript{A1}

**Heparin Levels**

Before CPB is established, the patient is anticoagulated by intravenous or intracardiac injection of heparin, usually in a dose of 300 to 400 units · kg\(^{-1}\) body weight (sometimes expressed as 3 to 4 mg · kg\(^{-1}\)). (Details of dosage of heparin and protamine, and of activated clotting time (ACT), are given later in “Heparinization and Later Protamine Administration” under Preparation for Cardiopulmonary Bypass in Section III). Heparin, one of a heterogeneous group of glycosaminoglycans, has an approximate molecular weight of 3000 to 100,000. It binds to and greatly amplifies the effect of antithrombin III, which is responsible for virtually all of its anticoagulant activity. Currently, a purified form derived from porcine intestinal mucosa is commonly used, whereas the form derived from bovine lung was used more commonly in the past. Experimental and limited prospective clinical studies suggested that lung heparin may be preferable for CPB, because bovine lung heparin has a more reliable protamine neutralization response.\textsuperscript{F14} However, current supply of heparin in the United States is 100% derived from porcine intestinal mucosa.

Heparin concentrations in plasma can be measured directly; the usual values during CPB are 3.5 to 4 units · mL\(^{-1}\). Usually these measurements correlate well with ACT.\textsuperscript{W24} One exception is the situation of antithrombin III deficiency, a state of heparin resistance.\textsuperscript{B5,B26} Two or three times the usual dose of heparin may be required to produce satisfactory anticoagulation (i.e., ACT of 480 seconds); if only the heparin level is measured, initiation of CPB might produce thrombosis in the pump-oxygenator system and introduce thrombus into the patient. The most common cause of antithrombin III deficiency is previous exposure to heparin in a dose-dependent fashion.\textsuperscript{B5,B26} If repeated ACTs indicate an unsafe level for CPB, antithrombin III supplementation must be considered. This is accomplished with either fresh frozen plasma or antithrombin III concentrate.

Although heparin used in the manner described has been clinically satisfactory, activation of the clotting cascade during CPB is not completely neutralized. At least factor XI, factor X, and prekallikrein are activated, and high-molecular-weight kininogen is cleared.\textsuperscript{C2} Thus, markers of fibrin formation can be detected in most patients during and early after CPB, and fibrin deposition and embolization can occur.\textsuperscript{B33} In most patients, this subclinical coagulation does not cause the concentrations of the soluble coagulation factors to become sufficiently low during or early after CPB to cause bleeding.\textsuperscript{H15}

Increasing the dose of heparin does not prevent this subclinical coagulation during CPB,\textsuperscript{G23} so maintaining ACT at 300 to 350 seconds (rather than 450 seconds) results in no more subclinical plasma coagulation than does the traditional method, requires less heparin, and may be associated with less bleeding after operation.\textsuperscript{C2,G23} Yet a 2008 survey of 54 cardiac surgery centers in the United States and Canada indicated that the majority of institutions (71% for U.S. and 69% for Canadian sites) used a target ACT for instituting CPB of between 400 and 480 seconds.\textsuperscript{L18}

The former use of aprotinin affected the concepts of heparinization for CPB for intracardiac surgery, because this agent prolongs both clotting time and ACT, depending on the method of measurement (see “Fibrinolytic Cascade” under Details of the Whole-Body Inflammatory Response later in this section).\textsuperscript{H42,N3,W7} If aprotinin is used, an optimal recommendation is to administer the usual initial dose of heparin and add additional heparin to maintain the ACT above 700 seconds if the activating agent is Celite (diatomaceous earth). Kaolin is a more dependable activating agent, giving ACTs in the presence of aprotinin similar to those without aprotinin in vitro and during CPB.\textsuperscript{B7,W6} Therefore, a preferable method when aprotinin is used during CPB is to use kaolin as the activating agent and maintain the usual ACT at 480 seconds. Alternatively, the heparin concentration is measured at intervals and kept above 3 mg · kg\(^{-1}\). Because of results of randomized trials demonstrating that aprotinin was associated with a higher risk of death after cardiac surgical procedures than other antifibrinolytic agents used to decrease the need for red blood cell transfusions,\textsuperscript{C9} Bayer Pharmaceuticals withdrew their drug Trasylol (aprotinin) from the market in May 2008. Subsequent meta-analysis\textsuperscript{G3} has confirmed higher morbidity and mortality associated with use of aprotinin.\textsuperscript{A2}

It has been estimated that 1% to 5% of patients who receive therapeutic anticoagulation with unfractionated heparin develop antibodies, with concomitant development of thrombocytopenia defined as HIT (heparin-induced thrombocytopenia).\textsuperscript{C12} HIT may complicate management of patients who require cardiac surgery using CPB when a large dose of heparin is required. In patients with established or suspected HIT, all heparin must be withheld and alternative forms of anticoagulation used.

Bivalirudin, a synthetic 20-amino-acid peptide analog of hirudin, has become the anticoagulant most commonly used to replace heparin in patients with HIT who require cardiac surgery.\textsuperscript{C01,1,12} A randomized, open label, multi-institution trial comparing bivalirudin (101 patients) with heparin (49 patients) provided an interesting yet sobering insight into evidence-based medicine. Aprotinin was introduced for its serine protease inhibitory properties, which are relevant to the damaging effects of CPB discussed later in this chapter. Its profound effect on blood loss during cardiac surgery was a serendipitous pleiotropic finding,\textsuperscript{C19} although this had been observed in cyanotic children with hematologic derangement by Urban and colleagues\textsuperscript{C13} and others.\textsuperscript{H14,L12,L13,C17} What was considered by some an unethical number of small randomized trials repeatedly demonstrated this effect on blood loss.\textsuperscript{C19} Nevertheless, in a thoughtful assessment, Angoustides and Fleisher\textsuperscript{H33} pointed out that at least three essential issues remained unexplored: (1) safety in specific subsets of patients, (2) platelet protection, and (3) organ protection. For example, many studies, such as those of Koch and colleagues, have demonstrated that morbidity and mortality of cardiac surgery steadily increase with number of transfused red cell units;\textsuperscript{C13,64} yet despite the substantial decrease in transfusion requirement with aprotinin, morbidity did not proportionately decline. It was the observational study of Mangano and colleagues that focused attention on safety of aprotinin despite its efficacy.\textsuperscript{C31} This study with numerous flaws,\textsuperscript{C31} combined with another randomized trial\textsuperscript{C08} and concern about the transparency of reporting of safety by the manufacturer, led to withdrawal of aprotinin from the market.

In developing an evidence base, even randomized trials can be misleading when they (1) focus on efficacy without sufficient power (sample size) to identify possible safety problems; (2) do not compare against placebo, just other drugs of the same class; (3) do not take into account differential effects on different patient subsets; or (4) fail to assess known primary effects of the drug when interesting and unexpected efficacy is discovered. The result is incomplete evidence that clouds decision making.
Box 2-2 Algorithm for Calculating Patient-Machine Hematocrit

The need for and amount of additional packed red blood cells to achieve a desired hemoglobin concentration early after commencing bypass is determined by the patient’s blood volume (VmB) and hemoglobin concentration prior to CPB (expressed as hematocrit, HCTp), and the volume of pump-oxygenator prime (VmRBC) and its hemoglobin concentration (expressed as hematocrit, HCTm). Patient blood volume is estimated as

\[ \text{VmB} = 1000 f \cdot \text{wt} \]

where \( f \) is the proportion of body weight attributable to blood volume; \( f = 0.08 \) for infants and children up to 12 years of age, \( f = 0.065 \) for older patients, and \( \text{wt} \) is weight in kg. (These are average values for the proportion of body weight that is blood volume. More complex regression equations are available for more accurate estimates.)

Patient (VmRBC) and machine (VmRBC) red cell volumes are:

\[ \text{VmRBC} = \text{VmB} \cdot \text{HCTm} \]

Then, mixed patient-machine hematocrit (HCTpm) is:

\[ \text{HCTpm} = (\text{VmRBC} + \text{VmB})/(\text{VmB} + \text{VmRBC}) \]

If no blood is in the prime:

\[ \text{HCTpm} = \text{VmRBC}/(\text{VmB} + \text{VmRBC}) \]

These calculations may be included in a computer-prepared printout for the perfusionist, available before the patient comes to the operating room.

---

patients) for operative procedures requiring CPB demonstrated similar procedural safety (freedom from death, Q-wave myocardial infarction, reperfusion for coronary artery surgery, or stroke) between the two groups at 7 days, 30 days, and 12 weeks.\(^22\) Secondary end points including mortality, 24-hour blood loss, transfusion requirements, and duration of operation were similar. Avoiding blood stasis was critical for patients receiving bivalirudin. A more recent single-institution study of 115 patients receiving bivalirudin during operations requiring CPB demonstrated procedural safety (similarly defined) of 99.4% at 7 days and 30 days.\(^6\) Although specific dosage protocols have not been determined, Czosnowski and colleagues, in a review of available randomized trials and other clinical studies, recommended a 1 mg · kg\(^{-1}\) bolus followed by a 2.5 mg · kg\(^{-1}\) · h\(^{-1}\) infusion (goal: ACT > 2.5 times baseline).\(^8\)

### Perfusate

**Diluent**

The diluent (which is used to prime the pump-oxygenator system, wholly or in part, and for any erythrocyte-free additions during CPB) is a balanced electrolyte solution with a near-normal pH and an ion content resembling that of plasma. There is some evidence for the concept that in both adults and young patients, it is disadvantageous to include either glucose or lactate in the priming solution\(^9\).\(^10\) (see “Biochemical Milieu” under Brain Function and Structure: Risk Factors for Damage in Section I). However, priming solutions containing glucose and lactate are used in some centers.\(^11\)

In pump-oxygenator systems without a venous reservoir or those using VAVR, mixing of blood and prime may be partially or wholly avoided, with residual prime discarded.

### Hemoglobin Concentration

At some institutions, in adult patients and even young patients, no effort is made to control hemoglobin concentration or hematocrit during CPB. Instead, the pump-oxygenator is routinely filled initially with a balanced salt solution. This provides sufficient oxygen delivery to maintain normal mitochondrial PO\(_2\) levels of about 0.05 to 1.0 mmHg, and average intracellular PO\(_2\) levels of about 5 mmHg, these being reflected in normal \( \text{Pvo}_{2} \) of about 40 (\( \text{Svo}_{2} \) of about 75%). When the hematocrit is abnormally high, oxygen content is high, but the increased viscosity tends to decrease microcirculatory blood flow. The rate of oxygen transport varies directly with hematocrit (because oxygen content varies directly with hematocrit), assuming normal red blood cell hemoglobin concentrations and adequate oxygenation) and inversely with blood viscosity (which is also determined primarily by hematocrit). Hypothermia increases blood viscosity; therefore, at low temperatures, a lower hematocrit is more appropriate than at 37°C.

A lower-than-normal hematocrit appears desirable during hypothermic CPB because the perfusate has a lower apparent viscosity and low shear rates and provides better perfusion of the microcirculation. Thus, a hematocrit of about 0.20 to 0.25 may be optimal during moderately and deeply hypothermic CPB, although a low hematocrit could predispose the patient to neurologic dysfunction, particularly when it exists during a period of low CPB flow and also in elderly and diabetic patients with poor cerebral regulation of blood flow. Several studies of infants suggest that a hematocrit of 0.25 is associated with better neurologic outcome than one of 0.20, but that there is no incremental improvement for hematocrit greater than 0.25 (up to 0.35).\(^12\)\(^13\) During rewarming, a higher hematocrit may be desirable because of increased oxygen demands, and the higher apparent viscosity of a higher hematocrit is appropriate during normothermia. This may be achieved by ultrafiltration (see “Components” under Pump-Oxygenator in Section III) or by adding packed red blood cells if the blood volume is too low to allow this.

The need for and amount of additional blood or packed red blood cells to achieve a desired hemoglobin concentration during CPB can be determined before the start of CPB (Box 2-2). If the calculated hematocrit is in the desired range, a blood-free priming solution is used. If the calculated hematocrit is lower than desired, an appropriate amount of blood (or packed red blood cells) is added.

**Banked blood** preferably less than 48 hours old is preferred, but older blood is accepted for adults when necessary. Banked blood is rendered calcium-free by the anticoagulant solution (citrate-phosphate-dextrose [CPD]) and is acidic, so additions of heparin, calcium, and buffer may be required before placing it in the pump-oxygenator, before or during CPB.
However, in at least a few institutions, no calcium is added before placing the blood in the pump-oxygenator, and none is added thereafter until the patient’s nasopharyngeal temperature reaches about 28°C during the rewarming process. It is important to monitor the ionized calcium level, and calcium is added if necessary. (The normal level is about 1.2 mmol · L⁻¹, with total calcium being about 2.5 mmol · L⁻¹ or 10 mg · dL⁻¹.) This practice results in extremely low levels of ionized calcium when CPB is first established. Unduly high levels of ionized calcium could be more deleterious (see “Damage from Global Myocardial Ischemia” in Chapter 3). A reasonable practice would be to initially add 3 mL of calcium chloride (10%) rather than 5 mL for each unit of banked blood used, and then add no more until the ionized calcium is measured.

**Albumin Concentration**

Concentration of albumin in the mixed patient-machine blood volume, as well as of hemoglobin, is affected by the amount of hemodilution. Theoretically, according to the Starling law of transcapillary fluid exchange (see “Pulmonary Venous Pressure” later in this section), a reduction of albumin and thus of the colloidal osmotic pressure of the plasma accentuates movement of fluid out of the vascular space into the interstitial space. That this occurs is indicated by the work of Cohn and colleagues, who showed that extracellular fluid volume increases more rapidly when hemodilution is used than when it is not.⁴²⁶

During CPB, microvascular permeability to macromolecules is increased;⁴²¹ some of the administered albumin leaks into the interstitial fluid and has an unfavorable effect on the relationships expressed in the Starling law. Homologous albumin may provoke an allergic response, which also increases microvascular permeability and causes leakage of albumin into the interstitial fluid.

These complex interrelations probably explain the failure of a randomized trial to find a favorable effect from adding homologous albumin to the prime in adults.⁴⁶⁷ It is not uncommon for cardiac surgical patients, particularly the elderly, to present with low-normal or below-normal albumin levels. Whether albumin concentration should be maintained at normal levels in some special situations such as this remains arguable.

Other colloidal solutions (dextran 40, dextran 70, hydroxyethyl starch) can also be added to the priming solution to attenuate loss of fluid from the intravascular space. However, none of them has been conclusively shown to have a beneficial effect.

**Other Additives**

Practices vary regarding addition of substances and drugs to the perfusate (by administering them into the priming volume of the pump-oxygenator or patient before CPB, or into the patient or pump-oxygenator during CPB), other than basic balanced salt solution and blood and its required additives.

Use of an osmotic diuretic may be advisable. Mannitol (=0.5 g · kg⁻¹), a pure osmotic diuretic, can be included as part of the prime. Mannitol also has the advantage of being an effective agent against oxygen free radicals generated during CPB.⁴¹¹,⁴¹² Glucose (added to the prime of the pump-oxygenator in sufficient quantity to obtain a glucose concentration of about 350 mg · dL⁻¹ in the prime) also produces diuresis. However, its use in the priming volume and its administration during and early after CPB, employing more than moderate hypothermia, may be unwise in view of the strong suggestion that hyperglycemia during cooling and early after hypothermic circulatory arrest increases the probability of brain injury.⁴¹⁸,⁴¹⁹,⁴₂⁰

Administration of a potent diuretic during CPB is generally useful. Incorporating furosemide in the pump prime is practiced by many groups. It may be more advantageous to give it as a bolus in a dose of 1 to 2 mg · kg⁻¹ at the start of rewarming, either after an interval of circulatory arrest or moderately or deeply hypothermic CPB.

The short-acting adrenergic α-receptor blocking agent phentolamine is capable of antagonizing the vasoconstriction produced by catecholamines and has been shown to produce more uniform body cooling and rewarming and improved tissue perfusion when given during CPB.⁴₅₂ A bolus of 0.2 mg · kg⁻¹ is administered just after the start of CPB and the initiation of cooling. When circulatory arrest is used, an additional dose of 0.2 mg · kg⁻¹ is administered with the resumption of CPB for rewarming.

Alternatively, the long-acting adrenergic α-receptor blocking agent phenoxybenzamine can be used in infants and children to produce total α-blockade for 8 to 10 hours. It is given in a dose of 1 mg · kg⁻¹ about 15 minutes before commencing CPB and at the beginning of rewarming after the period of circulatory arrest.⁴₅₃ A continuous infusion of nitropresside during cooling and again during rewarming is preferred to either of these agents by some groups. Nitropresside reduces arterial blood pressure (by = 25 mmHg), yet maintains cerebral blood flow during moderately hypothermic CPB.⁴₁⁹

Opinions differ about the advisability of routinely administering (or adding to the perfusate) corticosteroids and the appropriate agent to use. Available evidence suggests that corticosteroids improve tissue perfusion and lessen the increase in extracellular water that usually accompanies CPB.⁴⁰⁹ Although some studies have reported improved clinical status when steroids are given in the manner described, this matter remains controversial.⁴⁰⁸ Methylprednisolone in a single dose of 30 mg · kg⁻¹ or dexamethasone in a single dose of 1 mg · kg⁻¹ given at the onset of CPB and not repeated may be advantageous. These agents do not appear to reduce complement activation, but there is evidence to support the hypothesis that they attenuate complement-mediated leukocyte activation, particularly that associated with reperfusion of the heart and lungs in the latter part of CPB.⁴₁₃,⁴₁₅,⁴₁₆,⁴₁₇,⁴₁₈

In piglets, corticosteroids provide brain protection during operations that involve hypothermic CPB.⁴₁₈

The powerful antifibrinolytic agent aprotinin is a biological product that acts as a serine proteinase inhibitor. It may have a favorable effect on some platelet membrane-specific receptors, specifically GPIb. Aprotinin has been shown in several randomized studies to reduce bleeding after CPB by about 50%.⁴₂₇,⁴₂₈ F₂₀, F₂₈, R₂₄, V₆, V₇, W₁₇ but as mentioned previously, the drug is no longer available for use during cardiac surgical procedures. e-Aminocaproic acid (EACA) and tranexamic acid are two other antifibrinolytic agents that can be administered before, during, and after CPB to reduce bleeding and the need for allogeneic blood transfusions.⁴₅₅, C₄, G₂₉, L₄, L₅, M₃, M₃₂, N₁₅, T₇ EACA is administered using an empirical dose of 10 g before the skin incision, 10 g during the procedure, and 10 g early postoperatively.⁴₅₆
Alternatively, it can be given at a dose of 150 mg · kg⁻¹ at the time of the skin incision, with an additional 30 mg · kg⁻¹ for 4 hours upon initiation of CPB.⁵¹⁹ Tranexamic acid is given at a dose of 1 g before the skin incision, 500 mg in the pump prime, and 400 mg · h⁻¹ during the procedure.⁶⁴

Changes during Cardiopulmonary Bypass

During CPB for cardiac surgery, blood loss in the operative field and gradual increase in interstitial fluid and urinary output combine to steadily deplete the patient-machine blood volume. Usual practice is for the perfusionist to add increments of a balanced electrolyte solution to maintain the volume at a safe level; in adults, up to 2000 mL may be added. Unless special precautions are taken, such as avoiding return of irrigating fluids to the pump-oxygenator by cardiotomy pump suckers and using ultrafiltration during the final stages of CPB, severe hemodilution results and persists into the postbypass period.

In neonates and infants, ultrafiltration immediately after CPB (before removal of cannulae) is often advisable using the modified ultrafiltration (MUF) technique introduced by Elliot.⁵¹¹ Its efficacy has been confirmed by others.⁵¹²,⁵¹³ In children and adults, ultrafiltration may be performed during the latter part of CPB if the hematocrit is below about 0.25 and there is excess volume in the pump-oxygenator. If not, it may be performed after discontinuing CPB, slowly circulating blood through the patient before any cannulae are removed. A third option, and one that is frequently used, is ultrafiltration of the volume remaining in the pump-oxygenator after CPB is discontinued and the venous cannulae have been removed. Hemoconcentrated pump-oxygenator volume is then infused slowly into the patient before the arterial cannula is removed (see Pump-Oxygenator in Section III).

Total Systemic Blood Flow

Although total CPB has generally been considered to require two separate caval cannulae and occlusive tapes around each cannula, a single large, properly designed, and properly positioned venous cannula can direct all venous return to the pump-oxygenator and provide total CPB.

During total CPB, systemic blood flow (perfusion flow rate) is controlled by the perfusionist. It can be set at an arbitrary level or may be kept equal to the venous return from the patient. A rational approach is to set it at an arbitrary level.

In clinical practice, when body temperature is at 28°C or greater, a flow of 2.5 L · min⁻¹ · m⁻² is usually chosen for infants and children younger than about 4 years, and a flow of 2.2 L · min⁻¹ · m⁻² for older patients. For adults with a body surface area of 2.0 m² or more, a flow of 1.8 to 2.0 L · min⁻¹ · m⁻² may be chosen to avoid the disadvantage of high flow through the oxygenator. When moderate hypothermia is chosen, the CPB flow can safely be reduced to about 1.7 L · min⁻¹ · m⁻² for prolonged periods (Fig. 2-11). When cardiac operations are performed with body temperature reduced to 18°C to 20°C in neonates, infants, or adults, CPB flows of 1 L · min⁻¹ · m⁻² are adequate for prolonged periods, at least as judged by persistence of the somatosensory evoked response (SSER) under these circumstances.⁶²¹ Flows as low as 0.5 L · min⁻¹ · m⁻² (20-30 mL · min⁻¹ · kg⁻¹) have been shown to be adequate at these temperatures to maintain cerebral oxygen consumption and ATP levels for at least 30 to 60 minutes.⁵¹⁹,⁶²⁵,⁶³⁳,⁶³⁹

When flow rates are lower than optimal for more than a short time, VO₂ is considerably subnormal (<85% of the asymptote of the temperature-specific curve in Fig. 2-11 is considered subnormal), primarily as a result of perfusion of less than the total capillary bed. Also, the areas of the capillary bed that are open are underperfused, resulting in lactic acidemia and metabolic acidosis.

PO₂ and saturation (SVO₂) have been widely used as indices of adequate perfusion flow rate (see Box 2-3; for references, see Harris and colleagues⁵¹⁹), the assumption being that these values reflect average cellular PO₂. If Q is high and the entire microcirculation perfused, this is true. However, it has been shown that during CPB, with Q within the conventional range, SVO₂ is inversely related to VO₂.⁵¹⁹ This might have been predicted from the Fick equation:

\[
\dot{V}O_2 = \dot{Q} (CaO_2 - C\bar{V}O_2)
\]

(2-1)

where CaO₂ is arterial oxygen content, CVO₂ is mixed venous oxygen content, and Q is flow rate.

If VO₂ and CaO₂ are fixed, CVO₂ increases with Q. If instead Q and CaO₂ are fixed, CVO₂ increases as VO₂ decreases, and VO₂ may decrease, despite a perfectly adequate Q, if the capillary bed is not evenly perfused. In this case, the distance between perfused capillaries and many tissue cells increases, and these cells do not obtain their oxygen
requirement. In effect, this amounts to a shunt of arterial blood into the venous system. This effective shunt may at times amount to half the total flow. Rudy and colleagues, using microspheres in normothermic rhesus monkeys during CPB, found that shunting was only 1.4% of total $Q$.\textsuperscript{26}

A high $VO_2$ or $SV_0_2$ does not, therefore, mean that cellular oxygenation is satisfactory whatever the $Q$. A $VO_2$ at or around the whole-body requirement does. The $VO_2$ is not difficult to calculate during CPB; the problem is, rather, to decide what the oxygen requirement is in a given case.\textsuperscript{19,320} Moreover, if $VO_2$ is less than the usual levels at conventional $Q$, increasing $Q$ probably will not increase $VO_2$ (see Fig. 2-11). The fault is not in $Q$ but in the capillary bed or at the cellular level.

As might be expected, high $Q$ is achieved at the expense of some loss of safety and convenience in other variables. Blood trauma in the oxygenator is probably greater when high blood flows pass through it. With a bubble oxygenator, risks of gaseous emboli are also greater. Pressure gradients across the arterial cannula are greater at high $Q$. This increases cavitation, blood trauma, and the risk of bubbles forming as blood emerges from the cannula.

### Arterial Pressure Waveform

CPB is usually conducted in such a manner that the arterial pressure pulse is very narrow and essentially nonpulsatile, but if desired, a pulsatile arterial input can be achieved in several ways. One is by using left ventricular ejection. With no tapes around the caval cannulae, arterial flow to the patient may be temporarily increased over venous return, or venous return may be temporarily reduced by partially occluding the venous tubing. Atrial pressures and thus venous filling pressures are increased, left ventricular ejection augments systemic blood flow, and a somewhat pulsatile arterial blood flow results. In other words, pulsation is achieved by partial CPB. This mechanism is used during cooling and rewarming whenever cardiac action is sufficiently vigorous to prevent overdistention of the heart during the process. The procedure of partial CPB produces not only some arterial pressure pulsations but some pulmonary blood flow as well, with its favorable effect.

A pulsatile waveform can also be produced by using intraventricular balloon pumping during bypass.\textsuperscript{28} A third method is to use a pulsatile arterial pump.

Effects on the organism of using a system that results in a pulsatile rather than nonpulsatile arterial waveform during CPB have been questioned since the beginning of clinical CPB. Increasing the venous pressure requires more intravascular volume and often additional priming volume. Venous pressure should therefore be kept close to zero, and certainly not more than 10 mmHg, to minimize increases in extracellular fluid.

Extensive reviews of this subject have been presented.\textsuperscript{22,13}

A randomized clinical study by Singh and colleagues investigated pulsatile versus nonpulsatile flow during moderately hypothermic (25°C-30°C) CPB.\textsuperscript{319} No statistically significant differences between the two techniques were found in whole-body $VO_2$, blood lactate concentration, systemic vascular resistance, urine flow, or thermal gradients. Thus, no evidence was found that pulsatile flow improved perfusion of the microcirculation during clinical CPB. It is possible that pulsatile flow would result in fewer functional derangements at lower flows than were used in this study.\textsuperscript{321,322}

Bixler and colleagues found that nonpulsatile perfusion of a hypothermically fibrillating dog’s heart at a mean pressure of 50 mmHg resulted in subendocardial ischemia, whereas pulsatile flow did not.\textsuperscript{321} When the mean perfusion pressure was 80 mmHg, neither pulsatile nor nonpulsatile flow resulted in subendocardial ischemia.

It is also possible, but not proven, that pulsatile flow has an advantage over nonpulsatile flow in infants. Williams and colleagues drew this conclusion from a clinical study in which they found more rapid cooling and rewarming and greater urine flow with pulsatile flow.\textsuperscript{319} Results of this study are difficult to interpret, however. Finally, pulsatile flow could prove beneficial in high-risk patients who come to operation desperately ill with end-stage disease (low cardiac output, acidosis, or renal failure).\textsuperscript{319}

Currently, there is insufficient evidence to conclude that pulsatile flow from the pump-oxygenator importantly reduces the ill effects of the relatively short periods of CPB required for cardiac surgery in the great majority of patients.

### Systemic Venous Pressure

During CPB, systemic venous pressure is determined by the techniques used,\textsuperscript{13} because:

$$P_V = \frac{Q \times \text{viscosity}}{\text{Cannula size, venous tubing size}},$$

where $P_V$ is mean systemic venous pressure, $Q$ is systemic blood flow rate, and $f$ means “a function of.” The cross-sectional area and length of the single or multiple venous cannulae, and to a lesser extent (because it usually has a large diameter) those of the venous tubing, are fixed factors determining venous pressure during total CPB. For this reason, the largest venous cannulae compatible with the clinical situation are commonly used, mindful of the need for the cannulae to lie loosely, not snugly, in the caval veins. When smaller cannulae are used, the other variables in Equation 2-2 can be manipulated. For example, systemic blood flow can be reduced or suction applied to the venous return to ensure an acceptable venous pressure (see “Vacuum-Assisted Venous Return,” earlier).

There is no apparent physiologic advantage in having a central venous pressure greater than zero during total CPB. Increasing the venous pressure requires more intravascular volume and often additional priming volume. Venous pressure should therefore be kept close to zero, and certainly not more than 10 mmHg, to minimize increases in extracellular fluid.
Pulmonary Venous Pressure

Ideally, pulmonary venous pressure should be at zero during total CPB, and certainly not more than 10 mmHg. Undue elevations are dangerous because they produce increased extravascular lung water and eventually gross pulmonary edema, according to the Starling law of transcapillary fluid exchange (neglecting lymph flow):

\[ P_t - P_c = \pi_c - \pi_t \]  (2-3)

where \( P_t \) is effective blood pressure within the capillary, \( P_c \) is tissue turgor pressure (interstitial fluid pressure), \( \pi_c \) is osmotic pressure of the plasma (colloid) inside the capillary, and \( \pi_t \) is osmotic pressure of the extracellular fluid (tissue colloid osmotic pressure).

Increase in extracellular lung water is related to duration of elevation of pulmonary venous or pulmonary capillary pressure, other things being equal. Not only can pulmonary edema result, but a combination of the damaging effects of CPB and increased pulmonary venous pressure can lead to pulmonary hemorrhage. Maintaining a very low pulmonary venous pressure will not always eliminate these complications.

Maintenance of a low pulmonary venous pressure can be ensured by monitoring left atrial pressure in patients undergoing CPB (see Section III). In most clinical settings, there is little tendency for pulmonary venous pressure to increase. If it does, the pulmonary venous system can be decompressed by suction on either a catheter (or an opening) in the pulmonary trunk, because no valves are present in pulmonary veins, or a catheter inside the left atrium or left ventricle.

Temperature

Since the introduction by Brown and colleagues of an efficient heat exchanger for extracorporeal circulation, temperature of the perfusate, and secondarily of the patient, has been controlled by the perfusionist.\(^{854} \) In decisions regarding temperature of the patient during CPB, several facts must be considered. Flexibility of CPB is achieved when it is combined with hypothermia. Hypothermia of even moderate degree appears to blunt some of the damaging effects of CPB.\(^{855} \) It allows use of lower pump \( Q \) with less blood trauma and achieves better myocardial protection and protection of other organs than normothermic CPB.\(^{856} \) Systemic hypothermia also provides a margin of safety for organ protection if equipment failure occurs. The patient’s body temperature is the most important determinant of the length of safe circulatory arrest time (see Section I).

Moderate hypothermia is used in many patients, and we consider at least mild hypothermia (31°C-34°C) to be advisable in essentially all cases. A nasopharyngeal temperature of 14°C to 20°C is chosen when circulatory arrest is required.

During core cooling, blood entering the patient’s aorta should be kept no greater than 10°C to 14°C below the nasopharyngeal temperature to minimize the tendency for gas to come out of solution when the cold blood is warmed by the patient. This is a conservative recommendation, in that some groups use the coldest perfusate temperature obtainable (4°C-5°C) once CPB is initiated.

Because blood is damaged by temperatures greater than 42°C, and the boundary layer of blood next to the wall surface of the heat exchanger probably reaches the temperature of that surface and thus of the water on the other side of the wall, water temperature should not exceed 42°C during rewarming. Blood temperature should not exceed 39.5°C during rewarming. Solubility of gas in blood is decreased when blood is warmed, but this is not a problem when the heat exchanger is upstream (proximal) to the oxygenator. When it is downstream (distal) to the oxygenator, it is a potential problem during rewarming, and a bubble trap may be interposed in the arterial tubing downstream to both. In general, maintenance of a temperature gradient from the heat exchanger to the blood of not more than 10°C to 12°C will prevent bubble formation.

RESPONSE VARIABLES

Alberts and colleagues state in their textbook: “There is a paradox in the growth of scientific knowledge. As information accumulates in ever more intimidating quantities, disconnected facts and impenetrable mysteries give way to rational explanations, and simplicity emerges from chaos. The essential principles of a subject gradually come into focus.”\(^{857} \) The patient response to CPB using current techniques and equipment is still largely described by “disconnected facts and impenetrable mysteries,” but considerable effort has been made to develop simplicity and reduce chaos. Continued interest in this response has stimulated the search for more cohesive knowledge and ways of minimizing unfavorable outcomes of cardiac surgery using CPB and whole-body perfusion from a pump-oxygenator.

Unfavorable aspects of the response of the patient to CPB and use of a pump-oxygenator were evident during the early days of open cardiac surgery, but tended to be overlooked in the excitement generated by this new technology. Subsequently, surgeons observed that (1) diffuse bleeding was more common with CPB than after other types of surgery; (2) some patients, particularly small ones, became edematous during the procedure; (3) occasionally severe and truly malignant hyperthermia occurred with no demonstrable infection; (4) pulmonary dysfunction was sometimes unexpectedly prominent; and (5) the heart often did not perform as well as anticipated after its repair. Yet they also noted that many patients appeared to be free of these developments, and most survived. Since then, more information has been gathered, but not as much as is desirable.

Whole-Body (Nonspecific) Inflammatory Response to Use of a Pump-Oxygenator

Diversion of blood through nonendothelialized channels to, through, and from pumps and the oxygenator appears to stimulate the organism to recognize the extracorporeal system as nonself. Thus, potential is present for the specific immune and nonspecific inflammatory response systems to be activated. Specific immune responses of an immunologically naive (unprepared) patient are slow to develop and not in evidence during the first few days after CPB. In any event, they are generally not strong. Nonspecific inflammatory responses appear rapidly, and in a few patients they dominate the early minutes, hours, and days after use of a pump-oxygenator. We initially named this response the whole-body inflammatory response, which we hypothesized unified the many diffuse responses to exposure of blood to abnormal events.\(^{858} \) It is now often called the systemic inflammatory response.
response syndrome (SIRS) because processes other than CPB can stimulate it.

**Humoral Response**

Initial response is probably humoral, initiated by the contact of plasma with the foreign surfaces of the tubing and pump-oxygenator and with air. Gas exchange requires a large surface area; it is therefore in the oxygenator that the greatest stimulus to this response occurs. Humoral response appears to begin with activation of specialized plasma proteins, developed and conditioned throughout centuries of life to recognize and repel transcutaneous invaders. Whereas previously this invasion has generally been a relatively small, localized, and often extravascular process, in the patient exposed to a pump-oxygenator it is a massive intravascular process. Even though the patient is heparinized, parts of the coagulation cascade respond virtually immediately to the activating capability of the foreign surface, as do the complement, kallikrein, fibrinolytic, and other cascades. Activation of Hageman factor (factor XII) may be the initial event in activation of these cascades, although platelets appear to be independently activated at about the same time. Nearly all the split products resulting from these multiple activations can be found in the patient's blood during and, for a time, after bypass. Mechanisms for their disappearance have not been elucidated, but presumably they are to some extent metabolized, taken up by specific cell-surface receptors, dissipated into extravascular fluids, including peritoneal and pleural fluids, and excreted in the urine.

Products of activation of these cascades have powerful physiologic effects, both directly and by activation of other systems and cells. The complement cascade, once activated, results in the production of powerful anaphylatoxins (C3a and C5a) that increase vascular permeability, cause smooth muscle contraction, mediate leukocyte chemotaxis, and facilitate neutrophil aggregation and enzyme release. Complement activation occurs through either the classic or the alternative pathway.

Contact activation of Hageman factor also immediately initiates the kallikrein-bradykinin cascade, resulting in the production of bradykinin. Plasma kallikrein circulates in the blood as a precursor, prekallikrein, 75% of which is bound to high-molecular-weight kininogen (HMWK) in the plasma. Bradykinin, formed largely from HMWK, increases vascular permeability; dilates arterioles; initiates smooth muscle contraction, and elicits pain. Kallikrein also activates Hageman factor and plasminogen to form plasmin, again demonstrating the complex interactions and feedback loops between the various reactions of blood to nonself.

Once activated, the contact activation system overcomes its normal regulating system, and all the responses are amplified. Because plasma kallikrein leads to conversion of plasminogen to plasmin, whose basic function in the circulation is to digest fibrin clots and thrombi, the fibrinolytic cascade is activated by this and other humoral and cellular mechanisms.

**Cellular Response**

Blood cells and endothelial cells participate in the nonspecific inflammatory response to use of a pump-oxygenator. Lymphocytes (both antibody-forming B cells and T cells) are part of the specific immune system and, as indicated earlier, participate little in the response to CPB in the usual immunologically naive patient. Eosinophilic granulocytes also seem to have limited participation. Basophilic granulocytes (mast cells) may well participate, but the extent to which they do so is not clear, and the same is true of the natural killer (NK) cells within the leukocyte family. Monocytes, once activated, participate in the cellular response.

**Neutrophilic granulocytes** (polymorphonuclear leukocytes) play a major role in the response to CPB. Neutrophils are activated by complement and other soluble inflammatory mediators. When activated, they migrate directionally toward areas of higher complement concentration (usually in the tissues, but during CPB, probably in blood), change their shape, become more adhesive, and secrete cytotoxic substances, including oxygen-derived free radicals. Of importance—and possibly a clue as to why most patients recover uneventfully from cardiac operations in which CPB is used, despite the strong humoral and cellular response—is the fact that complement can also desensitize neutrophils, thereby reducing their ability to participate in the inflammatory response. Neutrophils are also activated by other humoral agents participating in the cascades in the blood, including kallikrein, as well as by other inflammatory mediators (cytokines) generated by cells, including tumor necrosis factor (TNF) and platelet activating factor (PAF). These molecules also have been shown to increase in amounts both during and early after CPB.

**Platelets** are strongly affected by CPB using a pump-oxygenator, but in a complex manner that has been well summarized by Edmunds and colleagues. As in the case of neutrophils, platelets must be activated from their normally passive state; this occurs within 1 minute of the start of CPB. The precise initial trigger is uncertain, but possibilities include direct surface contact, abnormal shear stresses, mechanical lysis, exposure to adenosine diphosphate, and unidentified chemical agonists. The mechanism for activation of platelets is exposure on the surface of the platelet of numerous specific membrane receptors. Exposure of the fibrinogen glycoprotein receptors (GPIIb-IIIa complex), and subsequent binding of fibrinogen to them, are essential for adherence of platelets to the foreign surfaces of the pump-oxygenator and for their aggregation. Many other specific receptor sites are expressed and exposed by activated platelets. Control, feedback, and amplification mechanisms regulate platelets as well as the humoral systems, all of which are involved in the response to CPB.

**Endothelial cells** do not pass through the pump-oxygenator, but their complex activities are affected while the patient is connected to it. Triggering mechanisms are not clearly defined, but they probably include abnormal pressures and shear stresses, localized ischemia, and increased concentrations of normal and abnormal substances and cells in the blood. As a result, endothelial surface receptors are exposed, substances are elaborated and extruded, and spaces between the endothelial cells and their membranes are enlarged. Endothelial and other cells, particularly those in the locally ischemic areas that surely exist during CPB, express phospholipid molecules derived from arachidonic acid (eicosanoids). These are important mediators of inflammation and include the prostaglandins, thromboxanes, leukotrienes, and lipoxins. Other cells in areas of acute inflammation that may be present during CPB can produce soluble factors (cytokines) that normally act on other cells to regulate their function; after
CPB, they can induce elevation of body temperature, among other things.

**Metabolic Response**
Magnitude of the acute elevation of catecholamine levels in the blood that develops during CPB (see “Catecholamine Response” later in this section) is a measure of severity of the stress reaction induced by most cardiac surgery using CPB. Thus, in addition to the responses induced by CPB, cardiac operations and CPB induce the important perturbations associated with other major operations and trauma. Characteristics of this “metabolic response to stress” have been intensively studied by a number of investigators and clinicians. Among the first was Cuthbertson in 1930, and among the most prominent, Francis D. Moore. The essence of this process has been well summarized by Wilmore.

The human body responds to these stresses with dramatic resilience. For example, following injury, clotting mechanisms are immediately activated to reduce blood loss; body fluids shift from the extravascular compartment to restore blood volume; blood flow is redistributed to ensure perfusion of vital organs; and respiratory and renal functions compensate to maintain acid-base neutrality and body fluid tonicity. Following these acute adaptations, other changes occur; these responses are more gradual and prolonged but are apparently necessary for recovery of the injured organism. A variety of immunologic alterations are initiated; leukocytes are mobilized, macrophages and specialized T cells are produced, and “acute phase” plasma proteins are synthesized by the liver. Inflammatory cells invade the injured area, set up a perimeter defense, and engulf the dead and dying cells and other wound contaminants. These initial steps are followed rapidly by ingrowth of blood vessels, appearance of fibroblasts that build collagen scaffolding, and a host of other local changes that aid wound repair.

Local changes that occur at the injury site are accompanied by systemic alterations in body physiology and metabolism. Cardiac output is elevated, minute ventilation is increased, and the patient becomes febrile. Lipolysis and skeletal muscle proteolysis are accelerated, providing an ongoing fuel supply and an immediate source of amino acids that are utilized for wound healing and synthesis of “acute phase” proteins and new glucose. The glucose provides essential energy for the brain and other vital organs and for healing of the wound.

Phenomena associated with CPB not only produce their own damage but also interfere with the metabolic response to stress, a process necessary for recovery. Uneventful recovery of most patients after cardiac surgery means that a vast array of control and counteractive phenomena of both humoral and cellular types is in place, many of which await discovery and exploitation.

**Details of the Whole-Body Inflammatory Response**

**Neutrophil Activation**
During CPB, an initial mild leukopenia develops, which soon returns to baseline values. Similar changes occur without an oxygenator in the system and are in part the result of transient movement of leukocytes out of the vascular system. By the end of CPB, leukocytosis is present, consisting primarily of mature segmented forms of neutrophils (coming primarily from the bone marrow, most of which are activated). Leukocyte count often increases to a peak of 12,000 to 24,000 cells · mL⁻¹ at 24 to 28 hours postoperatively. Both T and B lymphocytes are decreased early after CPB, and T-cell function is decreased.

Pulmonary sequestration of neutrophils occurs during CPB. An inflammatory response follows their disruption and release of proteolytic and vasoactive substances and powerful lysosomal enzymes, contributing to the increased vascular permeability associated with CPB (see “Complement Activation” later in this section). Also, activation of neutrophils during CPB by the C3a and C5a complement fragments liberates oxygen-derived free radicals; this contributes to the damaging effects of CPB. Neutrophil elastase, a connective tissue protease and product of neutrophil activation that appears in plasma, is considerably increased by CPB, and the peak concentration correlates positively and closely with the duration of CPB. Such proteases break down elastin, collagen, and fibronectin, destroying extracellular structures, and contribute to the capillary leak that leads to postoperative extracellular volume overload and electrolyte imbalance.

Neutrophils in healthy persons are distinct cells. By inference, these cells are inactive and unprepared for the numerous deleterious effects they exert during and early after CPB. However, when stimulated, neutrophils transiently aggregate and cluster with each other and to other cell types, such as vascular endothelial cells. The process of aggregation and clustering is rapid, mediated by cell adhesion molecules (CAMs), and a critical step in development of inflammatory and immune responses. In myocardial infarction, anti-CAM antibodies of specific types, which can be produced by monoclonal techniques and can attenuate or prevent neutrophil aggregation and clustering, have been shown to considerably reduce the extent of cell death produced by ischemia and reperfusion.

Gillinov and colleagues used the anti-inflammatory agent NPC15669 to inhibit neutrophil adhesion in a CPB model and found a marked decrease in pulmonary injury. Nifedipine, infused during CPB in doses of about 6 µg · kg⁻¹ · h⁻¹, appears to inhibit neutrophil activation. Hypothermia has been shown to delay, though not prevent, the expression of neutrophil adherence molecules. Other interventions that have been evaluated clinically and experimentally to reduce the adverse effects of neutrophil activation include leukocyte filtration and pharmacologic agents (aprotinin, oligosaccharide antagonists, antioxidants, corticosteroids, and omega-3 fatty acids).

**Platelet Response**
In vitro test circuits show that the platelet count (corrected for dilution) decreases within 2 minutes of the beginning of extracorporeal circulation to about 80% of the pre-CPB level. By 8 minutes, the count has decreased to about 70% of the pre-CPB level and then stays close to that level during the rest of CPB and the period thereafter. Decrease in platelet count during clinical CPB tends to be greater than this because of hemodilution. Cardiotomy sucker systems substantially reduce platelet count. Interestingly, membrane oxygenators are associated with greater reduction than bubble
oxygenators. As a result of these and other factors, the number of platelets in circulating blood post CPB decreases to about 60% of the prebypass value and does not correlate with duration of CPB.

Sequestration of platelets in the liver and other organs during CPB in humans is slight and therefore not a major factor in reducing the platelet count. Something other than mere loss of platelets by adhesion to foreign surfaces is involved, because the platelet count continues to be low in some patients for as long as 72 hours postoperatively. One factor may be reduced survival time of platelets after CPB. Shear stresses likely do not reduce either the number or function of platelets.

More complex and probably more important than the change in numbers are qualitative changes that occur in the platelets of patients undergoing CPB. Normally, platelets adhere only to cut ends of blood vessels and to subendothelial surfaces (presumably because subendothelial collagen causes them to adhere). Once CPB begins, platelets almost immediately adhere to foreign (nonendothelial) surfaces. Once this process begins, platelets also begin to clump (aggregate), primarily on the foreign surfaces they have already adhered to. There is some evidence that initial aggregation is in small clumps (primary aggregates) capable of deaggregating. If the stimulus is strong, however, these primary aggregates are transformed into larger aggregates. It is believed that only then do platelets begin to release the contents of their granules and become irreversibly activated. Aggregates break off on occasion and become particulate emboli. Either platelets aggregate and disaggregate for many days after CPB, or the aggregates formed during CPB persist in the circulation, because platelet aggregates can be seen passing through the retinal vessels of patients for days after cardiac surgery with CPB.

As blood circulates normally through endothelially lined tubes, platelets are generally inactive. The stimulus to platelet adherence and aggregation on the surfaces of the pump-oxygenator system, whatever it may be, also activates the platelets, a process that changes their form and internal architecture. This activation causes platelets to expose or assemble specific membrane receptors on their surfaces—for example, membrane glycoproteins Ib and IIa (which bind fibrinogen) and GPIb (which binds von Willebrand factor)—with a resultant cascade of further platelet adherence to the foreign surfaces and aggregation. The activation process simultaneously affects platelet granules, which are concentrations of selectively sequestered intraplatelet substances. These substances include (1) serotonin, ATP, adenosine diphosphate, pyrophosphate, and calcium in the “dense bodies”; (2) α-thrombin, β-thromboglobulin, platelet factor 4, and platelet-derived growth factor; and (3) lysosomes. When activated, prostaglandin synthesis (arachidonic acid cascade) and other reactions take place in the surface membrane of the platelet as well as within it and lead to external secretion of the highly reactive components of the platelet granules. The entire process may well contribute to a number of the damaging effects of CPB.

As is usual in the humoral and cellular cascades, the same processes that lead to platelet activation lead virtually simultaneously to processes that inhibit it. This proceeds because platelets, like most cells in humans, contain adenylate cyclase, which converts ATP to cyclic adenosine monophosphate (cAMP). This conversion is greatly stimulated by products of the arachidonic acid cascade, which is known to be accelerated by CPB. In sufficient amounts, cAMP leads to inhibition of platelet adhesion, aggregation, change of shape, and secretion. This is part of the normal autoregulatory process, but it may be abnormally amplified during CPB.

Although platelet adherence to the foreign surfaces of the pump-oxygenator is the initial feature of the platelet response to CPB, and is surely accompanied by other major and complex responses, there remains a degree of uncertainty about subsequent events. There are even doubts as to whether platelet depletion and dysfunction are the primary causes of the bleeding tendency usually present after cardiac surgery. In any event, a short time after the first few minutes of CPB, about 60% of circulating platelets have a normal smooth discoid form, as do about 80% 8 minutes after the start of CPB and at the end of CPB. The implication is that either these platelets have never been activated (because they have just been released into the bloodstream or because foreign surfaces of the pump-oxygenator, passivated by absorption and denaturation of fibrinogen and albumin, no longer activate platelets), or they have been reversibly activated and returned to an inactive state. The latter is supported by the work of Zilla and colleagues but is contested by Edmunds. Sufficient irreversible activation occurs that partially degranulated platelets, platelets with damaged membranes, and platelet fragments can be recovered both during and at the end of CPB, along with a large number of normal-appearing platelets. Thus, by the end of CPB, platelet aggregability is reduced by 60% and bleeding time is prolonged, abnormalities that may persist more than 24 hours.

Most events during CPB that profoundly depress platelet function appear to take place initially in platelet membranes. During CPB, there appears to be a loss or inactivation of the functionally important glycoprotein-specific surface receptor sites. It is possible that abnormal shear stresses are partly responsible. The GPIIb receptor (to which plasma von Willebrand factor must bind for platelet adhesion) is markedly reduced shortly after the onset of CPB and remains low throughout bypass (Fig. 2-12). The GPIIb and IIIa receptors...
(which bind fibrinogen in a process that leads to platelet aggregation in the presence of extracellular calcium) are markedly reduced by the end of CPB.²⁻¹¹ Other changes in the platelet membranes may occur. Zilla has postulated, as have others, that the key to preventing loss of platelet function during CPB, and therefore to preventing the sometimes strong bleeding tendency associated with cardiac surgery, is to avert loss of action of platelet membrane-specific receptor glycoproteins.²⁵

Whatever the mechanisms and despite the high probability that development of platelet abnormalities is inherent in CPB as it is currently used, these alterations can be favorably influenced. The true membrane oxygenator, made from silicone rubber, appears to cause less platelet (and erythrocyte) damage than occurs with bubble oxygenators.²⁴ Aprotinin, no longer available for clinical CPB, may further lessen the development of platelet abnormalities (see Fig. 2-12 and “Other Additives,” earlier).

**Complement Activation**

Complement is a group of circulating glycoproteins that function as part of the body’s response to various kinds of injury such as traumatic, immunologic, or foreign-body insults.³¹ The complement system can be activated upon contact of blood with nonbiological surfaces, perhaps by way of Hageman factor, but other substances (e.g., thrombin, plasmin) can also activate it.

Complement activation during CPB was reported by Hairston, Parker, and Hammerschmidt and their colleagues.²³,³⁰ Complement consumption during CPB was demonstrated by Chiu and Samson.²⁶ Chenoweth and colleagues identified C3a, a complement breakdown product, in blood shortly after commencing CPB for cardiac surgery, and found that its continuing production was directly related to body temperature and perfusion flow rate.²⁰ The result is that more than 50% of patients have serum C3a levels above 1000 ng · mL⁻¹ at the end of operation with CPB (Fig. 2-13). Complement activation has also been demonstrated to occur during hemodialysis from exposure of blood to the dialysis membrane.²⁹,³³,³⁴ Complement activation in this setting is through the alternative pathway, with depletion of C3 but not C1,³³,³⁴ During CPB, activation is also through the alternative pathway.²¹,²⁶ Further complement activation by the classic pathway occurs after administration of protamine at the end of CPB,²⁰ this may add to the whole-body inflammatory response in some patients.²⁶

Recent studies suggest that complement activation after CABG with CPB is biphasic, with a second phase occurring between 8 and 48 hours postoperatively.²⁵,²⁶ The second phase appears to be activated by the classical pathway, not by the alternative pathway.²⁶ Bruins and colleagues demonstrated that higher peak levels of C4b/c on the second postoperative day correlated with increased occurrence of arrhythmia.²⁶

Magnitude of complement activation is affected by several factors that probably interact with still other factors in complex ways.²¹,²³,²⁶ The nature of the foreign surface has some effect; nylon is apparently a particularly potent complement activator.²⁶ True membrane oxygenators are weaker activators of complement than bubble oxygenators.²³ Duration of CPB has a weak positive effect on the final level of C3a, but administration of protamine has a considerably stronger effect.²³,²⁶,²⁷ Pretreatment of the patient with methylprednisolone or other steroids may decrease the amount of complement activation.²³

Adverse effects of complement activation relate to depletion of a component (complement) necessary for normal immune response and to adverse effects of the intravascular production of anaphylatoxins (C5a and C3a). Hairston and colleagues showed a decreased ability of postbypass serum to inhibit the growth of certain bacteria and related this in part to complement depletion.²³ Adverse effects of anaphylatoxins probably account for the degree of complement activation as a risk factor for morbidity after clinical CPB (Table 2-4, Fig. 2-14).

Pulmonary sequestration of polymorphonuclear leukocytes and neutropenia have been shown to develop during hemodialysis and to be temporally related to complement activation.²³ Similar observations have been made during CPB (see “Neutrophil Activation,” earlier).²⁶,²² That these changes are functionally significant is evident from the increased alveolar-arterial oxygen difference that develops during hemodialysis and after CPB, and from the pulmonary edema observed after CPB.²³³ Activation of complement has

*Natural logarithmic transformation.

Key: CPB, Cardiopulmonary bypass; SD, standard deviation.
been shown to be directly involved in production of pulmonary edema. These findings suggest that neutrophil-mediated pulmonary endothelial injury (see “Cellular Response,” earlier) and increased lung vascular permeability, perhaps also mediated by reactive oxygen metabolites, may contribute to the adverse effects of CPB on pulmonary function. Similar sequestrations may take place in other organs.

That important complement activation is dependent on a large proportion of blood in the boundary layer (e.g., in an oxygenator or hemodialysis coil) is evident from the demonstration in sheep that a simple venovenous shunt produces no adverse effects on white blood cells, platelets, or pulmonary artery pressure. Addition of an oxygenator to the circuit results in a decrease in circulating white blood cells and in platelets (presumably from pulmonary sequestration) and in a marked increase in pulmonary artery pressure. Fountain and colleagues showed that infusion of complement-activated plasma produces the same result.

**Kallikrein-Bradykinin Activation**

Another humoral amplification system involves kallikrein and bradykinin. Several studies have shown important amounts of bradykinin to be present during CPB. Hypothermia itself appears rather ineffective in production of bradykinin. Immaturity, such as is present in young infants, results in less effective elimination of bradykinin. Exclusion of the pulmonary circulation probably also reduces the ability of the organism to cope with circulating bradykinin, because the lungs are the main site of bradykinin elimination. Bradykinin, a small peptide, is a powerful vasodilator, and this effect is probably important in the overall response of the organism to CPB.

Nagaoka and Katori demonstrated a reduction in peripheral resistance and in fluid requirement during CPB accompanied by the administration of aprotinin. This agent is known to neutralize the kallikrein-bradykinin system.

**Coagulation Cascade**

Coagulation, the formation of fibrin clots, is largely inhibited by heparin during CPB (see “Heparin Levels,” earlier under Controlled Variables), but the coagulation cascade is in part activated. Related or unrelated to this, coagulation is often defective for a period of time after CPB.

Normally, in the presence of damaged endothelium or an exposed subendothelium, platelets and soluble components of the coagulation cascade are activated. Through the contact phase, intrinsic phase, and extrinsic phase of activation, prothrombin is converted to thrombin, which acts on fibrinogen to produce fibrin monomers that polymerize spontaneously to form a fibrin clot. Were CPB to be started in a nonheparinized patient, the contact phase and intrinsic phase would be rapidly activated, and within a short time the pump-oxygenator would be filled with clot.

Because of the incomplete blockade of the coagulation cascade by heparin, small amounts of fibrin form even during routine CPB. Many of the soluble coagulation factors are mildly reduced by the end of CPB. Most authorities believe these changes are insufficient by themselves to be responsible for the bleeding tendency following CPB.

**Fibrinolytic Cascade**

The fibrinolytic cascade, another humoral amplification system, is probably activated to some degree in all operations in which CPB is used. Important hyperfibrinolysis was shown to be present in 159 (20%) of 774 patients undergoing CABG.

Naturally occurring inactive plasminogen (normally incorporated within thrombi) is transformed into the active fibrinolytic agent plasmin under certain circumstances, and measurable blood plasmin levels have been demonstrated in patients shortly after initiation of CPB. Because conversion of plasminogen to plasmin is facilitated by kallikrein, which also results from activation of Hageman factor, the fibrinolytic cascade may be initiated during CPB by activation of factor XII. However, extrinsic plasminogen activator expressed by endothelial cells has been shown to be the major stimulant for conversion of plasminogen to plasmin, and thus for the fibrinolytic cascade. A reasonable explanation for this behavior of endothelial cells during CPB is the abnormally high levels of such substances as catecholamines, bradykinins, and other molecules that are generated.

Because plasmin also serves as an activator of complement, prekallikrein, and possibly Hageman factor, the intravascular activation of plasminogen into plasmin (which in intact humans is usually a localized phenomenon) may continue to stimulate cascades of all the humoral amplification systems. Breakdown products of fibrinogen (produced to some extent by the coagulation cascade during CPB), when acted upon by plasmin, have been shown experimentally to lead to important pulmonary dysfunction. This is another example of the powerful effects of the intravascular occurrence of events that are usually localized and extravascular in intact humans.

For a time, it was conventional wisdom that excessive bleeding after CPB was primarily the result of platelet depletion and dysfunction. More recently, several lines of information strongly suggest that activation of the fibrinolytic cascade also contributes importantly to postoperative bleeding after cardiac surgery in which CPB is used. One of these is the favorable effect of aprotinin on bleeding, with most reports indicating a 50% reduction in bleeding after CPB when this drug is administered. However, its action is probably not limited to the antifibrinolytic effect of inhibition of plasmin. Plasmin itself appears
to cause platelet aggregation, and its inhibition by aprotinin could therefore favorably affect platelets as well as fibrinolysis.\textsuperscript{16}

**Arachidonic Acid Cascade**

The completely cellular arachidonic acid cascade is activated by a disturbance of cell membranes, which in turn activates phospholipase A\textsubscript{2}. This releases arachidonic acid from the phospholipid fraction of cells, but the arachidonic acid can also come from intracellular lipid pools. The cascade proceeds through the prostaglandin-endoperoxide (cyclooxygenase) pathway. Stationary, migrating, and intravascular cells are susceptible to the arachidonic acid cascade and liberate the active products, which exhibit a short half-life.

The lung, bypassed during CPB, is a major site of synthesis, release, and degradation of eicosanoids (products of the arachidonic acid cascade), although not necessarily the cellular source of those compounds. Prostacyclin and prostaglandin E\textsubscript{2} (PGE\textsubscript{2}) production appears to be sharply increased shortly after CPB is begun, but later when CPB becomes partial and some blood again passes through the lung, levels decrease.\textsuperscript{15} By contrast, thromboxane B\textsubscript{2} production (thromboxane B\textsubscript{2} is a stable metabolite of thromboxane A\textsubscript{2}) becomes apparent and reaches peak levels when total CPB becomes partial as the lungs again are perfused.\textsuperscript{15} Many researchers believe that most of the thromboxane A\textsubscript{2} comes from platelets, even though release occurs to a great extent in the lungs. PAF, another product of the cascade, appears to be an important mediator of inflammation.\textsuperscript{11,13}

Leukotriene B\textsubscript{4}, a product of the arachidonic cascade that promotes plasma leakage and leukocyte adhesion, is also increased during and for a time after CPB.\textsuperscript{15}

Details and overall effects of activation of the arachidonic acid cascade during CPB are not completely understood, but there is at least evidence that the magnitude of the release of both of these eicosanoids during CPB is greatest in the very young.\textsuperscript{24} The activation releases agents that are somewhat counteracting, including the vasoconstricting agent thromboxane A\textsubscript{2}, a PAF, and the vasodilating and platelet-inhibiting factors prostacyclin and PGE\textsubscript{2}.

**Cytokines**

Cytokines are soluble factors elaborated by cells of the immune system (e.g., T-cell lymphocytes) that normally act on other cells to regulate their function. During CPB, cytokines such as the interleukins (ILs) elaborate other mediators of the inflammatory process (e.g., TNF, leukocyte adhesion molecules, PAF), which in turn continue the process.

IL-1 is an intracellular derivative of stimulated mononuclear phagocytes and a mediator of fever, changes in endothelial cell function and permeability, and decreased vascular resistance.\textsuperscript{12,22} Its concentration in monocytes is increased during CPB and again 24 hours later.\textsuperscript{12} A positive correlation has been found between intracellular IL-1 activity and the patient’s temperature 24 hours after CPB.\textsuperscript{12} The interrelation between complement activation (which activates monocytes), prostaglandins (which also mediate IL-1 production), and IL-1 illustrates the complexity of the whole-body inflammatory response to CPB and the problems inherent in efforts to prevent its damaging effects.

IL-6 and IL-8 levels rapidly increase after initiation of CPB.\textsuperscript{12,25} Degree of cytokine response appears to correlate with duration of CPB and aortic clamping.\textsuperscript{12,3}

**Other Mediators of Inflammation**

TNF is released by activated monocytes (and macrophages) and is increased in many patients in the later stages of CPB and during subsequent hours.\textsuperscript{13} It is known to increase endothelial cell permeability and open interendothelial cell spaces, thereby promoting development of interstitial edema.\textsuperscript{52,53}

Endotoxin, a powerful stimulant of complement and endothelial activation, is also a potent agonist of release of TNF from macrophages and is elevated in some patients after CPB.\textsuperscript{14,60,61,62} Endotoxin release may be the result of translocation of bacteria from the gut as the result of splanchnic ischemia and possibly impaired function of Kupffer cells in the liver.\textsuperscript{72}

**Protein Denaturation**

Proteins are denatured by a blood/gas interface, such as in a bubble or stationary vertical film oxygenator, but are denatured considerably less in microporous and true membrane oxygenators.\textsuperscript{17} Denaturation of albumin has a nonspecific effect, but denaturation of immunoglobulins yields degradation products that activate the complement cascade.\textsuperscript{75}

**Oxygen Consumption**

**Total Body Oxygen Consumption**

Theoretically, total body \( \dot{V}_O_2 \) during CPB at normothermia (37\(^\circ\)C) should be that of an intact human under anesthesia, if all parts of the microcirculation are perfused. Yet, in two studies in humans, \( \dot{V}_O_2 \) during normothermic CPB at flows of 1.8 to 2.4 L \( \cdot \) min\(^{-1} \) \( \cdot \) m\(^{-2} \) was highly variable. Values of 74 to 162 mL \( \cdot \) min\(^{-1} \) \( \cdot \) m\(^{-2} \) were found in one study\textsuperscript{12,16}; in the other study, which consisted of 12 patients, mean \pm standard deviation of \( \dot{V}_O_2 \) was 131 \pm 20 L \( \cdot \) min\(^{-2} \).\textsuperscript{1,11}

A combined analysis of experimental studies in animals during normothermic CPB\textsuperscript{89,94,95} indicates a best-fit hyperbolic relationship between the perfusion \( Q \) and \( \dot{V}_O_2 \) (Fig. 2-15). \( Q \) in these studies was expressed in L \( \cdot \) min\(^{-1} \) \( \cdot \) m\(^{-2} \). (These units were not used in the excellent study of Andersen and Senning, nor could the data be recalculated in these terms, hence their exclusion.\textsuperscript{117}) The following linear regression equation was derived from the data:

\[
\dot{V}_O_2 = 0.4437 \cdot (Q - 62.7) + 71.6 \quad (2.4)
\]

where \( \dot{V}_O_2 \) is oxygen consumption expressed as a percentage of measured control value before bypass, and \( Q \) is flow from the pump-oxygenator, expressed as mL \( \cdot \) kg\(^{-1} \) \( \cdot \) min\(^{-1} \) (correlation coefficient = 0.83). Andersen and Senning noted, however, that \( Q \) and \( \dot{V}_O_2 \) must meet at zero and that the control value for \( \dot{V}_O_2 \) was usually reached at high flows (100-125 mL \( \cdot \) kg\(^{-1} \) \( \cdot \) min\(^{-1} \)).\textsuperscript{117} Visual observation of their scattergram suggests that the hyperbolic model derived from the combined analysis fits their data and ideas well.

Temperature of the patient is also related to \( \dot{V}_O_2 \) during CPB, as it is in intact, anesthetized, nonshivering subjects. Harris and colleagues were first to express mathematically the interrelation among \( Q \), temperature, and \( \dot{V}_O_2 \), but their data covered a narrow range of temperature.\textsuperscript{12,10} Complete data of the type desired are not available. Using the experimental data at 37\(^\circ\)C just described and the relation of \( \dot{V}_O_2 \) to flow at 20\(^\circ\)C measured during CPB in humans, a multivariable
Relationship of total body oxygen consumption \( (\dot{V}O_2) \) to perfusion flow rate \( (Q) \) at normothermia during nonpulsatile cardiopulmonary bypass. Figure contains two depictions. One is a scattergram of data from animal experiments \( (n = 213) \) performed at about 37°C by Cheng and colleagues\(^{23} \) \( (n = 33) \), Paneth and colleagues\(^{25} \) \( (n = 60) \), and Starr\(^{27} \) \( (n = 120) \). Note that scatter of data increases as flow increases. Second depiction is solid and dashed lines (presented as in Fig. 2-1), which is a solution of the hyperbolic equation (Appendix Equation 2A-2) derived from these data. The hyperbolic equation is chosen because the correlation coefficient, \( r \), was .69, whereas it was .39, .54, and .52 for the linear equation, log-log equation,\(^{106} \) and Arrhenius equation,\(^{81} \) respectively.

Cerebral Oxygen Consumption

Cerebral oxygen consumption is important during CPB, particularly hypothermic CPB at low flow, because cerebral \( \dot{V}O_2 \) that is reduced below the usual (normal) value at a given temperature implies incomplete or uneven cerebral perfusion (decreased effective capillary density). An equation has been developed from the data of Croughwell and colleagues that is reduced below the usual (normal) value at a given temperature implies incomplete or uneven cerebral perfusion (decreased effective capillary density). An equation has been developed from the data of Croughwell and colleagues that appears to be the best expression available of the normal relation during CPB at full flow \( (2.0 \text{ L min}^{-1} \cdot \text{m}^{-2}) \) between cerebral \( \dot{V}O_2 \) and temperature during CPB. It is presumably applicable to all ages\(^{37} \) (Fig. 2-16). Assuming that cerebral oxygen consumption at 37°C before CPB is the same as that at 37°C during CPB is inappropriate, because whole-body \( \dot{V}O_2 \) on CPB is a little less than off CPB. This may be from presumed uneven perfusion on CPB.

Cerebral oxygen consumption does not appear to change with the variations in cerebral blood flow that occur during clinical CPB.\(^{18,23} \) This is consistent with findings in experimental studies. For example, Fox and colleagues found that in monkeys on CPB at 20°C, cerebral oxygen consumption was the same at CPB flow rates of 0.5 and 1.6 L · min\(^{-1} \) · m\(^{-2} \), even though cerebral blood flow at 0.5 was 50% of that at 1.6.\(^{19} \)

Mixed Venous Oxygen Levels

Although mixed venous oxygen levels are related to the controlled variables of \( Q \), hemoglobin concentration of the perfusate, and \( P_aO_2 \) as expressed by the Fick equation (see Equation 2-1), they are also related to the patient’s response in terms of \( \dot{V}O_2 \) and thus to some partially controllable variables that affect \( \dot{V}O_2 \), such as pH and 2,3-diphosphoglyceric acid levels in red blood cells.\(^{341} \)

When most of the microcirculation is known to be perfused, \( P_vO_2 \) levels reflect the mean value for tissue oxygen levels. Thus, the assumption can be made that when \( P_vO_2 \) levels during CPB are relatively normal \( (P_vO_2, 30-40 \text{ mmHg}; S_vO_2, 60\%-70\%) \) and \( \dot{V}O_2 \) is relatively normal, tissue oxygen levels are relatively normal, and the whole-body perfusion is meeting the patient’s metabolic demands (see “Total Systemic Blood Flow,” earlier under Controlled Variables).

Metabolic Acid-Base Status

Metabolic acidosis tends to develop during CPB, even when apparently adequate flow rates are used.\(^{62} \) This is probably related to uneven distribution of flow during CPB, with the consequent development of underperfused areas that release lactic acid.\(^{22} \) Resultant metabolic acidosis is usually not severe, and the concentration of lactic acid rarely exceeds 5 mmol · L\(^{-1} \).\(^{318} \)

Hemolysis

Hemolysis of red blood cells during CPB has long been recognized. During the early years of open heart surgery, plasma hemoglobin levels during and after operation were monitored.
as an index of damage caused by the pump-oxygenator. However, serum hemoglobin levels during clinical CPB do not accurately reflect the amount of hemolysis, because hemoglobin either bound to haptoglobins or free when haptoglobin binding sites are saturated is continuously removed from the circulating blood by the reticuloendothelial system and kidneys. When the plasma free hemoglobin level exceeds about 40 mg · dL⁻¹, hemoglobin casts may form in renal tubules. There is little likelihood of renal shutdown from this effect unless the plasma hemoglobin level exceeds 100 mg · dL⁻¹.

Han and colleagues found plasma free hemoglobin levels to be 8.3 ± 1.3 mg · dL⁻¹ before CPB, 33 ± 3.6 mg · dL⁻¹ 10 minutes after the start of CPB, and 91 ± 8.4 mg · dL⁻¹ after CPB. The plasma free hemoglobin level may be still higher several hours after CPB. Classically, this has been explained as continuing destruction of erythrocytes damaged but not destroyed during CPB.

Red blood cell mass often declines still further during the first 3 or 4 postoperative days. Although in the past this has been attributed to the shortened half-life of damaged erythrocytes, the entire matter of hemolysis during and after CPB may be considerably more complex than this finding suggests. C₅b-₉, a product of complement activation, is deposited on the surface of erythrocytes during CPB. This may play a major role in hemolysis associated with CPB.

**Systemic Vascular Resistance and Arterial Blood Pressure**

At the onset of normothermic or moderately hypothermic CPB, systemic vascular resistance usually decreases abruptly. It then gradually increases toward normal throughout the period of CPB and may become higher than normal. Considerable variation exists from patient to patient in systemic vascular resistance and thus in systemic arterial blood pressure during perfusion. In patients with coronary artery disease, a high systemic vascular resistance tends to develop during CPB.

Precise mechanisms underlying these variations in systemic vascular resistance during clinical CPB have not been identified, except in one situation. When, after a protracted period of global myocardial ischemia, cardiac reperfusion is commenced, systemic arterial pressure and resistance decrease within about 30 to 45 seconds. This interval coincides with the time it takes the cardiac reperfusate to appear in the coronary sinus, return to the pump-oxygenator via the venous cannula, pass through that machine, and be returned to the patient. Contents of the coronary sinus blood first appearing after an appreciable period of global myocardial ischemia likely contain vasodilating substances that develop in the heart during the ischemic period. Some studies have suggested that this blood contains a large number of leukocytes that have been sequestered in the heart during global myocardial ischemia.

In general, it is not necessary to pharmacologically manipulate systemic vascular resistance during CPB, but some evidence indicates that cerebral blood flow is lower than desirable when mean arterial blood pressure during normothermic or moderately hypothermic CPB goes below about 40 mmHg. Therefore, when mean blood pressure is lower than 40 mmHg for more than a few minutes during rewarming, the rational approach is to increase systemic vascular resistance with pharmacologic agents that will elevate arterial blood pressure (see Chapter 4). Increasing Q above usual values during rewarming is generally ineffective in increasing arterial pressure. When systemic vascular resistance becomes so high during this phase of CPB that mean arterial blood pressure increases to more than 100 mmHg, it is prudent to reduce it pharmacologically to less than that level (see Chapter 4).

A vasoplegic syndrome (low systemic arterial pressure despite high cardiac output or CPB Q and adequate fluid infusion with low systemic vascular resistance) has been observed following onset of CPB. Patients who have a significant decline in mean arterial pressure early after initiation of CPB are more likely to become vasoplegic postoperatively and are more likely to die in the hospital or have a prolonged length of stay. Patients with the vasoplegic syndrome generally respond to an increase in systemic vascular resistance with an increase in mean arterial pressure.
syndrome have inappropriate low serum arginine vasopressin concentrations.\textsuperscript{21} Infusion of vasopressin increases blood pressure and reduces catecholamine requirements.\textsuperscript{21,112} Methylene blue has also been used to treat patients with catecholamine-resistant vasoparesis.\textsuperscript{114}

Other risk factors for developing the vasoplegic syndrome after CPB include preoperative angiotensin-converting enzyme inhibitor or beta-blocker use, low ejection fraction, use of pressors or aprotinin before CPB, low pre-CPB mean arterial blood pressure, longer length of CPB, higher temperature on CPB, and higher pre- and post-CPB hematocrit.\textsuperscript{21,10}

**Distribution of Blood Flow**

Distribution of blood flow during CPB cannot be assumed to be similar to that when the circulation is intact. Distribution (and thus regional and organ blood flow) during CPB may vary according to age of the patient, amount of hemodilution, $Q$, arterial pulse contour, any pharmacologic manipulation, temperatures of the perfusate and patient, and arterial $P_{CO_2}$, pH, and $P_O_2$. The specific effect of some of these variables on distribution of blood flow is unclear. There may well be species differences, making data based on human subjects the most useful.\textsuperscript{226}

**Cerebral Blood Flow**

Under conditions that often pertain in adults undergoing cardiac operations (nonpulsatile perfusion; flow 1.6 L · min$^{-1}$ · m$^{-2}$; temperature ± 25°C), cerebral blood flow (measured by radioactive xenon clearance) is about 25 mL · min$^{-1}$ · 100 g brain tissue$^{-1}$, with some variability depending on $P_{CO_2}$.\textsuperscript{221} During CPB in monkeys, a similar value has been found (using microspheres), representing about 6% of total systemic blood flow.\textsuperscript{118}

In humans, cerebral blood flow during CPB is no less in elderly patients than in other adult patients, and it appears to be proportionally similar in neonates and infants to that in adults.\textsuperscript{859,226,227} Thus, age appears to have little effect on the proportion of total flow represented by cerebral blood flow under usual circumstances of CPB.

During normothermic and moderately hypothermic CPB in adults and elderly patients, cerebral blood flow is not importantly altered with variations of mean arterial blood pressure.\textsuperscript{209,226} This is similar to the situation in normal awake adult humans, in whom cerebral blood flow does not vary significantly with variations of arterial blood pressure (mean) from about 60 to 150 mmHg. When arterial blood pressure during CPB falls below about 40 mmHg, cerebral blood flow may decline appreciably, with a concomitant decrease in cerebral oxygen consumption.\textsuperscript{99,17} A reasonable inference is that in adults on CPB, arterial blood pressure need not be manipulated pharmacologically unless it is less than 40 to 50 mmHg.

By contrast, during hypothermic CPB—at least in neonates, infants, and children—cerebral blood flow is dependent on arterial blood pressure.\textsuperscript{225,226,227} Corresponding variations in cerebral oxygen consumption have not been established with certainty. In view of this, arterial blood pressure should probably be kept above about 25 mmHg in this setting in young patients.

The effect of decreased CPB flow rate ($Q$) on cerebral blood flow in humans is incompletely understood, in part because of the interaction between perfusion $Q$ and arterial blood pressure (see Chapter 4).\textsuperscript{99} However, during moderately hypothermic CPB at the usual flow rates, there appears to be a direct correlation between CPB and cerebral blood flow rates, despite the poor or absent correlation between arterial blood pressure and cerebral blood flow.\textsuperscript{223}

Cerebral blood flow during CPB is affected by arterial carbon dioxide pressure ($P_{CO_2}$). Hypercarbia increases cerebral blood flow, whereas hypocarbia decreases it.\textsuperscript{221,1033,118} In children undergoing hypothermic CPB, the flow increases 1.2 mL · min$^{-1}$ · 100 g brain tissue$^{-1}$ for every 1-mmHg increase in $P_{CO_2}$ (measured at 37°C) between 33 and 50 mmHg.\textsuperscript{115} Infants have a slightly blunted response. Data gathered by Kern and colleagues are compatible with the hypothesis that under usual conditions of hypothermic CPB, metabolic needs of the brain are met with a $P_{CO_2}$ value of 33 mmHg.\textsuperscript{115}

Although autoregulation of cerebral blood flow has been described during normothermic and moderately hypothermic CPB, it may well be that it is the remainder of the body, not the brain, that accomplishes autoregulation. This was suggested by the experimental studies of Fox and colleagues.\textsuperscript{118}

Cerebral blood flow during CPB may at times be excessive in relation to cerebral oxygen consumption. For example, Croughwell and colleagues found that during CPB and reduction of the patient’s body temperature from 37°C to 28°C, cerebral blood flow decreased less than cerebral oxygen consumption. This was referred to as a situation of luxuriant cerebral blood flow accompanied by a narrowing of the cerebral arteriovenous oxygen difference.\textsuperscript{113} Similar luxury perfusion can result from hypercarbia, and it has been argued that this increases the risk of cerebral damage by microemboli.\textsuperscript{125,117} This is an argument against use of pH-stat strategy for control of $P_{CO_2}$ during CPB.

**Cutaneous Blood Flow**

Clinical information strongly suggests that blood flow to the skin is severely reduced during nonpulsatile CPB in humans. The small bald spot that develops on the back of the head after CPB in some patients is probably the result of the pressure produced by weight of the head on an area of poorly perfused skin in contact with even a well-padded pillow during operation. Ease with which burns are produced by the cautery pad may also be the result of poor blood flow to the skin during CPB.

Of interest, a study of the sublingual microcirculation in humans has shown that the proportion of perfused small blood vessels decreases importantly and similarly with induction of anesthesia in patients undergoing thyroidectomy, and cardiac surgery with or without CPB.\textsuperscript{256} In the CPB group, the proportion of perfused small vessels decreased after induction, improved slightly thereafter, failed to return to baseline, and persisted after 24 hours (Fig. 2-17). The off-pump cardiac surgery patients had less severe but statistically significant microcirculatory alterations immediately postoperatively. These alterations improved slightly but also persisted after 24 hours. Thus, microvascular perfusion was altered similarly in CPB and off-pump patients 6 to 24 hours after admission to the intensive care unit. In thyroidectomy patients, early changes reversed rapidly in the postoperative period. Severity of microvascular alterations correlated with peak lactate levels after cardiac surgery ($P < .05$).\textsuperscript{256} These findings suggest that
changes in the microcirculation cannot be attributed entirely to CPB.

Venous Tone

Veins constrict during CPB, and venous tone is increased. This mechanism may persist for some hours afterward. The mechanism has not been determined with certainty, but high levels of circulating catecholamines probably play an important role.

Catecholamine Response

Response of circulating epinephrine (released primarily from the adrenal medulla) and norepinephrine (which overflows into the bloodstream from generalized sympathetic nervous system discharge) has been studied by many groups, with somewhat conflicting results. However, it is now clear that CPB is associated with a massive catecholamine release, greater than that from nearly any other form of stress. With onset of CPB in adult patients with coronary artery disease, plasma epinephrine levels increase; they begin to decline after discontinuation of bypass (Fig. 2-18, A). Persisting elevation 1 hour after operation occurs only in patients with postoperative hypertension.

Plasma norepinephrine levels do not increase in adult patients who remain normotensive postoperatively, but in those with postoperative hypertension, it increases at the start of operation and reaches a peak at the start of CPB (Fig. 2-18, B). It remains elevated at 1 hour postoperatively in this group. These patients show arterial blood pressure responses typical for patients undergoing CPB, with a striking decrease at the onset of CPB from reduced systemic arteriolar resistance (Fig. 2-18, C).

Mean arterial blood pressure 1 hour after operation correlates positively with both plasma epinephrine and norepinephrine levels. Neonates, infants, and young children also demonstrate marked increase in catecholamine concentration during CPB.15,16,12,24

Sympathetic–adrenal system discharge during, and in some patients after, operation is presumably related to use of CPB. The increased catecholamine response, particularly of norepinephrine, is partly attributable to the fact that during CPB, blood does not pass through the lungs, where norepinephrine is largely inactivated.12

Adrenal Cortical Hormones

Clinical studies nearly uniformly demonstrate large increases in cortisol and adrenocorticotropic hormones with initiation of CPB. After CPB, patients exhibit markedly elevated levels of cortisol (free and total) for more than 24 hours. It is not clearly established whether the elevated corticosteroid concentrations during CPB are deleterious or beneficial.

Vasopressin

Vasopressin, or antidiuretic hormone (ADH), is secreted by the pituitary gland and is a potent regulator of renal water excretion. Cardiac operations employing CPB are associated with large increases in ADH concentration that exceed those during other major surgical procedures; they can persist early postoperatively.35,7,14,29

Body Composition

After CPB, extracellular fluid volume is increased.40 The increase is in the interstitial fluid compartment, as shown by increased interstitial fluid pressure during CPB. The plasma volume tends to be decreased. Plasma volume is also greater with hypothermia and higher CPB Q. The large thoracic duct lymph flow occurring during CPB is related to this tendency of the interstitial fluid volume to increase. Also, exchangeable sodium is increased after CPB, while total exchangeable potassium is decreased.

Amount and concentration of intracellular potassium are decreased. These acute changes are probably, at least in part, the result of some of the damaging effects of CPB, including increases in capillary permeability, which probably facilitate the changes in body composition.

Thermal Balance

Heat is lost during CPB. A study of 6 adult patients cooled to 30°C during bypass lasting 130 minutes showed a mean net loss of 1000 kJ of heat (1 kilocalorie = 4.2 kJ) by the end of hypothermia. Loss to the heat exchanger and pump circuit was 840 kJ, and evaporative and convective loss was 380 kJ; the patient’s metabolism supplied 220 kJ. During rewarming to a nasopharyngeal temperature of 37°C, the pump-oxygenator returned 670 kJ to the patient. Loss of heat during the period of anesthesia preceding bypass was not accounted for. Patients therefore left the operating room with a deficit of at least 330 kJ, equivalent to more than 1.5 hours of basal energy production. This deficit has to be restored early postoperatively, and the extra metabolism necessary to
Figure 2-18 Plasma catecholamines and arterial pressures (mean ± SE) in patients undergoing cardiopulmonary bypass (CPB) for coronary artery bypass grafting at various stages of operation and early postoperatively. C, Mean arterial blood pressure (MAP). Key: CICU, Cardiac intensive care unit. (From Wallach and colleagues.)

Figure 2.19 Relation between duration of cardiopulmonary bypass (CPB) and increment in extracellular fluid minus plasma volume soon after operation (patients with heart failure are not included). Key: ECF, Extracellular fluid; PV, plasma volume. (From Cleland and colleagues.)

do this places a strain on the circulation that at times may be substantial. When deeper hypothermia is used, the problem is magnified, because muscle rewarms slowly and heat loss during operation is greater. It is necessary to bear in mind that the temperature of the muscles and body fat remains considerably lower than that of the nasopharynx after a short period of rewarming.

After CPB, a hypermetabolic state exists for at least 6 hours, sometimes longer. $V_O_2$ and carbon dioxide production are increased during this period, and body temperature may rise precipitously. The possible relationship between intracellular levels of IL-1 and hyperpyrexia is discussed earlier in this section under “Cytokines.”

AGENTS OF DAMAGE

Foreign Surfaces

Recognition by the cells that the surfaces in the pump-oxygenator system are foreign is a fundamental inciting agent for the damaging effects of CPB, as previously described. All elements of blood, formed and soluble, are affected. These phenomena were perhaps first reported by Lee and colleagues in 1972 and termed protein denaturation. In subsequent years, further effects of CPB on the complement cascade, white cell, and platelet elements and humoral and endothelial systems have been elucidated. Selectins, kallikreins, kinins, leukotrienes, TNF, proteases, cytokines, and others are activated, liberated, or suppressed during CPB, presumably by exposure to foreign or nonbiological surfaces or the blood/gas interface.

Because it is only in the boundary layer of flowing blood that the foreign surface is encountered, opportunity for damage is directly related to the proportion of the blood flowing there. Thus, it is in the oxygenator, where this proportion is deliberately made as large as possible to promote efficient gas exchange, that the opportunity for surface
interactions and damage is greatest. This includes bubble oxygenators, because gases themselves are recognized as foreign surfaces when in direct contact with blood. It is next greatest in the heat exchanger, next in filters, and least in tubing and reservoirs.

Some artificial surfaces are more interactive with blood than others; nylon may be a particular offender. Surfaces may be passified to some extent in the initial few minutes of CPB by deposition on them of denatured albumin, platelets, and other substances, but in oxygenators this is disadvantageous to gas exchange. Experimentally, some of the surfaces of certain parts of pump-oxygenator systems have been seeded with endothelial cells, but this has not yet been made practicable.

Currently, most pump-oxygenator systems have coated circuits to reduce the formed blood elements’ response to the artificial surface of the perfusion circuit. These range from synthetic coatings, to covalent heparin bonded coatings, to albumin-based coatings. All have been associated with a decrease in the amount of formed blood elements deposited on the surfaces of the perfusion circuit.

Shear Stresses

Shear stresses are generated by blood pumps, suction systems, abrupt acceleration and deceleration of blood, and cavitation around the end of the arterial cannula. For the leukocyte, they are an important abnormal event during CPB. This is in part because leukocytes are the largest formed blood element and are normally exposed to nonendothelialized surfaces, and because they are capable of exiting from the vascular space by diapedesis and by migrating via chemotactic gradients. They are also capable of phagocytosis and, because of their proteolytic and enzymatic components, of digesting almost any biological material. Martin demonstrated that shear stresses not only increase leukocyte disruption but also increase degranulation and adherence and decrease aggregation, chemotactic migration, and phagocytosis in nondisrupted leukocytes.

Erythrocytes are damaged during CPB primarily by shear stresses. The amount of hemolysis and liberated free hemoglobin increases linearly as shear increases. In CPB systems, hemolysis is much less without the oxygenator in the system, and bubble oxygenators have been shown to produce more hemolysis than membrane oxygenators. Interaction of the damaging effects is again demonstrated by the fact that the critical shear stress for erythrocytes is lowered by presence of an unphysiologic surface. Intracardiac sucker systems are particularly damaging to erythrocytes, not only because of high shear stresses and deceleration injury but also because negative pressures are more damaging to erythrocytes than positive ones.

Incorporation of Foreign Substances

In intact humans, foreign substances rarely enter the arterial bloodstream, although when they do, the well-recognized pathologic state of arterial thromboembolism may develop. During CPB, air bubbles, particulate matter from the pump-oxygenator, platelet aggregates and fragments, fibrin aggregates, denatured protein particles, atheroma, and chylomicrons may be contained in the arterial blood and may be distributed throughout the patient’s arterial system.

Microembolization is greatest during the first 5 to 10 minutes of CPB. Perhaps related to this, the total amount of microembolization is not correlated with duration of CPB. The amount does seem to be decreased by a small-pore filter in the arterial tubing of the pump-oxygenator, but this is arguable. Microembolization is greater when bubble oxygenators rather than membrane oxygenators are used. Embolized particles, whatever they may be, usually cause only transient obstructions to flow; thus, after 5 to 10 days, there is usually little evidence of their presence. Nevertheless, there is some correlation between depressed neuropsychometric test scores postoperatively and number of microemboli.

There are many potential sources of microemboli. In some instances, pump-oxygenator surfaces have fine deposits of debris; this has led some to advocate preliminary filtration of blood that has passed through the system before CPB is established. Gas bubbles are commonly found in the arterial input to the patient; these must have multiple sources, although they have been shown to be more prevalent when bubble oxygenators are used. There is some suggestion from the work of Clark and colleagues and Donald and Fellows that large temperature gradients between the water bath and blood in the heat exchanger (i.e., rapid cooling and rewarming) are accompanied by a showering of gaseous microemboli. Adhesion and aggregation of platelets during CPB (see “Platelet Response,” earlier) and formation of fibrin despite heparinization (see “Humoral Response,” earlier) contribute importantly to microembolization. Intracardiac sucker systems incorporate gaseous macro- and microemboli, fibrin, platelet aggregates, and debris into the blood, some of which cannot be removed before the blood is returned to the patient.

Gradual improvements in techniques and equipment for CPB have decreased the prevalence of foreign substances and cellular debris entering the patient’s arterial system during cardiac surgery. This problem remains important and the subject of continuing research, because it probably contributes to neuropsychiatric abnormalities after CPB and to cardiac, pulmonary, and other subsystem dysfunction.

Heparin

Heparin is administered before and during CPB to prevent coagulation of blood (see “Heparin Levels” under Controlled Variables earlier in this section, and see “Heparinization and Later Protamine Administration” under Preparation for Cardiopulmonary Bypass in Section III). It is an agent of damage, in part because it is an imperfect anticoagulant that permits formation of microthrombi in the pump-oxygenator that can embolize to the patient. In rare instances, heparin produces an adverse effect such as severe thrombocytopenia.

Efforts continue to be made to avoid heparinizing patients in the usual manner, primarily by making surfaces of the pump-oxygenator biocompatible. The most common method involves bonding heparin to these surfaces.

Contraindications to use of unfractionated heparin include HIT, heparin allergy, or protamine allergy. Currently, alternative agents are undergoing laboratory and clinical investigation. These include low-molecular-weight heparin and heparinoids, ancord (a defibrinogenating agent derived from pit viper venom), hirudin (a coagulation
inhibitor derived from the salivary glands of the medicinal leech), and coagulation factor inhibitors such as factor IXa, an inhibitor of factor IXa, and argatroban, an inhibitor of factor IIa.

Protamine

Protamine is generally necessary after terminating CPB to reverse the effect of heparin. However, it is an agent with damaging effects because it activates the complement cascade through the classic pathway, and occasionally provokes temporary (5-15 minutes) severe bronchospasm, elevation of pulmonary vascular resistance, and hypotension.\textsuperscript{5,12} Whether prevalence of these undesirable reactions is reduced by slow administration of the drug or by infusing it into the left atrium or aorta rather than the right atrium is arguable.

PREVENTION OF UNDESIRABLE RESPONSES

True prevention of the fundamentally disadvantageous and undesirable responses to CPB has eluded the cardiovascular surgical community despite intensive efforts. Developments in molecular biology may provide techniques that some day accomplish this. To date, only palliative measures are available, some of which are described in “Other Additives” under Controlled Variables.

SAFE DURATION OF TOTAL CARDIOPULMONARY BYPASS

Partial CPB is better tolerated than total CPB,\textsuperscript{31} and its safe duration is measured in days if a true membrane oxygenator is used (see “Cardiopulmonary Support and Extra-corporeal Membrane Oxygenation” in Section I of Chapter 5). Safe duration of total CPB is much shorter and is measured in hours, although not fully defined. The safety of CPB is known to be adversely affected by certain incremental risk factors.

Duration of CPB is clearly a risk factor for morbidity (Fig. 2-20) and mortality after cardiac surgery, but the relationship between duration of total CPB and morbidity and mortality is affected by other risk factors as well. Type of oxygenator is probably one such risk factor; in general, true membrane oxygenators are the safest, followed by microporous oxygenators. Bubble oxygenators are generally the least safe. In contrast to moderate or deep hypothermia, normothermia throughout most of the period of total CPB is arguably a risk factor that affects the relationship between duration of CPB and unfavorable outcomes (see General Comments and Strategy in Section III). Absence of hemodilution is probably a risk factor. Very low venous oxygen levels, although no doubt interrelated with some of the previously mentioned risk factors, appear to increase the risk of unfavorable events after CPB.

It is arguable that patient age is a risk factor for unfavorable outcome events after CPB, but the impression is that very young (Fig. 2-21) and very old age have an unfavorable effect on the relation between duration of CPB and prevalence of unfavorable outcomes. Immature patients may have a greater tendency to develop increased capillary permeability than older patients, although this has not been well documented. Strength of the patient’s humoral and cellular responses to CPB also affects this relationship, with greater complement activation appearing to have an unfavorable effect (see Table 2-4).

Thus, the relationship between safety and duration of total CPB depends on a number of factors that have mitigated against a complete understanding of it. Duration of CPB has clearly been identified as a risk factor for poor outcome in a wide range of studies of open heart surgical procedures. Nevertheless, it remains a possibility, even a likely one, that longer duration of CPB is primarily a marker for an operation that has not proceeded as planned. For example, in fairly well standardized operations such as CABG or the arterial switch procedure for transposition, duration of bypass beyond the expected range likely is a marker for technical problems with the procedure. It is factors related to poor technical operation, and not CPB duration, that have a causal relationship with increased morbidity. Other indirect evidence suggests that safe duration of CPB may be many hours, rather than a
few. Patients can be supported on extracorporeal membrane oxygenation (ECMO) for days and even weeks without developing circulation-related complications. It must be fully acknowledged, however, that closed ECMO circuits and open CPB circuits have many differences.

Section III  Clinical Methodology of Cardiopulmonary Bypass

GENERAL COMMENTS AND STRATEGY

CPB should be used as a flexible clinical tool, recognizing its physiologic limitations, risks, and damaging effects. CPB is combined with at least some degree of hypothermia in many situations for the reasons given in Section II. An important advantage of hypothermia is that it allows safe periods of very low perfusion flow rate (≈0.5 L·min⁻¹·m⁻²) or circulatory arrest when needed, but the possible advantages of normothermic CPB continue to be explored. These include lower systemic vascular resistance and higher cardiac output in the early postoperative period and less blood loss. However, decreased oxygen saturation (<50%) in the cerebral venous blood has also been observed, particularly during the early period of CPB.

Size of the arterial and venous cannulae is determined primarily by perfusion flow rate and type of venous return, but total perfusion flow rate—even at normothermia—is not an absolute quantity but encompasses a range of acceptable values. Thus, if the surgical situation compels use of smaller cannulae, perfusion flow rate can be set at a smaller value, or assisted venous return (vacuum, centrifugal pump) can be used. Two venous cannulae may be used as a routine or only for congenital heart disease operations, including those in infants, and operations involving the right atrium, such as tricuspid valve surgery. A single two-stage venous cannula, having additional holes that come to lie in the right atrium while the tip is in the inferior vena cava (IVC), may be used for CABG; operations on the aortic valve, mitral valve, and ascending aorta; some operations for congenital heart disease; and combinations of these procedures. Such a cannula has been shown experimentally to efficiently decompress the right heart. On occasion, a single venous cannula may also be used with conventional CPB and without aortic clamping for simple operations such as replacement of a valved extracardiac conduit.

Method of cannulation, use of left atrial and left ventricular vents, monitoring catheters, and indeed all aspects of clinical CPB should be flexible within certain limits. The combined knowledge and experience of the surgeon, anesthesiologist, and perfusionist should allow adaptation to the surgical situation while ensuring the greatest possible safety for the patient.

Some operations traditionally performed with CPB support can be designed to avoid use of CPB. These include off-pump CABG (Chapter 7), bidirectional superior cavopulmonary shunt (Chapter 41, Section III), and extracardiac conduit Fontan operation (Chapter 41, Section IV). Percutaneous aortic valve replacement (Chapter 12), investigative percutaneous techniques to address mitral valve regurgitation, and intravascular aortic stent-grafting (Chapter 26) are examples of traditionally surgical procedures that are becoming catheter based or hybrid procedures that do not require CPB.

POSITIONING MONITORING DEVICES

Monitoring devices used for various cardiac operations in infants, children, and adults and specific positioning are discussed in Chapter 4.

POSITIONING PATIENT

The surgeon should collaborate with the anesthesiologist to position the patient correctly for operation, because an improperly positioned patient can make the operation more difficult and injure the patient. For a median sternotomy, both arms may be placed at the side to permit optimal access for the surgical team and avoid traction on the brachial plexus during operation. Alternatively, a carefully positioned arm board can be used for the left arm (and for venous and arterial catheters).

Particularly in infants, a pad is placed under the back to project the chest forward and extend the neck. The patient’s trunk must not be rotated, and the arms at the side must be secured and protected to prevent compression of the ulnar nerve at the elbow. A cauteried pad is placed under the buttocks or the back. Pads for external defibrillation may also be placed on the anterolateral left chest and the back. A draping framework is placed over the head of the patient and extended to either side to screen the patient’s head and the anesthesiologist from the sterile field. A urethral catheter containing a thermistor is inserted into the bladder. A thermistor probe is positioned in the nasopharynx.

PREPARING SURGICAL FIELD

The skin of the anterior thorax and abdomen is prepared with an antiseptic solution after mechanically cleansing it. In most patients, both groins should be prepared as well and draped into the surgical field so that the femoral vessels can be cannulated if necessary. Both legs are surgically prepared in their entirety for individuals undergoing CABG.

Appropriate sterile drapes are applied. Draping must shield the surgical field from the anesthesiologist, while at the same time allowing him or her an unobstructed view into the field.

Finally, the surgical field is covered by an impervious adhesive plastic sheet, in part to prevent the side drapes from falling away from the skin. It also prevents the drapes in the vicinity of the wound from becoming wet and thus losing their sterility.

Pump tubing is passed from the operating table to the perfusionist, who completes the CPB circuit. Tubing for infusion of cardioplegia, pericardial irrigation, suction, and venting is also positioned.

INCISION

Primary Median Sternotomy

A straight vertical midline skin incision is generally made in patients undergoing CPB through a median sternotomy. This incision commences several centimeters below the suprasternal notch and extends to the tip of the xiphoid.
An exception may be made in prepubertal girls in whom a bilateral submammary skin incision is made that follows the fourth intercostal space. A flap of skin and subcutaneous tissue is raised superiorly and inferiorly to expose the full length of the sternum for a vertical sternotomy. However, this incision may cause underdevelopment of the breasts in girls of this age and should be used judiciously. When used in female patients of all ages, this incision may cause hypoplasia or anemia of the anterior chest wall.

The exact midline over the sternum is scored with the cautery. A retractor elevates the upper angle of the vertical skin incision, placing the underlying tissues on tension. The soft tissue is separated from the superior surface of the manubrium, and a right-angled clamp is passed over the denuded manubrium into the space behind, hugging the bone. The clamp is spread to create a space for the tip of the sternal saw. The suprasternal ligament is cut with the cautery.

The blade of an electric or air-driven saw is held snugly against the posterior surface of the manubrium with the cutting edge against the superior manubrial surface. After activating the saw, the surgeon cuts the manubrium and sternum, staying precisely in the midline. The tip of the saw is kept elevated so that the toe of the saw hugs the back of the sternum. During sawing, the anesthesiologist should cease ventilating the patient and exert no pressure on the lungs, so that the soft tissue and pleura will fall away from the sternum. Drifting away from the midline with the saw must be avoided because the sternum will not spread evenly, and its later closure will be more difficult.

Alternatively, the sternum can be divided from the bottom up. The xiphoïd process is mobilized or excised, and the tip of the blade is introduced beneath it. In neonates and infants, the xiphoïd process may be excised, the costal margin on either side elevated by sharp retractors, and sharp, well-aligned scissors used to cut the sternum in the midline, from below upward.

When the incision is properly made, the pleural spaces are infrequently entered. A thin layer of bone wax is spread over the bone marrow, primarily where the bleeding is active. When the sternum is fragile, as in older patients, it is better to avoid wax altogether. Bleeding points in the cut edge of the anterior and posterior sternal periosteum are cauterized, but excessive cauterization should be avoided. A retractor is inserted and opened just enough to permit dissection. After a few minutes, it is opened further. It should be opened no more than is necessary for the procedure, because excessive retraction, particularly of the upper half of the sternum, may cause rib fractures, dislocation of costochondral junctions, injury to the brachial plexus, and damage to the stellate ganglion.

Dissection continues by incising the fascia that envelops the thymus gland. The right and left lobes of the thymus are separated up to the level of the brachiocephalic vein. In infants and children, and occasionally in adults, the thymus may be subtotally resected, leaving only the cervical portion cephalad to the brachiocephalic vein, to avoid expanding hematomas that may cause postoperative bleeding.

The pericardium is then opened longitudinally in the midline, from the diaphragm below to the brachiocephalic vein above. Where this incision meets the diaphragm, care must be taken not to incise the parietal peritoneum. If entry is made into the peritoneal cavity, the opening is sutured to avoid sequestration of blood and fluid in it. The pericardium is cut at right angles to the longitudinal incision at its diaphragmatic end, farther on the left than on the right, after pushing back the pleura to avoid entering the pleural spaces. Pericardial stay sutures are then placed.

Alternative Primary Incisions

Incisions other than a full median sternotomy are being used with increasing frequency. These incisions and the techniques of cannulation required for their use are described at the end of this section in Special Situations and Controversies.

The remainder of the general discussion on the clinical methods of CPB focuses on the median sternotomy approach to the pericardial cavity and its contents.

Secondary Median Sternotomy

The surgeon must estimate preoperatively the chances that catastrophic hemorrhage will develop from repeat sternotomy. This affects the decision regarding whether to cannulate peripheral vessels and establish CPB before sternotomy. It is helpful to study the chest radiograph and any available cineangiograms. However, cross-sectional imaging by CT or MRI provides the most useful information. When one of the great arteries, right ventricle, coronary artery bypass grafts, or a right ventricle to pulmonary trunk conduit is in close proximity to the back of the sternum, peripheral cannulation, establishment of CPB, and induction of moderate hypothermia before sternotomy are prudent precautions.

When a previous sternotomy has been performed, an oscillating saw is commonly used. Properly used with a light touch by the operator, this saw allows the sternum to be split without damage to underlying structures. Once the sternum is divided, a sharp handheld retractor is inserted to elevate the lower left sternal fragment. Dissection is commenced just beneath the xiphisternum, dividing the tissues just behind the sternum. Working from below upward, the surgeon frees the left sternal edge in this manner to the level of the suprasternal notch. The same maneuver is repeated on the right side. Returning to the left sternal edge, the surgeon fully elevates it with two retractors and carries the dissection leftward, keeping fairly close to the sternum until the divided edge of the pericardium is identified (when the pericardium has not been sutured at the first operation, it retracts well away from the midline). The left edge of the pericardium is separated from the underlying pericardial end, farther on the left than on the right, after pushing back the pleura to avoid entering the pleural spaces. Pericardial stay sutures are then placed.
of pericardium attached to the atrium if it is too densely adherent. This is often at the site of previously placed purse-string sutures.

It is very important during dissection of the aorta to remain outside the adventitial layer. The outer edge of the superior vena cava (SVC) is then dissected. To permit later clamping, the aorta requires further dissection, particularly posteriorly in front of the right pulmonary artery and on the left lateral margin.

Further dissection should be avoided unless it is necessary for proper exposure. Operations in which more extensive dissection may be necessary include redo CABG and repairs inside the right ventricle (see later chapters). When further mobilization is necessary, it is usually deferred until CPB has been established. The heart can then be emptied and dissection performed more precisely and more easily, with no hemodynamic disturbances. However, perfusion at this stage should be normothermic to prevent ventricular fibrillation and overdistention of the heart. If the heart cannot be completely mobilized, the left pleural space may be entered and opened widely, because this allows cardiac defibrillation and the usual de-airing maneuvers at the end of the operation.

**PREPARATION FOR CARDIOPULMONARY BYPASS**

Once the pericardial stay sutures are inserted, size and any abnormalities of the cardiac chambers are noted, anomalies of systemic venous return (especially a persistent left SVC) or pulmonary venous return are sought. A left atrial monitoring catheter, if indicated, may be inserted at this time or later, just before discontinuing CPB. For this, a 3-0 purse-string stitch is placed on the right superior pulmonary vein just posterior to the right atrium (Fig. 2-22). A fine polyvinyl catheter is threaded into a 16-gauge Tuohy needle, the needle is inserted into the left atrium through the purse string, the catheter is advanced about 2 cm, the needle is withdrawn, and the purse string is tied. A 5-0 stitch is placed in the adjacent pericardium and tied snugly around the catheter, very near the purse string. The other end of the catheter is brought through the skin and attached to a pressure gauge.

**Siting and Purse-String Sutures for Aortic Cannulation**

The site for cannulation of the aorta should be within the pericardial reflection whenever possible, because the aorta where the pericardium is fused onto the anterior surface is

---

**Figure 2-22** Schematic representation showing positions of sites for cannulae and catheters. As indicated in the text, not all are used in every patient. Key: IVC, Inferior vena cava; LA, left atrium; RA, right atrium; SVC, superior vena cava.
tougher and better for cannulation than the part outside (beyond and downstream to) the reflection. In this location, the cannulation site is proximal (upstream) to the origin of the brachiocephalic artery. The site should be a little to the left side of the anterior aortic surface (to the right side in patients with right aortic arch) as an added precaution against the cannula tip entering the brachiocephalic artery. At times in infants, in children with a previously constructed Waterston anastomosis or with truncus arteriosus, in adults with short ascending aortas or ascending aortic aneurysms, and in those about to undergo primary or redo CABG, the pericardial reflection over the cephalad end of the ascending aorta can be dissected off the aorta, the aorta retracted inferiorly, and the purse-string sutures placed on the anterior aortic wall at the level of, or if necessary distal (downstream) to, the orifice of the brachiocephalic artery on the aortic arch. In such situations, care is taken to position the aortic clamp proximal (upstream) to the orifice of the brachiocephalic artery.

Two purse-string sutures of 2-0 or 3-0 polyester or polypropylene are placed. They should catch only the adventitia and must not penetrate into the lumen. Tourniquets are placed on these sutures. When the aorta is scarred from a previous operation, a single pledgeted 3-0 polypropylene box stitch may be used at the cannulation site. A purse-string stitch is also placed for the cardioplegic needle or venting cannula (see Fig. 2-22).

The aorta of older patients, particularly those with coronary artery disease, may be arteriosclerotic, and its manipulation, cannulation, and clamping may result in dislodging and embolizing atheroma. It is prudent to perform epiaortic ultrasonographic scanning of the aorta in such patients to detect severe arteriosclerosis and position cannulae and clamps in areas where arteriosclerotic disease is minimal or absent (see Chapter 26). Alternatively, off-pump coronary revascularization may be used or on-CPB beating heart revascularization with peripheral cannulation and without aortic clamping (see “Cardiopulmonary Bypass Established by Peripheral Cannulation” under Special Situations and Controversies later in this section). 79

Siting and Purse-String Sutures for Venous Cannulation

Purse-string sutures for venous cannulation can be placed before or after heparinization and aortic cannulation. Number and sites of these purse strings depend on the perfusion technique to be used. When a single venous cannula is used, only a right atrial appendage purse-string suture is needed.

When two venous cannulae are used, the SVC and IVC may be cannulated directly. This approach is an old one, but has been refined by availability of smaller cannulae. With this method, venous drainage and exposure within the atria and ventricles are excellent, even in infants. An oval-shaped purse string is placed on the presenting surface of the SVC (see Fig. 2-22), and a tape is placed around the SVC. For this, an incision is made in the pericardial reflection over the right pulmonary artery on the medial side of the SVC and again lateral to the SVC. These incisions allow a right-angled clamp to be passed easily around the SVC to grasp the tape and pull it through. The tape is placed in a rubber or plastic tourniquet. Alternatively, the SVC may be cannulated through a purse string in the right atrial appendage. To pass a tape around the IVC, the pericardial reflection posterior to the IVC and just inferior to the right inferior pulmonary vein is incised. This maneuver clearly delineates the inferior border of the right inferior pulmonary vein and left atrium. It establishes a free communication between the two pericardial spaces, which permits better circulation of the external cooling fluid, and provides a space for the IVC tape to be placed. Alternatively, the IVC can be mobilized by first passing the fingers to the right of and behind the caval and breaking down the pericardial reflection posteriorly by blunt dissection. The hand is then removed and a right-angled clamp substituted. The tip of this instrument is exposed by retracting the lateral right atrial wall superiorly and to the left. Usually, the clamp slides around the IVC without further dissection. Occasionally, tissue must be divided with scissors, working lateral to the right atrium and below the inferior pulmonary vein. Then the surgeon, with tissue forceps or a sponge, retracts the right atrium superiorly and to the left to expose the presenting surface of the IVC, which may require limited dissection from the diaphragm. A purse-string stitch is placed at the junction of the right atrium and IVC, or on the IVC itself, in a transverse oval shape (see Fig. 2-22).

Heparinization and Later Protamine Administration

Measurement of activated clotting time (ACT) and calculation of a heparin dose-response curve allows heparin and protamine doses to be individualized for each patient. 81 First a baseline, or control, ACT is established after sternotomy. Heparin (300-400 units · kg⁻¹ or 3-4 mg · kg⁻¹) is then given. After 3 to 5 minutes, the ACT is again determined. Additional heparin is given as needed to achieve an ACT of greater than 400 seconds. Cannulation is then performed. Heparin (3 units · mL⁻¹) is added to the priming volume of the pump-oxygenator (e.g., 5000 units for a 1600-mL clear solution). After CPB is established, the ACT is determined every 30 minutes, and additional heparin is given to maintain the ACT at greater than 400 seconds during normothermic CPB and at greater than 480 seconds during hypothermic CPB (<30°C). The ACT should be measured more frequently if it does not respond appropriately to additional doses of heparin. (See cautions about the interference of aprotinin and other factors with interpretation of ACT, particularly when measured with Celite, in “Other Additives” in Section II.)

Protamine sulfate is given at the end of CPB, after removal of all cannulae. This biological product, obtained from the sperm of fish, is a simple protein of low molecular weight. It is a heparin antagonist, forming with heparin a heparin-protamine complex. Protamine has a rapid onset of action, but the heparin-protamine complex may be partially metabolized or react with fibrinolysin, thus freeing heparin and causing a heparin rebound.

Several methods are available to calculate the dosage of protamine to be administered at the end of CPB. 150 These methods and their advantages and disadvantages are listed in Table 2-5. A widely used method involves administering 1 to 1.5 mg of protamine for each 100 units (or each mg) of heparin; 1 mg of protamine neutralizes approximately 85 units of heparin. Extra protamine is given to prevent heparin rebound associated with heparin release from tissue stores or from heparin-protamine aggregates, and to compensate for the probable shorter biological half-life of protamine. 151

Arterial Cannulation

After heparin has been administered, the adventitia within the purse string is incised. With the aorta stabilized by a gauze sponge under the surgeon’s left index finger, a digitally controlled stab wound of sufficient length is made within the purse string. The aortic cannula can then be slipped into the aorta easily and usually bloodlessly. Care is taken to adjust the cannula so that only 5 to 10 mm projects into the aorta. If an angled cannula is used, it is positioned so that the opening faces distally into the aortic arch. The tourniquet on the purse-string suture is secured, and the cannula is tied to it. The arterial cannula is connected to the arterial tubing from the pump-oxygenator and carefully de-aired. All clamps are then removed from this tubing if a roller pump is used, but not if the arterial pump is of the controlled vortex type. This technique may be used in adults, children, infants, and neonates.

Alternatively in neonates, infants, and small children, a fine side-biting clamp (Cooley or Castaneda) is used. All layers of the aorta, including the adventitia, are thicker in these small patients, and an excluding clamp will not damage the intima. The excluded portion of aorta is opened longitudinally with a knife. The purse-string stitch is then positioned, and the cannula tip is inserted into the opening while releasing the clamp. With this technique, the arterial cannula can have a long tip beyond the collar and is positioned so that this tip lies in the transverse portion of the aortic arch, safely beyond the origin of the brachiocephalic artery. Alternatively, the arterial cannula may have a very short tip beyond its collar, and the cannula will be perpendicular to the aorta after its insertion.

Venous Cannulation

When a single venous cannula is to be used, a suitable clamp is placed across the right atrial appendage, the appendage is opened, hemostats or forceps are placed on both edges, and the cannula is inserted into the right atrium. A single two-stage venous cannula of variable diameter may be used in adults undergoing CABG, aortic valve replacement, or in some cases of mitral valve replacement. When properly positioned, the tip will be in the IVC and the side holes in the mid-right atrium.

When two venous cannulae and caval taping are to be used, a clamp is placed across the right atrial appendage, the appendage is opened, and one and then the other venous cannula is inserted through this opening. One is guided into the SVC and the other into the IVC. Alternatively, direct caval cannulation can be used. The right atrium adjacent to the IVC is retracted by the surgeon with tissue forceps or a sponge, a stab wound is made in the center of the IVC purse string, and the cannula is inserted. A stab wound is made in the center of the purse string on the SVC, and this venous cannula is inserted. CPB is then established (see Commencing Cardiopulmonary Bypass and Left Heart Venting later in this section). Direct caval cannulation can be difficult in neonates and infants when the heart is large. In these small patients, maneuvers required for exposure of the IVC can lead to severe hypotension.

After the cannulae are inserted, each tip must lie directly parallel to the walls of the vena cava, with the tip of the SVC cannula pointing upward and that of the IVC downward. Otherwise, venous obstruction will result. Precision in positioning the tips of the cannulae can be obtained by attaching the cannulae to the Y connector on the venous line in exactly the right orientation before their insertion. When exposure of the IVC is particularly difficult, the SVC may be cannulated first, partial CPB established, and the IVC then exposed for placing the tape and purse-string suture and for inserting the cannula.

Two venous cannulae inserted directly into the cavae as described are well suited for operations in children, infants, and neonates down to a body weight of about 2.5 kg. When the cannulae are placed as described, venous drainage is excellent; this can be verified by routine measurement of SVC pressure through an indwelling small catheter previously introduced into the internal jugular vein. An advantage of direct caval cannulation in cases in which the major portion of the operation is performed during hypothermic circulatory arrest is that the heart may be opened and the exposure arranged during the latter part of cooling and before the arrest period. The cardiac chambers can be closed during rewarming. A disadvantage is that when the heart is closed,
the inferior caval cannula may have to be repositioned into the right atrium to prevent its distention by blood returning from the coronary sinus, SVC, or both.

COMMENCING CARDIOPULMONARY BYPASS AND LEFT HEART VENTING

On command from the surgeon, the perfusionist commences CPB. The surgeon removes the arterial and venous line clamps (if present). The perfusion flow is gradually increased to about 2.2 L · min⁻¹ · m⁻², and after the proper flow has been obtained, perfusion cooling (if indicated) is begun.

In neonates and infants, the priming volume of the pump may be maintained at a temperature of 18°C to 22°C, 30°C, or 37°C. If a cold prime is used, myocardial function is immediately affected after establishing CPB. Heart rate slows and contraction is impaired. The contribution to total blood flow by the heart rapidly diminishes. Therefore, the arterial pump must rapidly reach full flow to maintain adequate systemic perfusion. The heart should be carefully observed during this period for ventricular distention, especially in infants and neonates with high ventricular compliance and a heart less tolerant of excessive preload. If distention occurs, pump flow must be reduced and the venous cannulae repositioned. If cardiac contractility is maintained during initiation of CPB, it is preferable to maintain ventilation until full flow is achieved.

For operations in adults and older children, the left-heart venting catheter is inserted from the right side directly into the left atrium through a purse-string stitch positioned at the junction of the right superior pulmonary vein and the left atrium (see Fig. 2-22). The stitch should pick up atrial wall and the adventitia of the pulmonary vein, and should not be large enough to compromise the pulmonary vein orifice when tied down. In most cases a long, soft, angled catheter is used, and it is advanced through the mitral valve into the left ventricle. This must be done precisely if the heart is beating, in view of the possibility that air can be introduced into it and embolize to the brain unless the aorta has been clamped. Therefore, venous pressure is increased by reducing venous drainage to increase the volume of blood in the heart. A small incision is made within the purse string, and the venting catheter is introduced. After the venting catheter has been advanced into the left atrium, the left hand is placed behind the heart to palpate the tip of the vent and guide it toward the mitral valve and into the left ventricle. The same precautions with respect to air are necessary as the vent is withdrawn at the end of the operation.

For operations in the right atrium or right ventricle in which increased pulmonary venous return is anticipated, venting of the left heart can be performed as described in the previous paragraph. Alternatively, when two venous cannulae are used for operations in the right ventricle or right atrium, the caval tapes are secured after cooling has been initiated and the right atrium opened through a small oblique atriotomy. If a patent foramen ovale or atrial septal defect is present, a sump catheter is placed partially across it and into the left atrium. If neither is present, a stab wound is made in the fossa ovalis directly beneath the superior limbus. If this landmark is not used and the stab wound is imprecisely made, the vent may come to lie outside the heart rather than in the left atrium. Because the sump catheter lies only partially across the atrial septum, it removes both left and right atrial blood. The right atrium remains open during the repair.

If the right superior or inferior pulmonary vein is not accessible for venting, the pulmonary trunk and apex of the left ventricle are alternative sites. If the pulmonary trunk is used, a catheter or sump is inserted through a purse string in it immediately above the pulmonary valve. Drainage and decompression of the left heart may be suboptimal with this technique. If the left ventricle is to be vented directly, a pledgeted mattress suture of 2-0 or 3-0 polyester or polypropylene is placed near, but not at, the apex of the heart on the anterolateral wall, and a catheter or sump is introduced after the ventricle has been incised with a stab blade.

For operations in which the heart is not opened (e.g., CABG), the left heart can be vented through the ascending aorta proximal to the aortic clamp, using a needle vent that can be connected either to the venous line (gravity drainage) or directly to the reservoir of the pump-oxygenator using a roller pump.

CARDIOPULMONARY BYPASS DURING OPERATION AND REWARMING

When the desired perfusion flow rate is achieved, perfusate temperature is reduced, the aorta is clamped, and cardioplegic solution is infused (see Chapter 3). Cooling by the perfusate is continued until the nasopharyngeal temperature reaches the desired level, and then the perfusate temperature is stabilized at that level. A broad range of temperatures can be used. In most cases, the nasopharyngeal temperature should be lowered to at least 32°C. When the temperature is lowered to less than this level, perfusion flow rate can be safely reduced. For example, if 25°C is chosen, the flow can be safely reduced to 1.6 L · min⁻¹ · m⁻². Brief periods of lower flow may be used.

After completing most or all of the repair, rewarming is begun. It is usually at this point that preparation for myocardial reperfusion is commenced. The precise moment for commencing rewarming depends on the strategy used for myocardial management (see Chapter 3). For rewarming, the water in the heat exchanger is raised to 42°C; the arterial myocardial management (see Chapter 3). For rewarming, the water in the heat exchanger is raised to 42°C; the arterial blood temperature should not exceed 39°C. It is advantageous but not essential to have the nasopharyngeal temperature at 37°C for about 10 minutes before CPB is discontinued, lest there be excessive downward drift of temperature in the postbypass period.

DE-AIRING THE HEART

After completing the repair and as the cardiac chambers are closed or as CABG is being completed, the heart must be freed of as much air as possible before it begins to eject into the systemic circulation. Clinical studies have demonstrated a correlation between the number of gaseous microemboli and the severity of neuropsychological impairment after surgical procedures employing CPB. Thus, special maneuvers are necessary to avoid air embolism, as has clearly been demonstrated by intraoperative echocardiography. The exact steps and sequences and the time of de-airing may vary, but the principles are well established:

- The heart is filled with fluid (blood or electrolyte solution) before closing to minimize air entrapment.
- The heart must be reperfused and beating.
- Residual air is aspirated from the heart before allowing it to eject.
- The lungs are intermittently ventilated to express air from the pulmonary veins.
- Continuous suction is applied on a needle vent or catheter in the ascending aorta as the heart commences ejecting blood to retrieve any air that may have remained in the heart or pulmonary veins (alternatively, a freely bleeding stab wound may be used).\(^{116}\)

The exact technique used will depend in part on the method used for myocardial management (see Chapter 3). One technique can be illustrated with the procedure for aortic valve replacement:

1. As the suture line for aortic closure is being completed, suction on the left atrial vent is discontinued, and flow is reduced to allow the heart to fill with blood. If blood is not freely escaping from the most anterior portion of the aortotomy before completing this suture line, fluid (saline or Ringer’s lactate) is injected into the opened aorta with a syringe. The suture line is completed. A needle vent connected to tubing from the pump-oxygenator is inserted into the ascending aorta. The anesthesiologist gently inflates the lungs to remove air from the pulmonary veins into the left atrium; vigorous inflation is inadvisable because when the lungs collapse, air can be drawn into the left ventricle through the still-opened aorta.

2. With a large-bore needle connected to a 20-mL syringe or to tubing from the pump-oxygenator, the left atrium is aspirated through its dome beneath the aorta. Air is almost invariably obtained. Aspiration is combined with gentle ventilation on two or three occasions until no further air appears. The left atrial appendage is inverted to evacuate air.

3. The heart is gently pulled forward and to the right, and needle aspiration of the left ventricular cavity is performed through the front of the left ventricular apex. This is a simple and effective way of removing the pocket of air that is almost always present at this site. The maneuver can be repeated several times.

4. The operating table is tilted, with the patient’s head down.

5. Perfusion flow rate is temporarily reduced as the aortic clamp is slowly released. Blood and air are gently aspirated from the needle vent in the ascending aorta. Left ventricular overdistention must be prevented.

6. The left atrial vent is removed while the lungs are gently inflated, and the central venous pressure is slowly increased to evacuate any residual air. The purse-string suture is secured. The heart is electrically defibrillated if not already beating. The left ventricle is shaken with the left hand several times.

7. Central venous pressure is slowly raised by the perfusionist. The heart begins to eject. Air may then appear in the aortic vent suction line. When the central venous pressure has been elevated to 10 mmHg and the heart has ejected for several minutes, CPB flow is slowly reduced. The ventricle is again shaken, and CPB is discontinued.

8. The table is leveled. Suction on the aortic needle is reduced and then discontinued, the needle is removed, and the stitch is tied. These maneuvers should not be hurried. The longer the aortic needle vent is in use, the better, and it should not be removed until the heart has been ejecting well for some time.

Because small amounts of intracardiac air have a low probability of causing any detectable damage, adherence to a strict protocol for removal of air, such as the one described, will suffice for most patients.\(^{118,214}\) Transesophageal two-dimensional echocardiography (TEE) is commonly used to monitor removal of air from the heart before CPB is discontinued. TEE enables the operating team to identify the presence of even small amounts of intracardiac and intraaortic air.\(^{312,325}\) The clinical benefit conferred by TEE during operations in which standard de-airing procedures are used has not been conclusively demonstrated. However, TEE is of particular value during operations employing small incisions, when the left-sided cardiac chambers are not fully mobilized, or when some of the usual maneuvers for removal of air, such as aspiration and manipulation of the left ventricle, cannot be used.

Flooding the operative field with carbon dioxide is used for displacing air from the cardiac chambers. Its use was first reported by Nichols and colleagues in 1988.\(^{318}\) The theoretical value of this technique is that carbon dioxide will displace air from the operative field because it is a heavier gas and because carbon dioxide emboli, if they occur, are better tolerated than air emboli.\(^{323}\) In a randomized trial of patients undergoing single valve surgery, the number of microemboli assessed by intraoperative TEE was significantly less in the left atrium, left ventricle, and ascending aorta among patients in whom carbon dioxide (CO\(_2\)) insufflation was used than in those in whom it was not.\(^{536}\) The median number of detectable microemboli after CPB fell to zero 7 minutes after CPB vs. 19 minutes in the control group. CO\(_2\) may have an important role in operations performed through small incisions or during reoperative procedures, but the potential for inducing profound systemic hypercarbia and acidosis exists.\(^{860,331}\) Thus, frequent monitoring of arterial blood gases and electrolytes is necessary when the technique is used. Persson and colleagues have shown in vitro that efficient de-airing of a cardiothoracic wound by carbon dioxide insufflation depends on its flow and velocity.\(^{714}\) To compensate for diffusion with the ambient air, they observed that the flow of carbon dioxide should be 5 L · min\(^{-1}\) and the outflow velocity about 0.1 m · sec\(^{-1}\) or less to avoid turbulence in the wound. This was best obtainable with a gas diffuser apparatus (Cardiac Innovation AB).

**COMPLETING CARDIOPULMONARY BYPASS**

As rewarming is being completed, two temporary pacing wire electrodes are positioned on the lateral wall of the right atrium.\(^{935}\) The bared end of the shielded wire electrode is secured to the atrium with 5-0 sutures or with small clips. In most patients, one or two pacing wire electrodes are similarly sutured to the right ventricular myocardium on the anterior or inferior surface.

When the patient has been rewarmed to a nasopharyngeal temperature of 37°C, perfusion flow rate is gradually decreased until the right and left atrial and aortic pressures...
are adequate, and CPB is then discontinued. The venous cannulae are removed and the purse-string sutures are tied. Protamine is administered slowly (see “Heparinization and Later Protamine Administration” earlier in this section).

Positioning Chest Tubes

There is considerable surgeon-to-surgeon difference in the location and number of chest tubes placed before closure of the median sternotomy incision. In general, to avoid unnecessary bleeding, the tubes are placed after CPB is discontinued and protamine has been administered. If the pleural spaces have not been entered, then one or two tubes are placed. A single tube can be positioned in the anterior mediastinum and brought out through a stab wound in the midline just below the sternotomy incision. Alternatively, two tubes—one in the anterior mediastinum as described and one (an angled or flexible tube) in the inferior-posterior portion of the pericardial cavity—are brought out through stab wounds in the epigastric region on both sides of the midline. If a pleural space has been entered, as often occurs when the left internal thoracic artery is dissected from the parasternal area, a tube is positioned with the tip well posterior and inferior in the pleural space to ensure maximum removal of fluid. This tube can be brought out through the epigastrium in the midline below the sternotomy incision or through a stab wound on the lateral chest wall.

COMPLETING OPERATION

After CPB is discontinued, aside from ensuring adequate hemodynamics, the surgeon’s primary task is to obtain hemostasis. This should be accomplished in a systematic fashion. All cardiac and aortic suture lines and purse strings are inspected. Fine (4-0 or 5-0) single or pledgeted polypropylene sutures can be placed in the adventitia or epicardium to control bleeding from suture lines.

Generally, electrocautery suffices to control bleeding from the mediastinal tissues and around the sternum. Troublesome bleeding from the sternum itself can be managed by tying heavy, encircling, absorbable sutures around it. The wound should be closed only after hemostasis is secure.

The pericardium is generally left open after operations with CPB through a median sternotomy. A few sutures may, however, be placed at the upper end to partially cover a particularly prominent aorta or an aortic graft. Reoperations have not posed a major problem with this technique. Advantages of leaving the pericardium open are (1) good blood drainage into the pericardial cavity (and then out through the drainage tubes) from the mediastinal and substernal tissues, thus preventing hematomas from developing in that area; and (2) reduction (but not elimination) of the tendency of retained blood to produce a positive intrapericardial pressure, thus lowering ventricular transmural pressure (tamponade).

Secure closure of the sternum is critically important. Stainless steel wire sutures are used, with the most cephalad one or two placed through the manubrium, the next three or four through the sternum or around the sternum close to the bone, and the most inferior one or two through the sternum. Different sizes and types of stainless steel sutures are available to match the patient’s size. The wires are twisted, not tied, to bring the sternum together; in adults, these are further twisted with an instrument to ensure that the sternal fragments are securely approximated. If the sternal edges are thin or fragmented, wire sutures can be passed vertically in the parasternal position in front of and behind the costal cartilages on one or both sides. These vertical sutures can then be incorporated into the closure by the transverse wire sutures. Absorbable sutures are used for closing the muscles over the sternum and the linea alba. The skin is closed with a subcuticular absorbable suture or with metal staples.

Some patients have a suboptimal hemodynamic state as preparations are made to close the chest. In most of them, the sternum should probably not be closed, because this frequently further depresses cardiac function. Rather, the sternum, subcutaneous tissue, and skin are left unsutured. An impervious sheet of silicone rubber can be fit into the cutaneous defect and sutured to the skin edges with a running monofilament suture. Alternatively, the wound can be packed loosely with sponges and covered by an impervious, sterile adhesive sheet. This maneuver is lifesaving in some patients. Usually a secondary closure can be performed 24 to 48 hours later.

PUMP-OXYGENATOR

The available apparatus for CPB changes continually, but some general points are important.

Components

A venous reservoir is currently used and is positioned to provide adequate siphonage by gravity if gravity drainage is used. Alternatively, the venous reservoir may be a hard-shell device providing for vacuum-assisted venous return. Such a reservoir allows escape of any air returning with the venous blood and provides storage of excess volume. This reservoir is generally incorporated within the housing of the oxygenator. Although useful, venous reservoirs substantially increase priming volume of the pump-oxygenator system.

The oxygenator is probably the most varied and yet most important part of the system, while at the same time it is probably the most damaging part of the extracorporeal apparatus. Microporous and true membrane oxygenators have advantages over bubble oxygenators and are currently indicated for cardiac surgery (see “Gas Exchange” under Controlled Variables in Section II).

An efficient heat exchanger is necessary. This may be integral within the oxygenator or freestanding. Integrated heat exchangers have generally been less efficient than freestanding ones, but they reduce priming volume.

The arterial pump is most commonly a roller pump. It should be adjusted before each perfusion so as to be slightly nonocclusive, and should be calibrated at frequent intervals so that the flow rate can be accurately established. A centrifugal pump may also be used.

The arterial line pressure in the pump-oxygenator must be continuously monitored. When this pressure exceeds 250 to 300 mmHg, risk of disruption of the arterial line and of caviation in the region of the arterial cannula increases. A proper arterial line pressure is ensured by a properly positioned cannula of adequate size.

The advantages, disadvantages, and need for a low-porosity filter in the arterial line remain somewhat controversial. A randomized study by Walker and colleagues (Walker DR, Blackstone EH, Kirklin JW, Karp RB, Kouchoukos NT,
Pacifico AD, et al: unpublished data, 1976) showed good neuropsychiatric function (determined by specialized testing) in patients after CABG, whether or not a low-porosity arterial filter was present in the circuit. A similar study in patients undergoing open cardiotomy provided the same result. However, studies using transcranial Doppler ultrasound have shown that gaseous microemboli, more prevalent with bubble than with membrane or hollow-fiber oxygenators, can be considerably reduced by 40-µm filters in the arterial line of the pump-oxygenator. Currently, routine use of a low-porosity filter of this type in the arterial line appears to be beneficial. The exact filter to be used and its compatibility with the other components of the pump-oxygenator must be determined within each institution performing cardiac surgery.

A device for ultrafiltration is incorporated into the circuit of the pump-oxygenator, usually between the cardiotomy reservoir and the arterial line. During CPB, if there is excess volume in the pump-oxygenator, the device is activated for removal of serum water by ultrafiltration (see “Perfusate” under Controlled Variables in Section II).

The CPB circuit generally should contain at least two cardiotomy suction ports for return of blood from the opened heart. This blood may contain particulate matter and boluses of air and must be passed through a low-porosity filter and defoamed in a separate chamber open to air before it is returned to the circuit. During the perfusion, blood should be promptly aspirated from the pericardium with these suckers. Blood left too long in the pericardium before being aspirated can promote thrombolysis. Ideally, these lines should be activated by a continuously and rapidly variable high-capacity vacuum system. Because this has so far proved to be impractical, roller pumps are used. With this system, when the open end of the line is blocked, the suction rapidly increases; this may damage either the tissue or the blood. Thus, constant monitoring of the roller pumps is necessary.

### Priming Volume

Each component of the pump-oxygenator adds to the priming volume, which explains why many cardiac surgical groups are unwilling to add unessential components to their system. However, pump-oxygenator systems can be so oversimplified that safety may be compromised. Even with the most stringent efforts, the typical pump-oxygenator systems currently in use have a priming volume considerably larger than is ideal.

### Miniaturized Cardiopulmonary Bypass Circuits

Miniaturized CPB circuits have been developed with the objective of reducing the damaging effects of conventional CPB. It is hypothesized that minimizing hemodilution and mechanical blood trauma will improve outcomes. These closed circuits with little or no blood/air contact consist of a controlled vortex blood pump and a membrane oxygenator as the only components. There is no venous reservoir and no integral cardiac suction device. The components, including the tubing, are heparin coated.

Clinical studies (nonrandomized) in patients undergoing CABG suggest that use of these circuits is associated with fewer transfusions of blood products, less release of cardiac troponin, less postoperative atrial fibrillation, a lower prevalence of acute kidney injury, suppression of thrombin generation and coagulofibrinolytic activation, and lower levels of IL-6 and SC5b-9.

A meta-analysis of randomized clinical trials comparing conventional CPB with miniaturized CPB circuits indicated that miniaturized circuits are associated with substantial reductions in neurologic injury, number of patients requiring transfusion of blood products, and peak cardiac troponin release (Table 2-6). No difference in early mortality was noted. The majority of patients had CABG, and the remainder had aortic valve replacement. A separate meta-analysis examined only the need for red blood cell transfusion and demonstrated an absolute risk reduction in this variable among patients undergoing CABG.

### SPECIAL SITUATIONS AND CONTROVERSIES

#### One Versus Two Venous Cannulae

Use of a single two-stage venous cannula is optimal for many cardiac operations (CABG, aortic valve replacement, and in many instances mitral valve replacement) in adult patients and is widely practiced. The technique is likewise optimal in neonates, infants, and children when the entire repair (including closure of the cardiac chambers) is performed during hypothermic circulatory arrest.

A single venous cannula may also be used in operations in which part of the repair is done during circulatory arrest, but a portion is left to be performed during CPB. Although convenient, the method has some disadvantages. Unless assisted venous return is used, an air lock may occur in the venous line during operations within the right ventricle or

Key: CPB, Cardiopulmonary bypass; MECC, miniaturized extracorporeal circuit.
pulmonary trunk, with the air entering the right atrium through the tricuspid valve. When this happens, venous return to the pump-oxygenator stops abruptly, and blood floods the right side of the heart. The perfusionist must not reduce the perfusion flow rate, but instead the intracardiac sucker is positioned outside the heart to keep blood from overflowing from the pericardial well, while the air lock is moved down the venous line and expelled into the venous reservoir. Principles for use of the single venous cannula in this setting are the same as those already described, including the need for the tip of the cannula to be in the IVC while its side holes remain in the right atrium.

Cardiopulmonary Bypass Established by Peripheral Cannulation

Femoral Cannulation

Closed-chest cannulation of the femoral artery and vein for CPB was practiced at the Mayo Clinic during the 1960s for establishing hypothermic circulatory arrest in patients undergoing intracranial operations. It has since been used with increasing frequency to establish CPB before opening the sternum in reoperations in which there is a high probability of entering a cardiac chamber or major artery during sternotomy. In these situations, a vertical or oblique incision in the groin crease is made over the femoral vessels. After identifying the inguinal ligament and working just inferior to it, the common femoral artery and vein are dissected, and a tape is placed around each. After the patient has been heparinized, a clamp is placed on the distal common femoral artery, any branches are temporarily occluded with ligature loops or small clamps, a clamp is placed proximally, and a transverse incision is made between the clamps. An arterial cannula of appropriate size is inserted into the vessel and, as the proximal clamp is removed, is gently advanced. The tape is snugged down around the cannula using a tourniquet, and the cannula is connected to the arterial line of the pump-oxygenator with the usual precautions to eliminate air. A large (28F-32F) long cannula is similarly inserted into the common femoral vein. This cannula must be advanced over the sacral promontory and into the IVC. When the right femoral vein is used, this is usually easily accomplished. If the left femoral vein is used, it is often necessary to first insert a guidewire, positioning the tip in the right atrium or the adjacent IVC, then a small-bore catheter which is passed over the wire, and then the venous cannula, which is inserted over the smaller catheter. After securing the tape and removing the smaller catheter and the guidewire, the cannula is connected to the venous line of the pump-oxygenator. Alternatively a two-stage cannula can be inserted over a guidewire from either femoral vein, positioning the tip in the SVC under TEE guidance. The upper openings in the catheter are located in the SVC and lower openings in the IVC. This permits placement of caval tapes and opening of the right or left atrium.

Axillary Artery Cannulation

Femoral artery cannulation may result in peripheral embolization, local thrombosis, or aortic dissection. Additionally, in the presence of an existing acute or chronic aortic dissection, retrograde flow from femoral artery cannulation may result in central malperfusion. An alternative is use of either axillary artery. Advantages include absence of malperfusion, establishment of brain blood flow during otherwise whole-body circulatory arrest, and presumably lack of retrograde particulate embolization. The axillary artery is exposed through a transverse incision below and parallel to the lateral two thirds of the clavicle. The pectoralis major muscle is divided in the direction of its fibers and the clavpectoral fascia incised, exposing the pectoralis minor muscle, which may be divided or retracted laterally. Using sharp dissection, the artery is dissected from surrounding tissue, taking care not to injure the branches of the brachial plexus. Proximal and distal control of the axillary artery is obtained. After administration of heparin, the artery can be cannulated directly. Alternatively, an 8- or 10-mm polyester or polytetrafluoroethylene graft is sutured end to side to the artery using a 6-0 polypropylene suture.

Other Sites

Other less commonly used sites for cannulation include the brachial, brachiocephalic, and carotid arteries. Another option for cannulation in high-risk reoperative sternotomy patients is to expose the brachiocephalic artery by dissecting just above the sternal notch, and the IVC by dissecting just below the xiphoid. The skin incisions used are simply the upper and lower poles of the sternotomy incision. Cannulation of the brachiocephalic artery with an appropriate-sized arterial cannula, and the IVC with a large, right-angled, venous drainage cannula can provide full CPB support while the sternum is opened. This technique is particularly useful for patients weighing 40 kg or less, in whom these vessels are easily accessible, and in very small patients in whom peripheral cannulation is not practical.

Indications

Indications for peripheral cannulation have been expanded to include operations performed through small midline or lateral chest incisions (see “Alternative Primary Incisions” earlier in this section), resuscitation of preoperative and postoperative cardiac surgical patients, and support of high-risk patients during percutaneous catheter interventions.

Both arterial and venous cannulation can be accomplished by percutaneous techniques. In this setting, the pump-oxygenator should be used in conjunction with a controlled vortex pump or vacuum-assisted venous return, which permits use of smaller (22F or 24F) venous cannulae.

Blood Conservation

Since the earliest days of clinical use of CPB, there has been concern about the relatively large amounts of allogeneic blood that often must be administered during and early after operations. This concern has been magnified by the prevalence of cardiac operations requiring CPB and the possibility of acquiring deadly diseases such as hepatitis and human immunodeficiency virus. Methods of testing the suitability of donor blood have improved greatly; in well-regulated institutional settings, the current risk of acquiring such diseases from transfused blood is small (see Chapter 5).

A major reason for the near-routine use of non-blood solutions for initial priming of the pump-oxygenator is the desire to minimize use of allogeneic blood. Removal of 500 to 800 mL of blood from adult patients with hematocrits greater than 33% to 35% after induction of anesthesia is safe and is commonly performed. The blood is collected in bags containing CPD anticoagulant, as used by blood banks, and
is left unrefrigerated in the operating room. (Refrigeration even for a short time renders platelets less effective.) This blood is not used during CPB, but rather is administered for its hemostatic and blood-volume effects after protamine is given and major bleeding has been controlled. Donation of blood by the patient several weeks before the operation, as well as by relatives and friends, is widely practiced. This blood has the disadvantages associated with stored blood.

The pump-oxygenator should incorporate one of the compact ultrafiltration devices currently available (see Pump-Oxygenerator earlier in this section). This provides the capability of concentrating the blood left in the machine after CPB, including plasma proteins (in contrast to blood salvage systems), and preparing it for prompt administration to the patient.

Blood aspirated from the surgical field by a standard high-power sucker during and after the cardiac operation can be processed through a blood salvage system. These systems separate, wash, and to some extent concentrate erythrocytes, which are then transfused to the patient. Anticoagulation is provided by heparin that is added to the apparatus. The components of plasma are lost. Postoperatively for about 12 hours, shed blood from the mediastinal and pleural tubes can be collected in the reservoir and returned intravenously to the patient. This blood has been defibrinated in the patient before its collection and has the disadvantage of having essentially no clotting factors.

Most bleeding after cardiac surgery results from coagulation disturbances associated with CPB, related primarily to platelet dysfunction and activation of the fibrinolytic cascade (see Chapter 5 and Response Variables in Section II). Prophylactic administration of antifibrinolytic drugs (epsilon-aminocaproic acid, tranexamic acid, and formerly aprotinin) decreases the frequency of reoperation for bleeding and need for allogeneic blood transfusions in patients after operations employing CPB. Comparative studies have demonstrated equivalent effectiveness of these three agents.

As mentioned earlier in this chapter, aprotinin was withdrawn from the market in May 2008.

Left Superior Vena Cava

A left SVC presents no problems in operations in which a single venous cannula is used. When other techniques for venous cannulation are used, several options exist. A simple method is to use cannulae in the SVC and IVC and to pick up the left SVC flow by the sump-sucker that is positioned partially across the atrial septum (see Commencing Cardiopulmonary Bypass and Left Heart Venting earlier in this section) or in the coronary sinus ostium.

Alternatively, the left SVC may be occluded with a tourniquet for short periods when exposure in the right atrium is suboptimal. As another alternative, a pressure-monitoring needle may be inserted into the left SVC, or the pressure in the left jugular vein may be monitored. As a test, the left SVC is clamped below the needle (downstream). If the monitored pressure does not increase, it may be assumed that the vein can be safely occluded during CPB (see Chapter 58). If the pressure increases substantially, an additional cannula is inserted into the left SVC either via the right atrium and coronary sinus ostium or directly via a purse string where the vein enters the pericardium lateral to the left atrial appendage. The latter is most easily done after CPB has been established but before the right atrium is opened. It is essential if cardioplegic solution is to be delivered retrogradely into the coronary sinus. When three cannulae are in use, two Y connectors are required to connect the venous return to the single venous pump line.

Other Systemic Venous Anomalies

Although a left SVC is the most common systemic venous anomaly that influences management of CPB, it is not the only one. Hepatic venous anomalies, which occur particularly in the various heterotaxy syndromes, can present similar challenges (see Chapter 58). The hepatic veins may attach to the right atrium or even the left atrium, independent of the IVC attachment. They may attach as a single confluent trunk or as several separate veins. The same concerns, considerations, and management options as described for the left SVC are applied to these anomalies.

Left Atrial Pressure Monitoring

Knowledge of left atrial pressure both intraoperatively and postoperatively is important. The most direct way of measuring this pressure is to insert a fine polyvinyl catheter into the left atrium. There is danger of accidental introduction of air into the left atrial line and of cerebral embolization from a tiny thrombus on its tip, but these complications are rare. The only major complication has been occasional bleeding when the catheter is removed. This can be sufficient enough in infants to require immediate blood replacement and, rarely, reoperation. Even in neonates and infants, bleeding after removal has not been encountered when removal is delayed until at least 48 hours postoperatively.

A less satisfactory but more commonly used alternative is to introduce a catheter into the pulmonary artery for intraoperative and postoperative monitoring (as discussed earlier). Unless pulmonary vascular disease is present, the pulmonary artery diastolic pressure approximates mean left atrial pressure. Many groups routinely insert a Swan-Ganz catheter after induction of anesthesia, rather than using a left atrial catheter as described.

Alternative Primary Incisions

Minimal Sternotomy and Thoracotomy

Currently, a number of smaller incisions are being used for procedures on the cardiac valves, the ascending aorta and aortic arch, and the coronary arteries in adults, and for correction of congenital cardiac defects in children and in adults. The various incisions used are shown in Fig. 2-23. They can be classified into three general types: a partial midline sternotomy (upper, lower, or middle), a parasternal incision with resection of one or more costal cartilages, and a more lateral approach through an intercostal space, with or without resection of a segment of costal cartilage or rib, and with or without partial or total transection of the sternum. The commonly used minimal incisions for CABG and for valve replacement or repair are described in Chapters 7, 11, 12, and 13.

Putative advantages of these less invasive incisions, when compared with the full sternotomy, include reduced blood loss, less pain and therefore a lowered requirement for analgesic agents, more rapid convalescence with
reduced hospital stay, reduced prevalence of infection, better cosmetic result, and lower overall costs. In a number of observational studies comparing minimal incisions with a full sternotomy, these advantages have not been consistently observed. In many instances, duration of CPB and total time of operation are prolonged with the minimal incisions. The resulting increase in operating room costs often offsets the reduced costs achieved by a shorter hospital stay.

It appears likely that the trend toward using smaller incisions will continue as new instruments and cannulae are developed that facilitate performing procedures on the heart and great vessels through smaller openings. However, until clear advantages of minimal incisions are demonstrated, full
sternotomy should continue to be used. Cardiac surgeons must be competent and experienced in use of the full sternotomy before attempting procedures through small incisions. Furthermore, they must recognize that the potential or real advantages of small incisions may be outweighed by the disadvantages that can result from limited exposure.

Right Anterolateral Thoracotomy
A right anterolateral thoracotomy through the fourth or fifth intercostal space may be used for cosmetic reasons in young women with developing breasts, for mitral and tricuspid valve operations, and for repair of atrial septal defects. It may also be used in patients who require reoperation only on the tricuspid valve and for reoperations on the mitral valve after one or more previous procedures. This approach provides excellent access to the left and right atria, although the field may be relatively restricted and cannulation of the ascending aorta may be difficult. When the aorta is inaccessible or when coronary artery bypass grafts have been anastomosed to the ascending aorta during a previous operation, the common femoral or axillary artery is used (see Cardiopulmonary Bypass Established by Peripheral Cannulation earlier in this section).

A double-lumen endotracheal tube is used to permit collapse of the right lung and enhanced exposure. The patient is positioned with the right side elevated 30 to 40 degrees. The right arm is flexed at the elbow and kept at the patient’s side. The left arm lies at the side. Groin areas are draped into the operative field. The skin incision follows the intercostal space to be entered and extends laterally to the anterior axillary line. The intercostal muscle is divided and a retractor placed. The pleural cavity is entered and the intercostal muscles are further divided laterally beneath the skin incision if exposure is not optimal. The collapsed lung is gently retracted posteriorly, and the pericardium is incised vertically 1 to 2 cm anterior and parallel to the phrenic nerve. If cannulation of both venae cavae is required, the cannulae are inserted through purse-string sutures in the SVC and in the right atrial wall adjacent to the IVC. Alternatively, a long cannula can be positioned in the IVC after insertion in the common femoral vein, or a two-stage long cannula can be inserted in the femoral vein and the openings positioned in the SVC and IVC. The aorta is cannulated on its right anterolateral aspect. For primary operations, the remainder of the procedure is similar to a median sternotomy approach.

For reoperations on the mitral valve, particularly after previous CABG, cannulating and clamping the ascending aorta may not be possible. In this situation, myocardial management is accomplished by hypothermic fibrillation. Temperature of the perfusate is lowered until the heart fibrillates or until the nasopharyngeal temperature reaches 18°C to 22°C. At that temperature, an external fibrillator is applied to the myocardium to induce ventricular fibrillation. The heart must be maintained hypothermic and in a fibrillating state to avoid ejection of air into the ascending aorta. Rewarming is not initiated until the left atrium has been closed. A soft rubber catheter attached to a cardiotomy suction line is positioned in the left ventricle through the mitral valve or a prosthesis, and is brought out through the atriotomy incision. Continuous suction is applied to this catheter during rewarming to evacuate air from the left ventricle. The catheter is removed just before CPB is discontinued and the left atrial suture line is secured.

Left Thoracotomy
A left thoracotomy may be used for primary or reoperative mitral valve replacement or repair, coronary artery bypass grafting (see Technique of Operation in Chapter 7). For mitral valve procedures, a standard posterolateral thoracotomy or minithoracotomy through the fourth or fifth intercostal space and a vertical incision in the left atrium anterior to the left pulmonary veins provide excellent exposure of the mitral annulus and valve. The procedure can be performed on a beating heart, with hypothermic fibrillation (see preceding Section), or with aortic occlusion and administration of cardioplegia. Peripheral cannulation is generally used (see earlier Section).

Port Access
Thorascopic, then robotically assisted, cardiac surgery through small thoracotomies and ports was introduced by Carpentier and colleagues in early 1996; length of incision for the first case was 5 cm. Subsequently, the technology has progressed to multiple degrees of freedom instrumentation, three-dimensional imaging, and 3- to 4-cm port incision. Conventional anesthesia is used with dual-lumen endotracheal intubation as for the anterolateral thoracotomy incision. CPB is established with peripheral cannulation (femoral artery and vein or venous cannulation via right internal jugular vein). The aorta is occluded either by an endoballoon or a trans-thoracic clamp and antegrade and retrograde cardioplegia are administered. For mitral valve repair, Mihaljevic, Gillinov, and colleagues insert the left arm of the robot through the third intercostal space in the anterior axillary line, the right arm through the fifth intercostal space in the midaxillary line, a working port in the fourth intercostal space in the midaxillary line, and a dynamic left atrial retractor in the midclavicular line.

Challenges of port-access surgery have led to a number of innovations, including new methods for mitral valve repair, arrested heart and beating heart CABG, atrial fibrillation surgery, epicardial lead placement for cardiac resynchronization, removal of cardiac tumors, atrial septal defect closure, and hybrid aortic valve replacement.

Port access procedures have permitted patients to proceed from surgery to a postanesthesia recovery unit rather than intensive care unit (Cleveland Clinic), with early extubation and shorter hospital stay than with conventional surgery via full sternotomy, partial sternotomy, or anterior thoracotomy, and with more rapid return to work (Jarrett C, Mihaljevic T: personal communication, 2010).

Section IV Clinical Methodology of Hypothermic Circulatory Arrest and Its Alternatives

GENERAL COMMENTS AND STRATEGY

Adults
Hypothermic circulatory arrest is widely used in adults for operations involving the ascending aorta, aortic arch, and descending thoracic and thoracoabdominal aorta. For operations involving the distal ascending aorta and aortic arch, it is used in conjunction with hypothermic CPB to provide
Brain protection and optimal exposure of the brachiocephalic vessels and proximal descending thoracic aorta. For operations involving the descending thoracic and thoracoabdominal aorta, it has been used in conjunction with hypothermic CPB, not only to provide brain protection and optimal exposure but also to eliminate the need to place occlusion clamps on the thoracic aorta, which reduces the risk for embolization of arteriosclerotic debris into the vasculature of the brain, kidneys, abdominal viscera, and lower extremities. Opinions differ regarding its use in these situations, because alternative methods of treatment exist. No studies to date have demonstrated the superiority of one technique over another. The various methods are discussed in detail in Chapter 24. Safe time limits of the arrest period are discussed in Section I of this chapter.

Neonates, Infants, and Children

Opinions differ regarding appropriate use of hypothermic circulatory arrest in the pediatric population. A 2003 survey of members of the Congenital Heart Surgeons’ Society indicated that about one third of respondents avoid using hypothermic circulatory arrest, and the frequency of use among the remaining respondents varied widely.

In previous eras, hypothermic circulatory arrest was essential for completing certain operations, such as neonatal operations requiring aortic arch reconstruction and a wide spectrum of other complex operations on neonates. Consensus opinion in the field also held that hypothermic circulatory arrest was a reasonable option for other operations, including most complex operations on full-term neonates and infants. Hypothermic circulatory arrest, however, was considered an unreasonable option for a large spectrum of congenital heart operations, including all simple operations regardless of age, and most if not all complex operations on older infants and children unless aortic arch reconstruction was involved.

In the current era, with technical- and equipment-related advances, it has been clearly established that all operations in neonates, infants, and children can now be performed using CPB strategies that do not use hypothermic circulatory arrest, but rather, continuous perfusion.

Hypothermic circulatory arrest is not essential for any operation, and becomes only one of several options for all operations. Currently, the primary alternative to hypothermic circulatory arrest is continuous full-body CPB for all operations not involving aortic arch repair, and continuous antegrade cerebral perfusion for operations involving aortic arch repair. The technique of continuous full-body CPB is described in detail in Section III. Continuous antegrade cerebral perfusion is described in this section. Controversy exists regarding the relative merits of both of these continuous perfusion techniques when used as alternatives to hypothermic circulatory arrest.

There are two major criteria for judging the efficacy of continuous full-body CPB and continuous antegrade cerebral perfusion relative to hypothermic circulatory arrest. First, in those operations that have traditionally utilized hypothermic circulatory arrest, continuous full-body CPB and continuous antegrade cerebral perfusion must achieve technical outcomes equal to or better than those using hypothermic circulatory arrest. Sufficient data have been accumulated over the last decade to confirm that this criterion is met.

All operations in neonates and infants, including those involving aortic arch reconstruction, can be performed using continuous CPB, including continuous antegrade cerebral perfusion when necessary, with technical outcomes that are at least as good as those achievable using hypothermic circulatory arrest. Second, continuous full-body CPB and continuous antegrade cerebral perfusion must preserve end-organ structure and function, particularly with respect to the brain, as well as or better than hypothermic circulatory arrest. This is a complex and controversial criterion with no definitive resolution at this time, and readers are referred to an editorial by Hanley that addresses the issue in depth. To date, no well-designed multicenter studies have addressed it.

TECHNIQUE IN ADULTS

The technique for establishing hypothermic circulatory arrest in adult patients is described in detail in Chapter 26 under “Aortic Arch Replacement” and “Thoracoabdominal Aorta Replacement.”

TECHNIQUE IN NEONATES, INFANTS, AND CHILDREN

Hypothermic Circulatory Arrest

Preparation for Cardiopulmonary Bypass

Preparation of the patient is the same as described for CPB in general (see Section III). Historically, surface cooling was used as an adjunct to core cooling. Now, most institutions use a cooling blanket and pack ice around the head. These maneuvers, plus a cool operating room, usually reduce the patient’s body temperature to 30°C to 32°C by the time CPB is initiated. The ice bags remain in place around the head until perfusion rewarming is begun after the period of circulatory arrest.

Cannulation

The aortic cannula is inserted into the ascending aorta in the usual manner. In some cases, particularly in infants, it is inserted near or into the brachiocephalic artery. It is critically important to remember that although the purse string around the aortic cannula may be hemostatic, it does not protect against the passage of air. This is important because when CPB is temporarily discontinued to establish circulatory arrest, the arterial pump may be sufficiently nonocclusive that suction initiated by gravity develops in the arterial system. With the aorta at essentially zero pressure, such suction draws air into the aorta and the cannula from the site of cannula insertion. The purse-string suture cannot be made snug enough to prevent this. Therefore, just before CPB is discontinued, the perfusionist clamps the arterial tubing and then discontinues CPB, making suction-driven air entry impossible because the arterial system has been “pressurized.” Just as CPB is recommenced, the perfusionist removes the clamp. These precautions are unnecessary if a clamp is placed on the aorta distal to the aortic cannula. The aortic cannula can then be used for delivery of cardioplegic solution.

Commonly, a single venous cannula is used (see “Siting and Purse-String Sutures for Venous Cannulation” and “One Versus Two Venous Cannulae” in Section III). Two venous cannulae and caval tapes may be used even if the patient weighs less than 3 kg. This allows maximal flexibility. The caval tapes are often left loose and then tightened during
cooling and periods of low flow. Some procedures can be performed at low flow rate with a single venous cannula.

**Cardiopulmonary Bypass for Cooling**

After CPB is established, cooling is begun as described in Section III. Relatively high CPB flows, 2.2 to 3.0 L·min\(^{-1}\)·m\(^{2}\), are used. The nasopharyngeal temperature in neonates and infants can sometimes decrease to 18°C within 10 minutes. However, rapid cooling has been demonstrated to be suboptimal for circulatory arrest (see “Characteristics of the Cooling Process” in Section I), probably because it is not homogeneous. Therefore, the cooling period should last at least 20 minutes and may at times approach 30 minutes.

The target temperature and its most appropriate site of measurement remain controversial (see “Brain Function and Structure: Risk Factors for Damage” in Section I). A nasopharyngeal temperature of 16°C to 18°C is a reasonable criterion to establish circulatory arrest.

Management of gas exchange during cooling is also controversial. The two management options, pH-stat and alpha-stat, each have advantages and disadvantages (see “Arterial Carbon Dioxide Pressure” in Section II). In any event, arterial P\(_{\text{CO}}\), and thus arterial pH—the important variables—are quite controllable with membrane oxygenators and online measurement of arterial pH and P\(_{\text{CO}}\). Mounting evidence suggests that pH-stat management results in superior neurologic outcome.\(^{113,114,111}\)

Hematocrit should not be allowed to drop below 0.25 throughout the operation. Although this variable has not been studied in enough detail to develop a linear relationship between hematocrit level and risk of neurologic injury, evidence suggests that levels of 0.20 result in greater neurologic injury than levels of 0.25, and there is no improvement with higher hematocrit levels.\(^{118,117}\)

During cooling, dilatation of the heart must be avoided. It may be necessary to manipulate the position of the venous cannulae to ensure adequate drainage. A single infusion of cardioplegic solution will usually suffice if circulatory arrest does not exceed 30 minutes.

**Circulatory Arrest**

Time constraints of safe circulatory arrest are discussed in Section I. There is no secure evidence that interposing a short period of CPB increases safe duration of circulatory arrest, presumably because cerebral blood flow is low early after resumption of CPB and presumably inhomogeneously distributed under that condition.\(^{59}\) (see Fig. 2-3). However, when time constraints are anticipated, intermittent perfusion to interrupt hypothermic circulatory arrest may be useful.\(^{11,3}\)

**Cardiac Operation**

The right atrial cannula is often removed from the heart. If arch reconstruction is part of the operation, the aortic cannula is removed as well. The heart and great arteries are opened where appropriate, and repair is performed. The right atrium is usually opened to close any atrial communication, including a patent foramen ovale, or to perform atrial septectomy, as appropriate. When the intracardiac repair is completed, the cardiotomy is closed.

**Rewarming**

The aortic and right atrial cannulae are inserted through the previous purse strings (if arch reconstruction is performed, depending on what reconstructive technique is used, a new arterial purse string may be needed). Extreme care should be taken to ensure that air entry into the aorta does not occur at the initiation of perfusion. Precise details of rewarming with CPB and time of its initiation, myocardial management, cardiac de-airing, and removal of the aortic clamp are highly interrelated and primarily dependent on the method of myocardial management. Each surgical group should determine these protocols individually, using the principles described in this chapter and in Chapter 3.

**Continuous Antegrade Cerebral Perfusion**

**Preparation for Cardiopulmonary Bypass**

This technique is reserved for operations in which aortic arch reconstruction or important aortic manipulation is to be performed. Preparation of the patient is the same as described for CPB in general (see Section III), with a few notable exceptions and areas of emphasis. Regional cerebral oxygen monitoring using near-infrared spectroscopy is performed routinely and has been shown to be beneficial.\(^{716}\) To achieve a technically precise repair using continuous CPB, exposure is of prime importance. The skin incision is taken to the sternal notch, with a retraction stitch placed at the upper pole of the incision. The thymus, when present, is completely resected. It is critical to both mobilize the brachiocephalic vein in its entirety and to open the fascia above the vein to fully expose the brachiocephalic artery. The dissection is continued by complete mobilization of the three major arch vessels and the ductus arteriosus. Mobilizing the left pulmonary artery to the pericardial reflection facilitates exposure of the aorta distal to the ductus arteriosus (if present).

**Arterial Cannulation**

Arterial cannulation is accomplished by direct cannulation of the brachiocephalic artery,\(^{341}\) although alternative methods exist.\(^{716}\) The arterial purse string is placed inferior to the brachiocephalic vein while retracting the vein superiorly using 6-0 polypropylene suture (Fig. 2-24). Care is taken to limit the width of the purse string to prevent narrowing the artery. For cases of interrupted aortic arch, a second arterial purse string is placed into the pulmonary trunk in preparation for lower-body perfusion through the ductus arteriosus. Standard setup also involves placing purse strings in the superior vena cava (SVC) and inferior vena cava (IVC) for bicalveal venous cannulation, and in the right superior pulmonary vein for venuing.

A 6F or 8F arterial cannula is selected for neonates, based on the patient’s weight and brachiocephalic artery size. Larger cannulae are used for larger patients. Before insertion, the obturator is withdrawn until it is flush with the catheter tip (Fig. 2-25). The artery is carefully cannulated to avoid obstructing flow in the brachiocephalic artery. Typically, the artery is opened with a fine-blade knife and the cannula placed directly, without using a vascular clamp. The cannula is advanced to the start of the wire spiral and no farther than 2 mm. The arterial line is then rigorously de-aired.

The cavae are cannulated with right-angled 12F venous drainage cannulae (for neonates weighing 2.0 kg or more), and CPB is initiated at a flow rate of 200 mL·kg\(^{-1}\)·min\(^{-1}\). The IVC cannula is initially oriented superiorly into the atrium to avoid any potential obstruction of lower-body venous return at these high flow rates. A vent is placed into the left side of the heart through the right upper pulmonary
Cardiopulmonary Bypass and Cooling

Once CPB is initiated and adequate venous drainage is confirmed, the patient is cooled to 22°C to 24°C for a minimum of 15 minutes to ensure uniform cooling of the central nervous system. The acid-base status is initially managed according to an alpha-stat strategy, and the perfusate hematocrit is maintained between 25% and 30%. After the cooling period is completed, flow is reduced to $120 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$, and the IVC cannula is redirected downward into the IVC. The aorta is clamped and cardioplegia administered through the aortic root in an antegrade fashion. This is achieved using a standard neonatal cardioplegia needle in cases of interrupted aortic arch, coarctation, and Damus-Kaye-Stansel procedure, and using a 22-gauge angiocatheter in cases of hypoplastic left heart physiology with very small ascending aorta. Snares are placed around the two vena caval cannulae.

Preparation for Cerebral Perfusion

The arch vessels are now prepared for cerebral perfusion. The brachiocephalic artery, left carotid artery, and left subclavian artery are each individually clamped with atraumatic neurovascular clips (Fig. 2-26). At this point, direct perfusion is isolated to the head and right arm, the flow rate is reduced to $40 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$, and acid-base management shifts to pH-stat. The ductus arteriosus is now formally ligated and transected (as appropriate), and the descending aorta, which has been extensively mobilized previously, is clamped distally.

Arch Reconstruction

At this point, any type of arch reconstruction can be performed. Specifics of the repair are tailored to the particular morphologic lesion. Associated intracardiac anomalies can be repaired during continuous antegrade cerebral perfusion; however, the preferred method is to reestablish total body perfusion (as described in the following text) after the arch repair, and then proceed with the intracardiac component of the repair.
Reestablishing Total Body Perfusion and Associated Intracardiac Repairs

After the arch reconstruction is completed, the descending aorta is unclamped. The neurovascular clips on the base of the brachiocephalic artery and the other arch vessels are also removed. Flow is increased to 120 to 150 mL · kg⁻¹ · min⁻¹, reestablishing total body perfusion. If no additional repairs are needed other than arch reconstruction, reestablishment of total body perfusion coincides with myocardial reperfusion. If any remaining intracardiac lesions are present, a standard aortic clamp is placed on the ascending aorta before the descending aortic clamp and the neurovascular clip on the brachiocephalic artery are removed. Additional cardioplegia is administered as necessary according to the general guidelines outlined in Chapter 3, and the intracardiac repair is performed.

Rewarming

After the arch repair (or combined arch and intracardiac repair) is completed, reestablishment of myocardial perfusion, de-airing, and rewarming are begun, again following general guidelines outlined in Section III of this chapter and in Chapter 3. Snares around the vena cava cannulae are removed, and the IVC cannula is again repositioned up into the right atrium. CPB flow rate is increased to 200 mL · kg⁻¹, and the patient is rewarmed using an alpha-stat strategy. Once normothermia is achieved, the patient is weaned from CPB support and the caval cannulae removed. To prevent obstruction or arterial thrombosis, it is important to remove the arterial cannula from the brachiocephalic artery immediately after separation from CPB.

Equations

The equation derived from the data in Fig. 2-1 is:

\[ \log_{10} V_{O2} = -0.69 \pm 0.061 + 0.043 \pm 0.0021 \cdot \text{temperature} \]

where \( P \) for intercept and slope < .0001, SD of regression = 0.12, and \( r^2 \) = .80.

Correlation (\( r^2 \)) of the data in Fig. 2-15 to a linear model \[^{127}\] was .39; to a log-log model \[^{128}\] .54; to the Arrhenius \[^{129}\] equation (log \( V_{O2} \) proportional to \( Q^{-1} \)) .52; and to a hyperbolic model.69. The equation for Fig. 2-15 is:

\[ 1 / V_{O2} = 0.0062 \pm 0.00024 + 0.0044 \pm 0.00020 \cdot Q^{-1} \]

where \( V_{O2} \) is oxygen consumption (mL · min⁻¹ · m⁻²) at 37°C; \( Q \) is perfusion flow rate (L · min⁻¹ · m⁻²) during CPB; \( P \) for intercept and slope < .0001; SD of regression = 0.0024; and \( r^2 \) = .69.

The equation represented by the nomogram in Fig. 2-11 is:

\[ 1 / V_{O2} = 0.168 \cdot 10^{-0.0587 \cdot T} + 0.0378 \cdot Q^{-1} \cdot 10^{-0.0253 \cdot T} \]

(2A-3)

where \( T \) is temperature in °C. This was derived as follows. The relationship between \( V_{O2} \) and \( Q \) at 37°C was established from published animal experimental data (Fig. 2-15 and Equation 2A-2). Fox and colleagues established these relationships at 20°C in humans during CPB.19 The equation is:

\[ 1 / V_{O2} = 0.0284 + 0.0118 \cdot Q^{-1} \]

(2A-4)

In mating these for the curves at intermediate temperatures, the first coefficient in Equation 2A-3 (relating to maximum \( V_{O2} \) at limitless flow) followed \( Q_{10} \), which happened to be 2.4. The second coefficient (relating \( Q \) slope change to temperature) followed a \( Q_{10} \) of 1.8. Both the experimental data at 37°C and the data of Fox and colleagues at 20°C are described by Equation 2A-3.

The logistic equation for Fig. 2-6 is:

\[ z = -7.3 \pm 1.56 + 0.08 \pm 0.026 \cdot \text{TCA} \]

(2A-5)
where TCA is circulatory arrest time (minutes), P for intercept < .0001, and P for TCA = .002. Also, among the 211 patients without such events, TCA time was 42 ±14.0 (SD) minutes, compared with 59 ±10.2 for the 8 patients with such events (P = .0008).

Chapter 2 Hypothermia, Circulatory Arrest, and Cardiopulmonary Bypass

Q

R

To whatever extent possible, injury to the myocardium must be avoided during operations utilizing cardiopulmonary bypass (CPB). During these operations, alterations of myocardial blood flow and oxygen demand are often imposed that, unmodified, might injure cellular energetics and morphology. We have chosen to call the following general discussion one of management rather than protection of the myocardium. Most efforts at management will result in protection of function. However, some techniques at times result in injury; at other times perhaps one or another technique may improve myocardial function. Almost all the techniques of myocardial management introduced in the past are in use.
today by one or more surgical groups, and at this time there is little secure evidence that one method is superior to another, or that the same method is optimal under all circumstances.\textsuperscript{19} This chapter is written, nonetheless, with the bias that few if any methods currently available perfectly protect the heart from the damaging effects of an appreciable period of global myocardial ischemia, but that such a method may evolve with additional knowledge. Emphasis is given to methods that are currently satisfactory.

**HISTORICAL NOTE**

In the early years of cardiac surgery, little mention was made of the possibility that fatal or nonfatal low cardiac output in the early postoperative period was related to damaging effects of the cardiac operation itself. Indeed, in two reviews of complications of open heart operations published in 1965\textsuperscript{182} and 1966,\textsuperscript{183} early postoperative low cardiac output was discussed extensively, but no mention was made of myocardial necrosis as a complication of the surgery or as a cause of low cardiac output, nor of temporary depression of myocardial function (stunning) as a result of the operation itself. Then, in 1967, Taber, Morales, and Fine described scattered small areas of myocardial necrosis, estimated to involve about 30% of the left ventricular myocardium, in a group of patients dying early after cardiac operations, and implicated this as the etiology of the patients’ low cardiac output.\textsuperscript{71} Najafi and colleagues showed in 1969 that acute diffuse subendocardial myocardial infarction was found frequently in patients who died early after valve replacement; these investigators suggested this was related to methods of intraoperative management of the myocardium.\textsuperscript{191} They discussed the possibility that disturbances of the myocardial oxygen supply/demand ratios might be implicated, and that proper perfusion of the subendocardial layer of the myocardium was a particular problem during CPB.

When coronary artery bypass grafting (CABG) began during the early 1970s, cardiologists and cardiac surgeons soon noted that a disturbingly high proportion of surgical patients developed a transmural myocardial infarction perioperatively (immediately before, during, or within 24 hours of operation).\textsuperscript{184,185} Although first widely publicized in connection with CABG, development of transmural myocardial infarction was soon shown to be a complication of cardiac surgery in general. In 1973, in a consecutive series of patients with normal coronary arteries who had undergone various open cardiac operations, Hultgren and colleagues documented a 7% occurrence of acute transmural myocardial infarction.\textsuperscript{185} These investigators recognized that “there is clearly a urgent need to further improve the protection of the heart during [cardiac] surgery.” Various autopsy studies have confirmed that acute transmural myocardial infarction, as well as scattered myocardial necrosis and confluent subendocardial necrosis, can occur after cardiac surgery in the presence of normal coronary arteries.\textsuperscript{186} The rarely occurring extreme manifestation of ischemic damage, “stone heart,”\textsuperscript{187} was recognized at about that time and has been confirmed to be essentially a massive myocardial infarction developing during reperfusion.\textsuperscript{182,183}

Development of knowledge in this area was facilitated by improved methods of identifying myocardial necrosis during life and, to some degree at least, quantifying its extent. Electrocardiographic criteria for diagnosing transmural myocardial infarction and ischemic changes were clarified\textsuperscript{188} and applied to postoperative patients. Appearance of cardiac-specific enzymes in plasma was shown to correlate well with other evidence of myocardial necrosis,\textsuperscript{189,190,191} and their concentrations were shown to correlate directly with amount of muscle that had become necrotic, as judged by other criteria.\textsuperscript{184,189} Isoforms of troponin I and T, sensitive and somewhat specific serum markers of myocardial injury following CPB,\textsuperscript{192,193} were found to be related to duration of ischemic time during cardioplegia, and elevated serum levels were associated with occurrence of delayed post-clamp recovery of ventricular function.\textsuperscript{191} Radionuclide imaging identified the presence and extent of perioperative myocardial infarctions.\textsuperscript{194}

With these methods, a number of clinical studies have supported the finding of autopsy studies that myocardial necrosis is an important and frequent complication of conventional cardiac surgery. In 1974, the frequency of myocardial necrosis in patients convalescing well was demonstrated in a study of isolated aortic valve replacement.\textsuperscript{195} Although hospital mortality was low (2%), 15% of the patients developed electrocardiographic evidence of transmural myocardial infarction, and 70% developed isoenzymatic evidence of myocardial necrosis. In 1974, it was shown that even after the short and simple operation for repair of an uncomplicated atrial septal defect, both adult patients and children developed isoenzymatic evidence of myocardial necrosis. Myocardial necrosis was demonstrated by enzymatic methods in children undergoing surgery for a number of different congenital cardiac defects.\textsuperscript{196}

In a 1975 study, early postoperative cardiac output was reported to be inversely proportional to the extent of myocardial necrosis, and thus the amount of myocardial necrosis was a determinant of the early postoperative condition of the patient and of the probability of survival\textsuperscript{186} (Fig. 3-1). Subsequently, it became clear that myocardial stunning also occurs after cardiac surgery, as well as after regional myocardial ischemia from coronary artery disease.\textsuperscript{197} This also results in a period of low cardiac output of variable duration, albeit without myocardial necrosis in some patients.

It is difficult to identify the individual who first thought about special methods of myocardial management to protect the heart itself from damage during operations. Probably the first special method was retrograde coronary perfusion for surgery on the aortic valve, reported by Lillehei and colleagues in 1956,\textsuperscript{198} and subsequently by Gott and colleagues.\textsuperscript{199} “Elective cardiac arrest” was advocated by Melrose in 1955,\textsuperscript{200} but its use at that time by Cleland in London was for intraoperative exposure, not myocardial management. The first deliberate attempts to protect the myocardium other than by simply perfusing it may have been made by Hufnagel and colleagues in 1961, who introduced profound cardiac cooling using ice slushes\textsuperscript{194} and Shumway and Gripp and colleagues, who used ice cold saline for the same purpose.\textsuperscript{201,202,203} Pharmacologic intervention, designed to provide myocardial protection against the damaging effect of ischemia, began during the 1970s as more knowledge of the pathophysiology of myocardial ischemia evolved.\textsuperscript{204} In the late 1970s, Clark and colleagues accumulated evidence of the favorable effect of nifedipine, a calcium channel blocking agent.\textsuperscript{205,206}

The concept of reducing global myocardial ischemic damage by inducing immediate cessation of electromechanical activity—cardioplegia—was discussed generally by cardiac
myocardial ischemic times greater than 150 minutes. About the same time, Hearse and Brainbridge and their colleagues in London were exploring induction of reversible cardiac arrest and its clinical application. Gay and Ebert studied and advocated potassium-induced cardioplegia in 1973, as did Roe and colleagues in 1977. Randomized trials soon confirmed the advantages of cold cardioplegia. Buckberg identified blood as the optimal cardioplegic vehicle in 1979. In the 1990s Wechsler, Damiano, and others began experiments using concepts of membrane hyperpolarization (nearer the resting state) via adenosine triphosphate (ATP)-sensitive K+ channels rather than hyperkalemic cell membrane depolarization; aprikalim and pinacidil are examples of K+ channel openers.

In 1960, Danforth, Naegle, and Bing showed the rapidity with which myocardial energy supply is replenished after ischemia when electromechanical quiescence is continued for a few minutes into the reperfusion period. This key observation remained unused until Buckberg and colleagues in 1978 showed experimentally that improved outcome could be obtained through use of an initially hyperkalemic reperfusionate. Subsequently, these investigators modified the reperfusionate: For acutely energy-deficient hearts, they introduced warm induction of cardioplegia with an enriched, modified, hyperkalemic blood perfusate. Control of perfusion pressure during reperfusion and continuance of controlled reperfusion until full recovery were additional contributions to cardioplegic and reperfusion techniques.

The mode of delivery of the cardioplegic vehicle was the latest contribution to cardioplegic management. Buckberg in North America and Menasche in Europe documented the efficacy and safety of retrograde and combined antegrade-retrograde infusion in valvar and coronary surgery. Metabolic demands of the heart were reduced by approximately 85% by sustained potassium arrest, even at normothermia. Therefore, using the delivery concepts of Buckberg and Menasche, Lichtenstein and Salerno reasoned that warm continuously delivered blood cardioplegia containing minimal amounts of potassium would provide adequate oxygen, substrate, and buffer to the arrested nonworking heart. They occluded the aorta and maintained the heart quiet and flaccid, but perfused.

### NEED FOR SPECIAL MEASURES OF MYOCARDIAL MANAGEMENT

**Conditions during Cardiopulmonary Bypass**

The heart of intact humans is perfused by blood, ejected from the left ventricle, that leaves the aorta via the right and left coronary arteries. Blood is continuously modified by the organism so as to be correct in its composition and free of damaging materials such as gaseous or particulate microemboli. The amount and distribution of myocardial blood flow (hence myocardial oxygen supply) are continuously regulated, primarily in response to myocardial oxygen demand. This flow is determined by coronary perfusion pressure (aortic pressure), tension in the various myocardial layers (related in part to ventricular wall thickness and size), and coronary vascular resistance. An appropriate coronary vascular resistance depends on proper function of the coronary endothelial cells and underlying smooth muscle. The ratio between flow to the inner one fourth of the myocardium (subendocardial
layer) and that to the outer one fourth (subepicardial layer) in normal hearts with intact circulation is maintained at 1 or a little greater. Although blood flow to the subepicardial layer occurs during both systole and diastole, blood flow to the subendocardial layer occurs almost exclusively during diastole, because intramyocardial tension during systole closes the branches of the coronary arteries that pass perpendicularly through the myocardium to arborize in the subendocardium. The well-known vulnerability to ischemia of the left ventricular subendocardial layer in shock, ventricular hypertrophy, and coronary artery disease, as well as during cardiac surgery, is dependent in part on this relationship, but in part on other factors as well, including a higher rate of oxygen consumption in the subendocardial layer.\(^{215}\)

During CPB, the heart is deprived of most of these protective regulatory factors. During total CPB, blood enters the arterial system through a cannula in the ascending aorta or at a more distal point. It then passes retrogradely into the most proximal part of the aorta and is distributed through the right and left coronary ostia into the coronary arteries. Arterial pulse pressure is narrow (essentially nonpulsatile), and mean arterial blood pressure is variable. The heart is usually more or less empty and thus smaller than usual, thereby increasing intramyocardial tension and transmural and subendocardial vascular resistance, and decreasing flow to the subendocardial layer.\(^{118,224}\) The effect is particularly powerful in the small heart and hypothermic heart.\(^{224}\) Ventricular fibrillation increases intramyocardial tension still more. Coronary vascular resistance during CPB is also affected by circulating vasoactive agents (see “Details of the Whole-Body Inflammatory Response” in Section II of Chapter 2). The perfusate is diluted blood of variable composition with highly abnormal physiochemical properties. The blood may contain microemboli of several kinds, and leukocytes and platelets with altered mechanical and humoral functions.

Thus, there is little reason to assume that the empty perfused human heart on CPB, even when beating, is managed optimally. Furthermore, clinical experience refutes that view.

Vulnerability of the Diseased Heart

In most patients undergoing cardiac surgery, coronary blood supply or the myocardium, or both, are not normal and are therefore particularly susceptible to ischemic and reperfusion damage. Hypertrophied ventricles have long been known to be particularly susceptible to ischemic and reperfusion damage.\(^{37}\) This vulnerability is a result of several factors. Transmural gradients of energy substrate utilization are markedly elevated, increasing the vulnerability of the subendocardium to ischemic damage.\(^{215}\) Xanthine oxidase levels are markedly elevated, increasing the opportunity for elaboration of oxygen-derived free radicals. Superoxide dismutase levels are markedly decreased, reducing the natural defenses against oxygen-derived free radicals.\(^{89}\) Also, wall characteristics of the hypertrophied ventricle make reperfusion of the subendocardium even more difficult than under normal circumstances.

The heart of the patient with chronic heart failure is chronically depleted in energy charge\(^1\) and is particularly susceptible to additional acute depletion and damage during ischemia and reperfusion.

The hearts of experimental animals made cyanotic have been shown to be considerably more susceptible to ischemic and reperfusion damage than are normal hearts.\(^{211}\) This may pertain also to severely ill, cyanotic patients. It is well known that the heart of a patient coming to the operating room in a hemodynamically unstable state or in cardiogenic shock is highly sensitive to the damaging effects of global myocardial ischemia.

Surgical Requirements

Cardiac operations can be performed with the heart perfused and either beating, in ventricular fibrillation, or in diastolic arrest. However, the probability of a precise and complete surgical procedure without air embolization is greatest when the heart is bloodless and mechanically quiescent. These optimal conditions are provided by global myocardial ischemia, but they necessitate appropriate myocardial management to limit the damage that would otherwise result from the period of global myocardial ischemia. The changes associated with myocardial ischemia and those associated with reperfusion are not often discussed as separate events; much of the literature does not allow interpretation of one or the other as a separate event. In contrast, the surgeon, by his or her manipulations, has a unique opportunity to control and influence each separately. Therefore, the following discussion must, for strategic purposes, attempt to distinguish the role of ischemia from that of reperfusion.

DAMAGE FROM GLOBAL MYOCARDIAL ISCHEMIA

Damage from a period of ischemia may result in a variable, and sometimes prolonged, period (many days) of both systolic and diastolic dysfunction without muscle necrosis.\(^{82}\) This condition is termed myocardial stunning.\(^{211,213}\) A period of ischemia may also result in irreversible damage (myocardial necrosis). Some investigators have obtained information indicating that this can develop in the subendocardium after as little as 20 minutes of normothermic ischemia.\(^{19,74}\)

Others have obtained evidence that at least 6 hours of normothermic myocardial ischemia is compatible with myocardial cell survival throughout the myocardium.\(^{82}\) Ischemic damage involves myocardial cells (myocytes), vascular endothelium, and specialized conduction cells (which, with many cardioplegic techniques, may be the last to recover).

Overall reviews of the damage from myocardial ischemia are available.\(^{156,224}\) Nayler and Elz stress the extreme heterogeneity among cells (and by implication among hearts) in the rate of progression of ischemic damage, as well as in the rapidity of the chain of events of ischemia (i.e., the switch from aerobic to anaerobic glycolysis occurs within seconds of onset of ischemia).\(^{224}\)

Although the phrase global myocardial ischemia is appropriately used to describe the situation during cardiac surgery when the aorta is clamped, some blood flow—originating in mediastinal arteries—continues from noncoronary collaterals.\(^{83}\) Generally, noncoronary collateral flow is less than 3% of total coronary flow. However, in patients with cyanotic congenital heart disease, advanced ischemic heart disease, extensive pericarditis, and other conditions, coronary collateral flow may be sufficient to initiate electromechanical

---

\(^1\) Energy charge describes the energy-producing capacity of the particular combination of adenosine nucleotides present in mitochondria and cytoplasm of myocytes of a particular heart. Normally, it is 0.85. It would be 1.0 if the nucleotides were present only as ATP, but 0.0 if they were present only as adenosine monophosphate.\(^{80,222}\)
activity in the heart rendered quiescent by cardioplegia, but insufficient to prevent continuing and important ischemia.

**Myocardial Cell Stunning**

Surgeons have long known that patients may have severely depressed cardiac function after cardiac surgery without evidence of myocardial necrosis, and that the duration of the depressed function may last minutes or days. Some instances of delayed recovery of cardiac function after cardiac surgery may be related to initially incomplete reperfusion of the microvasculature of the heart. However, myocardial stunning probably underlies at least some instances of prolonged postoperative low cardiac output. In general, stunning occurs after a state of acutely diminished myocardial blood flow followed by adequate reperfusion. After establishing “normal” blood flow, there remains for a time diminished contractility; that is, perfusion/contractility mismatch.²

Myocardial stunning, which can follow even brief periods of myocardial ischemia, is characterized by systolic and diastolic dysfunction in the absence of myocardial necrosis.⁵¹,²,³⁴ Myocardial stunning has been attributed to reduced oxygen consumption, which might protect against myocardial necrosis. This hypothesis is denied by the fact that stunned myocardium has a high, not low, oxygen consumption.⁶¹ Some have suggested that stunning may be a consequence of abnormal energy transduction or utilization secondary to depletion of high-energy phosphates. Stunned myocardium, however, responds to inotropic stimulation, indicating the presence of adequate ATP to produce active contraction.³³ Myocardial stunning, then, is a form of myocardial cell damage caused by ischemia and reperfusion.⁸¹ Stunning, like myocardial necrosis, tends to begin in the subendocardial layers and progress outward; recovery during reperfusion proceeds in the reverse direction.²⁰

Current information makes it unlikely that stunning is the result of prolonged posts ischemic depletion of myocardial cell energy charge.²¹ It does not appear to be the result of a continuing posts ischemic impairment of coronary blood flow or coronary reserve.¹⁵ It may be caused in part by the release of oxygen-derived free radicals, presumably by activated neutrophils and probably occurring to a major degree during the first few minutes of reperfusion.²¹,²² Experimentally, introduction of superoxide dismutase and catalase (free radical scavengers) before an ischemic period results in nearly full reduction of superoxide dismutase and catalase (free radical scavengers) before an ischemic period results in nearly full protection of contractile indices upon reperfusion, compared with prolonged depression in controls.²¹ Stun ning may be caused in part by an ischemia-induced increase in influx of calcium into the myocardial cells.³⁶,³⁰,³² This possibility has led to the hypothesis that cardiac stunning is related to a defect in calcium-mediated excitation–contraction (EC) coupling that results from the excess calcium.³³ This hypothesis must be reconciled with evidence that after short periods of ischemia, excess intracellular calcium that rapidly accumulates with the onset of reperfusion soon leaves the cells.²⁴

Techniques of myocardial management designed to minimize myocardial necrosis are probably effective against myocardial stunning as well. Thus, for optimal results, these techniques should be used even when the period of global myocardial ischemia is less than that anticipated to result in myocardial cell death.

**Myocardial Cell Necrosis**

Myocardial necrosis after cardiac surgery is the end stage of a complex process initiated by the onset of global myocardial ischemia, maintained by continuing ischemia, and aggravated by reperfusion. The final link in the chain of events, reperfusion, can be favorably modified so as to prevent necrosis, unless the duration of myocardial ischemia is excessive; “excessive” in this context has not yet been defined.³⁰

Immediately after the onset of ischemia, contractile force declines rapidly, as does myocardial pH.¹⁴,³¹ Oxidative metabolism, electron transport, and ATP production by oxidative phosphorylation (which take place in mitochondria) decline rapidly. Some ATP is still produced by relatively inefficient anaerobic glycolysis. Fatty acid utilization is rapidly reduced, while fatty acid acyl-CoA derivatives accumulate because of continuing uptake of fatty acids by myocardial cells. Intracellular acidosis develops because of accumulation of lactate and protons in the myocardial cytoplasm, suppressing anaerobic glycolysis. These developments contribute to damage to the cell membrane and loss of control of cell size, with consequent cell swelling, intracellular accumulation of calcium, and other disturbances of membrane ion transport.¹⁵ This entire process acutely diminishes myocardial energy charge and glycogen reserves, while adenosine, inosine, and other nucleotides that are the results of ATP catabolism and the building blocks for ATP repletion leave the cell. Ultrastructural changes during this early phase are limited to loss of glycogen granules and some intracellular and organelle swelling.

As the duration of ischemia lengthens, intracellular metabolic deterioration continues, still more fatty acids accumulate within the myocytes, and diastolic arrest occurs. Loss of control of sarcoplasmic membrane permeability—which begins within 15 minutes of onset of ischemia—is continuous, and nonspecific membrane permeability increases. Adenosine, lactate, and other small molecules leak still more rapidly out of the cell, as do cytoplasmic proteins and enzymes; these appear in the cardiac interstitium and in the lymph.¹,⁵ As macromolecules within myocardial cells are converted to smaller, more osmotically active molecules by ischemic metabolic conversion, cell swelling proceeds more rapidly.¹² Cellular metabolism and ATP production nearly cease, and glycogen stores are depleted.²² As glycolysis and mitochondrial function are totally lost, cellular autolysis begins, and cell contents leak more extensively into the interstitial space and cardiac lymph.

In many laboratory preparations, as the depletion of ATP continues and finally reaches critical levels, myocardial contracture begins to occur.⁶ The classic belief has been that once contracture is completed, functional recovery is suddenly more difficult, and the time to this end point has been an important criterion in many studies in isolated rat heart preparations.¹¹ However, the time to contracture (1) is

---

¹Myocardial hibernation vs. myocardial stunning: If stunning is characterized as a perfusion/contraction mismatch, hibernation is a perfusion/contraction match; in the latter, both are low.² Generally, hibernation is a chronic, potentially reversible state of segmental (less often, global) contractile dysfunction. Theoretically, dobutamine echocardiography, thallium scintigraphy, and positron emission tomography may distinguish hibernating from nonviable myocardium. However, the difference between stunned and hibernating segments may be vague. Marban³ suggests that a decrease in Ca⁺ transients at a cellular level is responsible for the contractile dysfunction in hibernation, whereas a decrease in myofilament Ca⁺ responsiveness accounts for the excitation–contraction decoupling seen in stunning.
endothelial cell activation following hypoxia, anoxia, or ischemia. Activated endothelial cells express proinflammatory properties, including induction of leukocyte adhesion molecules. These result in neutrophil accumulation at the arterial wall and release of oxygen-derived free radicals. Intracellular adhesion molecules (ICAM) are upregulated (see Fig. 3-2). endothelial cell swelling develops during ischemia and becomes more prominent during reperfusion, and secretion of endothelial relaxing factor, as well as of endothelin, the constricting factor, is affected. Boyle and Verrier have reviewed the role of the endothelium in events associated with ischemia and reperfusion (Fig. 3-2). There is

Figure 3-2  A, Hypoxic endothelial cell activation. Hypoxia stimulates Weibel-Palade bodies to release P-selectin and activates nuclear factor (NF)-κB. NF-κB is translocated to nucleus, where it promotes transcription of E-selectin, intracellular adhesion molecule (ICAM), tissue factor, interleukin (IL)-8, and IL-1. IL-1 feeds back to promote more endothelial cell activation through activation of NF-κB. B, Neutrophil adhesion is a multistep process that involves contact between neutrophils and members of the selectin family of adhesion molecules (P-selectin, E-selectin) expressed on activated endothelium. These low-affinity bonds result in rolling and slowing of leukocytes. As this occurs, neutrophils become activated, and a firm bond forms between integrins on the leukocyte surface (i.e., CD 11/18) and adhesion molecules on the endothelium (i.e., ICAM-1, vascular cell adhesion molecule, platelet-endothelial cell adhesion molecule). C, No-reflow phenomenon. Hypoxia results in activation of endothelial cell layer, which promotes leukocyte adhesion and degranulation, endothelial swelling, platelet activation, microthrombosis, and increased vasomotor tone. This contributes to impaired microcirculatory flow, despite what appears to be adequate perfusion through the large epicardial arteries. Adherent neutrophils infiltrate underlying myocardium and promote lipid peroxidation, enzymatic degradation of membranes, calcium overload, and excitation-contraction uncoupling. Collectively, these events result in impaired myocardial function. Key: LPS, Lipopolysaccharide. (From Boyle and colleagues.

highly species dependent, (2) is unknown but probably quite long in humans, and (3) in the rat heart, at least, has a greatly different implication in crystalloid vs. blood-perfused preparations. The appearance of contracture does indicate that the content of ATP has been depleted to a critically low level. Contracture first develops in the subendocardium, because of its higher metabolic rate and consequent more rapid depletion of ATP. Contracture develops more rapidly in hypertrophied than in normal hearts and is delayed in its onset by hypothermia.

Where the process becomes truly irreversible along this course of events, and cell death becomes inevitable, is not known with certainty.

Endothelial Cell Damage

As in the case of myocytes, distinguishing between ischemic endothelial cell damage and reperfusion damage is difficult. Endothelial cell swelling develops during ischemia and becomes more prominent during reperfusion, and secretion of endothelial relaxing factor, as well as of endothelin, the constricting factor, is affected. Boyle and Verrier have reviewed the role of the endothelium in events associated with ischemia and reperfusion (Fig. 3-2).
resistance that have been observed in humans during reperfusion after global myocardial ischemia, and in the no-reflow phenomenon seen after prolonged ischemia, particularly in the inner half of the myocardium. In children, cytokines such as interleukin (IL)-8 are liberated during CPB and may contribute to neutrophil adhesion and migration. Burns and colleagues\(^{B50}\) and Kilbridge and colleagues\(^{B55}\) report endothelial expression of P-selectin, E-selectin, and ICAM in myocardial biopsies taken during cardioplegic ischemic arrest in infants undergoing complex repairs. However, the degree to which endothelial activation and related subsequent events contribute to impaired microcirculatory flow and myocardial dysfunction during cardiac surgery is unknown.

Specialized Conduction Cell Damage

The specialized conduction cells become nonfunctional early in the course of global myocardial ischemia in humans; it may be speculated that their recovery takes longer than does recovery of myocytes. Some support for this is that 5 or so minutes after initially hyperkalemic reperfusion, the ventricular myocardium in some patients responds well and strongly to direct ventricular pacing, although it is quiescent with atrial pacing or without pacing. Then, after 5 or so more minutes, sinus rhythm may appear. Also, when blood cardioplegia and uncontrolled normokalemic reperfusion are used, about 50% of patients have atrioventricular (AV) conduction disturbances when CPB is discontinued.\(^{B3}\) This appears to be a form of specialized conduction cell stunning rather than necrosis, because these disappear by the time of hospital discharge in most of the patients in whom it had developed. Even third-degree AV block persisting as long as 2 months has been observed to give way to sinus rhythm.\(^{B3}\) Validation of this speculation remains to be obtained, however. These changes might also be ascribed to variation of specialized conduction fibers' sensitivity to chemical components of the cardioplegia infusate.\(^{B36}\)

DAMAGE FROM REPERFUSION

The morphologic changes following normal blood reperfusion of ischemic myocardium have been authoritatively presented by Jennings and Reimer.\(^{1,11}\) They stress the complexity of the process, including cell swelling, contraction band necrosis, calcium loading of mitochondria, accelerated washout of creatine kinase early in reperfusion, and the particular vulnerability of the subendocardium. It is clear that there can be no reperfusion damage in the absence of prior ischemia. What is not clear is whether there can be reperfusion damage in the absence of ischemic damage.\(^{S3,S41,S28}\) Clearly, limitation of the duration of ischemia and modification of the conditions during ischemia are fundamental to limiting reperfusion injury.

The following discussion assumes some degree of spontaneous ischemia (coronary obstructive disease) or induced ischemia (low blood flow or aortic clamping); it pertains to uncontrolled reperfusion, which is reperfusion by unmodified blood without control of pressure or flow.

Myocardial Cell Damage

The response of myocardial cells to uncontrolled reperfusion depends in large part on the time-related point along the pathway to cell death that has been reached during the ischemic period. Yet the critical point at which the “explosive cellular response” to uncontrolled reperfusion can be expected is not known with certainty. In the past, it has been defined (in the isolated rat heart) as the point at which contracture appears, a definition of little help in humans undergoing cardiac surgery, because the time to contracture—if it occurs—is unknown but probably quite long. Also, when the rat heart is blood perfused (rather than crystalloid perfused), reperfusion after contracture results in good return of function.\(^{W1}\)

When uncontrolled reperfusion is initiated after global myocardial ischemia in cardiac surgery, the response may be only myocardial stunning. A more severe response consists of reperfusion arrhythmias, particularly ventricular tachycardia and ventricular fibrillation. The more prolonged and the larger the area of myocardial ischemia, the more frequent, severe, and intractable the arrhythmias.\(^{B19}\) A still more severe response is the hard and fibrillating heart, sometimes termed stone heart.\(^{C18,414,214}\) The stone heart phenomenon may involve only some regions of the heart, typically the basilar portion of the left ventricle and the subendocardium. This phenomenon indicates that the heart has undergone severe damage and may be considered to have approached the critical “point of no return.” It has not necessarily reached this point, because the stone heart is, at least under some circumstances, capable of recovery. The histologic features of these advanced forms of reperfusion damage include disruption of the regular myofibrillar pattern and evident contraction bands.\(^{M5}\)

Clearly, the strong influx of calcium into myocytes, and particularly its accumulation in mitochondria, are obvious and fundamental features of reperfusion injury.\(^{22,23,35,314,415}\) Stiffness of cardiac muscle resulting from uncontrolled reperfusion after a period of ischemia is caused by the massive influx of calcium into mitochondria and cytoplasm of myocytes, as well as by edema and capillary disruption.\(^{B11}\) However, many other types of events are ongoing, most well underway within 1 or 2 minutes of uncontrolled reperfusion.

Chemotactic factors of cardiac subcellular origin, activated endothelial cells, activated complement fragments, such as C5a, and cytokines are generated locally in ischemic myocardium.\(^{D9,M6,R28}\) This process activates circulating neutrophils, which accumulate and play an important role in initiating and sustaining reperfusion injury.\(^{B44,C4,E7,M122}\) Neutrophils plug myocardial capillaries as reperfusion continues because of their large size and active adherence to ischemically damaged endothelial cells.\(^{M6}\) Leukocytes, and in particular neutrophils, release large amounts of oxygen-derived free radicals in these circumstances.\(^{155,M10}\) Activated neutrophils also release arachidonic acid metabolites that cause endothelial injury, vasoconstriction, and platelet aggregation. During reperfusion, certain leukotrienes are also released from platelets and endothelial cells.\(^{M3,R29}\)

Oxygen-derived free radicals generated during reperfusion represent one of the fundamental processes that produce damage.\(^{A13,P9}\) Oxygen-derived free radicals are characterized by presence of unpaired electrons and include superoxide (O2), hydrogen peroxide (H2O2), and the hydroxyl radical (OH). Normally, myocardial cells are constantly exposed to superoxide anions in very small amounts, produced in (1) mitochondria (where 95% of oxygen consumption occurs) during electron transport, (2) cell cytoplasm during prostaglandin synthesis and metabolism and oxidation of
tissue catecholamines, (3) vascular endothelium by xanthine oxidase-catalyzed reactions, and (4) extracellular fluids by activated neutrophils. Normally, these very small amounts of oxygen-derived free radicals are well controlled. Superoxide dismutase, which is normally present in myocytes, catalyzes the transformation of superoxide anions to hydrogen peroxide and water; metabolism of hydrogen peroxide to water and oxygen is accomplished by either catalase or glutathione peroxidase, or both.\textsuperscript{13}

The very onset of uncontrolled reperfusion can produce large amounts of oxygen-derived free radicals because of profound alterations imposed on this exquisite system by ischemia. Ischemia progressively decreases the cellular levels of the scavenger superoxide dismutase and also increases metabolic end products of ATP catabolism, such as hypoxanthine and xanthine. These catabolites may participate in producing oxygen-derived free radicals by supplying free radical substrates to endothelial xanthine oxidase.\textsuperscript{82} Also, during ischemia, normally present xanthine dehydrogenase is converted to xanthine oxidase. Superoxide anions are generated at the start of uncontrolled reperfusion. Xanthine oxidase is the catalyst for reoxygenation and metabolism of the considerable amounts of hypoxanthine and xanthine generated during ischemia. A chain reaction results, leading to the generation of other free radicals and of a direct attack by them on unsaturated fatty acids within cell membranes. As part of this chain reaction, iron plays a key role in converting relatively innocuous superoxide radicals into highly damaging hydroxyl radicals.\textsuperscript{82} Peroxidation of membrane lipids has been shown to result in increased membrane permeability, decreased calcium transport into the sarcoplasmic reticulum, and altered mitochondrial function,\textsuperscript{13} setting the stage for myocardial stunning or necrosis.

**Endothelial Cell Damage**

Reperfusion damage to the heart involves more than the myocytes. For example, myocytes surrounding a necrotic area of myocardium may be perfectly viable and functioning 1 hour after the start of reperfusion, only to become necrotic over the subsequent few hours.\textsuperscript{14} This has been shown to be due to delayed closure of coronary arterioles and capillaries and to the resulting no-reflow phenomenon.

The endothelial cells of large coronary arteries appear to be little affected by the damaging effects of ischemia and reperfusion.\textsuperscript{15} The coronary microvasculature is profoundly affected, however, and the resultant endothelial dysfunction appears to develop rapidly with the onset of reperfusion.\textsuperscript{14,15} This damage appears to be minimal after ischemia itself but is incited almost exclusively by reperfusion.\textsuperscript{14} In addition to changes in endothelial cell function, the endothelial cell swells, activated neutrophils and platelets aggregate and adhere to the endothelium, and microvascular obstruction can develop.\textsuperscript{14,15,16}

This rapidly induced reperfusion injury to the endothelial cells severely impairs normal endothelium-dependent relaxations to neutrophils and platelets as well as to thrombin, acetylcholine, and bradykinin.\textsuperscript{20,82,85,15} These alterations could play some role in the observed progressive increase in coronary vascular resistance during reperfusion. In addition, with damage to endothelial cells, smooth muscle beneath the cells is exposed, allowing additional mediators to induce direct smooth muscle contraction.

In addition to these phenomena, coronary vessels are compressed by myocardial areas with high wall tension and hemorrhage and by myocardial cell swelling. This all may lead to inhomogeneous distribution of the uncontrolled, unmodified blood reperfusate or actual “no-flow,” further aggravating reperfusion injury in the clinical setting. These unfavorable events are particularly damaging after prolonged (>24 hours) cardiac preservation,\textsuperscript{26} as may eventually be required for cardiac transplantation.

**Specialized Conduction Cell Damage**

Little specific information is available about reperfusion injury to the specialized conduction cells.

**ADVANTAGEOUS CONDITIONS DURING ISCHEMIA**

Advantageous conditions during ischemia delay the time required for the ischemic myocardium to reach the hypothetical critical point in the course of ischemic injury. This is classically considered the point at which uncontrolled, unmodified blood reperfusion produces explosive cell damage and accelerated myocardial necrosis, rather than recovery. For this discussion, it is this critical point that must be delayed. The common denominator may be delay in severe reduction of the energy charge of the myocardium.

Circumstances that decrease the rate of ATP utilization (or its surrogate, myocardial oxygen consumption) lengthen the safe ischemic interval. These circumstances include immediate cessation of electromechanical activity and hypothermia.\textsuperscript{112} The interrelationships are such that a great advantage is obtained by reducing myocardial temperature from 37°C to 27°C, a lesser advantage by reducing temperature from 27°C to 17°C, and a still smaller advantage by reducing temperature further (Fig. 3-3).\textsuperscript{118} However, for longer periods of arrest (6 hours), Rosenfeldt found an increase in protection with stepwise cooling from 20°C to 4°C.\textsuperscript{20} In a different experimental preparation, Balderman and colleagues\textsuperscript{84} found less satisfactory ventricular performance after 120 minutes of ischemia at temperatures of 6°C and 10°C compared with 14°C and 18°C.

Preoperative enhancement of cardiac substrates seems advantageous, but has been little used in cardiac surgery to date. Myocardial glycogen content can be increased by an intravenous infusion of a glucose-insulin-potassium solution during the 12 hours preceding operation.\textsuperscript{17,13} This can be combined with continuous retrograde coronary sinus infusion of a similar solution during the ischemic period.\textsuperscript{13,15,16}

Acute substrate enhancement before cold cardioplegia and ischemia by initial infusion of warm, hypokalemic, modified and substrate-enriched blood has been shown to benefit hearts that have become energy depleted before the cardiac operation.\textsuperscript{22,23,26} Continuation of the pressure-controlled, warm, enriched blood infusion for a few minutes after the onset of asystole takes advantage of increased coronary flow and better distribution brought about by cardiac asystole.\textsuperscript{31}

Preischemic administration of drugs such as lidoflazine has been shown to be advantageous,\textsuperscript{26,57} although the mechanism of their favorable effect remains arguable (see “Drug-Mediated Myocardial Protection” later in this chapter).
Preischemic myocardial conditioning may surface as an additional tactic to limit damage during an induced ischemic interval and as an adjunct to surgical myocardial management. The concepts of both ischemic preconditioning and postconditioning are well recognized in the science of myocardial ischemia and myocardial ischemia (reperfusion injury have not found general application in cardiac surgery. Ischemic preconditioning refers to brief periods of cessation of coronary blood flow prior to the longer ischemic event, and ischemic postconditioning refers to brief periods of coronary blood flow cessation during the early period of reperfusion. Ischemic preconditioning appears to stimulate potent innate cardioprotective mechanisms that attenuate ischemia-reperfusion injury. The protective mechanisms have been linked to stimulation of myocyte adenosine receptors, reduction of inflammatory responses to reperfusion, attenuation of endothelial dysfunction during reperfusion, reduction in tissue acidosis during ischemia, and prevention of ischemia-induced cell apoptosis.

Similar mechanisms have been invoked for ischemic postconditioning. Ischemia-induced cardiac preconditioning has been shown to reduce infarct size in dog, swine. Several reports suggest that in humans, prodromal angina may limit infarct size. Adenosine activation and α1-adrenergic stimulation are two pathways suggested as mediators of preconditioning. Protein kinase C has been identified as at least one of the factors that when activated by adenosine or phenylephrine results in protection by myocardial preconditioning in laboratory animals (Fig. 3-4). Experimentally in sheep, preconditioning has been produced by CPB alone and the response suppressed by α1-adrenergic blockade or adenosine receptor blocker.

Because of its simpler application to cardiac surgery, remote ischemic preconditioning is the object of numerous clinical trials. It refers to myocardial protection against ischemic injury by inducing ischemia in a distant organ, such as skeletal muscle of the arm. This, and the fact that a preconditioning factor can be transferred from animal to animal, suggests a humoral factor, although a mural component has been implicated as well. Remote ischemic preconditioning has been implemented during cardiac surgery simply by 5-minute cycles of upper-limb cuff inflation to 200 mmHg, separated by 5 minutes of cuff deflation. Clinical trials have thus far produced mixed results.

**ADVANTAGEOUS CONDITIONS DURING REPERFUSION**

Advantageous conditions during reperfusion (1) minimize the persistence of myocardial stunning into the post-CPB period, (2) provide for optimal recovery of function of reversibly damaged myocardium, and (3) resuscitate myocytes that would otherwise have undergone necrosis.

Buckberg and colleagues evolved the methods and demonstrated the advantages of controlling reperfusion. These ideas constitute a clinically useful body of knowledge. In essence, the advantageous conditions consist of:

1. Maintaining electromechanical quiescence during the first 3 to 5 minutes of reperfusion to permit more rapid repletion of myocardial energy charge, minimize regional heterogeneity of reperfusion flow, minimize myocardial energy expenditure until recovery has been established, and minimize intracellular accumulation of calcium.
2. Combating accumulated myocardial acidosis by controlling pH of the initial reperfusate and providing a large buffering capacity to permit more prompt morphologic, biochemical, and functional recovery.

3. Minimizing damage from oxygen-derived free radicals.

4. Reducing ionized calcium in the initial reperfusate to help minimize intracellular accumulation of calcium.

5. Increasing availability of substrate for repletion of myocardial energy charge.

6. Maintaining a low perfusion pressure (=30 mmHg) during the first 60 to 120 seconds of reperfusion to minimize endothelial cell damage and swelling, during which time reactive hyperemia, usually present, allows this low pressure to be maintained with adequate volume and distribution of flow.

7. Maintaining a flow sufficient to encourage near-uniform myocardial distribution of the reperfusate.

8. Continuing control of reperfusion pressure and flow until myocyte, endothelial cell, and specialized conduction cell recovery is essentially complete.

Specific comments about individual items follow, and the details of establishing these advantageous conditions during clinical cardiac surgery are described in “Cold Cardioplegia, Controlled Aortic Root Perfusion, and (When Needed) Warm Cardioplegic Induction” later in this chapter. New information continues to accumulate, and current practices must be changed whenever sufficient information becomes available to indicate the possibility of improving results by modifying methods.

Blood

Blood as the reperfusion vehicle has been shown to be superior to crystalloid solutions. The advantage is due in part to the red blood cell component, although it may not relate to the oxygen transport capacity of red blood cells. Among other things, red blood cells contain abundant oxygen-derived free radical scavengers, which have been shown to be important. The minimal effective level of hematocrit in the reperfusate is 0.15 to 0.20. The buffering capacity of blood proteins, especially their histidine and imidazole groups, is also advantageous.

Leukocyte Depletion

There is little doubt that activated leukocytes play an important role in reperfusion damage. Depletion of leukocytes from the blood reperfusate (by filtration) has been shown to reduce reperfusion injury considerably. Leukocyte fillers are commercially available for pediatric and adult CPB circuits.

Substrate

Addition of the amino acids L-glutamate and aspartate to solutions used to reperfuse the heart after an ischemic insult has been shown by Rosenkranz and by Buckberg and colleagues to be beneficial to metabolic and functional recovery. Their early work has been confirmed by Choong and Gavin and others. Addition of adenosine during reperfusion was theorized to improve postischemic function; there is experimental support for its efficacy. The delay in repletion of ATP after ischemic injury may well relate to lack of availability of adenosine, an important component of the process of rebuilding ATP stores because it is essentially converted to inosine and as such is washed out of cells during reperfusion.

Hydrogen Ion Concentration

The initial reperfusate should contain adequate buffering capacity to combat the intracellular acidosis developed during the ischemic period (see “Blood” earlier in this section). Various buffering agents have been used, but hydroxymethylaminomethane (Tris) and histidine have particularly favorable characteristics.

Calcium

During reperfusion, perfusate calcium content should be low to minimize the influx of calcium into potentially damaged myocytes. The special effects of calcium in the neonatal and infant myocardium are discussed under “Neonates and Infants” under Special Situations and Controversies later in this chapter.

Potassium

Hyperkalemic reperfusion permits rapid repletion of ATP and improved functional recovery, even in the face of ischemic contracture and myocardial accumulation of calcium. It also promotes better myocardial blood flow. Therefore, if controlled reperfusion is elected, the initial reperfusate should contain sufficient potassium to maintain electromechanical quiescence for at least 2 to 3 minutes, and preferably 5 to 10 minutes. The sufficient concentration is about 12 mmol · L⁻¹.

The advantages of hyperkalemic reperfusion in clinical cardiac surgery have been confirmed in a randomized trial by Teoh and colleagues, although these advantages may be difficult to demonstrate in low-risk patients undergoing uncomplicated CABG.

Pressure

After a period of myocardial ischemia, coronary vascular endothelial cells are in a state in which they are easily damaged by high reperfusion pressure, but that state appears to be rapidly reversed by gentle reperfusion. Therefore, in clinical cardiac surgery, it is prudent to keep reperfusion pressure at about 30 mmHg for the first 60 to 120 seconds of reperfusion. Because of reactive hyperemia present at that time, the reperfusion flow rate may nonetheless be large.

Some experimental studies have suggested that reperfusion pressure should be no higher than 50 mmHg, lest excessive myocardial edema develop; others have suggested that it may be as high as 100 mmHg. These differences may be the result of species differences. In a canine model, 1 hour of hyperkalemic reperfusion at 80 mmHg with electromechanical quiescence resulted in improved myocardial function with no more myocardial edema than from normokalemic reperfusion and rapid resumption of cardiac activity. The importance of maintaining a sufficient coronary perfusion pressure at this stage has been well documented in the
diastolically arrested canine heart exhibiting maximal coronary vasodilatation. In that model, endocardial flow falls steeply when coronary perfusion pressure is reduced from 70 mmHg to 40 mmHg. Reduction of perfusion pressure to 20 mmHg leads to substantially increased heterogeneity of flow (Fig. 3-5). Clinical experience at UAB demonstrated the efficacy and safety, after the first 60 to 120 seconds, of maintaining reperfusion pressure between 50 and 75 mmHg, or at the preoperative diastolic arterial blood pressure of the patient, whichever was lower.

Flow and Resistance

At the beginning of reperfusion, coronary resistance is very low, primarily as a result of reactive hyperemia, with additive effects from the cold temperature of the myocardium and the action of vasoactive substances, such as adenosine and lactic acid, that accumulate during the ischemic period. Thus, coronary blood flow is very high initially, even with low reperfusion pressure, but begins to fall within a few minutes of beginning reperfusion.

Subsequently, reperfusion flow is usually about 150 mL · min⁻¹ in adults (about 100 mL · min⁻¹ · m⁻² body surface area). This is about 40 mL · min⁻¹ · 100 g⁻¹ of heart muscle, approximately half the value for normal hearts, but it appears to be adequate in the nonworking empty heart being reperfused under these conditions. In similar experimental models of normal hearts, flow after the initial hyperemia is higher and near control level.

Temperature

In practice, the temperature of the reperfusate is initially about 35°C because of the characteristics of the heat exchange mechanism in the reperfusion circuit. After 2 to 3 minutes, the temperature rises to 37°C. There may be advantages to this gradual return to normothermia. Normothermia is advantageous to the normal function of enzyme systems.

Suppression of Formation of Oxygen-Derived Free Radicals and Enhancement of Free Radical Scavengers

Allopurinol, a xanthine oxide inhibitor, given just before reperfusion, protects the previously ischemic isolated rat heart from reperfusion injury, presumably by slowing conversion of hypoxanthine and xanthine to superoxide ions. Deferoxamine, given just before reperfusion, is also protective in experimental models, presumably by chelating iron and slowing formation of highly damaging hydroxyl radicals from superoxide radicals. Their use during early reperfusion has also been shown to be advantageous in experimental models. However, use of blood as the reperfusate, with its naturally occurring free radical scavengers, appears to obviate need for these agents in clinical cardiac surgery.

Duration

Recovery is not complete at the end of the hyperkalemic phase of controlled reperfusion. This may be because at this time (1) cellular recovery from ischemia is incomplete, and (2) inhomogeneity of myocardial perfusion probably persists. Controlled normokalemic reperfusion with adequate aortic root pressure should be continued until the heart is beating forcefully and is in sinus rhythm. This stage is usually reached 10 to 20 minutes after the beginning of reperfusion. In an experimental study, this length of time has been shown to be required for return of normal coronary vascular resistance, myocardial oxygen consumption, myocardial lactate levels, and ventricular function. Although ATP levels have not yet returned to normal, at this stage the heart itself is able to generate an adequate coronary perfusion pressure. Controlled aortic root reperfusion can therefore be discontinued by removing the aortic clamp, with proper precautions (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” later in this chapter).

Reperfusion with the aorta clamped, as described above, has been called “hot shot.” In practice, controlled reperfusion with the aorta clamped may not be necessary; reperfusion by pump flow supported by pharmacologic manipulation may be adequate.

Adenosine

Adenosine is a potent coronary vasodilator with effects that can reverse coronary artery spasm, increase flow to the myocardial microvasculature during reperfusion, replenish high-energy phosphates, and retard no-reflow effects through its antiplatelet and antineutrophil activity. Studies by Kim and
Ischemic Postconditioning

The proposed mechanisms of ischemic postconditioning are similar to ischemic preconditioning (see Advantageous Conditions During Ischemia earlier in this chapter). Although studies in cardiac surgery have shown a beneficial effect, this technique has not gained general application in clinical cardiac surgery.

METHODS OF MYOCARDIAL MANAGEMENT DURING CARDIAC SURGERY

The objective of any type of myocardial management during CPB should be limiting injury during ischemia by some combination of myocardial hypothermia, electromechanical arrest, washout, \( O_2 \) and other substrate enhancement, oncotic manipulation, and buffering.

No single method of myocardial management is unequivocally the best. Many different methods are in use by surgeons obtaining good results. Surgeons necessarily make a decision as to the method to be used each time they perform a cardiac operation, often based on “preferences” rather than on rigorous comparisons between methods. A number of factors influence the surgeon’s preference:

1. The surgeon’s specific surgical techniques or operative sequencing that influence duration of aortic clamping
2. Strength of the surgeon’s desire to have a quiet, bloodless heart
3. Strength of the conviction that cardiac surgery without myocardial necrosis or residual stunning is desirable and possible despite the added complexity to achieve these goals
4. Institutional environment
5. Costs

Continuous Normokalemic Coronary Perfusion

Empty Beating Heart

The earliest intracardiac operations were performed on normothermic, perfused, empty beating hearts. Experimental studies had been interpreted as showing “normal left ventricular function” after 30 minutes to 3 hours of CPB with the heart perfused, empty, and beating.

Current information indicates that the method is not ideal. Water tends to accumulate in the myocardium during CPB; as a result, ventricular distensibility in dog models is decreased by nearly 50% after 3 hours of CPB with the heart perfused, empty, and beating. The distribution of coronary blood is abnormal. The change in myocardial compressive forces and left ventricular wall geometry impede intracoronary collateral flow supplying potentially ischemic areas of myocardium. Occurrence of transmural myocardial infarction has been reported to be 15% when individual coronary artery perfusion was used for aortic valve replacement, with isoenzymatic evidence of myocardial necrosis in 70% of patients, proportions as high as in patients randomly assigned to cold ischemic arrest.

Despite these considerations, the method can serve well for various procedures and under certain circumstances may be combined with other methods of myocardial management. For example, in elderly patients or those with extensive arteriosclerosis of the aorta, CABG using both internal thoracic arteries may be performed using stabilizers without aortic clamping (“no-touch” technique) and CPB established by peripheral cannulation (e.g., axillary artery cannulation; see “Cardiopulmonary Bypass Established by Peripheral Cannulation” in Chapter 2). Tarakji and colleagues report that this technique reduces intraoperative and postoperative strokes in such patients (see “Coronary Artery Bypass Grafting Without Cardiopulmonary Bypass” in Chapter 7).

Mild or moderate whole-body, and thus cardiac, hypothermia are often combined with this method. McGoon and colleagues reported a series of 100 consecutive cases of isolated aortic valve replacement using this method, with no hospital deaths, evidence that, when properly used, the method can provide good results.

Perfusion of Individual Coronary Arteries

Individual coronary artery cannulation is necessary when perfusing the empty beating heart for surgery on the aortic valve. After CPB is established, the aorta is clamped (stopping flow of blood into the aortic root and ostia of right and left coronary arteries), and an incision is made into the first part of the ascending aorta. Small individual cannulae are placed into the ostia of right and left coronary arteries, and, by way of a separate pump, blood is infused into both. The cannulae tips are at least 3 to 4 mm long.

This technique works well in most patients, but it is not ideal. The tip of the cannula may extend beyond the bifurcation of the left main coronary artery, so that only the left anterior descending or circumflex artery is perfused. In about 1% of patients, these two arteries arise separately from the aortic sinus, making proper individual cannulation even more difficult. The prevalence of left dominant systems in patients with aortic stenosis secondary to congenital bicuspid valves is higher than normal; in left dominant systems, the left main coronary artery is shorter than normal, again making individual coronary perfusion more difficult. In about 50% of patients, the conus artery supplying the infundibulum of the right ventricle arises separately from the aortic sinus and is not perfused by a cannula inserted into the right coronary ostium. Also, mechanical injury to the coronary ostia can occur whenever techniques of direct coronary ostial cannulation are used; this results in intraoperative myocardial infarction and late coronary ostial stenosis.

The method in practice is not without periods of global myocardial ischemia. One occurs between aortic clamping and initiation of right and left coronary artery perfusion. This interval varies, depending on the sequences elected by the surgeon, but can seldom be reduced below 2 to 3 minutes.

If exposure for the operation is hampered by leakage of blood around the cannulae, coronary perfusion may have to be discontinued for short periods during the procedure.

When this method is used, the flow rate is of obvious importance, and information obtained for patients in whom...
the flow was delivered separately and directly into right and left coronary arteries during aortic valve replacement provides useful information in this regard.\textsuperscript{88} This information indicates that total coronary blood flow of about 200 to 250 mL·min\(^{-1}\) (≈120 to 150 mL·min\(^{-1}\)·m\(^{-2}\)) is optimal, at least at 30°C. This flow is below 300 mL·min\(^{-1}\), which under some circumstances produces histologic evidence of myocardial damage,\textsuperscript{52} yet is sufficient to prevent undesirable vasoconstriction, which leaves part of the microcirculation without flow or underperfused.

When this method is used, the heart should be kept beating; therefore, the perfusate should be warmer than 30°C. Sapon and colleagues\textsuperscript{522} showed that when ventricular fibrillation persisted throughout the period of coronary perfusion, risk of perioperative infarction and death was higher than if the heart were beating. This would be expected from knowledge of subendocardial blood flow during ventricular fibrillation.\textsuperscript{86,113}

**Hypothermic Fibrillating Heart**

In continuous coronary perfusion with ventricular fibrillation, fibrillation can be maintained by an electrical current, which is necessary when the perfusion is at 37°C, or it may be spontaneously or electrically induced and maintained by moderately hypothermic (25°C-30°C) coronary perfusion. The latter condition is desirable. Coronary perfusion can be through the intact aortic root (as in CABG) or by individual coronary perfusion cannulae during aortic valve replacement.

A number of theoretical objections to the method can be raised. For example, perfusion of the subendocardium is impaired during CPB and ventricular fibrillation, particularly in hearts with ventricular hypertrophy. However, good clinical results have been obtained using either normothermic CPB and electrically maintained ventricular fibrillation or moderate hypothermia and ventricular fibrillation sustained only by hypothermia, or profound cardiac hypothermia and ventricular fibrillation. Akins has reported excellent results from CABG using the latter method.\textsuperscript{55,66} Time constraints must apply to this method, as to most others, but they have not been defined. The surgical conditions that exist with this method are better than with the beating heart, but most surgeons find them less satisfactory than with a cardioplegic technique.

**Moderately Hypothermic Intermittent Global Myocardial Ischemia**

Use of intermittent cardiac ischemia with moderate cardiac hypothermia requires conducting CPB with the perfusate temperature at 25°C to 30°C. The surgeon works on or in the heart intermittently for periods of 10 to 15 minutes, during which time the ascending aorta is clamped (to stop coronary perfusion) or individual perfusion into the coronary ostia is interrupted. Between these periods, the aortic clamp is released (or individual coronary perfusion resumed) for 3 to 5 minutes. When the technique is used optimally, the heart is made to beat (not fibrillate) during this interval. This was the method most commonly used during the 1960s and early 1970s, but is used by some surgeons today.

The clinical results can be good, as was demonstrated by McGoon and by Bonchek and colleagues.\textsuperscript{116,24,111} McGoon’s analysis of one group of patients—those receiving valved extracardiac conduits—indicated no relationship between the proportion of nonsurvivors in the experience and cumulative aortic clamp time. However, because 35% of the 468 patients in the group had low cardiac output postoperatively\textsuperscript{111} (in which subset the mortality was 52%), the method must have been producing myocardial damage. Reduto and colleagues found no difference in left ventricular performance early after CABG, regardless of whether this or cold cardioplegic myocardial protection was used.\textsuperscript{65}

The method does not provide optimal exposure for operations inside the heart, but does provide reasonable working conditions for CABG. Unless the heart is electrically fibrillated just before aortic clamping, it continues to beat during much of the ischemic period, making precise repair difficult. Each time coronary perfusion is recommenced, coronary (and perhaps systemic) air embolization may occur, despite precautions against it. A considerable amount of blood comes into the heart during periods of coronary perfusion, stressing the intracardiac sucker systems and thereby increasing blood damage and interfering with the smooth and efficient flow of the operation. Moreover, each time the coronary arteries are perfused in this uncontrolled manner, a reperfusion injury may occur.

**Profoundly Hypothermic Global Myocardial Ischemia**

The heart may be profoundly cooled by the perfusate, by filling the pericardium with very cold saline solution, or by both, after which the aorta is clamped. The cardiac operation is done during a single period of aortic clamping.\textsuperscript{59,116,94,127,518} In clinical practice, myocardial temperature is generally about 22°C with these methods;\textsuperscript{117} most surgeons believe that this allows 45 to 60 minutes of safe global myocardial ischemia.

This technique provides better operating conditions than those discussed earlier, and good results have been obtained with it.\textsuperscript{110} Despite this important consideration, a randomized study of patients undergoing aortic valve replacement showed that this technique results in as much myocardial necrosis as does continuous individual coronary perfusion.\textsuperscript{54}

Profoundly hypothermic cardiac ischemia without cardioplegia may be preferred for infant cardiac surgery in which hypothermic circulatory arrest is used. Part of the rationale for this preference is that no perfusate passes through the heart to rewarm or inadequately reperfuse it during circulatory arrest, as may happen when CPB is continued.

**Drug-Mediated Myocardial Protection**

Both β-adrenergic receptor blocking and calcium channel blocking drugs, in conjunction with one of the other methods, have been used as part of the myocardial management by some groups.\textsuperscript{112,111} The calcium channel blocking agents verapamil and diltiazem have seemed particularly advantageous because of their prevention of calcium influx into cells and their coronary vasodilatory effects.\textsuperscript{85} However, these drugs are potent negative inotropes and produce prolonged electromechanical quiescence, at least when used clinically in cardioplegic solutions.\textsuperscript{67,110}

Particularly good results have been obtained by giving lidoflazine intravenously just before CPB and using moderately hypothermic intermittent cardiac ischemia.\textsuperscript{94,81} Lidoflazine is believed to be a nucleotide transport inhibitor, which
results in increased myocardial accumulation of endogenous adenosine during ischemia, increased lactate extraction during reperfusion, and improved postischemic function. The basic action of lidocaine is complex and appears to be different from that of β-blocking and calcium channel blocking drugs.

Certain drugs have been shown in experimental studies to reduce reperfusion damage related to oxygen-derived free radicals (see Advantageous Conditions during Reperfusion earlier in this chapter). However, when using blood cardioplegia and pressure-controlled, initially hyperkalemic, blood reperfusion, incorporation of free radical scavengers has not been demonstrated to provide additional protection.

Cold Cardioplegia (Multidose)

The underlying principles of all cardioplegic solutions are listed in Box 3-1. Inducing chemical arrest to conserve energy during the period of myocardial ischemia can be accomplished by one or more of the following methods:

1. Inhibition of the fast sodium current to prevent conduction of the myocardial action potential by one or more of the following methods:
   a. Extracellular hyperkalemia
   b. Sodium channel blockers (e.g., lidocaine)
   c. KATP channel openers (e.g., adenosine)

2. Inhibition of calcium activation of myofilaments to prevent myocyte contraction by one or more of the following methods:
   a. Zero extracellular calcium
   b. L-type calcium channel blockers (e.g., magnesium)
   c. Direct myofilament inhibition with agents such as 2,3 butanedione monoxime (BDM)

Cardioplegic Solution

There are both asanguinous solutions and those that are mixed with blood (at a 2 : 1 or 4 : 1 blood-to-solution ratio), and extracellular solutions and intracellular solutions as distinguished by their potassium concentrations (Table 3-1). Some believe that the components of the solution, particularly K+ concentrations, should be altered according to solution temperature, timing of infusion (initial, maintenance, and terminal), and presumed energy state of the myocardium. In general, K+ concentration is lowered for maintenance, and substrates are added for energy-depleted hearts. Delivery can be intermittent (multidose) or continuous; in the latter case the K+ concentration is lower than for intermittent delivery (Box 3-2).

Hyperkalemic cold sanguinous cardioplegia is advantageous and is preferred, although asanguinous cardioplegia may work equally well. The Buckberg formulation (cold, oxygenated, hyperkalemic blood-crystalloid mixture, with lowered free calcium concentration, added glucose, and added buffering capacity) may be preferable to simple hyperkalemic blood (see Table 3-1). The latter, however, is less costly because it involves only transferring blood perfusate from the CPB oxygenator to a separate reservoir–heat exchanger–pump system, adding sufficient potassium chloride to make it cardioplegic (potassium concentration about 22 mmol · L⁻¹).

Technique of Antegrade Infusion

After CPB is established with the perfusate at 32°C (under which conditions ventricular fibrillation should not develop), an aortic root catheter is inserted through a previously placed purse-string stitch, attached to the cardioplegia line, and de-aired. Optionally, the pressure line of the cannula may be attached to a strain gauge for continuous measurement of aortic root pressure. The aorta is clamped as soon as the aortic root catheter is in place, and in any event before the heart has been cooled sufficiently by the whole-body perfusion so that it becomes arrhythmic or develops ventricular fibrillation.

Cold cardioplegic infusion is begun promptly at a flow of 150 mL · min⁻¹ · m⁻² (based on the data for continuous direct coronary perfusion described earlier in this chapter) for

### Box 3-1 Principles of Cardioplegic Protection

**Arrest**
A rapid and effective induction of diastolic arrest to keep the myocardium relaxed and minimize cellular use of ATP

**Myocardial Protection**
Protective effects to delay the onset of irreversible injury caused by global ischemia and limit the extent of reperfusion injury

**Reversibility**
Readily reversible cardioplegic effects on washout of prompt resumption of heart function

**Low Toxicity**
A short half-life with no toxic effects on other organs after cessation of cardiopulmonary bypass

From Fallouh and colleagues.¹²

\(^a\)This formulation is intended for dilution by two or four parts blood (perfusate) to solution.
\(^b\)Concentration is diluent dependent.
\(^c\)Added to the commercially prepared solutions.
\(^d\)For warm induction and reperfusion strategies only.

3 minutes in adults; the average adult is given a dose of about 750 mL. In infants and children with a body surface area of less than 1 m\(^2\), the infusion is given at the same flow rate (150 mL · min\(^{-1}\) · m\(^{-2}\) body surface area), but for only 2 minutes. Occasionally the monitored aortic root pressure is less than 30 mmHg, in which case the flow rate, but not the total dose, is increased. However, low aortic root perfusion pressure may be due to aortic regurgitation, hidden by the action of a left ventricular vent; the surgeon must be certain that this is not the situation. In patients with severe ischemic heart disease, the aortic root pressure sometimes rises above 75 mmHg, but the flow should not be reduced.

External cooling of the heart may be established while the cardioplegic infusion is being administered. An isolating pad can be placed between the heart and the left side of the pericardium containing the phrenic nerve. A thin layer of ice slush (or ice-cold saline) is placed over the anterior surface of the heart. Later, whenever the heart will be in a stable position for a time, a thin layer of ice slush can be placed on the surface. The slush is never placed in the pericardial space itself, because left phrenic nerve damage may result. As the slush melts, the fluid is aspirated with the high-vacuum sucker. If it is surgically inconvenient, the slush is omitted.

Neither left nor right ventricle is allowed to become distended at any time. A left ventricular vent (introduced through a right pulmonary vein) is used for some operations, suction through an aortic root catheter for others, and simple needle aspiration of the ventricle across the ventricular septum for others.

Cardioplegic solution is reinfused about every 25 minutes. The initial flow rate is used, and the surgeon must be certain that the aortic valve has closed as the infusion begins. If it has not, a few pinches of the proximal aorta usually accomplish valve closure. Reinfusion is given for 30 to 60 seconds. After the first infusion, the potassium concentration of any subsequently infused cardioplegic solution is reduced to about 10 mmol · L\(^{-1}\).

Should serum potassium levels reach 7 to 8 mEq · L\(^{-1}\) (a rare occurrence), a bolus injection of 400 mg · kg\(^{-1}\) of glucose (as 50% glucose) and 0.2 unit · kg\(^{-1}\) of soluble insulin may be given after the beginning of myocardial reperfusion. Because the levels of both whole-body intracellular
potassium\textsuperscript{1} and circulating insulin\textsuperscript{2} are abnormally low at
this point, these maneuvers are physiologically reasonable. Alternatively, the technique of ultrafiltration during CPB (see “Changes during Cardiopulmonary Bypass” in Chapter 2) may be used to lower elevated serum potassium levels induced by multidose cardioplegia.

**Technique of Retrograde Infusion**

Retrograde infusion of cardioplegic solutions directly into the coronary sinus was suggested by Lillehei and colleagues in 1956.\textsuperscript{1,10} Many have found this technique as effective as antegrade infusion,\textsuperscript{2,20} although the right ventricle (particularly its midportion) and right atrium are less well perfused. When instead retrograde infusion is administered through the right atrium and right ventricle, this problem may be avoided.\textsuperscript{21} Retrograde coronary sinus infusion is particularly advantageous in the presence of acutely developing high-grade coronary artery stenoses or obstructions.\textsuperscript{22}

The surgeon should arrange to deliver either antegrade or retrograde cardioplegia, or both. Either before or after CPB has been established, a purse-string stitch is placed in the right atrial wall, and a small stab wound is made in the middle, through which the retrograde infusion catheter is introduced and under digital control manipulated into the coronary sinus.\textsuperscript{23} The catheter is attached to one arm of the cardioplegia infusion line and de-airred. The pressure measuring arm of the catheter is connected to a manometer. Coronary sinus pressure must not be allowed to rise above 50 mmHg during coronary sinus infusion.

Indications for combined antegrade-retrograde or totally retrograde infusion vary among surgeons,\textsuperscript{24} in part because no clear advantage of retrograde over antegrade infusion of cardioplegic solutions has been identified in patients undergoing elective operations.\textsuperscript{25} However, for aortic valve replacement and during mitral valve operations, refinements of cardioplegic solution are often more conveniently given by the retrograde method. The same may be true for many operations performed through the right atrium for congenital heart disease.

A conscious decision to use both the antegrade and retrograde routes of cardioplegia routinely, delivered in either an alternating sequential fashion or simultaneously, has evolved in the practice of some institutions.\textsuperscript{26,27} This method allows rapid electromechanical quiescence, protects against uneven cardioplegic distribution, and may maximize the duration of ischemia while avoiding cardioplegia overdose. The combined approach has also been successful in pediatric patients.\textsuperscript{28,29} Thus, we believe retrograde cardioplegia is better viewed as synergistic and complementary to antegrade cardioplegia rather than as the sole method of myocardial management.\textsuperscript{30}

Severe obstructive manifestations of coronary artery disease are perhaps the best example for the superiority of retrograde cardioplegia. These include left main lesions and acute coronary syndromes.

Various procedures on the aortic valve and the ascending aorta demanding long clamp times are safely accomplished using coronary ostial infusion supplemented by retrograde infusion. These include acute aortic dissections and the Ross procedure.

Retrograde cardioplegic myocardial protection has some disadvantages. It clearly has various degrees of maldistribution to the right ventricle.\textsuperscript{31,32} There is the occasion when a left superior vena cava is encountered and is unrecognized. Infrequently, the retrograde cannula cannot be placed or is dislodged. There may be less satisfactory protection in hearts with severe left ventricular hypertrophy. Application may be difficult in children and sometimes impossible in neonates. Coronary sinus rupture is a well-known complication (it can be dealt with before separation from CPB by closure of the rupture with fine suture or oversewing the sinus at the site of rupture). Finally, retrograde cardioplegia demands more cannulae, and in some situations seems to clutter the field in greater measure than its benefit.

**Results of Cold Cardioplegia**

Despite several randomized trials and numerous observational studies, the quantitative advantage of the cold cardioplegic technique over other methods of myocardial management in low-risk patients is not unequivocally defined. This alone suggests that it may be small in routine operations performed with reasonable dispatch. The technique facilitates the cardiac operation, and it is the technique most widely used today.

Even with cold cardioplegia, the safe duration of global myocardial ischemic time is not unlimited. Furthermore, it varies according to preoperative ventricular hypertrophy, ventricular function, and energy charge of the myocardium. In general, it is probably about 100 minutes with this particular technique and without controlled reperfusion.

Antegrade cardioplegia has proved safe and effective over many years and in many clinical settings. It is easily accomplished and requires little special equipment. However, myocardial protection in some situations is imperfect using classic antegrade cardioplegia, and thus outcomes may be improved with retrograde cardioplegia delivery.

Retrograde delivery may be superior or synergistic in redo CABG, particularly in the presence of narrowed or obstructed saphenous vein grafts or with an open left internal thoracic artery to an obstructed left anterior descending coronary artery. When CABG is planned in the presence of mild aortic regurgitation (valve not replaced), retrograde cardioplegia is optimal for induction and maintenance. This is also true for other procedures with mild aortic regurgitation in which the aorta need not be opened for direct infusion.

**Single-Dose Cold Cardioplegia in Neonates and Infants**

An opinion has been expressed elsewhere in this chapter that (1) no compelling evidence exists that a different method of myocardial management is required in neonates and infants than in older patients, even though some of the characteristics of the heart in these small patients are different from those in older patients, and (2) the optimal method of myocardial management in general remains arguable.

A method that has given excellent results in neonates and infants is single-dose, oxygenated St. Thomas solution (see Table 3-1). Using a simple pressure bag, it is infused into the aortic root proximal to the aortic clamp. The dose is 20 mL · kg\textsuperscript{-1} and is not repeated.

An exception is the first stage of the hypoplastic left heart operation (Norwood operation). The ascending aorta is thin and small in this situation. Simple cold ischemic arrest may be used, primarily because this avoids inserting a needle into
the delicate ascending aorta. However, because of the critical importance of right (single) ventricular function in this and other operations for single ventricle, many neonatal cardiac surgeons use single-dose cardioplegia administered through a fine catheter or other techniques (see Chapter 49).

The del Nido pediatric cardioplegic solution is discussed later under “Neonates and Infants” under Special Situations and Controversies.

Continuous Cardioplegia

**Cold Perfusion**

Continuous antegrade cold blood cardioplegia has been used as an alternative to single-dose and multidose intermittent cold cardioplegia. Khuri and colleagues have reported data from measurement of myocardial pH indicating that, at least in hypertrophied hearts, the myocardial milieu is more normal, although not completely normal, with this method than with intermittent cold cardioplegia. Clinical experiences suggest that retrograde continuous cold cardioplegic perfusion through the coronary sinus also provides an excellent method of myocardial management during cardiac surgery. Some have used this method after giving an initial antegrade dose of cold cardioplegia. Under experimental conditions, cold retrograde blood cardioplegia after initial antegrade cold blood cardioplegia has been found to maintain optimal myocardial pH.[15]

**Warm Perfusion**

Continuous warm blood cardioplegia, administered by antegrade infusion or by retrograde coronary sinus infusion after an initial antegrade dose, has also been used for CABG and other cardiac operations.[17,52,53] Some groups have found recovery of ventricular function better with use of warm continuous blood cardioplegia than with intermittent cold cardioplegia.[17] Others have found similar efficacy between warm and cold.[57] Although continuous warm blood cardioplegia provides good protection of the myocardium, it is surgically inconvenient for certain operations.

Cold Cardioplegia, Controlled Aortic Root Reperfusion, and (When Needed) Warm Cardioplegic Induction

In the belief that control of all aspects of the reperfusion may be even more important than details of cold cardioplegia, and that acutely ill patients coming to the operating room require a special form of myocardial management, the technique described in this section may be used. During reperfusion the heart is separated from the ongoing events in the remainder of the body for a brief time. The technique is surgically convenient, prolongs the operation only mildly, is essentially devoid of ventricular fibrillation, minimizes myocardial stunning and myocardial necrosis, and appears to result in better postoperative cardiac performance than methods previously used.[19,39] Yet the proof of its advantages has remained as difficult to obtain as for other techniques, which probably accounts for the fact that it is not, as yet, widely used in its entirety.

Some may wish to use simpler methods for routine operations and to restrict the use of this method for more complex high-risk operations. The problems with such a plan are the usual operational disadvantages of a surgical method that is used infrequently rather than routinely (see “Human Error” in Chapter 6), and the fact that even routine operations have a small mortality and occasionally considerable morbidity, which may be nearly eliminated by more perfect myocardial management.

**Circuitry**

A small, separate system on the pump-oxygenator, with its own miniaturized heat exchanger[9] and two pumps, manages aortic root infusions, retrograde infusions, or both. It enables the solution of choice to be infused at controlled temperature and pressure. Although the circuitry seems complex, from the surgeon’s standpoint its use is simple and extremely flexible. Perfusionists have demonstrated their ability to manage it both effectively and efficiently.

**Technique for Elective Surgery**

After the operation is completed, using cardioplegic myocardial management and with the aortic clamp still in place, controlled aortic root reperfusion is begun, initially using warm, hyperkalemic, modified, and enriched blood cardioplegia. The aortic root pressure is kept at 30 mmHg for the first 60 to 120 seconds of the reperfusion, for the reasons discussed earlier. The flow is then increased until the aortic root pressure is 50 to 75 mmHg in adults (or to the normal systemic arterial diastolic pressure in infants and children whose body surface area is <1 m²). A total of 500 mL of the modified blood reperfusate is administered. For patients with a body surface area of less than 1.5 m², the reperfusate volume = 500 × BSA + 1.5. Once that has been infused, the perfusionist continues the controlled aortic root reperfusion by arranging the circuit so aortic root perfusion continues with normothermic, normokalemic, unmodified blood.

During the controlled aortic root reperfusion, the surgeon must concentrate on avoiding ventricular distention, the adverse effects of which have been fully documented.[39,84] The heart remains flaccid and electromechanically quiescent for 2 to 10 minutes after the onset of the controlled aortic root reperfusion. During this time, the coronary resistance may rise, requiring the perfusionist to reduce the flow rate to maintain a constant aortic root pressure. Should that occur, boluses of 5 mL of nitroglycerin[5] may be administered into the line by the surgeon, although the value of this is uncertain.

When the period of quiescence passes and cardiac action begins, the initial rhythm frequently is AV dissociation. Very rarely, it is ventricular fibrillation.[19] The controlled aortic root perfusion continues. Small-volume pulmonary ventilation is begun, because the right ventricle pumps some blood through the lungs. Even the vented left ventricle will eject some blood into the isolated aortic root. The perfusionist must be alert to the need to reduce the aortic root perfusion flow rate to keep the aortic root pressure from becoming excessively high (>120 mmHg). At times, the perfusionist may need to place suction on the aortic root pressure catheter to prevent this problem. Controlled aortic root perfusion is continued until sinus rhythm has returned and ventricular contractions are strong. The interval between the beginning of the controlled aortic root reperfusion and the reaching of these end points

---

1Bentley (surface, stainless steel; priming volume, 120 mL; efficiency 0.8) or Shiley (surface, anodized aluminum; priming volume, 150 mL; efficiency 0.6).

2One milligram of nitroglycerin in 5 mL of a balanced salt solution.
is usually 10 to 25 minutes. When the end points cannot be reached, myocardial management was in some way imperfect, and the patient almost certainly will require pharmacologic or mechanical support after CPB.

When the end points are reached, the perfusionist places strong suction (rather than perfusion) on the aortic root catheter and partly occludes the venous line so that some blood passes into the right ventricle and through the lungs; the anesthesiologist intermittently inflates the lung to assist in moving any air that is present out of the pulmonary veins and left atrium into the left ventricle, which ejects it into the aortic root. The suction on the aortic root catheter evacuates any mobilized boluses of air as the surgeon ballots the left atrium and pulmonary veins. These procedures are repeated several times. Although strong suction continues on the aortic root catheter, the aortic clamp is released. As the clamp is released, the patient’s blood volume is rapidly augmented to bring left atrial or pulmonary artery wedge pressure to 6 to 10 mmHg so that the heart’s ejection will continue to maintain a good systemic arterial pressure and a good coronary perfusion pressure. Thereafter, the usual detailed de-airing procedure is followed (see “De-Airing the Heart” in Section III of Chapter 2). CPB is then discontinued; usually nothing remains but to establish hemostasis and close the chest.

**Technique for Energy-Depleted Hearts**

Patients who come to operation in acute cardiac failure with hemodynamic instability or are severely cyanotic have energy-depleted hearts. Specific efforts to improve the energy charge of the heart before submitting it to the period of global myocardial ischemia probably result in better cardiac structure and function postoperatively. Survival should thereby be enhanced.

After making the median sternotomy, CPB at 35°C is established as expeditiously as possible. The aortic root catheter is inserted. The aorta is clamped, and warm hyperkalemic, modified and enriched blood infusion is begun. The infusion is given at the usual flow rate for induction of cardioplegia and continued for 5 minutes. The perfusionist then makes the cardioplegic solution as cold as possible while the aortic root infusion of the same cardioplegic solution continues for another 3 minutes.

Subsequent cold infusions are given every 20 to 30 minutes as usual, except with a potassium concentration of about 10 mmol · L⁻¹. After completing the cardiac procedure, warm reperfusion is performed in the standard manner. (See Special Situations and Controversies in this chapter for details on myocardial management when an acute coronary occlusion immediately precedes the operation.)

**ANCILLARY MEASURES FOR PREVENTING MYOCARDIAL DAMAGE**

Important myocardial necrosis can develop between induction of anesthesia and start of CPB in as many as 30% to 40% of patients undergoing CABG when anesthetic and supportive management is suboptimal (Roe CR: unpublished data, 1976). Lell and colleagues have shown that this proportion can fall to almost 3% under optimal circumstances.¹⁶ No doubt patients other than those undergoing CABG are also at risk of developing myocardial damage during this period, particularly those with marked ventricular hypertrophy or reduced myocardial energy charge. Proper intraoperative management before and after CPB avoids increased myocardial oxygen demand (which can be caused by arterial hypertension, tachycardia, and increased endogenous catecholamine secretion from anxiety and excitement). It avoids high ventricular end-diastolic pressures and the concomitant detrimental effect on perfusion of the subendocardium.²¹¹ Good management maintains an optimal myocardial oxygen supply by maintaining adequate arterial oxygen levels and arterial blood pressure and adjusts ventricular preload and afterload to achieve a reasonable compromise between adequacy of cardiac output and avoidance of deleterious effects (see Chapter 4 for details).

Important perioperative myocardial necrosis can develop because of events occurring after CPB, either before or after the patient leaves the operating room. These may be events that produce imbalances between myocardial oxygen demand and supply. Use of catecholamines for treating low cardiac output early after CPB can result in myocardial necrosis.²¹¹,²³²

**SPECIAL SITUATIONS AND CONTROVERSIES**

**Species and Model Differences**

Possible species and experimental model differences pose a major problem in generating inferences regarding myocardial management during cardiac surgery in human subjects. For example, extensive myocardial edema is frequently observed after ischemia and reperfusion in experimental studies of many different types in many different animal models. Yet in clinical experience it has been rarely evident, except for instances of prolonged and severe damage and of some operations in young patients. In support of this, a careful study in humans using two-dimensional echocardiography failed to disclose any increase in left ventricular mass (a reasonably sensitive indicator of increased myocardial water) after ischemia and reperfusion in experimental studies of certain cardiac events begin at birth and change the characteristics of the neonatal heart into those of a mature heart. The time frame of many of these events is not known. As a result, the rather noncompliant neonatal heart gradually becomes more compliant and proceeds from having little functional reserve to having that of the mature heart. Coronary reserve may be greater in immature hearts.¹¹¹

**Neonates and Infants**

Certain cardiac events begin at birth and change the characteristics of the neonatal heart into those of a mature heart. The time frame of many of these events is not known. As a result, the rather noncompliant neonatal heart gradually becomes more compliant and proceeds from having little functional reserve to having that of the mature heart. Coronary reserve may be greater in immature hearts.¹¹¹
In general, the normal neonatal and infant heart is believed to be more resistant to ischemic and reperfusion damage than is the normal adult heart, even when both are protected by hypothermia during the ischemic period. This greater resistance is not necessarily present in hearts of cyanotic neonates and children or those in acute or chronic heart failure.

**Ischemic Damage**

The cell membrane (sarcolemma) of myocytes from immature hearts is generally believed to be more resistant to the calcium paradox and other forms of calcium damage than that of myocytes from mature hearts. Related to this is the finding that the sarcolemma of immature hearts binds calcium more effectively than that of mature hearts. All this points to greater stability of the sarcolemma of immature hearts and tighter glycolylyc junction, and consequently to greater resistance to the intracellular influx of calcium during and after ischemia. (However, some data suggest less membrane stability and less resistance to calcium influx in the newborn, in contrast to the neonatal heart.) By contrast, immature hearts do not have as good a capacity to sequester (immobilize) intracellular calcium as do mature hearts, making them more vulnerable to damage once calcium has entered the cell.

The adult myocardium normally relies primarily on fatty acids to produce energy for myocardial contraction and cell survival. This is also true in the neonatal heart; in contrast to the adult heart, the neonatal heart has relatively large glycogen stores and thus a relatively large capacity for anaerobic glycolysis. This feature begins to disappear shortly after birth and has disappeared completely by about 2 months of age. ATP utilization appears to be slower in immature hearts because of lower contractile energy requirements. These mechanisms and perhaps others probably provide to both neonatal and immature but otherwise normal infant hearts a higher tolerance to ischemia than that possessed by adult hearts.

Larger stores of amino acids in neonatal hearts also contribute to their increased capacity for anaerobic metabolism, including ATP production, and this persists throughout infancy. This anaerobic ATP production appears to be for the transamination and substrate level phosphorylation of glutamate and pyruvate. This may be expected to result in better maintenance of cellular integrity during ischemia and thereby better functional recovery after ischemia than experienced by adult hearts. These considerations also help explain the demonstrated value of amino acid supplementation for improving tolerance of the immature heart to ischemia and hypoxia. However, some have found the immature myocardium (less than about 18 months old) to be deficient in cytosolic 5'-nucleotidase and thereby less able than mature myocardium to convert cyclic AMP and inosine back to ATP.

**Reperfusion Damage**

Complement activation and leukocyte infiltration play as important a role in reperfusion injury in immature hearts as they do in mature hearts. Other than this, little is known about possible differences in susceptibility of immature hearts to reperfusion (as compared with ischemic) injury, compared with mature hearts.

**Abnormal Immature Hearts**

These characteristics of normal neonatal and infant myocardium may or may not be characteristic of abnormal neonatal or infant hearts. Neonates and infants who come to cardiac surgery are unlikely to have normal myocardium, because they are usually either cyanotic or in heart failure, or both. Julia and colleagues have shown that immature hearts in acute cardiac failure or recently subjected to hypoxia develop profound functional depression after periods of ischemia well tolerated by normal immature hearts. Thus, neonates and infants who come to open heart surgery probably have hearts that are not unusually resistant to the damaging effects of global myocardial ischemia. Cyanosis, both acute and chronic, accelerates these damaging effects and lessens posts ischemic recovery, probably as a result of its effect on myocardial metabolism.

Buckberg has demonstrated experimentally that cyanotic neonates and infants may suffer myocardial injury simply by exposure to reoxygenation during CPB, particularly the initial stages of CPB. This hypoxic/reoxygenation injury may be avoidable by beginning CPB at the ambient oxygen tension of the hypoxic subject. Reoxygenation injury is linked to oxidant damage and a lack of antioxidant reserve capacity in cyanotic immature myocardium. Reoxygenation is associated with elevation of conjugated dienes, generation of hydroxyl radicals causing lipid peroxidation, and release of nitric oxide. Buckberg's studies further suggest that adding desferrioxamine and antioxidants (N-[2-mercaptopropionyl]-glycine, catalase, and coenzyme Q10) to the CPB prime might limit in vivo oxidant damage and improve myocardial functional reserve. The importance of these observations made in animal preparations has yet to be clarified in human neonatal myocardial management.

**Methods of Myocardial Management**

The effectiveness of cold cardioplegia in the immature heart is arguable. A paper by Bull and colleagues is often cited in the introduction to experimental papers on the subject, in support of the idea that cold cardioplegia as used in adults is not effective in young patients. However, these investigators found the “safe” ischemic time to be 65 minutes when intermittent aortic clamping was used and 85 minutes when cold cardioplegia was used. Another early experience found cold crystalloid cardioplegia advantageous in neonates and infants, as did Schachner and colleagues in a small randomized trial.

From experimental models, many different and sometimes conflicting inferences have been derived. In one experimental study, cold cardioplegia was found to reduce ischemic injury in immature hearts. Multidose administration of cardioplegic solutions was shown to be disadvantageous in immature hearts. Various crystalloid solutions have been found experimentally to be superior to others for use in immature hearts. At least one study detected superior myocardial protection in infants and young children with cardiac surgery using cold blood cardioplegia rather than crystalloid St. Thomas solution. Other experimental studies have shown that including glutamate and aspartate in the warm induction of cardioplegia and in the reperfusion provides additional benefit.

One point of view, compatible with all available evidence but not with the opinions of some, is that the basic methodology for myocardial management in neonates, infants, and
Buffers crystalloid solution closer to a pH of 7.4

Lidocaine 1% 13 mL
KCl 2 mEq · mL⁻¹ 13 mL

Plasma-Lyte A Electrolyte-balanced and pH-adjusted carrier solution
Sodium bicarbonate Buffers crystalloid solution closer to a pH of 7.4
Mannitol Used to decrease myocardial edema and serve as an oxygen free radical scavenger

From del Nido and colleagues.⁹⁴

Ca²⁺ concentration is lower to address the evidence of protective calcium overload.⁴²,⁶,⁷,⁸

The del Nido cardioplegic solution (Baxter) is combined with blood in a ratio of four parts solution to one part blood. The accumulated clinical experience with del Nido solution in neonates, infants, and children has been very favorable, with most surgeons noting more rapid return of sinus rhythm and excellent cardiac function despite longer recommended periods between cardioplegia administration (30-45 minutes vs. 20-30 minutes) compared with Buckberg cardioplegia.

When using the technique of cold cardioplegia, controlled aortic root reperfusion, and (when needed) warm cardioplegic induction, all catheters, cannulae, doses, flow rates, and pressures should be scaled appropriately to small patients, as has been described.

Aortic Valve Surgery

When aortic regurgitation is mild in patients requiring aortic valve replacement or other operations, the initial cardioplegic induction may be administered antegradely in the usual way through the unopened aortic root or retrogradely via the previously placed coronary sinus cannula. If the aortic root infusion maintains an adequate pressure in the aortic root, and thus confirms that runoff is minimal, the left atrial vent line is clamped, the infusion continued, and the left ventricle gently massaged manually during the infusion period. This prevents left ventricular distention and assists in perfusing the coronary arteries. If runoff is excessive, an aortotomy is made and the cold cardioplegic infusion is given directly into the coronary ostia (see “Perfusion of Individual Coronary Arteries” earlier in this chapter).

Unless the aortic valve is completely competent, which is uncommon, induction of cold cardioplegia for aortic valve repair or replacement is best accomplished by direct infusion of the solution into the coronary ostia, preceded by retrograde induction via the coronary sinus. The apparently complex sequence about to be described is unnecessary for cardioplegia with the capability for retrograde delivery, but is needed until retrograde reperfusion is established as a useful modality.

The circuit is modified at the operating table in such cases by placing a Y connector in the antegrade cardioplegia tubing, one distal arm of which connects to the aortic root infusion catheter and the other to a second Y, to each arm of which an O-ring direct coronary perfusion cannula is connected. A clamp is placed just beyond the first Y on the tubing leading to the second Y and the direct coronary perfusion cannula. After CPB has been established and the aortic root catheter has been inserted, properly connected, de-aired, and the line leading to it clamped and the line to the second Y unclamped, the aorta is clamped, and the aortic root is opened transversely but not completely. One of the O-ring cannulae is inserted into the left coronary ostium and about three fifths of the initial cardioplegic infusion given. A second O-ring cannula is similarly placed in the right coronary ostium and the remaining two fifths of the cardioplegic infusion given. Ideally, and when easily accomplished, both infusions are given simultaneously. A 5-0 or 6-0 polypropylene suture is placed around each of the cannulae, brought out of the

---

children should be similar to that in adults. Little concerted effort has been made to overcome the technical difficulty of accomplishing this in very small hearts. For example, in many operations in neonates, the procedure is done largely through the right atrium; retrograde infusion of the sanguinous cardioplegic solution into the coronary sinus should be particularly convenient. In fact, the feasibility, safety, and efficiency of retrograde coronary sinus infusion of blood cardioplegic solution as maintenance cardioplegia has been demonstrated in the arterial switch operation and in complex arch reconstruction.⁶⁵

Despite the general point of view expressed earlier (that the methodology of myocardial management in infants should be similar to that in older and larger patients), there is considerable interest in and increasing experience with a cardioplegic solution that has a focused application in neonates, infants, and children. The del Nido cardioplegic solution (Table 3-2)⁵⁴ has undergone several modifications at various pediatric centers but contains the basic extracellular composition used in the Buckberg solutions, with the following major differences:

- Calcium concentration is lower to address the evidence that pediatric myocardium relies more on calcium flux for excitation-contraction and is less tolerant of postischemic calcium overload.
- Magnesium is increased to further depress cell excitability (and therefore cellular metabolism and ATP utilization) during the ischemic period.
- Magnesium is increased to further depress cell excitability (and therefore cellular metabolism and ATP utilization) during the ischemic period.
- Calcium concentration is lower to address the evidence that pediatric myocardium relies more on calcium flux for excitation-contraction and is less tolerant of postischemic calcium overload.
- Magnesium is increased to further depress cell excitability (and therefore cellular metabolism and ATP utilization) during the ischemic period.
- Calcium concentration is lower to address the evidence that pediatric myocardium relies more on calcium flux for excitation-contraction and is less tolerant of postischemic calcium overload.

adjacent aortic wall, and secured with a “snugger.” Subsequent cardioplegic infusions may be given in this manner or retrogradely via the coronary sinus (see “Technique of Retrograde Infusion” earlier in this chapter).

A major reason for preferring this arrangement for the induction and maintenance of cardioplegia lies in the reperfusion phase. All devices for aortic valve replacement, except the allograft, autograft, and stentless xenograft valve inserted free hand or as an aortic root replacement, leak a variable but usually considerable amount of blood from the aortic root back through the sewing ring, at least, into the left ventricle. The left ventricular vent can keep the vent decompressed, but maintaining desired aortic root pressure frequently becomes impossible during reperfusion via the aortic root. Therefore, the usually warm and initially hyperkalemic modified blood reperfusion after aortic valve surgery is infused through the direct coronary perfusion cannulae. Many surgeons use simultaneous retrograde coronary sinus infusion as an adjunct to this reperfusion phase, beginning with substrate-enhanced hyperkalemic blood, then switching to normothermic normokalemic blood. While this is proceeding, closure of the aortotomy begins. The left ventricular vent keeps the operative field dry even after cardiac action begins. The last few sutures of the aortotomy closure are placed but left loose.

When the heart is beating well and the criteria previously described for ceasing the controlled aortic root reperfusion are met, suction on the left ventricular vent is reduced to a low level or stopped. If necessary, the venous tubing is occluded briefly to drive a little blood through the lungs and back into the left ventricle. Blood ejected by the left ventricle now essentially fills the aortic root and escapes through the loose part of the suture line. An assistant clamps the tubing leading to the Y connector with its direct coronary perfusion cannulae and unclamps the line to the aortic root catheter, the perfusionist places mild suction on the aortic root catheter, and the surgeon removes the “snuggers” on the sutures around the coronary cannulae; the sutures and then the cannulae are removed, and the aortotomy sutures are snuggled and tied. Because the heart is beating well, aortic root pressure (being monitored by the aortic root cannula as usual) may tend to rise, but the perfusionist controls this by increasing suction on the aortic root pressure monitoring catheter as needed. The aortic clamp is still in place, so systemic air embolization is not possible.

By slightly occluding the venous line, the perfusionist causes the left ventricle to receive sufficient blood so that its ejection maintains an aortic root pressure of about 100 mmHg systolic. Suction continues on the aortic root catheter with minimal or no suction on the left ventricular vent, and usual de-airing procedures are accomplished (see Chapter 2). The aortic clamp is then removed, and the entire de-airing procedure is repeated. The remainder of the operation proceeds in the usual manner.

Coexisting Mild Aortic Regurgitation

Some cardiac operations are complicated by the presence of aortic regurgitation, too mild to justify aortic valve replacement (or repair) but sufficient to complicate myocardial management. If an appropriate aortic root pressure can be maintained during induction of cold cardioplegia and reperfusion, standard aortic root infusions are used.

If the regurgitation is such that an appropriate aortic root pressure cannot be achieved during administration of the cold cardioplegic solution or during reperfusion, cold cardioplegic solution is administered retrogradely through the coronary sinus. In the reperfusion phase, the heart can be carried through the initially warm hyperkalemic reperfusion and then the normokalemic reperfusion until cardiac action fully resumes, using exclusively retrograde perfusion through the coronary sinus.

Alternatively, the aortic valve can be made surgically competent for subsequent multidose aortic root cardioplegia administration. With or without an initial antegrade cardioplegia dose into each coronary ostium, a 5-0 or 6-0 polypropylene suture is placed through the midpart of each cusp’s free edge (Frater stitch). The suture is pulled up to verify good leaflet apposition, after which the aortotomy is closed, bringing the polypropylene suture out through the suture line. With a now competent aortic valve, subsequent doses of cardioplegia can be administered through the aortic root. During reperfusion, the polypropylene suture is removed when cardiac contraction resumes.

Acute Occlusion of the Left Anterior Descending Coronary Artery

Patients brought to the operating room shortly after acute occlusion of the left anterior descending coronary artery (LAD) are usually hemodynamically unstable or in cardiogenic shock. Because of both the acute occlusion and the hemodynamic state, these patients present a special challenge. The principles set down and tested by Allen and Buckberg and colleagues form the basis for the management program described here.\(^8\) These principles include:

- Initial controlled administration of warm cardioplegic solution (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” earlier in this chapter), administered antegrade for 2.5 minutes and retrogradely (through the coronary sinus) for 2.5 minutes
- Use of at least a vein graft to the LAD (or another coronary vessel if it is responsible for the acute infarction)
- Prolonged (20 minutes) controlled reperfusion with hyperkalemic modified blood of the LAD (or another coronary artery if it was the culprit responsible for the area of acute ischemia)

The general plan of the operation is as described under Technique of Operation in Chapter 7. Initial warm cardioplegia (administered as just described) followed by usual cold cardioplegia produces cardiac quiescence. During the grafting procedure, it is supplemented in the usual manner by additional intermittent infusions of the cold cardioplegic solutions. Antegrade and retrograde routes of infusion are used alternately, or as dictated by ease of delivery, or by number of grafts in place.

Large Noncoronary Collateral Flow

Occasionally in patients with long-standing severe coronary artery disease, noncoronary collateral blood flow may be large and, under the usual circumstances of the coronary operation, can actually restart cardiac electromechanical activity by
washing out the cardioplegic solution, despite cardiac venting and multidose cardioplegia. Clinical experience indicates that under these circumstances, risk of important myocardial damage is increased. Therefore, at the first sign of this development, the whole-body perfusate temperature is made as cold as possible until the patient’s temperature reaches 20°C; the perfusate temperature is then set at 20°C and CPB flow is reduced to about 1 L · min⁻¹ · m⁻². Another dose of cold cardioplegia is then administered.

**Active Rheumatic Pericarditis Necessitating Multiple Valve Surgery**

Patients with active rheumatic pericarditis necessitating multiple valve surgery present special problems because of their extensive and vascular pericardial adhesions. If divided, these adhesions cause excessive bleeding and contribute an excessive collateral coronary flow. Such patients are critically ill, usually with aortic and mitral regurgitation. If cold cardioplegia is used, low-flow hypothermic perfusion and repeated cardioplegic infusions are necessary.

**Reoperative Surgery**

Reoperative CABG also may present special issues for myocardial management. In general, cardioplegic myocardial protection should be established early in the procedure—usually before mobilization of the cardiac mass. Antegrade and retrograde infusions are complementary; it is thus imperative that the retrograde catheter be placed accurately in the coronary sinus. This can be accomplished by minimal sharp dissection over the acute margin of the right ventricle followed by accurate posterior freeing dissection. In most cases, a patent internal thoracic artery graft should be identified by careful dissection, partially mobilized, and occluded during aortic inflow. Whether patent vein grafts should remain in situ is controversial; however, for induction of cardioplegia, aortic root is clamped. This can be accomplished by minimal sharp dissection over the acute margin of the right ventricle followed by accurate posterior freeing dissection. In most cases, a patent internal thoracic artery graft should be identified by careful dissection, partially mobilized, and occluded during the cardioplegic period. Alternatively, it can be left open and CPB conducted at 20°C to 25°C with frequent cardioplegia administration and intermittent fibrillation.

Because of adhesions, the myocardium tends to rewarm more quickly than usual. More frequent cardioplegia infusion, low systemic perfusion temperature, or both are appropriate.

Section I  Anesthetic Consultation for Adult Cardiovascular Surgery

The principal tasks of the anesthesiologist are to provide relief from pain for patients during operation and to provide optimal operative conditions for surgeons, both in the safest manner possible. To do this, the anesthesiologist must be a competent physician and a clinical pharmacologist, with a broad knowledge of surgery and the ability to utilize and interpret correctly a variety of monitoring devices.

— Dripps, Eckenhoff, and Vandam

Introduction to Anesthesia: The Principles of Safe Practice

Anesthetic management specifically for adult cardiovascular surgery is differentiated from management for general surgery by the high-risk profile and unique perioperative needs of the patient. Despite increasing age and comorbidity, operative mortality has been decreasing in these patients, likely reflective of advances in surgical technique, better management of comorbidity, and advances in monitoring and care by dedicated cardiothoracic anesthesiologists. Furthermore, implementation of evidence-based medical practice to better justify clinical decisions continues to favorably influence patient outcomes.

PREOPERATIVE PREPARATION AND EVALUATION

Consultation with a cardiothoracic anesthesiologist is essential to optimal preoperative evaluation and management. A thorough history, physical examination, and understanding of the presenting cardiac pathology and proposed surgical procedures are critical. Particular focus should be on areas that may affect perioperative management, such as concomitant patient comorbidity, potential for drug interactions, challenges to airway management and invasive monitoring, as well as acuity of presenting clinical status.

Management of Preoperative Medications

Cardiovascular Medications

Medical management of cardiovascular comorbidity often necessitates extensive pharmacologic support. In general, most anti hypertensive and antianginal cardiac medications are continued preoperatively. Whether to continue or when to withhold preoperative antihypertensive therapy requires careful consideration of patient risk/benefit. Acute withdrawal of particular antihypertensive medications such as β-blockers or clonidine may result in considerable perioperative hemodynamic instability; conversely, their continuation results in better hemodynamic stability, antiarrhythmic properties, and improved patient outcome.

Preoperative management decisions to continue angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor subtype I antagonists (ARA) are controversial. Patients in whom ACE therapy was maintained until the morning of surgery had increased probability of hypotension at anesthesia induction. ARA-treated patients had more postinduction hypotension refractory to conventional vaspressors than those on other antihypertensive therapy (β-blockers, calcium channel blockers, or ACE inhibitors), thus, some recommend discontinuing ARA before surgery.

Comfere and colleagues examined the relationship between timing of discontinuing chronic ACE inhibitors and ARA and development of hypotension after induction of general anesthesia. Patients receiving chronic ACE inhibitors or ARA therapy less than 10 hours prior to general anesthesia were at elevated risk of developing moderate hypotension within 30 minutes of induction. However, this responded to conventional therapy and was not associated with increased occurrence of postoperative complications.

Hemodynamic instability with continuation of ACE or ARA therapy is not consistent. Licker and colleagues reported that patients treated long term with ACE inhibitors and who had normal left ventricular function did not have altered endocrine response or hemodynamic instability during cardiac surgery. Furthermore, continuing therapy has beneficial effects on the myocardium and kidneys. If it is elected to continue these drugs on the day of surgery, one should recognize that episodic hypotension necessitating vasopressor support may occur.

Thus in general, continuation of preoperative cardiovascular medications is recommended.

Statins

Beyond lipid-lowering properties, statins possess pleiotropic effects that have been reported to reduce postoperative morbidity and mortality. Among patients undergoing percutaneous coronary interventions, Pascual and colleagues reported that statin pretreatment was associated with reduced early ischemic events, primarily in those with high levels of inflammatory markers. Pretreatment with fluvastatin of patients undergoing coronary artery bypass grafting (CABG) reduced P-selectin levels, an adhesion molecule that plays a role in the pathogenesis of arteriosclerosis, below those of patients given a placebo. Berk and colleagues reported less use of inotropic agents among patients treated with fluvastatin, speculating that myocardial injury caused by cardiopulmonary bypass–induced inflammatory changes was reduced. Others have reported a protective effect of statin pretreatment in reducing myocardial damage after CABG. Based on these beneficial pleiotropic effects, statin therapy should be continued routinely in the perioperative period.

Medications Affecting Hemostasis

Preoperative antiplatelet therapy affects perioperative hemostasis and may contribute to excess bleeding and increased blood product requirements.

Aspirin

In a meta-analysis of preoperative aspirin (ASA) use, Alghamdi and colleagues reported more blood loss and red blood cell (RBC) transfusion, yet similar platelet transfusion and reexploration for bleeding, among patients who received ASA preoperatively. Patients stopping ASA 2 days or less before surgery had higher RBC transfusion requirements than those stopping it more than 7 days preoperatively, patients discontinuing ASA 3 to 7 days before surgery had little increased requirement for RBC transfusion.
Discontinuing ASA 2 to 3 days preoperatively may be sufficient for return of adequate platelet function. Thus, there is little evidence to recommend a preoperative 7-day ASA-free interval.\textsuperscript{3,6} There are, however, reported benefits to continuing ASA therapy perioperatively. Dacey and colleagues reported that continuation of ASA therapy in isolated CABG was associated with reduced mortality without substantial risk of hemorrhage or blood product requirement.\textsuperscript{3,1} Similarly, Bybee and colleagues reported that preoperative ASA was used within 5 days of CABG was associated with lower in-hospital mortality and similar risk of reoperation for bleeding and blood product requirements as in those not receiving preoperative ASA.\textsuperscript{1,9}

Practice guidelines from the Society of Thoracic Surgeons (STS) state that although evidence indicates ASA is beneficial, recent ingestion has been associated with perioperative bleeding.\textsuperscript{3} Guideline recommendations are as follows: class IIA recommendation to discontinue ASA 3 to 5 days before elective CABG to reduce bleeding risk; class IIA recommendation for continuation of ASA in urgent and emergency CABG, recognizing that benefits of ASA outweigh the small bleeding risk; and class I to start ASA early postoperatively to take advantage of improved graft patency and mortality benefits.\textsuperscript{3,5}

**Clopidogrel** Clopidogrel, an inhibitor of platelet aggregation, works by irreversibly blocking adenosine diphosphate (ADP)-mediated platelet activation. Clopidogrel reduces thrombotic complications following coronary stenting and improves outcomes after acute coronary syndromes. Patients who undergo CABG within 3 to 5 days of clopidogrel treatment are at increased risk for bleeding, RBC requirement, and need for reoperation.\textsuperscript{8,10,26,21} (Fig. 4–1). Reichert and colleagues examined the effects of a waiting period after clopidogrel treatment before CABG. Patients who received clopidogrel treatment within 72 hours of operation vs. those delayed at least 5 days after clopidogrel treatment had higher transfusion requirements (95% vs. 52%).\textsuperscript{26}

Others, however, have reported no increase in bleeding, RBC transfusion, or reexploration for bleeding in CABG patients receiving clopidogrel.\textsuperscript{6,2} Ebrahimi and colleagues examined the effect of clopidogrel in patients with non-ST-segment elevation acute coronary syndromes (NSTE-ACS) requiring CABG in the Acute Catheterization and Urgent Intervention Triage strategy (ACUITY) trial.\textsuperscript{31} The trial enrolled 13,819 patients with NSTE-ACS undergoing early invasive management; 11.1% underwent CABG before discharge. Clopidogrel-exposed patients had longer median duration of hospitalization than nonexposed patients, but experienced fewer ischemic events within 30 days and had similar occurrence of non-CABG-related major bleeding and post-CABG major bleeding. Multivariable analysis demonstrated that clopidogrel use before CABG was a predictor of reduced 30-day composite ischemia.

**Combination Antiplatelet Therapy** Cannon and colleagues reported dual antiplatelet therapy within 5 days of CABG was associated with a moderate increase in bleeding; however, combined therapy conferred no appreciable risk for bleeding if discontinued more than 5 days before CABG.\textsuperscript{51} ASA and clopidogrel taken together until 2 days before operation is associated with higher postoperative blood loss, but not increased occurrence of reoperation for bleeding.\textsuperscript{70} Others report increased blood product requirement with preoperative dual antiplatelet therapy.\textsuperscript{34} For patients undergoing off-pump CABG, Shim and colleagues reported that preoperative ASA and clopidogrel exposure even within 2 days of operation did not increase perioperative blood loss and blood transfusion requirements.\textsuperscript{39} Of note, the authors used strict transfusion guidelines and intraoperative blood salvage techniques.

**Glycoprotein IIb/IIIa Inhibitors** Both short- and long-acting glycoprotein IIb/IIIa inhibitors cause profound platelet dysfunction. In patients requiring emergency operation, they are associated with increased risk for bleeding. Recommendations for discontinuation prior to surgery vary, depending on whether the agent used is a short- or long-acting inhibitor (4 to 6 hours for short acting; 12 to 24 hours for long)\textsuperscript{15} (Table 4–1). Lee and colleagues recommend delaying surgery for the appropriate time interval and transfusing platelets as needed rather than prophylactically.\textsuperscript{12} De Carlo and colleagues state that emergency surgery can be performed safely in patients treated with all glycoprotein (GP)IIb/IIIa inhibitors, and similarly note that platelet transfusion should be for clinically relevant bleeding.\textsuperscript{10} Lincoff and colleagues report that urgent CABG can be performed for abciximab-treated patients without excess mortality or important morbidity.\textsuperscript{6,6}

**Herbal Supplements**

Complementary medicine is growing, with 32% to 37% of Americans using herbal supplements in a given year.\(^{B18,317}\) Herbal supplements are frequently underreported and taken in conjunction with conventional drugs. This results in the potential for herb-drug interactions that may affect absorption and metabolism and/or potentiate or antagonize cardiovascular medications.\(^{A2,A5,A9,A12}\)

There are no clear data on specific herbal-anesthetic interactions, but increased bleeding tendency, cardiovascular instability, and sedation have been associated with their use.\(^{A17}\) Garlic, ginkgo biloba, and ginger possess antiplatelet activity that may increase bleeding risk, particularly for patients on ASA therapy.\(^{A2,A9,317,F3}\) Garlic inhibits platelet aggregation in a dose-dependent manner. Ginkgo inhibits platelet activating factor; based on pharmacokinetic data and bleeding risk, patients should discontinue ginkgo at least 36 hours preoperatively.\(^{A9}\) Coumarin-containing medications such as chamomile, horse chestnut, motherwort, and tamarind also enhance bleeding risk.\(^{A2}\) In addition to increased bleeding risk, ginkgo biloba has been associated with elevated blood pressure when combined with thiazide diuretics.\(^{H12}\)

Prolongation of anesthesia may result from kava, valerian, and St. John’s wort. Kava, an anxiolytic and sedative, may prolong benzodiazepine sedation secondary to its ability to potentiate central nervous system depressants.\(^{A9,317,F3}\) Concomitant use of opioids with valerian and kava may lead to increased central nervous system depression. Valerian produces dose-dependent sedation, which appears to be mediated through modulation of \(\gamma\)-aminobutyric acid (GABA) neurotransmission.\(^{A9}\) Ginseng may inhibit the analgesic effect of opioids.\(^{A2}\)

Other direct effects of herbal medicines in the operative setting include cardiovascular instability from ephedra ("ma huang") and hypoglycemia from ginseng.\(^{A9}\) Ephedra contains alkaloids, including ephedrine and pseudoephedrine, that can increase blood pressure and heart rate. Tachyphylaxis may result from long-term use secondary to depletion of endogenous catecholamine stores, which may necessitate use of direct-acting sympathomimetic agents for hypotension.\(^{A9}\) Ginseng may lower postprandial glucose, resulting in hypoglycemia, particularly in fasting patients.\(^{A9}\) Immunosuppressant properties of echinacea theoretically increase risk for poor wound healing and infection.\(^{B15,H8,317}\) Short-term use of echinacea has immunostimulatory effects that may diminish effectiveness of immunosuppressive medications in the perioperative period.\(^{A9}\)

In general, current recommendations are for patients to discontinue herbal medicines at least 2 weeks before surgery.\(^{A9,317,F1,F2}\) (Tables 4-2 and 4-3).

**MONITORING**

**Cannulae**

In addition to standard American Society of Anesthesiologists monitoring, large-bore intravenous (IV) and brachial or radial arterial cannulae are placed prior to induction of anesthesia. Central venous access is commonly obtained following induction of anesthesia. Decisions about whether to use a central venous triple-lumen catheter vs. a pulmonary artery flotation catheter are case and surgeon/anesthesiologist specific, as is use of ultrasound guidance for placement.

Transesophageal Echocardiography

Transesophageal echocardiography (TEE) is integral to monitoring cardiovascular patients.\textsuperscript{23,31,12,33} It is useful in identifying and determining the mechanism of cardiac pathology, can assist with separation from cardiopulmonary bypass (CPB), and may identify unsatisfactory surgical results. In 12,566 consecutive cardiac surgical patients, Eltzschig and colleagues found that TEE influenced surgical decision making in 7% of patients pre-CPB and 2.2% post-CPB.\textsuperscript{33} Minhaj and colleagues recommended that TEE be used routinely in all patients undergoing cardiac surgery, because the information provided substantially influences subsequent patient management. They found that TEE demonstrated new cardiac pathology in one of every three patients, and in 3% of patients, it influenced decisions regarding use of CPB.\textsuperscript{11} Similarly, Qaddoura and colleagues support use of TEE in primary CABG, noting that it provided new findings pre- and post-CPB in 13% of patients.\textsuperscript{23} Early work by Leung and colleagues revealed an association between new and
persistent post-CPB wall motion abnormalities and increased risk for postoperative mortality and myocardial infarction.\(^4\)\(^,\)\(^5\)

TEE Doppler-derived hemodynamic indices can provide noninvasive quantitative information on intracardiac velocities, pressure gradients, and valve area.\(^6\)\(^,\)\(^7\) Estimates of forward flow (stroke volume and cardiac output) provide useful information, particularly in cases in which a pulmonary artery flotation catheter is not used (Fig. 4-2). Pulmonary artery systolic pressure can be estimated with use of the modified Bernoulli equation (Box 4-1), which converts instantaneous velocities to pressure gradients.\(^6\) Stroke volume can be calculated as the product of the cross-sectional area and time velocity integral using two-dimensional and Doppler measurements.\(^6\) Figure 4-3 and Box 4-2 illustrate TEE-derived noninvasive calculation of aortic valve area.

Intraoperative TEE has particular utility and is considered standard of care for patients undergoing mitral valve repair. It allows immediate assessment of reconstructed mitral valves, revealing residual or de novo regurgitation. Whether to intervene for residual mitral regurgitation following repair is controversial. Gillham and colleagues suggest not returning to CPB for a second attempt at mitral valve repair for mild mitral regurgitation based on TEE findings alone.\(^6\) In their

**Figure 4-3** Use of transesophageal echocardiography (TEE) for noninvasive calculation of aortic valve area. **A,** Midesophageal imaging plane for left ventricular outflow tract diameter measurement (2.98 cm). **B,** Continuous-wave Doppler velocity time integral (VTI) of aortic valve (1.43 m). **C,** Pulsed-wave Doppler of left ventricular outflow tract (0.232 m).
investigation, 61% of patients with mild mitral regurgitation identified by intraoperative TEE had zero to trace regurgitation at follow-up transthoracic echocardiography. On the other hand, others have reported a trend toward increased need for reoperation when TEE identifies residual mitral regurgitation following mitral valvuloplasty. TEE is critical in assessing and detecting patients at risk for a rare complication following mitral valve repair: left ventricular outflow obstruction secondary to systolic anterior motion of the anterior mitral valve (Table 4-4). Advances in ultrasound technology with real-time three-dimensional TEE will enhance the ability to image and add to the utility of intraoperative echocardiography in cardiac surgery.

**Cerebral Oximetry**

Use of noninvasive measures of regional cerebral oxygen saturation in adult cardiac surgical patients is controversial because there are conflicting data regarding the ability of cerebral oximetry to predict outcomes following cardiac surgery. Hong and colleagues reported cerebral oximetry was not predictive of cognitive decline following heart surgery; however, patients who exhibited intraoperative desaturation required longer postoperative hospitalization. Similarly, Reents and colleagues reported that use of cerebral oximetry was not predictive of postoperative cognitive performance. In contrast, Slater and colleagues reported that intraoperative cerebral oxygen desaturation was associated with increased risk for cognitive decline and prolonged hospital stay after CABG. More data are clearly needed to demonstrate whether complications associated with modifications in patient care are reduced by noninvasive monitoring of regional cerebral oxygenation.

**MEDICATIONS**

**Premedication**

With a majority of patients being admitted the same day as their surgical procedure, preoperative medications for anxiolyis are commonly administered in the preoperative holding area or operating room once the IV cannula is placed. A short-acting sedative such as midazolam is administered in doses of 1 to 2 mg and is preferred over longer-acting agents.

**Induction Agents**

Propofol (substituted isopropylphenol) and etomidate (a carboxylated imidazole-containing compound) are commonly used induction agents in combination with a low-dose opioid and muscle relaxant, with the goal of facilitated recovery (Table 4-5). Propofol has several properties that make it an advantageous induction agent, particularly for procedures of short duration. It facilitates more rapid awakening compared with other induction drugs, and its antiemetic effects minimize postoperative nausea. Etomidate possesses minimal cardiovascular side effects, making it an ideal agent for induction in hemodynamically unstable patients and those with impaired ventricular function. However, it has a number of side effects, including pain on injection and transient adrenocortical suppression through inhibition of 11-β-hydroxylase. Use of etomidate, particularly in the critical care setting, is controversial because of its adrenal suppression side effects. Ketamine (a phencyclidine derivative) is less commonly used as an induction agent, primarily because of cardiovascular side effects including increases in heart rate and blood pressure, myocardial depression, and episodic emergence delirium. Thiopental is also less commonly used for induction of general anesthesia in cardiac surgery because of less favorable properties. Some centers use high-dose narcotics for induction of anesthesia in cardiovascular patients.

**Maintenance of Anesthesia**

The goal of maintenance anesthesia is to maintain stable hemodynamics while allowing for facilitated recovery in a majority of patients. Maintenance of general anesthesia

**Epiaortic Scanning**

Epiaortic scanning may aid surgical decision making. Djaiani and colleagues modify their surgical management in one third of patients based on its results in CABG. Similarly, Rosenberger and colleagues report that it changed epiaortic surgical decision making in 4.1% of patients, including using cardiac arrest, performing aortic atherectomy or replacement, using off-pump support; avoiding aortic clamping; using ventricular fibrillatory arrest; changing arterial cannulation site; and avoiding aortic cannulation.

Modified from Stoelting (p. 83).

Table typically consists of a balanced anesthetic technique employing low-dose opioid in combination with a volatile inhalational anesthetic agent or IV agent. The specific choice of opioid, inhalational agent, and muscle relaxant depends on the surgical procedure and patient hemodynamics.

No specific anesthetic maintenance regimen is more advantageous than another in terms of patient outcomes, but evidence supports the potential role of inhalational anesthetic agents in myocardial preconditioning. In a double-blind randomized controlled trial of patients undergoing CABG, Meco and colleagues reported beneficial preconditioning effects of desflurane on myocardial injury (lower troponin I) and myocardial functional recovery following surgery.

Regional anesthesia with or without a general anesthetic has produced mixed patient outcomes. There have been reports of regional anesthetic techniques using epidural blockade in off- and on-pump cardiac surgical patients, however, regional anesthetic techniques have not been generally adopted.

Opioids

Semisynthetic opioids—fentanyl, sufentanil, and remifentanil—are differentiated by potency, onset, and duration of action. All have demonstrated safety and effectiveness for use in cardiac surgery (Table 4-6). Cheng and colleagues conducted a multicenter randomized controlled trial on the efficacy and resource utilization of remifentanil and fentanyl in fast-track recovery from cardiac surgery. Both anesthetic techniques permitted early and similar times to tracheal extubation, less intense monitoring, and reduced resource utilization after CABG. Similarly, Howie and colleagues compared remifentanil to fentanyl combined with isoflurane/profentanil for early extubation following CABG. Both allowed for fast-track cardiac anesthesia. In a randomized clinical trial, Mollhoff and colleagues demonstrated the efficacy and safety of remifentanil and fentanyl for fast-track CABG. Time to extubation was longer, and occurrence of shivering and hypertension were higher in the remifentanil group. However, the groups had similar intensive care unit (ICU) and hospital lengths of stay. Engoren and colleagues compared three opioids used for fast-track cardiac anesthesia: fentanyl, sufentanil, and remifentanil. Exubation times and costs were equivalent. Shorter duration of action of remifentanil allowed for faster recovery, but it is more expensive than fentanyl, and trachal extubation times were similar.

Antifibrinolytic Drugs

e-Aminocaproic acid inhibits conversion of plasminogen to plasmin by binding to the lysine binding sites on the plasminogen molecule; tranexamic acid is an alternative antifibrinolytic agent. Lysine analogs have class IA level of evidence indication for use in cardiac surgery to reduce blood loss and transfusion requirements. These drugs play an important role in blood conservation practices in cardiac surgery.

Heparin Management

Monitoring

Several automated devices are available for anticoagulation management following heparin administration; the activated clotting time (ACT) monitor is the most common. Unfractionated heparin is commonly administered on a weight-based protocol (300-400 units per kilogram) with the goal of achieving an ACT greater than 480 seconds prior to initiation of CPB. In general, if an ACT of 480 or greater has not been achieved with doses of heparin (up to 600 units · kg⁻¹), one should suspect heparin resistance.

Heparin Resistance

Reports of heparin resistance in cardiac surgical patients requiring CPB range between 4% and 22%. Chan and colleagues statistically modeled predictors of heparin resistance in 400 patients for elective cardiac surgery. Eight percent met predefined criteria for heparin resistance, defined as a

Data from Bojar.¹¹⁴

Key: ACT, Activated clotting time; ECT, ecarin clotting time; PTT, partial thromboplastin time.

Heparin requirement greater than 5 mg · kg⁻¹ to achieve a pre-CPB ACT greater than 400 seconds. Preoperative use of heparin, low-molecular-weight heparin, a platelet count of 300,000 or more, and albumin plasma concentration of 35 g · dL⁻¹ or less were risk factors for heparin resistance.

Treatment options for heparin resistance include fresh frozen plasma administration and antithrombin III therapy, but few randomized clinical trials have addressed the merits of these therapies for treating heparin resistance.¹¹⁵ In one of the few randomized clinical trials, Avidan and colleagues concluded that antithrombin III was effective in restoring heparin responsiveness for a majority of patients exhibiting heparin resistance prior to CPB (the authors defined heparin resistance as an ACT < 480 seconds after 400 units · kg⁻¹ of heparin).¹¹¹ Interestingly, among the 52 patients randomized to antithrombin III, 21% also required fresh frozen plasma.

**Heparin-Induced Thrombocytopenia**

Heparin-induced thrombocytopenia (HIT) is an immune reaction occurring in 1% to 3% of patients following cardiac surgery.²⁰² HIT is the most frequent antibody-mediated drug-induced thrombocytopenic disorder.³ It develops as a result of platelet factor 4–heparin complexes, subsequent platelet activation, and thrombocytopenia following heparin exposure, and is induced by immunoglobulin (Ig)G antibody production.¹⁶⁶ Paradoxically, heparin-induced antibody-mediated activation of platelets and the coagulation system may result in thrombosis.²⁰² Clinical features may include thrombocytopenia, defined as a 50% or greater reduction in platelet count or decrease to less than 100,000 · dL⁻¹, thrombosis (50%-70% of patients), and heparin-induced skin lesions (5%-10% of patients). Diagnosis rests on one or more clinical features of thrombocytopenia and thrombosis as well as detection of HIT antibodies.²⁰²

Guidelines recommend use of unfractionated heparin for patients with a history of HIT who require cardiac surgery and are HIT antibody negative. Repeat exposure to heparin is an option if the prior HIT episode occurs more than 100 days before surgery, because HIT antibodies are transient and generally not regenerative during the brief heparin reexposure. Guidelines also recommend that heparin be restricted to CPB and that alternative anticoagulants be used pre- and postoperatively. For patients with acute HIT—thrombocytopenia and HIT antibody positive—requiring surgery, it is recommended that surgery be delayed until HIT is resolved and antibodies are negative. Alternatively, a non-heparin anticoagulant such as bivalirudin can be used (Table 4-7).

**Heparin Reversal**

Following discontinuation of CPB and decannulation, heparin is reversed with protamine sulfate (typically 1 mg of protamine for every 100 units of heparin). Heparin-protamine titration may also be used to provide a more precise amount of protamine to be administered. Protamine administration has well-recognized adverse side effects, from hypotension with rapid administration to anaphylactic and anaphylactoid reactions.⁶⁶

**WEANING FROM CARDIOPULMONARY BYPASS**

A number of factors require attention before CPB separation: achieving normothermia, proper electrolyte balance (potassium, glucose, ionized calcium), adequate hemoglobin, anticipation of inotropic and vasopressor support, reestablishing ventilatory support, heart rhythm, and need for pacing. TEE plays an integral role in weaning from CPB, particularly for patients who have undergone valve repair or who have compromised ventricular function. TEE permits rapid recognition in the partial bypass period of circumstances that could complicate separation from CPB, such as persistent valvar regurgitation, intracardiac air, or regional wall motion abnormalities related to graft failure.

**Inotropic and Vasopressor Support**

Muller and colleagues examined clinical, surgical procedure, and intraoperative factors related to the need for inotropic support following CPB, including previous myocardial infarction, heart failure, higher New York Heart Association functional class, and aortic clamp time.⁵⁴⁶ McKinlay and colleagues incorporated information from the intraoperative TEE examination along with demographic and clinical factors to predict the need for inotropic use following separation from CPB.⁶⁸ Reoperation, wall motion score index, combined CABG and valve repair or replacement, left ventricular ejection fraction less than 35%, moderate to severe mitral regurgitation, and longer aortic clamp time were risk factors. Ahmed and colleagues added laboratory and hemodynamic factors and identified four risk factors for inotropic requirement: low cardiac index, left ventricular end-diastolic pressure 20 mmHg or higher, left ventricular ejection fraction 40% or lower, and chronic kidney disease stage 3 to 5.⁵⁴

Table 4-8 lists the mechanism of action for commonly used sympathomimetic and vasopressor agents. In addition, milrinone, an inodilator, acts by inhibiting phosphodiesterase III to increase intracellular cyclic adenosine monophosphate levels. Levosimendan, a new calcium sensitizer, possesses...
vasodilatory and inotropic properties without increasing intracellular calcium concentrations or increasing myocardial oxygen consumption. It acts by inducing a calcium-dependent conformational change of troponin C and enhances both rate and extent of cardiac contraction.\textsuperscript{55,51,110} Levosimendan has demonstrated utility in facilitating weaning from CPB.\textsuperscript{55}

### SPECIFIC MANAGEMENT ISSUES

**Fast-Track Anesthesia**

Early work by Cheng and colleagues was instrumental in establishing a new standard of care for recovery from cardiac surgery by demonstrating the safety and feasibility of facilitated recovery.\textsuperscript{67} They tested extubation within 1 to 6 hours vs. conventional tracheal extubation within 12 to 22 hours after CABG in a randomized clinical trial. Post-extubation intrapulmonary shunt fraction improved and ICU and hospital lengths of stay were shorter, without increased morbidity.\textsuperscript{67} Similarly, Reis and colleagues reported that fast-track and ultra–fast-track (extubated on ICU arrival) anesthesia were not associated with increased patient morbidity and mortality following CABG.\textsuperscript{87} In off-pump CABG, Djaiani and colleagues reported facilitated operating room extubation, lower nurse-to-patient ratio, and earlier patient discharge without need for reintubation with ultra–fast-track anesthetic techniques.\textsuperscript{88} Risk factors for delayed extubation of patients planned for fast-track anesthesia are advanced age, female gender, postoperative use of intraaortic balloon pumping, inotropes, and postoperative bleeding and atrial arrhythmias.\textsuperscript{81,111}

**Perioperative Glucose Control**

Poor control of perioperative glucose is associated with adverse outcomes following cardiac surgery.\textsuperscript{52} Ouattara and colleagues reported a 7.2 increased odds of morbidity in patients with poor intraoperative glucose control (four consecutive blood glucose concentrations $> 200$ mg · dL$^{-1}$ without any decrease despite insulin therapy).\textsuperscript{52} Lipshutz and Gropper performed an evidence-based review of perioperative glycemic control, noting that hyperglycemia in the perioperative period is a risk factor for morbidity.\textsuperscript{127} An appropriate glucose target and specific populations who might benefit from intensive insulin therapy have yet to be identified. van den Berghe and colleagues reported that intensive insulin therapy to maintain blood glucose at or below 110 mg · dL$^{-1}$ reduced morbidity and mortality among surgical ICU patients.\textsuperscript{52} However, there are conflicting results about whether intensive insulin therapy to normalize glucose perioperatively improved outcomes. Gandhi and colleagues examined the effect of intensive intraoperative insulin therapy vs. conventional glucose management on morbidity after cardiac surgery and found increased morbidity with glucose levels at normoglycemia.\textsuperscript{52} Target glucose range at Cleveland Clinic is 70 to 150 mg · dL$^{-1}$. Cleveland Clinic’s intraoperative insulin management protocol and adjustment schedule are described in Appendix 4A and Table 4A-1.

**Blood Management**

RBC transfusion practices vary considerably throughout the world, despite published transfusion guidelines.\textsuperscript{81,122} This variability reflects insufficient information on risk-to-benefit ratio of anemia vs. transfusion and lack of randomized controlled trials examining RBC transfusion and patient outcomes. Hence, transfusion decisions tend to be based on opinion rather than evidence.\textsuperscript{81} There have been a number of investigations demonstrating a strong association between RBC transfusion and morbidity following cardiac surgery.\textsuperscript{10,99,118,114} RBC transfusion has been associated with excess risk of cardiac and serious infectious complications, renal failure, neurologic complications, prolonged

Key: NC, No change; Pao, mean arterial pressure.
ventilatory support, in-hospital mortality, and increased resource utilization and cost. Infectious complications such as sepsis, bacteremia, and superficial and deep sternal wound infections are higher for transfused patients. Possibly this is related to immunomodulatory effects known as transfusion-associated immunomodulation (TRIM). Additional evidence supports persistent and increased late risk related to perioperative RBC transfusion, including a higher hazard for death and lower functional health-related quality of life.

Structural and functional changes occurring during RBC storage may partially account for complications associated with transfusion. Many of these changes are time dependent and include decreases in pH, 2,3-diphosphoglycerate, and adenosine triphosphate (ATP), and increases in free hemoglobin, potassium, and lactate. Reduced deformability is also time dependent and begins at 2 weeks and progresses throughout the storage period. These time-dependent changes have been demonstrated in both the laboratory and clinical arena to contribute to adverse consequences.

Laboratory investigation demonstrates increased thrombin generation for RBC products with longer storage duration. Centrifuged supernatant of stored RBC demonstrates that some RBC microvesicles express phosphatidylserine that is capable of facilitating thrombin generation. This may be a mechanism for adverse thrombotic effects for RBC with increased storage duration that has been observed in clinical investigations. Concern about complications related to length of RBC storage requires further investigation to determine whether patients undergoing cardiac surgery are adversely affected by prolonged storage. The role of storage time on microcirculation, tissue oxygenation, and outcomes is currently under debate.

The risk and benefit balance of anemia and RBC transfusion is complex and at this point unsettled. Although transfusion is beneficial in subsets of patients, there is uncertainty about whom to transfuse, and when; unrestricted liberal use of RBC transfusion requires closer scrutiny. Hebert and colleagues in the Transfusion Requirements in Critical Care trial reported that restrictive transfusion strategies for RBC were as effective as liberal ones. Blood conservation methods should be more widely applied and instituted, including optimization of preoperative hematocrit, use of intraoperative cell salvage, lower hemoglobin thresholds for transfusion, and use of antifibrinolytic agents. Evidence suggests that centers that have implemented evidence-based transfusion guidelines reduce use of RBC products without increasing patient morbidity.

### REOPERATION

Principles of anesthetic induction, maintenance, and facilitated recovery are similar for patients undergoing reoperation. Because of an increased risk for complications on sternal reentry, patients typically have additional IV access and RBC immediately available prior to sternotomy. Communication with the surgical team is essential before sternal reentry, particularly if alternative cannulation techniques (e.g., femoral or axillary artery cannulation) will be used. Surgical dissection can be challenging and lengthy, with a risk for excess bleeding, ischemia due to manipulation of prior grafts, and arrhythmias due to positioning of the heart.

### Off-Pump Coronary Artery Bypass Grafting

Revascularization without CPB has several reported benefits over on-pump surgery: fewer transfusions, less early neurocognitive dysfunction, and less renal insufficiency. Goals for anesthetic management are similar to those for on-pump surgery; however, a number of special considerations pertain specifically to case management for off-pump CABG (OPCAB). Invasive monitoring is similar, as is facilitated recovery with extubation in the operating room or soon after in the ICU. Heparin management is surgeon and institution specific, ranging from partial to full-dose heparinization. TEE is particularly useful for detecting regional wall motion abnormalities, accessing volume status, and determining the effect of lifting and retracting the heart and stabilizer devices on hemodynamics. OPCAB can be particularly challenging in managing acute changes in hemodynamics that occur with necessary positioning and stabilization of the heart to perform coronary artery anastomosis.

TEE monitoring for OPCAB typically identifies transient regional wall-motion abnormalities during vessel occlusion. Temporizing measures to maintain hemodynamic stability include the Trendelenburg position, vasopressors, and IV fluids. Couture and colleagues examined mechanisms of hemodynamic changes during OPCAB, noting that mobilization and stabilization of the heart or myocardial ischemia can produce important changes in hemodynamics. They report that suction- and compression-type stabilizers produce hemodynamic changes via different mechanisms. For suction-type stabilizers, hemodynamic changes are due to heart dislocation (90-degree anterior displacement) and right ventricular compression. Compression-type stabilizers compress the left ventricular outflow tract and produce abnormal diastolic expansion secondary to direct deformation of the left ventricular geometry. Depending on collateral flow, coronary occlusion during the anastomosis can variably affect the status of left ventricular function. Bainbridge and Cheng highlighted anesthetic considerations for both less invasive direct CABG and OPCAB procedures, noting goals similar to those for conventional CABG but with some key differences, including use of regional techniques for postoperative pain (unilateral paravertebral blocks or intercostal blocks).

### Heart Transplantation

The approach to anesthetic management for heart transplant recipients follows principles similar to those for heart failure patients, recognizing, however, that transplant recipients often have ingested food or drink within hours of surgery. Potential heart transplant recipients typically have IV and arterial access prior to rapid-sequence or modified rapid-sequence anesthetic induction. Although alternative induction agents may be used successfully, etomidate and succinylcholine with small doses of narcotic are effective agents for this, recognizing that circulation time is longer and important hemodynamic instability secondary to reduced ejection fraction may occur. Central venous access is obtained following anesthetic induction. Maintenance of anesthesia is similar to that for other cardiovascular procedures, using a balanced technique of narcotic, muscle relaxation, and low-dose inhalation agent. Similar to other procedures, anesthetic goals are to maintain hemodynamic stability and facilitate recovery following surgery.
The newly implanted heart is denervated without vagal tone. In general, post-implantation, agents with direct-acting catecholamines are preferred; agents with indirect activity (e.g., ephedrine) may have diminished effect. Similarly, medications such as atropine and glycopyrrolate will not provide typical heart rate responses. B13, M17

TEE has particular utility in heart transplantation as a guide for separating the patient from CPB, detecting presence of intracardiac air, and evaluating ventricular function. It is particularly useful for detecting right ventricular dysfunction that may ensue, especially in patients with pulmonary hypertension.

Lung Transplantation

Similar to heart transplant recipients, lung transplant recipients typically have eaten within hours of surgery. A special consideration for anesthetic induction of lung transplant recipients is avoiding prolonged positive pressure with mask ventilation, which may lead to important hypotension. Central venous access is obtained following anesthetic induction. Some centers use a pulmonary artery flotation catheter pre-transplant and pull it back into the pulmonary trunk before clamping the pulmonary artery. Lung isolation is commonly achieved with a left-sided double-lumen endotracheal tube. However, use of a single-lumen endotracheal tube with a bronchial blocker for lung isolation is also an option. Ability to tolerate one-lung ventilation is assessed early, because failure to do so necessitates use of CPB. TEE may guide in assessing ventricular function during transplantation, right ventricular function upon pulmonary artery clamping, and pulmonary vein stenosis, and also in detecting intracardiac air.

Feltracco and colleagues report that lung transplantation for severe pulmonary hypertension has distinct challenges compared with other etiologies. F11 Common echocardiographic features of patients with severe pulmonary hypertension include right ventricular enlargement, tricuspid regurgitation, and diastolic dysfunction. The authors recommend ventilation strategies that include avoiding excessively increased intrathoracic pressure, moderate hypercapnia, and optimal positive end-expiratory pressure to prevent increases in pulmonary vascular resistance. They recommend CPB support in the following circumstances: intractable hypoxemia, greater than 30% reduction in cardiac output during trial of pulmonary artery clamping, doubling of pulmonary vascular resistance, an increase in systolic pulmonary artery pressure to greater than 80% of systemic systolic pressure, surgical manipulation that severely compromises cardiac function, and severe ventricular wall motion abnormalities. F11

Baez and colleagues similarly noted that hemodynamic instability may ensue from myocardial depressant effects of induction agents, with excessive positive pressure ventilation on anesthetic induction, and with surgical retraction to gain exposure while removing the lungs. B1 They recommend reducing lung hyperinflation, such as by decreased tidal volumes, lowering respiratory rate to maximize expiratory time, and permissive hypercapnia. TEE can be used to assess presence and degree of right ventricular dysfunction, which may necessitate use of pulmonary vaso dilators. Those available vary in selectivity for pulmonary vasculature and cost. Agents used include milrinone, inhaled nitric oxide (preferred, because of greater selectivity for the pulmonary vasculature vs. systemic vasculature), and inhaled epoprostenol (similarly efficacious and less costly). B11

If risk from CPB is low, some centers place epidural catheters prior to anesthetic induction. M13 Goals of ventilation management include prolonging expiratory time to allow for more complete emptying of the lungs, along with permissive hypercapnia, with the thought that hypoventilation reduces hemodynamic effects of dynamic hyperinflation and auto positive-end-expiratory pressure. Miranda and colleagues list various methods to decrease pulmonary vascular resistance, such as use of vasodilators and induction with 100% fraction of inspired oxygen to reverse hypoxic pulmonary vasoconstriction. M13

Descending Thoracic Artery Aneurysm

Open repair of descending thoracic aorta aneurysm requires considerable anesthetic preparation. Monitoring typically necessitates large-bore IV access, right-sided brachial and femoral arterial catheter placement, central access with a large French introducer and pulmonary artery flotation catheter, a cerebro spinal fluid drainage catheter, and TEE. Depending on extent of the disease, repair may require use of CPB and circulatory arrest. OPCAB procedures employ a double-lumen endotracheal tube or single-lumen endotracheal tube with an endobronchial blocker for lung isolation. Additional venous access, if needed, is obtained via the right femoral vein, because the surgeon may choose to use left atrial–to–left femoral artery bypass. If partial bypass is used, the perfusionist can adjust flow to maintain upper-extremity mean blood pressure typically greater than 80 mmHg, and lower mean greater than 70 mmHg. Intrathecal preservative-free papaverine may be requested prior to clamping as a spinal cord protective measure. Additional neuroprotective measures include maintaining cerebrospinal fluid (CSF) pressure at less than 10 mmHg and passive cooling. Estrera and colleagues recommend early management using free CSF drainage to maintain CSF pressure at less than 10 mmHg, but later limiting cerebrospinal drainage unless neurologic deficit occurs. E16

In addition to hypothermia and CSF drainage for spinal protective measures, monitoring of somatosensory (SSEP) or motor-evoked potentials (MEP) has been reported to provide additional protection. K11 Keyhani and colleagues note that MEPs and SSEPs are highly correlated only when intraoperative changes are irreversible, and these irreversible changes are associated with immediate neurologic deficit. E5 Normal SSEP and MEP findings have strong negative predictive value, indicating that patients without signal loss were likely to be without a neurologic deficit. E5 Some centers have used epidural cooling with epidural catheters placed at thoracic (T) T-12 to lumbar (L) L-1 and a 4F intrathecal thermistor catheter placed at L-3–L-4. G14

Jacobs and colleagues reported that MEP is a highly reliable technique to assess spinal cord ischemia and is useful in reducing paraplegia during thoracoabdominal aneurysm repair. G2 Their protocol includes CSF drainage, moderate hypothermia, and left heart bypass with selective organ perfusion. MEP was used to monitor spinal cord function, and when important decreases occurred, hemodynamic (raising distal aortic and mean arterial pressure) and surgical (realignment of visible intercostal arteries) strategies were employed. G2
Endovascular stenting of thoracic aortic aneurysms is a less invasive approach to repair. Anesthetic management may be regional (spinal or epidural) or general. Disadvantages of regional anesthesia include patient movement, inability to use TEE as a monitoring tool, potential for hypotension with sympathectomy, and difficulty establishing an airway should complications occur during the procedure.\textsuperscript{69}

Transcatheter Aortic Valve Replacement

Transcatheter aortic valve replacement (TAVR) is currently used for patients with aortic stenosis who have important comorbidity and are not surgical candidates because of high operative risk. Cheung and Ree summarized the procedure’s four key steps: surgical access (via femoral vein or artery, or left ventricular apex), native aortic valvuloplasty (predilatation by balloon valvuloplasty), positioning and deployment of the prosthesis, and surgical closure.\textsuperscript{69} TEE can assist with proper sizing by providing measurement of aortic annular dimension, guidewire advancement, and valve prosthesis positioning. TEE has particular utility in identifying complications with placement, such as device embolization, tamponade, perivalvar regurgitation, and coronary ostial obstruction with resultant regional wall-motion abnormalities.\textsuperscript{69} Pharmacologic agents (adenosine or β-blockers) or, more commonly, rapid ventricular pacing are used for device deployment to attenuate left ventricular ejection. The procedure is performed under general anesthesia, which is beneficial for patient immobility, tolerance of rapid ventricular pacing, and better management of complications.\textsuperscript{69}

Ventricular Assist Devices

Anesthetic management for placing left ventricular assist devices (LVAD) focuses on considerations similar to those for severe heart failure, recognizing that these patients are critically ill with limited cardiac reserve and may have considerable hemodynamic instability on anesthetic induction.\textsuperscript{610} TEE is a critical monitoring tool (Table 4-9). Identifying intracardiac shunts, such as a patent foramen ovale (PFO), has implications post implantation. An unrecognized PFO may lead to hypoxemia because unloading of the left ventricle leads to decreased left atrial pressure, which may result in substantial right-to-left shunting. TEE detection of aortic regurgitation is also critical, because this will reduce forward flow from the LVAD. In addition, TEE is useful for identifying right ventricular dysfunction, position of the inflow cannula, and de-airing.\textsuperscript{611}

Bleeding is not uncommon following LVAD insertion and is often multifactorial, with hepatic dysfunction, preoperative anticoagulation, and excessive fibrinolysis.\textsuperscript{62} Patients with severe right ventricular dysfunction may need a right ventricular assist device, use of pulmonary vasodilators (nitric oxide), or both.\textsuperscript{66}

**CONCLUSION**

Practice of contemporary cardiothoracic anesthesia requires expertise in monitoring, coagulation, and pharmacology. Continued advances in perioperative monitoring, more selective pharmacologic agents, and focused research supporting evidence-based care will further advance the specialty and ultimately contribute to improved patient outcomes.

Modified from Mets.\textsuperscript{610} Key: CPB, Cardiopulmonary bypass; LVAD, left ventricular assist device.
Physiologic monitoring includes routine noninvasive monitoring as well as an arterial catheter, central venous catheter, and temperature probes. In term newborns, a 22-gauge radial arterial catheter is preferred. In small babies or premature infants, a 24-gauge catheter is used. Posterior tibial and dorsalis pedis arterial catheters should be avoided because of their tendency to function poorly after CPB. Femoral artery catheters may be used, but because of future need for cardiac catheterizations, they are not preferred. In extremely low-birth-weight babies, a 22-gauge axillary arterial line can be placed. Use of an umbilical artery catheter for up to 7 days is appropriate for newborns.

Many centers employ percutaneous central venous catheters as a standard monitoring tool. When available, these catheters must be placed under ultrasound guidance to increase safety and decrease risk of complications. Placing percutaneous central catheters should be carefully considered in infants with single-ventricle physiology, because thrombosis of upper-extremity vessels could preclude or complicate a future bidirectional Glenn procedure. Size and length of central venous catheters placed percutaneously should be based on age and weight of the patient. Others rely on directly placed transthoracic catheters placed before or after repair of the malformation to obtain information for separation from CPB. However, these do not allow central venous pressure monitoring in the prebypass period or effective monitoring of superior vena cava (SVC) pressure during CPB. Although not universally employed, direct measurement of left atrial, right atrial, and pulmonary artery pressures via small indwelling catheters provides more accurate assessment of central pressures than other methods used to guide treatment in the postbypass and postoperative periods.

Temperature

Thermistor probes are placed for measuring rectal (core) and either nasopharyngeal or tympanic membrane temperatures. Nasopharyngeal and tympanic membrane temperatures provide a reasonable estimate of brain temperature. Large gradients between rectal and nasopharyngeal or tympanic membrane temperature may reflect inadequate total-body cooling and may predispose the patient to unanticipated warming during periods of circulatory arrest or low-flow CPB.

Intraoperative Echocardiography

Intraoperative TEE is important for monitoring myocardial function and detecting air emboli, in addition to providing a morphologic map for surgical repair. In the postinduction period, TEE provides an opportunity to assess the anatomy and revise the operative plan if necessary. It permits assessment of systolic and diastolic function, identification of valvar dysfunction, and estimation of pulmonary artery pressure. These observations may lead to modifying the anesthetic plan. After CPB, previously unidentified malformations and residual defects can be identified and corrected in the same operative setting, which may reduce morbidity and mortality. In patients weighing less than 2.5 kg, the TEE probe should be placed with caution because of risk of esophageal injury and airway obstruction. In such instances, use of an intracardiac echocardiography (ICE) probe should be considered. To do this, a 4.0 uncuffed endotracheal tube is placed in the esophagus and taped to the angle of the mouth. The ICE probe is passed through this esophageal tube for the TEE exam; following the exam, it is withdrawn and placed in cold water to cool the end of the probe.

Neurologic Monitoring

The ICE probe is passed through this esophageal tube for the TEE exam; following the exam, it is withdrawn and placed in cold water to cool the end of the probe.
Although not yet standard of care, near-infrared spectroscopy (NIRS) monitoring, either alone or with transcranial Doppler (TCD) and some form of electroencephalography (EEG), is used in several children’s heart surgery programs. It is our practice to routinely monitor NIRS during heart surgery, on or off CPB. TCD is valuable in detecting emboli and during antegrade cerebral perfusion to determine optimal flow. However, the angle of insonation is important, and changing this will change the velocity of flow measured. Positioning the TCD probe in infants is challenging. TEE is also an invaluable monitor of emboli, a use that must not be overlooked. Of the modalities, EEG is least useful in the operative setting, because it is susceptible to changes in intraoperative temperature and the type of anesthetic agents used.

Near-Infrared Spectroscopy

Light in the near-infrared (700-1300 nm) range has three important physical properties that make it useful for diagnostic assessment:

- It penetrates tissue.
- It is non-ionizing.
- It is absorbed differentially by relevant chromophores depending on their oxygen-binding state.

When near-infrared light is emitted across a tissue (e.g., brain) and detected at its exit, absorption of the light can be used to calculate chromophore concentration using variants of the Beer-Lambert equation. All optical spectrometers consist of the same basic components: a light source of known intensity and wavelength, a light detector to measure the intensity of the light exiting the tissue, and a computer to translate the changes in light intensity into clinically useful information such as the concentrations of HbO₂, hemoglobin, or oxidized cytochrome aa₃.

When photons impinge on biological materials, their transmission depends on a combination of reflectance, scattering, and absorption effects. A light source (light-emitting diode or laser source) emits near-infrared light that passes through a “banana-shaped” reflectance path in the frontal cerebral cortex to two to three detectors placed 3 to 5 cm from the emitter. Absorption occurs at specific wavelengths, determined by the molecular properties of the material in the light path. Optical path length for reflected light is linearly related to spacing between transmission and receiving sites, so many NIRS measurement instruments place the transmitting and light detector several centimeters apart on the head. Although this spacing results in a measurable signal intensity, it affects the amount and depth of tissue monitored.

On a practical level, the available instruments space their transmitting and receiving sites differently, thus measuring different quantities and depths of tissue, which makes comparisons between instruments difficult.

Shallow arcs of light travel across skin and skull but do not penetrate the cerebral tissue. Deep arcs of light cross skin, skull, dura, and cortex. Subtracting the absorbance measured in the narrow arc from that measured in the deep arc leaves absorbance that is due to intracerebral chromophores. This is one of the distinguishing characteristics of cerebral oximeters compared with pulse oximeters. Cerebral oximeters use spatial resolution techniques to differentiate cortical from extracranial blood, whereas pulse oximeters differentiate pulsatile (arterial) from nonpulsatile (venous/capillary) blood. Cerebral oximetry measures predominantly venous saturation (75:25 or 85:15, depending on age and model used). NIRS could be a surrogate for jugular venous oxygen saturation (SjvO₂) monitoring without being invasive. It does not depend on pulse, blood pressure, or body temperature. This makes the technique ideally suited for monitoring oxygenation during CPB, hypothermic circulatory arrest, shock, or cardiovascular collapse.

Validation of NIRS

Studies in humans have focused on measuring SjvO₂ under controlled experimental and clinical conditions and determining its correlation with cerebral oximetry. NIRS correlates well with SjvO₂ as well as with superior vena cava oxygen saturation (ScvO₂). NIRS values also have been validated in piglet studies that correlate regional oxygen saturation (rSO₂) values and metabolic markers of cerebral oxygenation, such as cerebral ATP, phosphocreatine (PCr), and brain lactate concentrations. Human and animal data support the ischemic threshold value of approximately 45%. Prolonged periods of NIRS values in this range have been correlated with adverse postoperative neurologic magnetic resonance imaging (MRI) findings in newborns undergoing surgery for hypoplastic left heart physiology. In piglets, increasing lactates and decreasing ATP concentrations were noted at cerebral oxygen saturation (ScO₂) values of 33% to 44%.

Clinical Applications

To use the device, one or two cerebral oximeter probes are placed on the forehead below the hairline. Andropoulos and colleagues reported that during antegrade cerebral perfusion, left-sided cerebral saturation was substantially lower than the right (92%-94% right and 60%-65% left). However, the left-sided values were well within normal limits, and the right-sided values suggest luxury perfusion. Such large differences have not been our observation in more than a decade of neuromonitoring (unpublished), suggesting that the circle of Willis is intact in most neonates, and blood flow is adequate to both hemispheres during antegrade cerebral perfusion. However, with ongoing miniaturization of oximetry probes, it may be possible to place bilateral NIRS oximeters (Table 4-10).

The landmark Austin and colleagues observational study using multimodality neurologic monitoring must be credited with the interest in NIRS for pediatric open heart surgery. These authors reported a 26% postoperative adverse neurologic outcome when intraoperative desaturations were not treated vs. only 6% when the changes were treated. ScO₂ is a balance between oxygen delivery and utilization. If the latter remains unchanged, then any decrements in cerebral saturation must be due to decreased cerebral oxygen delivery. This could be due to decrease in arterial saturation, hemoglobin, or cerebral blood flow. Hence, if ScO₂ decreases in the face of normal pulse oximetry (SpO₂), it is important to decide why cerebral oxygen delivery has changed. Conditions of increased utilization include hyperthermia, seizures, and change in level of arousal; these must be treated. During initiation of CPB, one of the common causes for decreased rSO₂ is arterial cannula malposition or occlusion to venous drainage, which decreases cerebral perfusion pressure and reduces cerebral blood flow. Moreover, cerebral oximetry could be a guide to hypothermic circulatory arrest and intermittent perfusion, making circulatory arrest safer.

Outcomes after Heart Surgery and NIRS Monitoring

randomized trial of NIRS has been conducted in children. Recently, Hunaid and colleagues\textsuperscript{55} addressed the issue of whether intraoperative cerebral oximetry during cardiac surgery could lead to improved clinical outcomes. They reviewed nearly 500 papers, of which 8 were included in the best-evidence topic analysis. The only study that included children was the one by Austin and colleagues (class 1b level of evidence); the other seven were studies of adults undergoing coronary artery bypass grafting or valve surgery. In all of these, the authors noted reduced postoperative neurocognitive deficits (class 1b to 2b level of evidence) and concluded that judicious use of cerebral oximetry reduced major organ morbidity and mortality; despite the moderate cost associated with its use, all support using the device routinely during open heart surgery.

Although Dent and colleagues\textsuperscript{56} showed a correlation between prolonged low rSo₂ (<45% rSo₂ for ≥180 minutes) and new MRI abnormalities in a group of neonates who underwent the Norwood procedure with ACP, more recently in a prospective study of neonates with either single- or two-ventricle physiology undergoing surgery with CPB and ACP,\textsuperscript{57} they were unable to show an association between new white matter injury on postoperative MRI and prolonged low perioperative rSo₂.\textsuperscript{58} However, it is important to note that in this study, 50% of patients in the single-ventricle group had prolonged low rSo₂ (<45% for 240 minutes), a third of whom had new white matter injury in the postoperative period. No patients in the two-ventricle group had prolonged rSo₂% below 45% for 120 minutes. Although stroke and chorea are obvious neurologic abnormalities, subtle neurocognitive changes are difficult and expensive to establish. Thus, despite lack of level 1A evidence that NIRS improves neurocognitive outcomes, we recommend intraoperative cerebral oximetry as a tool to optimize anesthesia (ventilation, oxygenation), perfusion (alpha-stat, pH-stat, hemoglobin, flow, temperature) and surgical techniques (cannulation). Figure 4-4 shows the Stanford management strategy for maintaining rSo₂ within 20% of baseline.

Anesthetic Agents

A wide variety of anesthetic drugs have been used successfully and safely, including inhalation agents such as sevoflurane, and IV agents such as propofol, fentanyl, midazolam, thiopental, and ketamine (IV or intramuscular).\textsuperscript{10,19} For critically ill neonates, opioid drugs with or without benzodiazepeine are generally preferred. Fentanyl is most often used, titrated in 5 to 10 μg · kg⁻¹ increments with or without midazolam (0.1 mg · kg⁻¹ per increment) until the patient is no longer responsive. A nondepolarizing muscle relaxant is then administered (e.g., vecuronium, rocuronium, pancuronium). Alternatively, combined infusions of opioids and benzodiazepeine may be used.\textsuperscript{64} Pancuronium causes a mild vagal blockade and an increase in heart rate. This effect—which is undesirable in adults with coronary artery disease—is appropriate in infants and children, who have a greater dependence on heart rate for augmenting cardiac output. Additionally, use of an opioid tends to reduce heart rate, and pancuronium will prevent this reduction. Ketamine in doses of 1 to 2 mg · kg⁻¹ is an IV agent, has minimal effects on hemodynamics, and allows the concentration of inhalation agent to be reduced or turned off altogether. Regardless of the anesthetic used, 80% of children with poor myocardial function experience hypotension requiring treatment.\textsuperscript{37}

Presence of intracardiac shunts affects anesthetic induction. Presence of right-to-left shunt leads to rapid IV induction but can slow inhalational induction with a volatile anesthetic because of decreased pulmonary blood flow.\textsuperscript{514} Left-to-right shunts generally do not affect speed of induction. These physiologic effects must be considered when choosing an anesthetic. This also makes de-bubbling all medications and IV fluid mandatory.

Intubation and Ventilation

Endotracheal intubation can be performed orally or nasally; the preference is based less on science and more on institutional choice. An orotracheal or nasotracheal tube of proper diameter and length is introduced and fixed in position.\textsuperscript{515} Cuffed endotracheal tubes (ETTs) have traditionally been avoided in children younger than 8 years of age. A recent multicenter randomized trial in patients younger than age 5, including neonates, found cuffed ETTs to be reliable in infants and children.\textsuperscript{517} In fact, the number of attempts at tube changes to place the correct-sized tube was reduced, and cuffed tubes did not increase the risk of post-extubation stridor. It is important to measure ETT cuff pressure and maintain it below 20 cm H₂O to minimize risk of tracheal mucosal ischemia. In neonates and extremely low-birth-weight infants, it is prudent to obtain an intraoperative chest radiograph to confirm ETT position.

Traditional anesthesia ventilators have limitations that make accurately ventilating pediatric patients challenging.\textsuperscript{514} If indicated, an intensive care ventilator is set up in the operating room.

High fractional concentration of inspired oxygen (FIO₂) is avoided in children with shunt physiology or a nonrestrictive ventricular septal defect. Oxygen is a potent pulmonary vasodilator, and use of high concentrations can reduce systemic cardiac output (Qs) by diverting more of the cardiac output
through the shunt into the pulmonary circulation (Qp). Similarly, a low partial pressure of arterial carbon dioxide (PaCO₂) can reduce pulmonary vascular resistance (Rp), increase Qp, and reduce Qs. Increased PaCO₂ increases Rp and thus also may be hazardous in patients with intracardiac or extracardiac shunts. Therefore, induction with reduced FiO₂ and a normal or slightly elevated PaCO₂ is helpful in balancing blood flow between the systemic and pulmonary circulations.

**Maintenance of Anesthesia**

A combination of an opioid, usually fentanyl, and an inhalation anesthetic, usually isoflurane, is used for anesthesia maintenance. In general, children with limited cardiac reserve are maintained primarily on an opioid anesthetic, with low concentrations of inhalation agent as a supplement when tolerated. Historically, use of high-dose opioids has been advocated to blunt the stress response in neonates and infants. More recently, lower doses of opioids have proved to be equally effective, with less release of inflammatory mediators and a lesser degree of endothelial injury.

In patients in whom early extubation is planned, anesthesia in the postbypass period is maintained with an inhalation anesthetic, and use of fentanyl is limited. Remifentanil is a synthetic ultra–short-acting narcotic metabolized by plasma cholinesterase, with a half-life of 3 to 5 minutes, and has been used for fast-track anesthesia in children. Onset of CPB affects plasma levels of anesthetic drugs because of dilution and drug binding to oxygenator, and additional dosing is necessary adjustments made.

In combination with general anesthesia, both epidural and spinal anesthesia have been safely used in children undergoing open heart surgery. Maintenance of anesthesia is accomplished with inhalation of isoflurane and supplemental IV midazolam. This technique facilitates early extubation and provides excellent postoperative pain control.

**INFANTS AND CHILDREN UNDERGOING HYPOThERMIA WITH OR WITHOUT CIRCULATORY ARREST**

In neonates and infants who require complex operative repairs, hypothermic low-flow CPB or hypothermic circulatory arrest may be used. During the prebypass period, the patient’s temperature should be maintained above 30°C to 32°C to minimize the effects of hypothermia on cardiac output and prevent dysrhythmias. Using CPB, the patient is cooled to between 15°C and 20°C nasopharyngeal or tympanic membrane temperature and rectal temperature. The goal is to achieve optimal uniform cooling through a combination of core cooling using CPB and surface cooling using a cooling blanket beneath the patient. Room temperature is lowered after arterial and venous catheter placement. When circulatory arrest is planned, ice packs are placed around the child’s head after initiating CPB.

**Cardiopulmonary Bypass**

With initiation of CPB, cooling is started. In neonates and infants undergoing hypothermia, the pump prime may be maintained at a temperature of 18°C to 22°C (cold), 30°C (moderate), or 37°C (warm). Duration of cooling before reducing flow to low levels or initiating circulatory arrest is generally 20 to 25 minutes. Cooling should proceed at a controlled rate so that temperature does not fall more than 1°C per minute (see Chapter 2). A reduced rate of head or rectal cooling may indicate suboptimal tissue perfusion or a malpositioned temperature probe. If pump flow is inadequate, vasodilators (e.g., phentolamine, phenoxybenzamine) can be added directly to the CPB circuit. During cooling and before circulatory arrest, arterial blood gases and hematocrit are measured and necessary adjustments made.

In children, the appropriate arterial blood gas management strategy during hypothermia is the pH-stat technique. This technique is favored more in children than adults. The reason is that pH-stat management leads to more cerebral emboli, the primary etiology for postoperative cognitive dysfunction in adults; in children, it is hypoxic ischemia. During cooling and rewarming periods, pH-stat provides better cerebral blood flow, particularly in patients with aortopulmonary collaterals and is also useful during antegrade cerebral perfusion, because the increased cerebral blood flow allows for rapid cooling. Data are unclear but suggest overall that pH stat is useful in most pediatric patients; however, crossover strategies may be another option (see Chapter 2).

**Separation from Cardiopulmonary Bypass**

---

Figure 4-4: Stanford’s approach to maintaining cerebral oxygen saturation (ScO₂) within 20% of baseline in children undergoing heart surgery. On cardiopulmonary bypass (CPB), if ScO₂ decreases 20% below baseline and persists for more than a minute, intervene. Transient decreases with cannulation usually resolve, but if they do not, cannulae should be repositioned. Decreases are most often seen during normothermic beating heart surgery. Under these conditions, if anesthetic doses are adequate, cool further or liberalize the PaCO₂ on CPB, or both. Key: Hct, Hematocrit.
The patient is rewarmed to a core temperature of 35°C to 36°C, the heart is filled and allowed to eject, arterial blood gases are obtained to ensure adequate acid-base balance, and calcium level is corrected to normal values for neonates and infants. Pacing wires are applied to the heart and tested, and the heart rate is maintained at an age-appropriate level using atrial or atrioventricular sequential pacing if needed. In most patients, low-dose dopamine (5 µg · kg⁻¹ · min⁻¹) is begun prior to weaning from CPB.

If high doses of inotropic agents are required despite adequate preload and ventilatory support, presence of a residual anatomic defect or poor adaptation to new loading conditions resulting from the operative repair may be contributing factors. TEE is helpful for determining the cause of the low output state.

Rationale for Specific Therapies

Right Ventricular (Pulmonary Ventricle) Dysfunction

Primary right ventricular (RV) dysfunction may occur after intracardiac surgery in neonates, infants, and children. Diagnosis of RV dysfunction is suggested by high right-sided filling pressures, liver distention, hypotension, tachycardia, reduced cardiac output, and systemic venous desaturation (low mixed-venous saturation).

Treatment of RV dysfunction is directed toward improving oxygen delivery by increasing preload, augmenting contractility directly or indirectly, enhancing coronary perfusion, and reducing afterload.

The RV is generally less responsive to inotropic support than the left ventricle and therefore may require higher doses of inotropic agents. Epinephrine enhances RV contractility. By improving systemic arterial pressure, epinephrine can augment RV coronary blood flow. Maintaining a normal to slightly elevated systolic arterial pressure will maximize coronary perfusion and augment RV contractility. Milrinone, a phosphodiesterase-3 inhibitor, is a useful inotrope with pulmonary vasodilation properties. In a randomized controlled trial of infants and children after heart surgery, a bolus of 75 µg · kg⁻¹ followed by a 0.75 µg · kg⁻¹ · min⁻¹ infusion reduced the occurrence of low cardiac output syndrome by 55%. Stanford’s institutional preference is a bolus of 25 to 50 µg · kg⁻¹ · min⁻¹ during rewarming, followed by an infusion of 0.5 µg · kg⁻¹ · min⁻¹. Communication with the surgeon is important prior to administering the bolus even on CPB, because some surgeons are concerned with the hypotension that could result.

RV afterload can be decreased by mechanical ventilation with or without nitric oxide (NO). Mechanical ventilation should be adjusted to optimize preload and decrease afterload. The RV is extremely sensitive to alterations in intrathoracic pressure; therefore, ventilation that enables the lowest possible mean airway pressure should be the goal. Increased mean intrathoracic pressure increases RV afterload by direct compression of alveolar and extra-alveolar pulmonary vessels.

NO is an endothelium-derived smooth muscle relaxant. It has been used in neonates with persistent pulmonary hypertension and in pulmonary hypertension related to congenital heart disease. NO decreases RVp and reduces intrapulmonary shunting, which may improve oxygenation. However, results of its use in the postoperative period are conflicting. In a randomized controlled trial of more than 100 infants at high risk for pulmonary hypertension, 20 ppm not only failed to show any benefit but did not prevent pulmonary hypertensive crisis in children after congenital heart surgery. However, in a similar population, others have shown it to be effective even at lower doses. If NO is used, NO2 levels should be monitored and NO should not be abruptly withdrawn, because rebound pulmonary hypertension can occur.

If these measures are unsuccessful, extracorporeal membrane oxygenation (ECMO) should be implemented (see Chapter 5). ECMO unloads the RV and favorably shifts the oxygen supply-demand ratio, often allowing the injured myocardium to recover.

Left Ventricular (Systemic Ventricle) Dysfunction

After separation from CPB, the contractile state of the systemic ventricle may be depressed. Contributing factors include preoperative condition of the myocardium (myocardial hypertrophy, elevated end-diastolic pressure, systolic dysfunction), response of the myocardium to the new loading conditions imposed by the operative repair, effects of hypothermia on myocardial compliance, suboptimal myocardial management, and residual anatomic problems.

Systemic ventricular dysfunction is managed by optimizing preload, afterload, and heart rate (see Chapter 5). Tachycardia (>180-190 beats · min⁻¹) may impair ventricular function in newborns and infants and should be treated with β-adrenergic blocking agents and, if necessary, vasopressors. When the heart rate is less than 120 to 130 beats · min⁻¹, atrial or atrioventricular sequential pacing is appropriate.

If inotropic support is necessary, it is usually initiated with dopamine (5-10 µg · kg⁻¹ · min⁻¹) (see Table 4-8). Infusion of calcium intravenously is an important step to augment ventricular contractility in pediatric patients (20 mg · kg⁻¹ · h⁻¹). Epinephrine is also a potent inotropic agent and is particularly useful in patients with important systemic ventricular dysfunction.

Clinical studies of the effects of milrinone in pediatric patients have shown considerable benefit, especially in those whose myocardium is afterload sensitive, such as patients who have had an arterial switch operation. Other trials suggest a different dosing regimen.

Management of Hypoplastic Left Heart Physiology

In the preinduction period, ductal patency must be maintained with prostaglandins to ensure systemic cardiac output. Management depends on optimizing systemic oxygen delivery (by increasing cardiac output) and restricting Qp.

In patients with hypoplastic left heart physiology, Rp decreases within hours of delivery, thereby redistributing blood flow away from the systemic circulation. Excessive Qp can be reduced by hypoxia or hypercarbia, because both raise Rp. In the preoperative period, 3% CO2 mixture compared with a 17% hypoxic gas mixture improved not only ScvO2 but also cardiac output. During administration of CO2, the patient must be sedated or given a muscle relaxant to eliminate increased respiratory effort. When transporting patients with single-ventricle physiology to the operating room, monitoring of hemodynamic state and arterial oxygen saturation is essential.

Before discontinuing CPB, ionized calcium levels and hematocrit must be optimized to ensure adequate
oxygen-carrying capacity. Myocardial function is supported by judicious use of inotropes. Tidal volume is increased to account for a reduction in lung compliance, and minute ventilation is adjusted to maintain normocarbia. After separation from CPB, FiO₂ is adjusted to maintain SaO₂ between 75% and 85% and an arterial PaO₂ of 40 to 50 mmHg.

Modified ultrafiltration has been shown to improve myocardial function, decrease lung water, and remove inflammatory mediators in patients with hypoplastic left heart physiology as well as other complex malformations (see Chapter 2).

Excessive Qp is less common in the immediate postbypass period. After modified ultrafiltration and before chest closure, the anesthesiologist should estimate Qp/Qs and attempt to adjust FiO₂ and minute ventilation accordingly.

Chest closure can markedly reduce lung compliance and worsen hemodynamics. Leaving the chest open may improve Qp and heart filling by reducing mean airway pressure.

Rationale for Managing Fontan, Hemi-Fontan, and Bidirectional Glenn Procedures

Patients undergoing a bidirectional Glenn or hemi-Fontan procedure usually have had either a pulmonary trunk band or a systemic–pulmonary artery shunt in the neonatal period. Cardiac performance may be impaired by either a small non-compliant ventricle or a large dilated ventricle, the latter resulting from excessive aortopulmonary shunt flow. Inotropic support may therefore be necessary in the prebypass period as well as postoperatively.

After the bidirectional Glenn or hemi-Fontan procedure, cardiac output is generally well maintained because inferior vena cava flow mixes with pulmonary venous blood in the physiologic left atrium. Low systemic arterial saturation and reduced Qp, however, are problems in the postoperative period. A marked discrepancy between end-tidal carbon dioxide (PETCO₂) and PaCO₂ is an early sign of reduced Qp. If Qp is reduced with no residual cardiac abnormalities, cardiac output should be optimized and interventions to lower Rp employed. To optimize cardiopulmonary interactions, children undergoing bidirectional Glenn or Fontan operations should be considered for fast-track anesthesia.

INFANTS AND CHILDREN NOT UNDERGOING CARDIOPULMONARY BYPASS (CLOSED PROCEDURES)

The most common procedures that do not involve CPB are palliative (systemic–pulmonary artery shunting and pulmonary trunk banding) or corrective (ligation of patent ductus arteriosus or repair of coarctation of the aorta).

Palliative Procedures

Palliative procedures are performed under general anesthesia with monitoring of systemic arterial pressure. Measurement of arterial pressure, SaO₂, and PETCO₂ are necessary to assess the procedure’s adequacy. Important reduction in PETCO₂ after pulmonary trunk banding indicates that Qp may be excessively reduced. This is followed by a precipitous drop in SaO₂. If the banding procedure is optimal, systemic arterial blood pressure should increase by approximately 10 to 15 mmHg. The gradient between PETCO₂ and PaCO₂ should be about 6 to 10 mmHg. SaO₂ should be no lower than 75% to 80%, and pulmonary arterial pressure should decrease to about 50% of systemic pressure.

Closure of Patent Ductus Arteriosus

Anesthetic considerations for patent ductus arteriosus (PDA) closure depend on the ductus size and clinical condition and age of the patient. Babies with a large PDA and low Rp generally present with excessive Qp and heart failure. Neonates and premature infants also may have left ventricular dysfunction from coronary ischemia due to substantial diastolic runoff to the pulmonary circuit. Thus, patients range from the relatively healthy young child to the sick ventilator-dependent premature infant on inotropic agents. Healthy children can tolerate a variety of anesthetic techniques with extubation in the operating room and use of epidural/caudal analgesia. Symptomatic neonates and premature infants require a carefully controlled anesthetic and fluid management plan.

Most preterm infants who fail medical management consisting of indomethacin, diuretics, and fluid restriction require admission to a neonatal ICU. A common finding is sepsis, so it is important to ascertain a history of medical treatment and verify negative blood cultures before surgical intervention. Premature neonates with ductal patency are operated on in the neonatal ICU, thereby avoiding transport hazards such as hypothermia, multiple transfers to and from infant incubators, inadvertent extubation, and venous access disruption.

In the neonatal ICU, the patient is positioned on a warmer, and access to the patient must be shared among the anesthesiologist, surgeon, surgical assistant, and scrub nurse. Careful positioning of an IV catheter and rapid access to a manual resuscitator or equivalent should be established before the baby is draped. Anesthesia is induced with fentanyl (usually in 1- to 5-µg aliquots) to maintain appropriate arterial pressure and perfusion. Muscle relaxation is obtained with pancuronium to prevent reduction in heart rate and preserve cardiac output. Hypotension following anesthesia induction should be anticipated, because these neonates are often on large doses of diuretics to manage their ventilation. The patient may temporarily require ventilation with 100% oxygen if SaO₂ drops below 90% or is associated with changes in heart rate and blood pressure. Oxygen is weaned once both lungs are allowed to expand after ductal closure. Manual ventilation is often necessary during retraction of the lung in small neonates or in those with preexisting increased oxygen requirements.

Complications include ligation of a pulmonary artery or the aorta. If SaO₂ remains low and PETCO₂ decreases, this alerts the perioperative team to possible pulmonary artery ligation. Similarly, placing a pulse oximeter on the foot ensures that aortic blood flow below the duct is maintained and can signal a possible aortic ligation.

In older children, PDAs are often closed in the interventional cardiac catheterization laboratory. Large PDAs or those with a short segment, however, often require intervention in the operating room under combined general and regional anesthesia. One-lung ventilation is seldom necessary because the procedure is brief.

Coarctation of the Aorta
Coarctation of the aorta is a common cardiac defect and in infants often is associated with anomalies of the mitral valve and left ventricular outflow tract, and with malformation of the great arteries. As with PDA, neonatal repairs are performed in critically ill patients. Coarctation in the newborn is typically associated with left ventricular dysfunction, and these patients may be receiving prostaglandins to ensure ductal patency. Usually they are also receiving mechanical ventilation and inotropic agents. Central IV, arterial, and peripheral IV catheters are normally placed for operation. Optimal placement of an arterial pressure catheter is in the right radial artery so that pressure can be monitored during aortic clamping. If right-sided arterial access is not achieved, a blood pressure cuff is placed on the right arm, and the arterial catheter in the left arm or lower extremity. Anesthesia is administered with a combination of fentanyl and an inhalation agent. During aortic clamping, proximal systemic arterial pressure is allowed to rise by 20% to 25% over baseline to optimize spinal cord perfusion. Intravascular volume loading with 10 to 20 mL · kg⁻¹ of crystalloid is given just before removal of the aortic clamp. The anesthetic concentration is decreased, and additional fluid is administered until arterial pressure rises. In inotrope-dependent neonates, 1 to 2 mL · kg⁻¹ of bicarbonate is administered before clamp release.

Avoidance of hyperthermia along with mild cooling is appropriate for patients undergoing aortic coarctation repair. Intraoperative hyperthermia has been associated with risk of spinal cord ischemia and paraplegia. A target core temperature of approximately 35°C is appropriate.

In older subjects, post-repair rebound hypertension caused by heightened baroreceptor reactivity often occurs and requires therapy. After aortic clamp release, systemic hypertension is most effectively lowered by institution of β-adrenergic blockade using esmolol or combined α and β blockade with labetalol. Sodium nitroprusside may be a necessary adjunct to control refractory hypertension; however, it increases calculated ventricular wall stress in the absence of β-adrenergic blockade by accelerating dP/dt. An effective alternative to nitroprusside is the calcium channel blocker nicardipine. Again, neonates are unlikely to require or tolerate lung isolation.

One-Lung Ventilation in Children

Lung isolation is helpful during thoracoscopic procedures or unifocalization via thoracotomy or coarctation repair in older children and adolescents. Lung isolation in infants and toddlers can be achieved with endobronchial intubation or bronchial blocker. The latter can be placed under fiberoptic or fluoroscopic guidance. It is Stanford’s institutional preference to use a bronchial blocker rather than endobronchial intubation for lung isolation in children. The former allows expansion of the surgical side, if necessary, by deflating the blocker to improve oxygenation. Both techniques are associated with complications and should be undertaken judiciously. Lung isolation in cyanotic pediatric patients requires close communication between surgeon and anesthesiologist, as further reductions in oxygen saturation may be associated with ischemic changes on the electrocardiogram or persistent declines of ScO₂.

Effects of Anesthetic Medications on the Developing Brain

In the last decade, interest has focused on the role anesthesia and sedation might play in affecting the developing brain and has been the subject of considerable debate and review. Studies in rat pups exposed to prolonged volatile anesthetic agents resulted in learning disabilities and associated histopathologic changes in the brain. In a retrospective population-based study, Wilder and colleagues examined the medical and school records of children born to mothers residing in Olmsted County, Minnesota, from 1976 to 1982 who still lived in the community at age 5 years. Of the 5357 children in this cohort, 593 received general anesthesia before age 4 years (years associated with rapid synaptogenesis) and 4764 did not (controls). A single exposure to anesthesia (n = 449) was not associated with learning disabilities. However, children receiving two or more anesthetics were twice as likely as controls to have learning disabilities. The risk for learning disabilities increased with longer cumulative duration of anesthesia exposure (≥120 minutes)—a dose-response relationship. Complete anesthesia records were available, and anesthetic techniques were consistent, with most children (88%) receiving halothane as a primary anesthetic. In addition, those with learning disabilities had a lower birth weight, were of younger gestational age, and were more likely to be male. Although from this study one cannot answer whether anesthesia caused learning disabilities, the repeated need for anesthesia could be a marker for them. Prospective multicenter studies are currently underway to answer whether anesthesia affects the developing brain. The findings could affect timing of complex neonatal heart surgery and should therefore be a concern for healthcare providers involved in caring for children with heart disease.

Blood Glucose Management in the Perioperative Period

Among infants undergoing the arterial switch operation, those who spent more than 50% of the time in a 24-hour period with blood glucose levels in the 80 to 110 mg · dL⁻¹ range were at higher risk for postoperative adverse events than hyperglycemic infants with blood sugars greater than 200 mg · dL⁻¹ 50% of the time. A study in infants had similar results. Among infants undergoing the arterial switch operation, those who spent more than 50% of the time in a 24-hour period with blood glucose levels in the 80 to 110 mg · dL⁻¹ range were at higher risk for postoperative adverse events than hyperglycemic infants with blood sugars greater than 200 mg · dL⁻¹ 50% of the time. A study in infants had similar results. On the other hand, Polito and colleagues reported that pediatric patients with blood glucose greater than 126 mg · dL⁻¹ in a 72-hour period had a longer ICU stay following surgery, suggesting that hyperglycemia could be detrimental in infants as well. However, all these studies were retrospective.

A placebo-controlled prospective study of 700 patients in a pediatric ICU reported that tight glycemic control resulted in shorter ICU length of stay, reduced lactate levels, decreased C-reactive protein, and reduced occurrence of infections. However, occurrence of hypoglycemia (blood glucose < 40 mg · dL⁻¹) was higher in the intensive insulin treatment group (25%) vs. the conventional group (1%), for whom insulin was administered only if blood glucose exceeded 200 mg · dL⁻¹ on at least two occasions. The majority (80%) of patients who had hypoglycemia were infants, but those who developed hypoglycemia did not have a
substantially increased risk of mortality. No early neurologic abnormalities were detected related to either hyper- or hypoglycemia. More studies of this nature with long-term follow-up are required before insulin infusion and tight glycemic control can be recommended routinely in children during and after heart surgery.

4A

Intraoperative Insulin Management Protocol (Cleveland Clinic)

Starting insulin: Start if pre-CPB blood glucose > 120 mg · dL⁻¹ and if on-pump or post-pump blood glucose > 150 mg · dL⁻¹.

Bolus dose: 0.03 units · kg⁻¹ (maximum bolus is 3 units). Initiate continuous infusion: initial rate 0.03 units · kg⁻¹ · h⁻¹ (maximum initial rate is 3 units · h⁻¹). See Table 4A-1 (Insulin Infusion Adjustment) for adjustment of insulin rate.

1. Blood glucose monitoring
   Measure blood glucose every 30 to 60 minutes.

2. Hypoglycemia protocol
   If blood glucose ≤ 60 mg · dL⁻¹: stop insulin infusion, give 25-50 mL of 50% dextrose solution, obtain blood glucose level every 30 minutes until blood glucose >

The primary determinants of a cardiac operation’s success are events in the operating room (OR), but even patients who are seriously ill when they leave the OR can survive and have a good long-term result when postoperative care is appropriate and intensive. Conversely, ill-advised or overly energetic interventions early after operation can put a patient at risk. Generally, they have adequate function of all subsystems, as uncomplicated convalescence devoid of findings or events that increase the probability of hospital death, complications, or a suboptimal late result is what patients can now expect. Generally, they have adequate function of all subsystems, as determined by standard criteria. So long as this pattern of normal convalescence continues, testing and intervention can be safely minimized. In these situations, expeditious discharge from the intensive care unit (ICU) can be accomplished and a short subsequent hospital stay anticipated.

But alertness to deviations from the pattern of an uncomplicated convalescence is mandatory; deviations are an indication for closer observation and possibly more intensive testing and treatment. Analysis of early convalescence can place the patient into one of three categories: optimal, suboptimal but in control, and critically ill. Each category carries therapeutic implications.

- Optimal: routine care; no change or important modification is currently necessary or foreseeable.
- Suboptimal but in control: careful consideration is given to a change in therapy, and a new modality is likely (e.g., additional catecholamine support for low cardiac output...
or lidocaine drip for frequent premature ventricular contractions [PVCs]).

- Critically ill: a modification, change, or new intervention is necessary and urgent (e.g., treatment of oliguria or metabolic acidosis; return to the OR for bleeding).

Both the suboptimal and critically ill categories define abnormal convalescence.

The patient convalescing normally and without complications after cardiac surgery usually appears at a glance to be doing well. Although there is always pain, varying in intensity from patient to patient, there is no restlessness, agitation, or anxiety. Eyes and skin look normal, and the pulse is full but may be rapid. Breathing is neither labored nor excessively rapid. The patient is oriented and lucid and—whether a neonate, infant, or adult—exhibits generally appropriate behavior. Few tests and interventions are needed.

When convalescence is abnormal, observations and interventions must be intensive and at times complex. In these situations in particular, care must be well organized and follow specific patient-management protocols that allow all members of the intensive care team to be clear about details of management.

Use of protocols is facilitated by considering the patient to be a complex, integrated system composed of a number of separate but interrelated subsystems (i.e., cardiovascular, pulmonary, renal, nervous, gastrointestinal). Care of such a patient can be accomplished effectively using a “subsystems analysis” approach. This analysis begins in the OR as CPB is discontinued (see Chapters 2 and 4) and continues into the early and late postoperative period. This is not to say that care can be carried out in an automatic fashion. Optimal postoperative care requires overall direction by a knowledgeable and experienced physician using, when indicated, specialized methods of securing information and the skills of personnel in a dedicated cardiovascular ICU.

Management of patients after cardiac surgery has become in some institutions a specialty of its own. Literature on the subject abounds. Around the world, numerous institutions with extensive experience in the surgery of both congenital and acquired heart disease have developed their own protocols and specific systems of management. These include “fast track” protocols and critical pathways that integrate the goals of all caregivers and other interested parties. Within the context of these developments, this chapter discusses general principles, along with enough specific details to be helpful to those desiring to change or develop their own protocols.

Section I Subsystems during Early Convalescence after Cardiac Surgery

CARDIOVASCULAR SUBSYSTEM

Cardiac Reserve

Cardiac reserve is the capacity to increase (or at least maintain) cardiac output as a response to a variety of stressful sudden developments, including increased total body oxygen consumption (\(\text{VO}_2\)), increased ventricular afterload, and decreased ventricular preload. Providing that capacity are all the cardiac and extracardiac mechanisms for maintaining and increasing the force of ventricular contraction and cardiac output. Most of these reside in myocardial contractility and coronary blood flow. In patients convalescing from cardiac surgery, adequacy of cardiac performance alone is insufficient for a high probability of normal convalescence and survival. There must, in addition, be adequacy of cardiac reserve.

Inadequacy of cardiac reserve may become apparent only during periods of increased \(\text{VO}_2\) (from struggling or hyperthermia), suddenly increased ventricular afterload (from paroxysmal pulmonary arterial hypertension in a neonate), or acute reduction in ventricular preload (from sudden blood loss). Such inadequacies of cardiac reserve probably explain “sudden death” occurring early after cardiac surgery.

Cardiac reserve is highly dependent on the preoperative condition of the patient. When, because of disease, reserves are being nearly fully utilized to maintain adequate cardiac performance in nonstressful situations, that which remains may be insufficient to successfully meet the stresses of the intraoperative and postoperative period. Reserves probably cannot be increased before the operation unless they are acutely impaired by a reduced myocardial energy charge. Energy charge may be increased by the cardioplegic technique used in the OR (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” under Methods of Myocardial Management during Cardiac Surgery in Chapter 3).

Limited cardiac reserves are specifically compensated for by many features of early postoperative care.

Adequacy

Although not often conceptualized and not specifically measurable, adequacy of blood flow (cardiac output) in meeting the patient’s needs during recovery from cardiac surgery is the central issue with respect to the cardiovascular subsystem. Arteries and veins are infrequently the primary limiting factors, so emphasis is on adequacy of performance of the heart itself in providing adequate blood flow to the body.

Cardiac Index

Cardiac index (cardiac output expressed as L \(\cdot\) min\(^{-1}\) \(\cdot\) m\(^{-2}\)) is one measure of adequacy of the cardiovascular subsystem, as evidenced by the oft-demonstrated relation between cardiac index and survival (described by Dietzman and colleagues in 1969\(^{11,12}\)). In adults, a cardiac index of at least 2.0 L \(\cdot\) min\(^{-1}\) \(\cdot\) m\(^{-2}\) during the first few hours in the ICU and one of at least 2.4 on the morning after operation are required for normal convalescence (Fig. 5-1). This is at the lower end of the range of normal, which is 2.2 to 4.4.\(^{82}\) Infants and small children appear, in general, to require a somewhat higher cardiac index for normal convalescence (Fig. 5-2). Also, in young patients, cardiac index tends to be lower about 4 hours after operation than it was soon after discontinuing CPB, and then begins to rise after 9 to 12 hours.\(^{11}\)

Cardiac indices below these values are usually inadequate for maintaining a normal convalescence; this can be formalized in the inverse relation between cardiac index early

\(^{11}\)The familiar exercise stress test is a test for cardiac reserve.
postoperatively and the probability of hospital death. This relation can be refined by considering not only cardiac output but also mixed venous oxygen levels, with lower levels worsening prognosis at any given value of cardiac output.\textsuperscript{2}

**Arterial Blood Pressure**

Arterial blood pressure is an insensitive method of estimating adequacy of cardiac output early postoperatively, primarily because systemic vascular resistance (Rs) is usually elevated.\textsuperscript{112}

This may be related to increased levels of circulating catecholamines,\textsuperscript{114} plasma renin,\textsuperscript{110} angiotensin II, or other mechanisms. This high resistance may result in a normal or high arterial blood pressure even when cardiac output is low.

Some patients tend early postoperatively to have low Rs and arterial blood pressure, even when cardiac performance is good. This may occur more frequently in children with cyanotic heart disease, adults with diabetes, and patients with sepsis or drug interactions (especially preoperative use of angiotensin-converting enzyme [ACE] inhibitors).\textsuperscript{13,M20} Arterial hypotension is an indication for thoughtful evaluation. Children cannot be considered to be convalescing normally when mean arterial blood pressure is lower than about 10% below normal for the patient’s age (Table 5-1). For adults, particularly the elderly, arterial blood pressure may mandate maintenance at or above commonly accepted normal values to ensure adequate perfusion of various organs like the brain, viscera, and kidneys.

**Pedal Pulses**

Simple observation of pedal pulses is a commonly used, useful, but not infallible method of estimating adequacy of cardiac output in children and young adults. Normal (grade 4) pedal pulses early postoperatively are highly but not perfectly correlated with adequate cardiac output and a high probability of survival.\textsuperscript{K15,K16} In older adults, estimation of the adequacy of perfusion by amplitude of pedal pulses is often confounded by the presence of peripheral arterial occlusive disease.

**Skin Temperature**

Skin temperature in the foot is another indirect but reasonably reliable estimator of adequacy of cardiac output. A study of cardiac surgery in infants younger than 3 months of age indicated that pedal pulses and skin temperature predicted probability of hospital death from cardiac causes and thus were reasonably good estimators of adequacy of cardiac output.\textsuperscript{K15} As with assessment of pedal pulse amplitude, in older adults skin temperature offers guidance but not solid evidence for adequacy of perfusion.

Data from Nadas and Fyler.\textsuperscript{K11}

\textsuperscript{a}Mean arterial blood pressure has been calculated as the diastolic pressure plus one third of the pulse pressure.

\textsuperscript{b}40 mmHg in infants <1 month of age.

\textsuperscript{1}Although dye dilution or thermodilution is the standard for measuring cardiac output, caution is required in interpreting measurement values. In small individuals, confidence intervals around the measurement may be large; low core temperature may diminish accuracy; and tricuspid regurgitation, absence of an adequate mixing chamber, lack of steady state, and intracardiac shunts (as originally articulated by Stewart and Hamilton\textsuperscript{112,K15}) invalidate the measurement.
**Whole Body Oxygen Consumption**

Whole body VO\textsubscript{2} is infrequently calculated, but knowledge of it is useful, in some circumstances, it is a better basis for prognostic and therapeutic inferences than cardiac output or mixed venous oxygen levels. Whole body VO\textsubscript{2} can be calculated by a rearranged Fick equation,\(^3\) which states:

\[
\text{VO}_2 (\text{mL} \cdot \text{min}^{-1} \cdot \text{m}^{-2}) = Q \cdot (\text{CaO}_2 - \text{CvO}_2) \quad (5-1)
\]

The normal value for VO\textsubscript{2} at 37°C is 155 mL \cdot min\(^{-1} \cdot \text{m}^{-2}\). The value for whole body VO\textsubscript{2} in the patient recovering from cardiac surgery must be interpreted in light of his or her body temperature; residual hypothermia is the most common explanation for the somewhat low VO\textsubscript{2} usually present within the first few hours after open heart surgery. This reduced VO\textsubscript{2} is in part due to reduced capillary density (reduced area of capillary flow) and increased heterogeneity of capillary flow through the muscle mass and other tissues of the body in the early hours after CPB.\(^{28}\) Normally convalescing patients operated on with hypothermic CPB generally require 4 to 8 hours for this to disappear and their peripheral perfusion to return to normal.\(^{29}\)

When VO\textsubscript{2} is appreciably reduced below the normal level for the existing body temperature, a hazardous condition exists; indeed, one useful definition of shock is “a condition characterized by an acute reduction in VO\textsubscript{2}.” Abnormally low VO\textsubscript{2} may result from reduction or extreme heterogeneity of capillary flow (of which “no reflow” is an extreme example) in one or more organs of the body (sometimes termed a *reduction in capillary density*), lengthening of the diffusion path between capillaries and cells, or intracellular metabolic derangement. One or all of these may exist in patients early after cardiac surgery. When important reduction in VO\textsubscript{2}, considering the temperature, persists for more than a few hours, probability of death increases.

**Mixed Venous Oxygen Level**

Mixed venous oxygen level, generally expressed as oxygen tension (\(\text{PvO}_2\)) or saturation (\(\text{SvO}_2\)), is a useful index of circulatory adequacy, because it reflects to some extent mean tissue oxygen levels.\(^{20}\) When \(\text{PvO}_2\) is less than 30 mmHg, cardiac output is likely to be inadequate; when it is below about 23 mmHg, the inadequacy is apt to be severe (Fig. 5-3). However, normal or near-normal venous oxygen levels are not reassuring as to the adequacy of cardiac output, unless it is known that VO\textsubscript{2} is approximately normal for the existing body temperature.

In a nonsurgical but critically ill ICU population, Jain and colleagues\(^{13}\) found a weak relationship between \(\text{SvO}_2\) and cardiac index. There was considerable variability among all patients in various conditions, but when normalized for VO\textsubscript{2} and hemoglobin concentration, the correlation coefficient improved (Fig. 5-4). Using indwelling fiberoptic reflectance oximetry,\(^{14}\) other investigators have found no or only a very weak relationship between \(\text{SvO}_2\) or \(\text{PvO}_2\) and measured cardiac index.\(^{28,29}\) Following CPB, changes in \(\text{SvO}_2\) may be useful in detecting low cardiac output, one of many causes of decreased oxygen delivery. Identifying decreases may be of particular value in patients coming to surgery with a high severity of illness index. Online continuous oximetry is useful in critically ill patients because it reflects unanticipated events or occasionally the usefulness (or nonusefulness) of therapeutic maneuvers.\(^{25}\) These aspects of postoperative care illustrate the need for uniformity in monitoring techniques and highlight the conflict between overreliance on devices and the ability to form accurate estimates (in this case, of cardiac performance) based on previous correlations.\(^{28}\) However, many surgeons rely on continuous \(\text{SvO}_2\) monitoring to detect deviations from normal convalescence early postoperatively. Catheters that allow measurement of both \(\text{SvO}_2\) and cardiac output are optimal.

**Urine Flow and Serum Potassium**

Urine flow and serum potassium levels are useful indirect guides to the adequacy of cardiac output. Early postoperative
oliguria suggests inadequate cardiac output and thus is often an indication for treatment of the cardiovascular subsystem. Hyperkalemia rising over a 4-hour period (with sampling every 2 hours) to a level of about 5 mEq·L⁻¹ is a sensitive indicator of a low or falling cardiac output in neonates and infants, and hence an indication for intensifying treatment. Hyperkalemia is usually accompanied by a fall in pedal skin temperature and a rise in esophageal temperature, but it often precedes the appearance of a base deficit or of arterial hypotension.

**Metabolic Acidosis**
A frequently used but somewhat nonspecific and insensitive indicator of the adequacy of cardiac output is the acid-base status of blood. Metabolic acidosis during and after cardiac surgery is almost always a result of lactic acidemia. Lactate production is a byproduct of anaerobic metabolism, which most often occurs under conditions in which cardiac output and oxygen consumption are suboptimal. Occasionally, excess lactate may occur with high measured cardiac output under conditions of high metabolic rate, diabetes, sepsis, or intestinal ischemia.

Concentration of lactic acid in blood may be measured directly. Normally, little or none is present, normal values in plasma being 0.7 to 2.1 mEq·L⁻¹. A concentration of about 5 mEq·L⁻¹ correlates in general with moderate metabolic acidosis, and one of 10 mEq·L⁻¹ with severe metabolic acidosis and usually markedly reduced cardiac output. Moderate elevation of lactic acid concentration is a common finding early after cardiac surgery, but in the normally convalescent patient, lactic acid gradually declines to normal values within 12 to 24 hours.

When arterial pH is less than about 7.4, acidosis is present but may be the result of retention of carbon dioxide; this is reflected in an arterial $P_{aCO_2}$ greater than 40 mmHg. Alternatively, acidosis may be “metabolic” and due primarily to accumulation of lactic acid. Quantification of metabolic acidosis is expressed by a derived value obtained from an equation after measuring arterial pH and $P_{aCO_2}$. Either the buffer base deficit or the standard bicarbonate is calculated. Most commercially available equipment calculates the buffer base deficit or excess (which takes account of the buffering capacity of blood as well as that of bicarbonate) after measuring $P_{aO_2}$, $P_{aCO_2}$, and pH of whole blood. The
normal buffer base is about 48 mEq \cdot L^{-1}, and the normal base excess or deficit is 0.

Cardiac Output and Its Determinants

The cardiac index in normally convalescing adults is often 2.5 to 3.5 L \cdot min^{-1} \cdot m^{-2} after cardiac surgery performed with modern methods of myocardial management. It is generally higher 4 to 6 hours after operation than it is in the OR and still higher the next day, although exceptions occur. Even in patients who convalesce well, some variability in cardiac output occurs.

Risk factors for low cardiac output seem primarily to be those that affect cardiac output in the OR, which in turn is strongly correlated with cardiac output 4 to 6 hours later and the next day.\textsuperscript{59} Cardiac output after operations using CPB is usually correlated with age of the patient (older patients have lower output), cardiac condition, functional state of the patient just before operation (the higher the New York Heart Association [NYHA] class, the lower the output), duration of CPB, and duration of global myocardial ischemia. During the early postoperative period, a heart rate within usual ranges correlates directly with cardiac output, and arterial blood pressure within usual ranges correlates inversely with it.\textsuperscript{411} Within the usual ranges, the higher the atrial pressures, the higher the cardiac output\textsuperscript{411} (Fig. 5-5).

Determinants of cardiac output are ventricular preload, afterload, myocardial contractility, and heart rate. Most normally convalescent patients require no special measures to adjust these fundamental determinants; patients with impaired or inadequate cardiac performance require at least adjustment of preload and afterload, and at times adjustment of heart rate and/or pharmacologic or interventional augmentation of contractility. In many patients who have undergone cardiac surgery, it is specifically either the left (LV) or the right ventricle (RV) that limits cardiac output, less commonly both (see “Relative Performance of Left and Right Ventricles” later in this section).

Ventricular Preload

Ventricular preload, which is correlated directly with the force of contraction, is equated with sarcomere length at end-diastole, and thus with change in ventricular volume between end-systole and end-diastole. This volume change is determined by transmural pressure during diastole, compliance and thickness of the ventricular wall, and curvature of the wall (La Place effect). Transmural geometric arrangement of fibers also plays a role but changes little during the postoperative period.

Transmural pressure is determined by intraventricular pressure and intrapericardial pressure. Intraventricular pressure at end-diastole (which is a determinant of the force of contraction) is related to phasic changes in atrial pressure, and these are affected by blood volume and systemic venous capacitance. The latter is decreased early after CPB.\textsuperscript{52} Because transmural pressure is affected by intrapericardial pressure, it is affected by closure of the pericardium and sternum, both of which increase intrapericardial pressure and decrease transmural pressure. Daughters and colleagues\textsuperscript{53} have demonstrated that pericardial closure in the setting of cardiac surgery, both itself and independent of sternal closure, increases intrapericardial pressure, decreases transmural pressure, and unfavorably affects cardiac performance. Changes in myocardial compliance during and after cardiac operations are due primarily to changes in myocardial water content.

After cardiac surgery in patients with normal atioventricular (AV) valves, most acute changes in preload are equated with acute changes in mean left (in the case of the LV) or right (in the case of the RV) atrial pressure. This is because in this setting, and when the atria are functioning normally as reservoirs,\textsuperscript{59} ventricular end-diastolic pressure is similar to the mean pressure in the corresponding atrium. Therefore, mean atrial pressure is measured in cardiac surgical patients to deduce ventricular end-diastolic pressure. Right atrial pressure is usually measured using a fine polyvinyl catheter introduced through the right atrial appendage or internal jugular vein. Left atrial pressure is measured through a fine catheter introduced through the right superior pulmonary vein (or the left atrial appendage in neonates and young infants). In the absence of pulmonary vascular disease and important pulmonary congestion or edema, pulmonary artery diastolic pressure is a reasonable approximation of left atrial pressure. In most adult patients following CPB, pulmonary capillary wedge pressure exceeds left atrial pressure, and this discrepancy increases through the twelfth postoperative hour. It is thought this difference is due to accumulation of interstitial lung water\textsuperscript{544} (Fig. 5-6).

Ventricular Afterload

In the intact ventricle, afterload is defined as systolic wall stress. This is the analog of the load that resists shortening in the isolated papillary muscle. Other things being equal, increased afterload results in decreased stroke volume. In the intact ventricle, afterload is related to (1) ventricular transmural pressure during systole, (2) ventricular wall curvature as determined by ventricular volume (La Place effect), (3) ventricular wall thickness, and (4) shape of the ventricle.
Ventricular wall determinants of afterload change little during and early after operations. Instead, acute changes in afterloads of the LV and RV are usually produced by changes in intraventricular pressures during systole. These changes are equated with changes in proximal aortic and pulmonary arterial systolic pressures. During and early after operation, proximal pulmonary arterial pressures may be monitored directly, but proximal aortic pressures are not. They must be inferred from measured radial (or femoral) artery pressures. Because of the many determinants of the magnitude of systolic amplification, systolic blood pressure at the radial artery is usually higher than in the ascending aorta, except in the situation of peripheral vasoconstriction secondary to low cardiac output or high-dose α-adrenergic agents. In most instances, systolic pressure variability between the aorta and peripheral arteries is not clinically important, but an awareness of it is advantageous in some situations. Mean pressures are similar in the two areas.

A tendency toward arterial hypertension is present in many adult patients early postoperatively, related to increased systemic arteriolar resistance. This complication (1) increases ventricular afterload and thereby decreases stroke volume, (2) increases aortic wall tension and thereby increases the likelihood of tearing the aortic purge-string sutures and suture lines, and (3) increases LV metabolic demands that exacerbate any latent myocardial ischemia. An appropriate criterion for treatment to lower arterial blood pressure in this setting is a mean arterial blood pressure of 10% above the normal value. Mean arterial blood pressure, not systolic pressure, is monitored for this purpose because of the interrelations between peripheral and central arterial pressures discussed earlier. However, the patient’s preoperative blood pressure must be taken into account, and to avoid cerebral complications, markedly hypertensive patients must not be rendered hypotensive. In the ICU, sodium nitroprusside is generally used for this purpose (see Appendix 5A), but nitroglycerin may be preferred when myocardial ischemia is present, because it decreases coronary resistance. Negative intrathoracic pressure also increases LV load resisting shortening by increasing LV transmural pressure. Positive-pressure ventilation negates this effect, but labored spontaneous ventilation may augment afterload, and this may decrease cardiac output.

Myocardial Contractility
When a change in stroke volume cannot be explained by a change in end-diastolic fiber length (preload) or load resisting shortening (afterload), it is considered to result from a change in the contractile state. Contractility in a given ventricle can be acutely depressed or increased. When an attempt is made to compare ventricular contractility from patient to patient, and from time to time in the same patient, problems arise. A papillary muscle that is twice as thick as others might appear to have twice the contractility when studied in the usual way. In the ventricle, and at least theoretically in papillary muscle, data interpreted in terms of contractility must be normalized according to muscle thickness and length.

In vivo assessment of myocardial contractility and the resultant quantification of ventricular pump function are desirable goals postoperatively. The simplest representation of the capacity of the heart as a pump is a determination of any of several modifications of the Frank-Starling mechanism. For instance, the measured change in cardiac output (or stroke volume) with aliquot infusions of blood or blood substitute serves as a surrogate for assessment of contractile function. Clearly this is not reflective of intrinsic contractile properties of the myocardium, because the pressure-volume relationship is affected not only by preload but also by load resisting shortening, myocardial compliance, and intact vagal and sympathetic reflex activity. Changes in the instantaneous ventricular pressure (or aortic pressure) over time, dp/dt, may reflect myocardial contractility, but this quantity is exquisitely sensitive to afterload and preload and cannot be assumed to be an index of contractility that can be transferred from one patient to another or within the same patient over a period of time.

The relationship between ventricular pressure and volume (pressure-volume loop) is currently the nearest approximation to an in vivo assessment of contractility. Additionally, the area within the loop represents stroke work. The end-systolic pressure and the pressure at end-diastole of several different loops allow an expression of contractility and stiffness, respectively. The loops are composed of four segments: isovolumic contraction, ejection, isovolumic relaxation, and filling (Fig. 5-7). When ventricular volume or resistance is altered, a group of points at end-systole fall along a line, the slope of which Suga and colleagues called Emax. Emax is an index of contractility (Fig. 5-8). Changes of the slope in a steeper direction reflect increased inotropy. A shift in the rightward direction represents negative inotropy. With the use of catheters to measure LV pressure and transesophageal echocardiography (TEE) for instantaneous border detection, pressure-volume loops and Emax (contractility at zero volume) can be interpreted online in the ICU. It is paradoxical that the least clearly and directly defined determinant of the force of cardiac contraction is the one most discussed and treated. Its specific treatment is by the administration of inotropic drugs, usually catecholamines (see “Treatment of Low Cardiac Output” later in this section).
Chapter 5  Postoperative Care

**Figure 5-7** Diagrammatic representation of a pressure-dimension relationship of the left ventricle, on which events of the cardiac cycle have been indicated. (From Foex and Leone.25)

**Figure 5-8** When resistance to ejection is altered, pressure-dimension loops at end-systole extend to a straight line termed the *end-systolic pressure-dimension line*. Slope of this line is an index of contractility. Increase in inotropy causes an increase in the slope of the line. It can also be seen that an increase in inotropy causes widening of the loop as ejection shortening is increased. Extrapolation of end-systolic pressure-dimension line to zero pressure defines 

\[ V_0 \]  

(or \( D_0 \)), the dimension the ventricle would attain if intracavitary pressure became zero. (From Foex and Leone.25)

From Kirkin and colleagues.63

**Relative Performance of Left and Right Ventricles**

During and early after cardiac operations, one of the two ventricles is usually the factor limiting cardiac performance, not both. It is usually advantageous to consider and treat patients with this concept clearly in mind. The clue of greatest importance in this regard, when the AV valves are normal, is the relation between the left and right atrial pressures, because they represent the closest approximation available to ventricular end-diastolic pressure and, by implication, sarcomere length.514 When the cardiac valves are normal, the ventricle with the highest corresponding atrial pressure is the one limiting cardiac performance. Echocardiography can often provide supportive information.55

**Heart Rate**

Sinus rhythm is optimal postoperatively, and with this rhythm a wide range of heart rates at various ages is compatible with survival (Table 5-2). The normal compensatory response to increased \( \text{O}_2 \) demand is increased heart rate. Often in the elderly and also in patients with diseased myocardium, this response is absent. It is prudent to manipulate heart rate in otherwise normally convalescing patients with slow sinus (or junctional) rhythm to improve cardiac output. For this, atrial pacing via two temporary atrial leads placed at operation is used. In these situations, atrial pacing is also helpful to suppress premature beats (both atrial and ventricular) and may limit the onset of an established arrhythmia.

**Cardiac Rhythm**

Disturbances of cardiac rhythm may also contribute to low cardiac output. Junctional (AV nodal) rhythm reduces cardiac output by 10% to 15%. Junctional rhythm is less efficient than sinus rhythm because the atrial contribution to ventricular filling is absent in the former. Because junctional rhythm is usually transient and its effects are easily overcome by atrial pacing (unless the rate is rapid),106 its presence does not connote an added immediate risk.

Bradyarrhythmias due to damage to the AV node or His bundle, hypoxemia, or drugs can result in low cardiac output. Tachyarrhythmias in the form of atrial fibrillation or flutter or paroxysmal atrial tachycardia may result in hypotension. Risk of tachyarrhythmias increases during infusion of catecholamines. A complete discussion of postoperative rhythm...
disturbances and their treatment is found later in this section under “Cardiac Arrhythmias.”

Causes of Acute Dysfunction (Low Cardiac Output) after Cardiac Surgery

Inadequate Operation
The surgeon’s responsibility for obtaining an adequate operation demands that he or she continue to search for evidence of this postoperatively, particularly when the patient has low cardiac output. Using the methods described in this and other chapters, a search is made for residual intra- or extracardiac shunting, pathway obstructions, valvar regurgitation, graft or conduit dysfunction, or cardiac compression. If the operation is found to be inadequate in any of these respects, prompt reoperation is usually indicated.

Myocardial Dysfunction
Myocardial dysfunction was once thought to explain low cardiac output after cardiac surgery when atrial pressures were elevated above the usual postoperative values in the absence of any other explanation. The availability of two-dimensional echocardiography in the OR and ICU, particularly TEE, makes possible both direct demonstration of ventricular wall motion and assessment of end-diastolic and end-systolic volumes. These studies can lead more directly to the inference that low cardiac output is due to myocardial necrosis or stunning or to impaired cardiac reserve in the face of increased stress. This inference can be supported by the finding of increased creatine kinase (CK)-MB isoenzyme or troponin in the serum.

Reduced Preload
Hypovolemia. The most common cause of reduced preload is overlooked hypovolemia. This may be a relative intravascular loss secondary to vasodilatation, bleeding into undrained cavities (pleural spaces, retroperitoneum, or free peritoneal space), or uncharted chest tube drainage. The most obvious cause of hypovolemia, of course, is bleeding associated with cardiotomy or CPB, reflected by excessive chest tube output. Low cardiac output or low arterial blood pressure associated with low filling pressures (left or right atrial pressure, central venous pressure, or pulmonary capillary wedge pressure) is the sine qua non of hypovolemia. Echocardiography showing vigorous wall motion and small chamber size is simply confirmatory.

Occasionally there is a sympathetic response that supports blood pressure, but often this is blunted early after anesthesia. There may be reflex tachycardia, but ultimately cardiac output suffers.

Infrequently, excessive diuresis leads to relative hypovolemia and lowering of cardiac output. In this instance, the picture may be complicated by hypokalemia leading to arrhythmias.

Diastolic Dysfunction. In the presence of LV hypertrophy, fibrosis, or myocardial edema, filling pressures do not reflect ventricular volume. In this situation, ventricular compliance is diminished. The root problem is inadequate resting (diastolic) sarcomere length. In these situations, echocardiography is especially useful. The picture is characterized by a small ventricular chamber in the presence of high filling pressure, tachycardia, small stroke volume, low arterial blood pressure, and low cardiac output. Appropriate interventions should be aimed at decreasing heart rate, initiating β-blockade, and subsequent volume infusion. Some inotropic agents may be detrimental in this situation.

Acute Cardiac Tamponade. Acute pericardial tamponade (with its resultant acute decrease in ventricular preload in the face of elevated atrial pressures) must always be considered when low cardiac output is present early postoperatively. Undrained intrapericardial bleeding may cause acute cardiac tamponade. It may also occur as a result of marked myocardial edema and chamber dilatation inside the closed chest, because the pericardium can be constricting under these circumstances even when it has not been resutured. Acute dilatation of the RV during an acute pulmonary hypertensive crisis may result in acute atypical tamponade in neonates and infants. It is these phenomena that explain the advantage of leaving the sternum open and covering the mediastinum with an impermeable sheet sutured to the skin edges in critically ill patients, or of opening it in the ICU when this form of cardiac tamponade is limiting cardiac output.

After an early period of adequate and stable cardiac output, cardiac tamponade is a likely cause of rapid deterioration that cannot be easily explained otherwise. It is usually associated with rapidly rising right and left atrial pressures that often, but not always, equalize. Often, drainage from chest tubes is initially brisk and then ceases, and serial chest radiographs show progressive widening of the cardiac and superior mediastinal shadows. Arterial pressure falls, and a paradoxical pulse may be replaced by a narrow pulse pressure. Characteristically, arterial pressure shows a minimal response to a bolus injection of an inotrope. TEE examination is indicated as soon as cardiac tamponade from retained intrapericardial blood is suspected, and is often diagnostic.

Cardiac tamponade can also manifest in multiple atypical presentations that must always be considered when acute low cardiac output develops. For example, right and left atrial pressures may differ widely in the setting of impacted clot adjacent to the right atrium. Neither TEE nor transthoracic echocardiography (TTE) is reliable for detecting this impacted clot, creating the potential for misdiagnosing tamponade as acute RV failure secondary to other causes such as pulmonary hypertension. Therefore, when the diagnosis of cardiac tamponade is considered as a possible etiology of low cardiac output that does not promptly respond to nonsurgical intervention, emergent reoperation is advisable (or reopening the sternum at bedside, especially in infants).

Increased Ventricular Afterload
Increased RV afterload may appear quickly as a result of a sudden rise in pulmonary artery pressure and vascular resistance. Consequently, during an episode of paroxysmal pulmonary hypertension (often provoked by intratracheal suctioning), cardiac output may fall rapidly and apparently “sudden” death may occur, particularly in neonates and infants. These outcomes are probably not purely the result of increased RV afterload, because they reflect impaired RV reserve as well.

Increased LV afterload may result from a sudden elevation of systemic arterial pressure, such as may occur during suctioning, restlessness, or hypoxia. These result in a sudden increase in LV afterload that, combined with impaired LV reserves, can result in low cardiac output early postoperatively. Sustained increase in systemic vascular resistance and LV afterload is present early after cardiac operations in at least
half the adult patients operated on for acquired heart disease.\textsuperscript{E13,F13,W4}

Often, disturbances of afterload (afterload mismatch) and preload (preload reserve)\textsuperscript{E17} are neither independent nor isolated events. Increased RV afterload leads to decreased LV preload. Similarly, but not as important, increased LV afterload leads to decreased RV preload. A common situation in which a corrective operation leads to increased LV afterload is restoration of mitral valve competence or closure of a ventricular septal defect (VSD). In a physics analogy, mitral regurgitation or left-to-right flow through a VSD represents a pair of resistors in a parallel circuit in which $R_T = 1/r_1 + 1/r_2$, where $r_1$ and $r_2$ represent resistances in the two outflow streams and $R_T$ is total resistance. Closure of one outflow ($r$) increases downstream resistance to ventricular shortening; by inference, wall tension and myocardial oxygen consumption ($MVO_2$) increase.

### Risk Factors for Low Cardiac Output

A number of circumstances increase the probability of low cardiac output after cardiac surgery. These have been determined for the most part by numerous multivariable analyses of outcomes after surgery for specific conditions (see Chapters 7 through 58).

#### Patient-Specific

Chronic impairment of ventricular preload, afterload, and/or contractility by any mechanism (ventricular hypertrophy, stiffness, chronic heart failure) increases the risk of low cardiac output after the cardiac surgical procedure. These are for the most part immutable risk factors for low cardiac output, because they do not change quickly after the operation. However, when a patient who had been alive and ambulatory preoperatively has inadequate cardiac output postoperatively, the assumption must be that intraoperative damage has been superimposed on the chronic state. On the other hand, certain surgical procedures, such as ablation of the regurgitant volume of aortic regurgitation or closure of a defect with a large left-to-right shunt, have an immediately favorable impact on cardiac output. Thus, the cardiac surgical procedure itself often increases cardiac output; it is myocardial damage during the procedure that decreases it.

Acute reduction in ventricular contractility preoperatively can sometimes be ameliorated by intraoperative maneuvers. For the most part, these maneuvers are directed toward increasing an acutely reduced energy charge (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” under Methods of Myocardial Management during Cardiac Surgery in Chapter 3).

#### Procedural

The most important intraoperative risk factor for low cardiac output early postoperatively, other than an incomplete operation, is a discrepancy between the duration of any global myocardial ischemia and the efficacy of the measures used for myocardial management (see complete discussion in Chapter 3). This is often reflected in the finding of long global myocardial ischemic time as a risk factor for low cardiac output and for death after operation. Coronary air embolization during CPB is said to adversely affect cardiac performance after the operation, but most air entering the coronary arteries while the heart is not supporting the circulation passes quickly into the coronary sinus and may have little deleterious effect.

The extensiveness of the “whole body inflammatory response” to CPB affects the heart as well and relates to the probability of low cardiac output after operation. This is one aspect of the association of duration of CPB with death after operation; another is that long CPB duration is sometimes the result, rather than the cause, of poor cardiac performance.

Low cardiac output can be the result of (1) an incomplete or inadequate operation; (2) acute myocardial ischemia, with or without necrosis, from impaired coronary blood flow resulting from failure of some part of a coronary artery bypass operation (CABG); (3) incomplete relief of ventricular inflow or outflow obstruction; (4) important residual or created AV valve or semilunar valve regurgitation that may increase the stroke volume requirements of the ventricle; and (5) residual VSD and large left-to-right shunt that may similarly increase LV stroke volume requirements.

One of the reasons for placing temporary fine polyvinyl catheters in the left atrium, right atrium, occasionally the pulmonary trunk via the RV and uncommonly the LV, and for placing temporary epicardial atrial and ventricular wires, is that they can be helpful in intraoperative and early postoperative efforts to identify an inadequate or incomplete operation as the cause of low cardiac output. TEE with color flow Doppler imaging is also important in identifying an incomplete or inadequate operation. The possibility of residual left-to-right shunting contributing to low cardiac output must always be considered after repair of congenital heart disease. With the materials now used as patches for repair of VSDs, an appreciable left-to-right shunt ($Q_p/Q_s > 1.5$) early postoperatively must be assumed to represent an incomplete repair or an overlooked defect. The shunt can be quantified by double indicator dilution, a method rarely used in the current era.\textsuperscript{W29} Alternatively, the left-to-right shunt may be estimated in terms of the pulmonary (Q\textsubscript{p}) to systemic (Q\textsubscript{s}) flow ratio by simultaneously removing samples from the radial artery, right atrium, and pulmonary artery and solving the simplified shunt equation:

$$Q_p/Q_s = \frac{SaO_2 - SaO_2}{SaO_2 - SpO_2}$$

where $SaO_2$ is the percent oxygen saturation of arterial blood, $SaO_2$ that of blood withdrawn from the right atrium, and $SpO_2$ that of blood withdrawn from the pulmonary artery.

TEE with color flow Doppler imaging now can sometimes settle the issue simply, but without the desirable quantification. Intraoperative TEE has become standard of care for intracardiac repairs of congenital heart disease for patients 3 kg or larger. In one study, intraoperative TEE during post-repair evaluation led to surgical revision in 4% of cases.\textsuperscript{E11}

#### Course of Low Cardiac Output

The heart is in an especially vulnerable position early postoperatively, because its poor function adversely affects coronary blood flow; this in turn further worsens cardiac function. This explains the observation that low cardiac output early after cardiac operations rarely resolves spontaneously. Aggressive treatment is indicated.
With treatment, most patients with low cardiac output early postoperatively recover, and unless it was produced by a large area of myocardial necrosis, most patients have no demonstrable ill effects from it late postoperatively.

Treatment of Low Cardiac Output

Experience indicates that it is worthwhile to intensively treat patients with low or inadequate cardiac output early after cardiac surgery, because cardiac performance often improves after 1 or 2 days, followed by good recovery.

Many causes of low cardiac output are reversible. Investigating whether cardiac tamponade or compression is the cause is one of the first steps (see “Acute Cardiac Tamponade” earlier in this section). If tamponade is present and is caused by retained blood in the pericardium, emergency reoperation is indicated. If there is acute cardiac dilatation, such as may occur in a pulmonary hypertensive crisis, the sternum and pericardium should be rapidly opened (if they were closed). In patients at an increased risk of low cardiac output, this complication can be prevented by leaving the sternum open at operation and closing it 24 to 48 hours later. The pericardium should rarely be closed after cardiac operations, because this has a restrictive effect on the heart early postoperatively.

When cardiac constriction is believed not to be present, treatment is directed at increasing cardiac output by manipulating preload, afterload, contractile state, and heart rate and improving tissue oxygen levels. When these measures fail, use of devices to support the circulation must be considered (see “Intraaortic Balloon Pump” and “Temporary Ventricular Assistance” later in this section). All such devices have their own risks and imponderables; except for the intraaortic balloon pump, they are typically not used unless it seems likely the patient will not survive without them. The decision to use such devices is always made with concern for the possibility the patient may survive but be left seriously disabled, and with knowledge of the costs of such interventions.

Noninvasive Methods

When cardiac output is low, preload is manipulated by increasing blood volume with an appropriate fluid until the higher of the two atrial pressures is about 15 mmHg. If the wall thickness of the LV is unusually great or its contractility or compliance is decreased, it may be helpful to raise mean left atrial pressure to 20 mmHg. However, the tendency to pulmonary edema is increased when left atrial pressure is elevated to this level. When the RV is the limiting factor in cardiac performance, right atrial pressure usually can be raised advantageously only to about 18 mmHg. Above this, a descending limb on the Starling curve usually becomes apparent, and cardiac output falls. Also, the tendency to whole body fluid retention, pleural effusion, and ascites is increased by high right atrial pressure.

When LV performance is the limiting factor and systemic arterial blood pressure is more than 10% above normal (see Table 5-1), vasodilating agents should be used to reduce LV afterload to between normal and 10% above normal. Nitroprusside is generally the drug of choice because it is a potent arterial, and to a lesser extent venous, dilator with a short half-life (see Appendix 5A). The drug appears to be as safe in very young patients as it is in adults. Calcium channel antagonists (e.g., nifedipine, diltiazem) lead to similar arteriolar vasodilatation and may improve coronary perfusion in this setting. However, their longer half-life and depressive effect on ventricular contractility make nitroprusside the preferred drug.

Rarely in patients with severe long-standing mitral valve disease or congenital heart disease with pulmonary vascular obstructive changes, RV dysfunction associated with elevated pulmonary artery pressure may limit cardiac performance. Reduction of RV afterload with vasodilating agents is occasion-ally dramatic in its increase of RV, and thus stroke volume. Nitroprusside (0.5 to 3 μg · kg⁻¹ · min⁻¹), nitroglycerin (0.5 to 3 μg · kg⁻¹ · min⁻¹), or phenolamine (1.5 to 2 μg · kg⁻¹ · min⁻¹) may be effective in this setting. In infants, maintaining near-anesthesia for 24 to 48 hours with fentanyl or another intravenously administered agent may minimize paroxysms of pulmonary artery hypertension and the consequent increased RV afterload (see “Pulmonary Hypertensive Crises” later in this section).

Alternatively, management of neonates and infants may be based on use of the long-acting α-receptor blocking agent phenoxybenzamine (see Appendix 5A). It is administered first at the commencement of CPB (see “Other Additives” under Perfusate in Section II of Chapter 2). An additional dose is usually given about 12 hours after returning to the ICU.

Heart rate is adjusted to optimal levels when necessary by atrial pacing, by ventricular pacing when atrial fibrillation is present, or by AV sequential pacing when AV dysynchrony or dissociation is present. When tachyarrhythmias are present, pharmacologic means of control may be used (see text that follows).

If these relatively simple measures do not quickly bring cardiac performance to an adequate level, inotropic agents are begun (see Appendix 5B for details), although their disadvantages are recognized. There is no ideal inotropic agent, nor are there specific indications for specific agents. In their review, Doyle and colleagues classified inotropic drugs based on their effect on intracellular cyclic adenosine monophosphate (cAMP): cAMP-independent drugs include calcium, digoxin, and α-adrenergic agonists; cAMP-dependent agents include epinephrine (and levarterenol), dobutamine, and isoproterenol. These are β-adrenergic agonists that, coupled with dopaminergic drugs (dopamine), have variable effects on peripheral resistance. Phosphodiesterase inhibitors (aminidine, milrinone, enoximone) may enhance contractility while producing myocardial relaxation (lusitropism) and relaxation of vascular smooth muscle. They are not susceptible to receptor down-regulation.

Initially, dopamine may be infused at 2.5 μg · kg⁻¹ · min⁻¹. This dose can be increased to 15 or 20 μg · kg⁻¹ · min⁻¹ if needed, but if a favorable response is not obtained at 10 μg · kg⁻¹ · min⁻¹, it is not likely to be obtained at higher doses. Dopamine has the advantage of augmenting renal blood flow in addition to increasing cardiac contractility. Dopamine increases ventricular automaticity (hence the probability of ventricular arrhythmias), but to a lesser extent than isoproterenol. At low doses (2 to 4 μg · kg⁻¹ · min⁻¹), systemic peripheral vascular resistance is decreased or unchanged by dopamine, whereas higher doses (>6 μg · kg⁻¹ · min⁻¹) increase peripheral resistance. Tachycardia may limit the rate at which dopamine can be administered. When dopamine is ineffective, dobutamine is gradually added in similar doses. Dobutamine, although more expensive than dopamine, appears to augment myocardial blood flow more, in
general, its effectiveness is similar to dopamine.\textsuperscript{D15} Isoproterenol may be preferred initially and is probably superior in the presence of predominantly RV dysfunction and decreased or normal heart rate because of its favorable effect on pulmonary vascular resistance.

Occasionally, hypotension exists in the presence of normal and adequate cardiac output. Under that special circumstance, norepinephrine administered through a central venous catheter is rational treatment; a very low dose (0.01 µg · kg\(^{-1} \cdot \text{min}^{-1}\)) is often sufficient under these circumstances. Under more dire circumstances, larger doses can be used.

Epinephrine is the catecholamine of choice of some, but its powerful vasoconstricting effects make it less desirable than dopamine or dobutamine. When an insufficient response is obtained from other drugs, or excessive tachycardia develops, epinephrine is added or substituted. The drug is initially infused at a dose of 0.01 to 0.05 µg · kg\(^{-1} \cdot \text{min}^{-1}\), which may be increased as needed.

Milrinone also is useful in patients with low cardiac output after cardiac surgery, because it combines a peripheral vasodilator action with its inotropic effect.\textsuperscript{G12} This drug is different in structure and mode of action from catecholamines in that it is a phosphodiesterase enzyme inhibitor in cardiac and vascular tissue, not a β-adrenergic receptor agonist. Administration is usually initiated with a loading dose of 5 µg · kg\(^{-1}\) over 10 minutes, followed by a maintenance dose of 0.3 to 0.75 µg · kg\(^{-1} \cdot \text{min}^{-1}\). The drug is effective in neonates and infants as well as adults, but in small patients, particular care is necessary to maintain an adequate blood volume because of the vasodilatory effect of the drug.\textsuperscript{12} The indications for this drug vs. catecholamines remain arguable. However, it appears to cause less tachycardia and fewer atrial arrhythmias than catecholamines.\textsuperscript{R18}

Additionally, 10% calcium chloride is administered in a dose of 0.1 mmol · kg\(^{-1}\), with supplemental doses if the ionized serum calcium level is below 1.2 mmol · L\(^{-1}\).

Once the acute problems have subsided, some patients in sinus rhythm appear to require chronic augmentation of ventricular contractile function. Use of digitalis in this setting has long been argued, but there is evidence that it does increase contractility.\textsuperscript{G21} Digitalization appears to be useful, particularly in children (see “Atrial Arrhythmias” under Cardiac Arrhythmias later in this section), but it is not recommended in neonates because it may impair diastolic function.\textsuperscript{530}

**Intraaortic Balloon Pump**

The concept of intraaortic balloon pumping (IABP) to produce diastolic augmentation of coronary and systemic blood flow was elucidated by Moulopoulos, Topaz, and Kolff in 1962.\textsuperscript{M29} The procedure was first performed clinically by Kantrowitz and colleagues in 1968.\textsuperscript{K30} IABP uses the principle of diastolic counterpulsation, which augments diastolic coronary perfusion pressure, reduces systolic afterload, favorably affects the myocardial oxygen supply/demand ratio, and augments cardiac output.

IABP is used in adult patients with inadequate cardiac performance not responsive to optimized preload, afterload, and heart rate or to moderate doses (up to 10 µg · kg\(^{-1} \cdot \text{min}^{-1}\)) of dopamine or equivalent doses of dobutamine or epinephrine (see Appendix 5B). Whenever possible, the decision to insert an IABP is made in the OR rather than postoperatively. It is used in preference to catecholamines postoperatively for patients with severe LV dysfunction, with or without evidence of myocardial necrosis, and for patients with evidence of myocardial necrosis and inadequate cardiac output or severe ventricular arrhythmias. This technique has led to survival of some patients who would otherwise have died.\textsuperscript{D18,D19,P14} Survival is less than 50% if renal failure develops from low cardiac output postoperatively.\textsuperscript{D19} IABP has been effective in patients with ischemic heart disease and valvar and congenital heart disease.\textsuperscript{D19}

Preoperative prophylactic insertion of the IABP is sometimes advisable. In addition to its use in myocardial infarction with low cardiac output or shock, preoperative insertion is often helpful in unstable angina, left main disease with ongoing ischemia, and ischemia leading to ventricular arrhythmias. In the era of more complex arterial revascularization for ischemic heart disease (see Chapter 7), IABP support is helpful intraoperatively for pre-bypass support of patients with low ejection fraction. For patients with acute mitral regurgitation or ventricular septal rupture, insertion upon diagnosis is often lifesaving. Perhaps the most frequent indication for preoperative IABP insertion is poor perfusion from either low cardiac output or peripheral arterial disease. It follows that the best survival following IABP occurs when the device is in place preoperatively.\textsuperscript{D19}

Insertion by arterial puncture is generally used, despite its somewhat higher prevalence of vascular complications,\textsuperscript{G14} because of the technical ease of balloon insertion and removal. When the patient is still on CPB, or the femoral pulse cannot be palpated because of hypotension, an incision only in the skin is made over the femoral artery. Through this incision, the femoral artery can nearly always be palpated and the arterial puncture technique used.

Important aortoiliac occlusive disease and abdominal aortic aneurysm greatly increase the risk of vascular complications or failure of insertion when the femoral route is used.\textsuperscript{G15} In their presence, the balloon can be inserted into the ascending aorta through a purse-string suture. This is usually performed before discontinuing CPB. A pledged mattress suture of 2-0 or 3-0 polypropylene is placed in the midportion of the ascending aorta. A tie is placed on the shaft of the intraaortic balloon to indicate the point that should be level with the aortic wall when the balloon is in proper position within the descending aorta. An aortic stab wound is made and controlled digitally, and the balloon is introduced through the wound and passed into the descending aorta. Proper position is verified by appearance of the characteristic aortic pressure pulse when pumping is begun. The balloon shaft is usually brought out through the lower end of the sternotomy incision. When pumping is no longer needed, the patient is returned to the OR, the median sternotomy reopened, and another pledged mattress suture placed outside the original one. As the balloon is removed, the stab wound is controlled digitally, and the pledged mattress suture is made snug and tied. In severe atheromatous aortic wall disease, use of other assist devices is probably indicated (see “Temporary Ventricular Assistance” in text that follows).

IABP is begun in a 1:1 ratio with ventricular diastole, as judged by electrocardiographic (ECG) and arterial pressure pulse signals. Often the patient’s hemodynamic state improves promptly; consideration is then given to weaning the patient from IABP as early as 6 to 12 hours after insertion. If catecholamines have also been required, they are reduced as
is established by connecting the right atrium via the right superior pulmonary vein or via the roof of the left atrium through a purse-string stitch with a short tourniquet. The purse-string stitch may be felt-reinforced if tissues are thin or friable, because bleeding around the perfusion cannulae is frequently troublesome and may require reexploration. An arterial cannula (24F wire thin-wall) is placed in the pulmonary trunk.

**Left heart bypass** is established by connecting the left atrial cannula to the aortic cannula via a centrifugal pump. This ventricular bypass circuit provides continuous blood flow.

**Right heart bypass** is established by connecting the right atrial cannula to the pulmonary trunk cannula via a centrifugal pump. Pump flow is increased gradually to 4.0 to 5.0 L · min⁻¹ for adult patients as CPB flow is reduced and discontinued. The cannulae are brought through the fascia, muscle, and skin into the left and right upper quadrants of the abdomen at the time of insertion or connection to the extracorporeal circuit. Polytetrafluoroethylene (PTFE) felt strips are placed tightly around the cannulae in the subcutaneous tissues to seal the exit tract. In some cases, the cannulae are simply brought through the wound. The midline incision may be closed primarily in some cases. More often, cardiac compression results from wound closure. The skin only may then be closed, leaving the sternal edges apart; alternatively, a silicone membrane is sewn to the skin edges to seal the mediastinum. The edges of the membrane are sealed with iodine ointment to eliminate ingress of air and present a barrier to bacteria. Bulky dressings are applied and sealed to the skin with a large iodine-impregnated plastic adhesive.

Heparin-coated tubing and centrifugal pumps are desirable to reduce trauma to blood elements by providing a more blood-compatible extracorporeal circuit. Roller pumps can also be used but seldom are, because of the perception that more blood elements are injured. Short tubing reduces foreign blood contact surface and heat loss in the extracorporeal circuit.

An alternative, pulsatile extracorporeal blood pump system is also available (ABIOMED Inc., Danvers, Mass.). The pump consists of a compliant inflow chamber to which blood is drained by gravity, separated from a rigid pumping chamber by a polyurethane inflow valve. The pumping chamber is fitted with a polyurethane outflow valve. A sac within the pumping chamber is expanded pneumatically to propel the blood. Components of the system are arranged vertically and placed at the bedside. A console provides pneumatic power, senses filling of the pumping device, and synchronizes pumping so that little attention to the system is required. Anticoagulation with heparin is necessary, and the patient must remain immobile, as with other temporary systems. It may be used in left, right, or biventricular assist configuration. Although the system provides the possible advantages of pulsatile flow and less operator attention, it costs substantially more than centrifugal pump systems.

Bypass support of a single failing ventricle is used when possible. It is frequently possible to bypass a failing RV using an extracorporeal ventricular assist system combined with IABP to support the LV. Bypass support of the failing LV seems more complicated. In theory, the LV can be sustained by left atrial–to-aortic bypass while the unassisted RV continues to provide adequate pulmonary flow. Experience has shown, however, that RV function also declines. Biventricular support is frequently advisable even when there is apparent isolated LV failure.
**Management.** Each of these devices has specific methods and equipment for insertion and late management. In general, anticoagulation with heparin followed by warfarin is required for all devices with mechanical valves, and low-dose anticoagulation with heparin, warfarin, or aspirin is used for those with biological valves. However, management details vary among institutions and devices.

Bleeding from the primary operative site is controlled by reversal of heparin with protamine. Platelet infusion, transfusion of fresh frozen plasma (FFP) or other blood products, and pharmacologic agents to promote normalization of the blood clotting subsystem are administered as indicated. A heparin-bonded extracorporeal circuit is adequate to prevent clotting in the short term. When bleeding from the operative site has ceased or slowed, heparin therapy is restarted. Usually this occurs within 12 hours after completing the operation. Activated clotting time (ACT) is used to monitor heparin effect; desired ACT is approximately 160 to 200 seconds (assuming a control level of 100 to 120 seconds).

Postoperative care of patients on left, right, or biventricular bypass is labor intensive. Continuous bedside care, often by more than one nurse, is required, as is ready availability of a cardiopulmonary perfusionist or other personnel capable of managing the extracorporeal assist system. Bleeding is frequently a nuisance or even a major complication requiring frequent monitoring of blood clotting by ACT. Smooth operation of the system requires frequent infusion of blood products to maintain adequate atrial pressures. Body temperature is monitored continuously, and measures are taken to heat or cool the blood in the extracorporeal circuit or the patient’s body with a heating/cooling blanket. The VAD system may be fitted with ports for hemofiltration to remove excess extracellular fluid if there is marked edema. Occasionally, hemodialysis is necessary. Ventilatory assist is required.

Separating the patient from temporary ventricular assistance requires judgment and patience. There is a tendency to remove systems too early to avoid complications directly related to prolonged extracorporeal circulation. It is advisable to wait a day or so longer rather than rush the process of separation. Ability of the heart to support the circulation is tested by reducing flow into the extracorporeal circuit, thereby raising atrial pressures and allowing flow through the supported ventricle. There is a limit to which flow in an extracorporeal circuit can be reduced without introducing danger of clotting. Flow of less than about 1 L · min$^{-1}$ should be avoided. Heparin levels should be maintained, and duration of testing interval should be short. Cardiac function is monitored by TEE and continuous measurement of arterial and pulmonary artery pressures, atrial pressures, cardiac output, and $\text{SvO}_2$. If the heart cannot sustain adequate cardiac output under conditions of low-flow bypass, the separation process is abandoned, full flow is resumed, and plans are made for later attempts at separation or conversion to an implantable device. Simply removing the temporary device in anticipation that the heart will sustain adequate function is usually unsuccessful.

**Results.** Results are judged either by recovery and long-term survival after removal of the device or by success in maintaining the patient until cardiac transplantation is accomplished. Clearly, some patients not only survive but also have an excellent long-term functional result.$^{37,42,13,6,42}$ Of some importance in this regard is the finding that myocardial cellular atrophy is not a complication of prolonged ventricular assistance.$^{32}$ Despite excellent intensive care, patients with VADs are at risk of thromboembolism, hemorrhage, and infection.

The report of the combined registry for clinical use of mechanical VADs summarized experience with 965 patients.$^{23}$ For about half of them, successful weaning from the device was accomplished, and about half of those weaned were discharged from the hospital alive. Two-year survival among patients discharged from the hospital was 82%, with most being in NYHA functional class I or II. A higher proportion of patients receiving LV assist devices had satisfactory outcomes than was the case in those receiving biventricular assist devices. The probability of survival was similar in patients receiving nonpulsatile centrifugal pump devices and those receiving pulsatile pneumatic devices. Survival to discharge for the multi-institutional experience was about 30% for postcardiotomy support. Individual institutions have recorded discharge of up to 60%, and this seems to be related to greater experience with the devices and earlier establishment of support.$^{35,64,72}$

**Indications.** The complex scientific, surgical, ethical, moral, political, philosophical, and financial considerations necessarily involved in the decision for mechanical circulatory support do not permit a simple listing of indications for this therapy.

There is general agreement that a low cardiac output (cardiac index $\leq 1.5$ L · min$^{-1}$ · m$^{-2}$) and elevated ventricular diastolic pressure (reflected in high left or right atrial pressure) after continuing CPB an hour beyond the usual time of discontinuance, with IABP support and administration of catecholamines in moderate doses, indicate a low probability of survival.$^{19}$ Trial separation from CPB has failed (usually reflected in a progressive drop of systemic arterial blood pressure, elevation of atrial pressures, reduction of venous oxygen saturation, and metabolic acidosis). Under these conditions, in institutions prepared for it and, if necessary, cardiac transplantation (even if this means transportation to another institution), temporary ventricular assistance is usually indicated. Patients with continuing low cardiac output in the ICU despite IABP and catecholamine support also should be considered for temporary ventricular assistance. Use of temporary ventricular assistance is appropriate for patients of any age whose myocardial problem is expected to resolve within a few days, and for patients younger than 65 to 70 years of age whose myocardial problem is not expected to resolve but who are acceptable candidates for cardiac transplantation. In the latter group, the temporary device is used for support while it is determined whether there is good function of major organ systems and the patient is neurologically intact.

Further experience with VADs may lead to discarding current criteria in favor of more liberal use; in part, this is because LV assistance is more effective than IABP in preserving myocardial structure and function, at least in experimental studies.$^{52}$ In general, the younger the patient, the better the prognosis from the now-repaired cardiac disease, and the fewer the other subsystem diseases and failures, the stronger the indication for temporary ventricular assistance.

**Cardiopulmonary Support and Extracorporeal Membrane Oxygenation**

Right and left heart bypass (biventricular assist) works only if pulmonary function is adequate to support gas exchange. In situations of severe compromise of the respiratory system,
support of that system is also required. Portable CPB systems (cardiopulmonary support [CPS]) include both a centrifugal blood pump and a membrane oxygenator, with heparin-coated tubing. These systems are usually referred to as extra-corporeal membrane oxygenation (ECMO). Successful use has been reported, particularly in infants and children, and there is little doubt that in some patients, it is an effective means of biventricular support. (It may be used occasionally in venovenous configuration to support respiration in the face of severe postoperative arterial desaturation from impaired pulmonary function. This methodology has also been used in patients undergoing myocardial infarction or sustaining a catastrophic event in the cardiac catheterization laboratory, and as a support technique during angioplasty.

Only two cannulae have to be inserted, one in the right atrium and the other in a systemic artery. These cannulae are present during surgery and may simply be attached to the system. Oxygenation is achieved in a closed system without an air-to-blood interface. Alternatively, separate venous and arterial cannulae may be inserted through the femoral artery and femoral or jugular vein by percutaneous technique (see “Cardiopulmonary Bypass Established by Peripheral Cannulation” under Special Situations and Controversies in Section III of Chapter 2). This places the cannulae in a position for ready control of hemorrhage. Centrally placed cannulae are removed so that the wound may be closed. Percutaneous placement of cannulae and use of the CPS system can be used for emergency support of the failing circulation at the bedside. The CPS system does not ordinarily provide decompression of the LV. LV unloading depends on total diversion of blood from the right atrium to the extracorporeal circuit and the ability of the LV to empty pulmonary venous return to the aorta. A beating heart and absence of aortic valve regurgitation are necessary.

**Management.** Heparin anticoagulation is required to prevent clotting or excess fibrin formation in the oxygenator membrane. ACT is maintained at approximately 160 to 220 seconds by continuous infusion of heparin.

**Results.** In the pediatric population, overall survival after ECMO support following a cardiac operation is 30% to 40%. It may be more effective in situations complicated by pulmonary hypertension or in the presence of a two-ventricle repair, for example, CAST patients for the most part had persisting ischemia; most postoperative patients (coronary disease or not) are probably well revascularized. In the postoperative period, however, many antiarrhythmic agents are proarrhythmic; therefore, treating ventricular arrhythmias other than ventricular tachycardia is probably not necessary.

In patients with an ejection fraction under 40% with postoperative ventricular tachycardia, early electrophysiologic study is indicated. Paradoxically, patients in whom such studies demonstrate acute suppression of PVCs or ventricular tachycardia with the administration of drugs have a good prognosis without drug treatment; such patients probably should be discharged from the hospital on no drug therapy. By contrast, patients whose ventricular arrhythmias cannot be suppressed with drugs have a relatively poor prognosis, and consideration should be given to implating an implantable cardioverter-defibrillator (ICD; see “Ventricular Tachycardia and Ventricular Fibrillation in Ischemic Heart Disease” in Section V of Chapter 16).

When during the first day or two of convalescence, ventricular electrical instability develops in the form of PVCs occurring more than six times per minute or ventricular tachycardia persisting more than 20 to 30 seconds, treatment is prudent even if cardiac performance is good (Appendix 5C). Often, PVCs or bursts of ventricular tachycardia can be suppressed by atrial or ventricular pacing using temporary electrodes, without need for drug therapy. When the hemodynamic state is impaired by ventricular tachycardia,
immediate direct current cardioversion (100 J initially in adults and, if ineffective, 200 J) is indicated. When these measures are ineffective, advice of an experienced electrophysologically oriented cardiologist is indicated.

**Atrial Arrhythmias**

**Prevalence and Risk Factors for Atrial Fibrillation.** Reported prevalence of atrial fibrillation after adult cardiac operations is 20% or higher.\(^3^4\) New-onset atrial fibrillation usually occurs within 5 days of cardiac surgery, with peak occurrence on the second day.\(^3^8\) This arrhythmia uncommonly results in major morbidity or death but can complicate convalescence considerably. It is most likely to develop in patients in whom chronic atrial fibrillation has been present before operation and who have left the OR in sinus rhythm.\(^3^7\)

The largest group of patients in whom atrial fibrillation occurs but who did not have it preoperatively are those undergoing CABG. In this group, discontinuance postoperatively of a β-adrenergic receptor blocking agent that has been taken regularly before operation increases the risk of developing atrial fibrillation during the postoperative period; this complication can be expected in about 40% of such situations.\(^3^1\) Older age at operation is also a risk factor for developing atrial fibrillation postoperatively. This arrhythmia develops in about 4% of patients younger than 40 years of age undergoing CABG, compared with 30% of those aged 70 or older.\(^1^9\) Chronic obstructive pulmonary disease, chronic renal disease, valvar heart disease, atrial enlargement, increased sympathetic tone, obesity, and prior pericarditis\(^3^0,3^1^6\) also appear to increase its prevalence.\(^1^8\) Other preoperative and intraoperative variables do not appear to be correlated with development of atrial fibrillation after cardiac operation.\(^1^9\)

New-onset atrial fibrillation after cardiac surgery increases morbidity, length of stay, and cost.\(^3^1\) Morbidity includes hemodynamic compromise and occasionally embolic events. New postoperative atrial fibrillation is statistically correlated with advanced age but is also seen across a wide spectrum of adult cardiac operations. The peak incidence is 2 to 3 days postoperatively, but it may occur earlier or following discharge. Postoperative atrial fibrillation is usually transient; with treatment, most patients return to sinus rhythm within 2 to 3 days. Patients with preoperative atrial fibrillation are unlikely to return to sinus rhythm, especially if atrial fibrillation has been present for more than 6 months.

**Prevention of Atrial Fibrillation.** Prevalence of new atrial fibrillation after cardiac surgery can be reduced by prophylaxis with a β-adrenergic receptor blocking agent.\(^3^1\),\(^3^5\) Three drugs are available. For this purpose, propranolol may be given in doses of 10 to 20 mg three or four times a day, beginning the morning after operation. Alternatively, atenolol may be given in doses of 25 mg three times per day, which is often better tolerated than propranolol. The benefit from β-blockers as prophylaxis against postoperative atrial fibrillation is greatest when the drug is initiated either prior to or immediately after surgery.\(^3^1\) Amiodarone (a class III antiarrhythmic agent) is also an effective drug for preventing atrial fibrillation, with approximately a 4% to 50% reduction in its prevalence after cardiac surgery. A meta-analysis suggested that amiodarone provided similar protection against postoperative atrial fibrillation as β-blockers and sotalol (another class III antiarrhythmic agent).\(^3^2\) Pretreatment with digoxin or verapamil does not reliably prevent atrial fibrillation.\(^3^0,3^3\)

**Treatment of Atrial Fibrillation.** When atrial fibrillation develops postoperatively, several protocols are appropriate, depending on need for rate control versus conversion to sinus rhythm. In postoperative patients with **chronic atrial fibrillation** with stable and effective hemodynamics who are not in the ICU, digoxin is usually effective for rate control, and is indicated for patients with heart failure and LV dysfunction. In the ICU, rate control of atrial fibrillation with preserved ventricular function is most effectively accomplished with intravenous administration of β-blockers (esmolol, metoprolol, or propranolol)\(^3^1\) or non-dihydropyridine calcium channel antagonists (verapamil, diltiazem), exercising caution in the presence of hypotension. Intravenous amiodarone is also useful for rate control (Table 5-3). It should be noted that intravenous digoxin or calcium channel antagonists should not be used in patients with a preexcitation syndrome; these agents may paradoxically accelerate the ventricular response.

When digoxin is used for rate control, a recommended protocol is found in Appendix 5D. When approximately two thirds of the estimated digitalizing dose has been given and has not accomplished control of the ventricular rate, oral administration of propranolol should be started unless the patient has poor ventricular function or pulmonary disease. If the situation is urgent, propranolol may be given intravenously in doses of 0.5 mg every 2 minutes, to a total intravenous dose of 4 mg in adults. Alternatively, treatment with verapamil may be initiated in doses of 40 mg orally two to three times daily. This drug may be infused intravenously in a dose of 0.075 mg · kg\(^{-1}\) to a maximum dose of 5 mg, but its action is very short when given in this manner, and oral administration should be started promptly.

In patients with new-onset or recurrent postoperative atrial fibrillation, successful conversion to sinus rhythm is usually possible and is advantageous for postoperative hemodynamics. Digoxin is not effective in converting postoperative atrial fibrillation. Amiodarone is currently the first-line drug for pharmacologic conversion of atrial fibrillation.\(^3^8\) A bolus dose of 5 mg · kg\(^{-1}\) in saline is given over a 30- to 40-minute period, followed by a continuous infusion of 0.25 to 0.5 mg · min\(^{-1}\) for 4 to 8 hours. Following conversion, oral amiodarone is generally recommended for 4 to 6 weeks.\(^3^9,3^6,3^8\)

Ibutilide (a class III antiarrhythmic agent)\(^3^3\) is also highly effective in converting postoperative atrial fibrillation and is at least as effective as amiodarone at converting new-onset atrial fibrillation (greater than 75% success).\(^3^1\) Adult patients are pretreated with intravenous magnesium (1-2 g) to reduce risk of torsades de pointes, and the serum potassium level is normalized. Higher doses of magnesium (up to 4 g divided into pre- and post-ibutilide infusion) have been recommended by some.\(^7^4\) Under continuous ECG monitoring, 1 mg of ibutilide is administered intravenously over 10 minutes. The dose can be repeated once. The major risk is a 1% to 4% occurrence of torsades.\(^3^6,3^7\) Ibutilide should be avoided in patients with very low ejection fraction, because of the high risk of ventricular arrhythmias.\(^3^6\) When ventricular response rate is rapid, pretreatment with esmolol may increase the efficacy of conversion with ibutilide.\(^3^1\)

Theoretical concerns have been raised about using ibutilide (which can be proarrhythmic with prolongation of QT interval) after amiodarone (which also prolongs QT interval but rarely causes torsades). When intravenous amiodarone is

not effective in conversion to sinus rhythm, several studies indicate that ibutilide is frequently successful and reasonably safe.²⁰,²¹ In a study of ICU patients (noncardiac surgical) who were not successfully converted from atrial fibrillation to sinus rhythm with amiodarone, 80% were successfully converted with ibutilide.²⁰,²¹ Non-sustained torsades de pointes occurred in 11% of patients, all of whom had depressed LV function. Torsades de pointes has been reported in about 5.5% of women and 3% of men who receive ibutilide.²⁰ It usually occurs within 45 minutes of completion of ibutilide infusion and resolves without treatment in about 40% of patients. Treatment of more than transient torsades includes intravenous magnesium plus lidocaine or cardioversion if the patient is hemodynamically unstable.²⁰,²¹ Deaths from torsades have rarely been reported in this setting.²⁰,²¹ Similarly, amiodarone can be safely administered if initial treatment with ibutilide fails.²¹⁴

Alternatively, in patients in whom atrial fibrillation or flutter is importantly embarrassing circulation, electrical cardioversion is indicated.²⁰,²¹ Using bipolar temporary atrial wires placed at operation (one each on the right atrium and left atrium), low-energy cardioversion techniques have been developed that result in an 80% conversion early postoperatively; anesthesia is unnecessary.²⁰,²¹

When atrial fibrillation persists for more than 48 hours, anticoagulation with heparin or warfarin is indicated for stroke prevention.²⁰,²¹

**Atrial Flutter.** Atrial flutter can be a difficult arrhythmia to control when it occurs postoperatively. Although not always successful, the best treatment is rapid atrial pacing via the two atrial epicardial wires placed at operation (see Appendix 5E).

Ibutilide is also effective in converting atrial flutter (>80% success) and is probably more effective than amiodarone.²¹ Ibutilide is also effective in converting atrial flutter in pediatric patients.²¹ The recommended dose is 0.01 mg · kg⁻¹ intravenously over 10 minutes.

**Paroxysmal Atrial Tachycardia.** Important episodes of paroxysmal atrial tachycardia or paroxysmal atrial contractions occurring after cardiac operations may also be treated by rapid atrial pacing. If these arrhythmias persist, however, the diagnostic and therapeutic advice of an electrophysiologically expert cardiologist is needed. Specific treatment depends on the precise nature of the supraventricular tachycardia. In general, administration of catecholamines should be reduced as much as possible; if additional support is necessary, milrinone is considered (see “Noninvasive Methods” under Treatment of Low Cardiac Output earlier in this section). β-Adrenergic receptor blocking agents such as propranolol are useful (see earlier discussion). Multifocal atrial tachycardias are often best treated by verapamil given intravenously.

**Junctional ectopic tachycardia (JET)** may be a particularly difficult problem in children, with a prevalence of 5% to 8%.²⁰,²¹ It is associated with operations to close VSDs, perioperative transient AV block, repair of AV septal defect,²¹ and young age. In 70 of 71 patients with postoperative JET, Walsh and colleagues obtained control of the arrhythmia and hemodynamic stability using a combination of sedation, hypothermia to 34°C, and procainamide.²¹⁰ Amiodarone may also be effective.²¹

**PULMONARY SUBSYSTEM**

**Adequacy**

**During Intubation**

Adequacy of pulmonary function early postoperatively while the patient is still intubated and receiving controlled ventilation is judged by the response of PaO₂ and arterial carbon dioxide pressure (PaCO₂) to the minute volume of ventilation and ventilating gas mixture being used. The response of the arterial oxygen levels can be expressed as the alveolar-arterial oxygen difference, P(A − a)O₂, which in intact humans is normally only a few mmHg. Nearly all patients early after cardiac operations have abnormally large alveolar-arterial oxygen differences due to intrapulmonary right-to-left shunting of 3% to 15%.²³,²⁹,³¹¹ This assumes that no right-to-left intracardiac shunting is present. Response of
the carbon dioxide levels can be expressed as the minute volume of ventilation required to maintain $P_{aCO_2}$ at 30 to 45 mmHg. Usually this is about 15 to 20 mL · kg$^{-1}$ in both adults and children.

When anesthesia and heavy sedation are no longer present and the ventilator is in a mode of intermittent mandatory ventilation (IMV), the patient’s ventilatory rate is a useful guide to the ease with which the respiratory center’s needs are met, and thus to the adequacy of pulmonary function. In an adult, a patient-triggered respiratory rate of 8 to 12 breaths · min$^{-1}$, with the usual tidal volume, inspiratory gases, and end-expiratory pressure, indicates adequacy of lung function.

Positive end-expiratory pressure (PEEP) may be used as a routine or on indication, with a setting of 5 to 8 cm H$_2$O for adults and children older than 12, and 4 cm H$_2$O for younger patients. Unless the hemodynamic state is suboptimal, PEEP does not alter it, even in infants.$^{13}$ PEEP is used because of studies that suggest it is associated with larger lung volumes, fewer perfused but nonventilated alveoli during ventilation, and smaller $P_{a}/(A – a)O_2$ after extubation.$^{14,15}$ PEEP is generally not advisable in patients with chronic obstructive lung disease (to avoid air trapping and rupturing a bulla, with consequent pneumothorax) and in infants and children who have undergone a Fontan operation or cavopulmonary anastomosis (to avoid still further elevation of jugular venous pressure; see Chapter 41).

Continuous positive airway pressure (CPAP)$^{41,85,86}$ may be used in infants once their cardiovascular state is stable, obviating the need for intermittent positive-pressure breathing (IPPB) and IMV. Should IPPB be required initially, the

![Figure 5-9](image)

**Figure 5-9** A, Arterial oxygen tension ($P_{aO_2}$), venous admixture ($Q_{\text{va}}/Qt$), and arteriovenous oxygen content difference [$\{C(a – v)O_2\}$] measured preoperatively and at intervals early postoperatively in 10 adults undergoing operation with cardiopulmonary bypass. B, Pre- and postoperative values for minute ventilation ($V_e$), frequency ($f$), and tidal volume ($V_t$) in the same patients. Air- and $O_2$-breathing results have been combined, and mean values for the group at each time are shown. (Data from Rea and colleagues.$^{84}$)

Infant is transferred to IMV and sometimes to CPAP for several hours before extubation.

**Exubation**

Traditionally, continued intubation after cardiac operations has been recommended to maintain more precise control of cardiopulmonary physiology. However, early extubation may shorten ICU and hospital stay. Therefore, a protocol beginning with anesthesia induction may be designed to expedite awakening and spontaneous breathing.

Once the patient has been extubated, $P_{aCO_2}$ and $P_{aO_2}$ levels, as well as the visually estimated work of breathing, are useful indices of pulmonary function. $P_{aCO_2}$ of less than 45 mmHg in adults, less than 50 mmHg in young children, and less than 55 mmHg in small infants indicates an adequate minute volume of ventilation. Higher values indicate inadequate alveolar ventilation. $P_{aO_2}$ is often mildly depressed at this time and usually remains so for the first few days after cardiac surgery performed with CPB (Fig. 5-9). This results from the somewhat widened alveolar-arterial oxygen difference. These measurements are valuable, but when a patient is comfortable, breathing easily and slowly, and the chest radiograph is essentially normal, it is highly probable pulmonary function is adequate and convalescence will be satisfactory.

**Causes of Dysfunction**

After cardiac surgery with CPB, the lungs are more likely to have dysfunction, albeit mild and transient, than any organ other than the heart itself. This dysfunction has multiple
Figure 5-10 Relationship between age at operation and duration of cardiopulmonary bypass (represented by solid isobars and their dashed 70% confidence limits) to probability of pulmonary dysfunction after cardiac surgery. Nomogram depicts specific solutions of a multivariable equation; value entered for C3a was 882 ng·mL⁻¹ (see original publication for details). (From Kirklin and colleagues.)

Causes. In part it is caused by absence of pulmonary blood flow during total CPB and by its near absence during partial CPB. Among other things, this results in very low shear stresses in the pulmonary capillaries. This appears to accentuate neutrophil activation, because neutrophils appear to be exquisitely sensitive to shear stress. Leukocytes are also activated by the general damaging effects of CPB and incite an inflammatory response in the pulmonary vasculature. During total CPB and lung ischemia, plasma thromboxane B₂ increases, and this may contribute to a pulmonary vascular inflammatory response. Cytokines interleukin (IL)-6 and IL-8 increase with CPB and may also contribute to membrane damage and neutrophil activation in the lung. The alveolar-capillary barrier becomes more permeable than normal and after cardiac surgery using CPB, macromolecules enter the pulmonary interstitium and ultimately the alveoli, promoting development of pulmonary edema. During the early hours after CPB, radioactive albumin injected intravenously can be detected in considerable quantity in fluid aspirated from the tracheobronchial tree (Digerness SB, Kirklin JW: personal communication; 1972). Postoperative disturbances of lung function and increases of alveolar polymorphonuclear leukocytes have been linked to important reduction of pulmonary surfactant activity. In addition, multiple and not yet totally defined factors encourage development of large areas of atelectasis, either segmental or occasionally lobar; in particular, the left lower lobe has a strong tendency to atelectasis, even in patients who are otherwise convalescing normally.

In some patients, direct trauma to the lungs occurs and contributes to pulmonary dysfunction. Should secretions be retained during or early after the operation, these also contribute to dysfunction. Left (and occasionally, right) phrenic nerve injury may occur after carefully performed cardiac operations, increasing the tendency to pulmonary dysfunction early postoperatively. However, left lower lobe atelectasis is considerably more common than left phrenic nerve paralysis; Markand and colleagues found the left phrenic nerve to be paralyzed in only 11% of patients experiencing left lower lobe atelectasis early after open heart operations. In most patients, the left phrenic nerve recovers within 6 months from its paralysis. Mechanical obstruction of the lower trachea or the bronchi can produce pulmonary dysfunction that may go unrecognized unless care is taken to identify and treat it. Localized or more extensive pulmonary edema may develop in the presence of low or normal left atrial pressure, no doubt related to changes in pulmonary venular and capillary permeability, the causes of which are only partially understood. This phenomenon seems to be more marked in elderly patients. Less commonly, frank pulmonary hemorrhage developing as CPB is discontinued or early thereafter can cause serious bronchial obstruction and contribute in a major way to pulmonary dysfunction. This is probably a more severe result of the same factors that lead to pulmonary edema in patients with normal or low left atrial pressures.

Risk Factors for Acute Dysfunction

Patient-Specific

Patient-specific risk factors for pulmonary dysfunction after cardiac surgery have long been recognized, but formal identification and quantification are rare. In a formal observational study, young age at operation was identified as a risk factor, particularly when the patient was younger than about 2 years old (Fig. 5-10). Similar observations were made by Lell and colleagues. Increased risk with young age is associated with the increased tendency of the very young to develop whole body edema after CPB. In the experience of most institutions, and in a study by Gallagher and colleagues, older age, particularly older than 60 years, has also been associated with increased prevalence of pulmonary dysfunction after cardiac surgery. Chronic obstructive lung disease is an important risk factor for pulmonary dysfunction postoperatively and increases the overall risk of operation because it predisposes patients to increased work of breathing and air trapping. Preoperative pulmonary arterial hypertension, even when associated with low pulmonary arteriolar resistance, predisposes infants to pulmonary dysfunction and also to paroxysms of pulmonary
arteriolar constriction and pulmonary hypertension early postoperatively (see “Pulmonary Hypertensive Crises” later in this section). Congenital morphometric pulmonary abnormalities like the alveolar hypoplasia frequently present in patients with congenital heart disease and Down syndrome increase the prevalence of postoperative pulmonary dysfunction. \textsuperscript{71} Some drugs given during the period before operation increase the prevalence of pulmonary complications postoperatively; amiodarone, used to control cardiac arrhythmias, has been linked to severe pulmonary dysfunction after cardiac surgery. \textsuperscript{D22,K12,M9}

**Procedural**

The type of oxygenator used is probably related to the amount of pulmonary dysfunction generated by the operation, with oxygenators other than membrane-type being risk factors for pulmonary damage. \textsuperscript{K21} Proper filters in the arterial tubing may reduce pulmonary dysfunction postoperatively. \textsuperscript{K17} Longer duration of CPB is a risk factor. This is probably related in part to the direct correlation between duration of CPB and increase in the patient’s extracellular water. \textsuperscript{E1,E16,P1} (Fig. 5-11). The amount of C3a generated by complement activation during CPB is a risk factor for pulmonary dysfunction; this may relate to a greater amount of neutrophil activation with higher levels of C3a. \textsuperscript{K18} Use of external cardiac cooling, particularly by ice slush rather than cold saline, increases the prevalence of left phrenic nerve paralysis, hence the tendency to postoperative pulmonary dysfunction. \textsuperscript{K12}

**Postoperative**

Postoperative events can increase the probability of pulmonary dysfunction. Elevated left atrial pressure, with consequent elevation of pulmonary capillary and venular pressures, aggravates the tendency toward increased lung water and pulmonary dysfunction. The longer the patient is on a ventilator, the greater the chances of continuing pulmonary dysfunction. Paralysis of the phrenic nerve and the consequent elevation of the left hemidiaphragm predispose patients to continuing pulmonary dysfunction, particularly small patients. \textsuperscript{R20,S25}

**Course of Dysfunction after Cardiac Surgery**

Mild pulmonary dysfunction in normally convalescing patients slowly improves without specific therapy except for ambulation and breathing exercises; however, residues of dysfunction may still be present 10 days after operation. \textsuperscript{K24} Occasionally in the patient who appears to be convalescing normally and is out of the ICU for 3 to 6 days, orthopnea and paroxysmal nocturnal dyspnea may develop insidiously. This is particularly likely to occur in patients who have marked LV hypertrophy or poor LV function preoperatively, and it may occur even though their left atrial pressure was less than 15 mmHg when last monitored in the ICU. The chest radiograph may have been normal or may have shown evidence of a mild increase in interstitial fluid. Response to diuresis in such a patient is dramatic and, as a rule, terminates the problem. The hypothesis is that fluid that has accumulated in the interstitial spaces throughout the body during and early after CPB returns to the vascular space 24 to 72 hours after operation. Blood volume is thereby increased at a time when the renal response is subnormal, and diuresis and control of blood volume do not follow. \textsuperscript{C18,P1} In this setting, LV end-diastolic, left atrial, and pulmonary venous pressures rise and symptoms develop. Weight gain and other gross evidence of fluid retention may be absent.

Occasionally, patients who have convalesced without difficulty begin to cough up thick tracheobronchial secretions 48 to 72 hours after operation. Often, seemingly paradoxically, whatever dyspnea and tachypnea may have been present begins to lessen with these events. Presumably at this time, protein-rich fluid that has been in the alveoli and interstitium of the lung since CPB (or soon thereafter) begins to be moved by ciliary action out of the terminal bronchioles and into the larger airways, from which it can be cleared by coughing.

**Figure 5-11** Relationship between duration of cardiopulmonary bypass and increase in interstitial fluid (ECF-PV) 4 to 6 hours after operation. The x’s represent patients undergoing closure of left-to-right shunts; circles represent those undergoing operation for valvar heart disease. Patients with heart failure were not included. The regression equation is:

\[
\text{Ln (ECF−PV)} = -3.248 + 0.8248 \times \text{Ln (CPB time)}
\]

\[r = 0.86; \ P < 0.0001\]

Key: CPB, Cardiopulmonary bypass; ECF, extracellular fluid; \text{ln}, natural logarithm; PV, plasma volume. (Data from Cleland and colleagues. \textsuperscript{K16})
Lung volumes are usually reversibly decreased early after cardiac surgery, particularly vital capacity and total lung volume. This is probably the result of the summation of multiple small areas of atelectasis, occasionally left lower lobe collapse, occult pulmonary edema and pleural fluid, and reduced inspiratory efforts. These usually revert to normal within 3 to 6 months.

Management and Treatment

The goal of treatment of the pulmonary subsystem is the earliest possible return of the patient to extubated spontaneous breathing and ambulation. In an era characterized by the ability to intensively treat both large and small patients after cardiac surgery, the distinctly beneficial effects of early extubation are often forgotten. These include a decline in intrapleural pressure and an increase in LV end-diastolic diameter (or volume), improved ventricular systolic function (due to increased preload associated with shifting of some of the blood volume toward the chest), and improved cardiac output.

General Measures

Patients who are convalescing normally are extubated either in the OR or during the early hours after operation. In most ICUs, it is advisable to extubate patients in the daytime rather than at night; this consideration is a reasonable cause of delay of extubation for a few hours. Otherwise, when pulmonary function is good, extubation should be delayed only under special circumstances, including the presence of cardiac assist devices and the possibility of early reoperation. In general, criteria for extubation include stable and satisfactory cardiac performance, lack of important cardiac arrhythmia, and appropriate awakening with satisfactory neurologic status. There should be no anticipation of return to the OR (e.g., for bleeding) and satisfactory mechanics and ventilatory lung function, as assessed by arterial blood gas analysis and a clinical estimate of inspiratory force and volume. Increasing emphasis has been placed on the advisability of routine extubation of the normally convalescing patient within 6 hours of arrival in the ICU.

A major cause of postoperative pulmonary dysfunction is atelectasis and the associated loss of functional alveolar units. Standard prophylactic measures include chest physiotherapy and use of devices to encourage deep inspirations to recruit atelectatic areas. Zarbock and colleagues demonstrated a beneficial effect of prophylactic nasal positive airway pressure at 10 cm H₂O for at least 6 hours.

Treatment of patients with pulmonary dysfunction who are still intubated during the early hours after operation is in large part an intensification of the usual management, as effective specific therapy is not available. Fractional inspired oxygen (FIO₂) is appropriately adjusted upward if P(A – a)O₂ is large. Minute volume of respiration (not only measured, but judged visually by excursion of the chest wall) and respiratory rate are adjusted to maintain PaCO₂ at about 30 to 35 mmHg. The airway is kept clear by appropriate tracheal suctioning (see “Pulmonary Hypertensive Crises” later in this section for special precautions in neonates and infants). When hemoconcentration develops from leakage of plasma from the intravascular space into the interstitial space of the lungs, and at times into all other organs and the pleural and peritoneal spaces, administration of concentrated serum albumin is helpful in counteracting this trend. Diuretics are useful because they reduce extracellular fluid volume and, in turn, extravascular lung water. During all this, efforts continue to reduce ventilatory support and work toward extubation of the patient (see Appendix 5F). Spontaneous breathing trials and decreasing levels of pressure support appear equally effective in patients who are difficult to wean.

Prolonged Intubation

A prolonged period of endotracheal intubation is necessary when:

- Criteria for extubation are not met.
- Neurologic complications are present.
- Severe dysfunction of the cardiac subsystem is present.
- Persistent chest drainage or a residual cardiac defect make early return to the OR likely.

During periods of prolonged ventilation, active decisions are required regarding use of continuous vs. intermittent sedation and neuromuscular blockade, depending on hemodynamic stability, effectiveness of ventilation, and timing of ventilator weaning. Commonly used sedation and paralytic agents are described in Tables 5-4 and 5-5.

When patients are agitated after cardiac surgery, particularly during ventilator weaning, the first priority is evaluating cardiac and pulmonary subsystems to ensure that agitation is not an indicator of important cardiac or pulmonary dysfunction. If these subsystems have satisfactory function, the next level of intervention targets communication with the patient by nursing or physician staff, or both, to allay patient anxiety. When these interventions are insufficient, pharmacologic agents commonly used to alleviate agitation and anxiety in the ICU include benzodiazepines (e.g., diazepam, lorazepam, midazolam), opioid analgesics (e.g., fentanyl, hydromorphone, morphine, remifentanil), propofol, dexmedetomidine, and neuroleptics (e.g., haloperidol).

Prolonged intubation (≥48 hours) entails problems necessitating fastidious care of the patient. A pneumothorax occasionally develops from positive-pressure breathing, usually requiring urgent aspiration and underwater drainage. Bronchospasm may become a particular problem, probably as a reflex response to proteinaceous tracheobronchial fluid often present under these circumstances. Administration of nebulized isethionate every hour can be helpful. In extreme cases, aminophylline is given as a continuous intravenous infusion in 10% dextrose in a dose of 0.15 mg · kg⁻¹ · min⁻¹. An initial loading dose of about 4 mg · kg⁻¹ is given over 20 minutes. Neonates, infants, and young children who require intubation and ventilation for more than about 14 days often have phrenic nerve paralysis; in these patients, plication of the hemidiaphragm often permits prompt extubation.

In those unusual circumstances when intubation in older children and adults is necessary for more than about 10 days, consideration is given to tracheostomy. Both patient comfort and effectiveness of ventilation are thereby usually increased. This procedure has disadvantages but is sometimes helpful in weaning the patient from the ventilator. Tracheostomy is rarely performed in neonates, infants, and young children, because it is difficult to manage in this age group.

Reintubation

When the patient meets all criteria for extubation, reintubation is usually unnecessary. However, reintubation is indicated when:

- PaCO\(_2\) rises above 50 mmHg over 4 hours in the absence of appropriate respiratory compensation for metabolic alkalosis.
- Signs of decreasing cardiac output are noted.
- Signs of exhaustion from breathing spontaneously are observed.
- Excessive pulmonary secretions with ineffective coughing are evidenced.

When the situation is borderline, proper management requires careful observation by senior members of the team. Reintubation should be performed by a competent professional.

Pulmonary Hypertensive Crises

Description. **Pulmonary hypertensive crisis** is a phrase used to describe a serious syndrome of hyperacute rise in pulmonary arterial pressure usually accompanied by bronchospasm, often followed within seconds or accompanied by profound reduction in cardiac output and fall in SaO\(_2\); these sequelae may be irreversible. The syndrome occurs most commonly, but not exclusively, among neonates and infants who are intubated after an operation for repair of a congenital cardiac defect associated with pulmonary arterial hypertension. Pulmonary artery pressure is usually essentially normal or mildly elevated after repair, until an episode of pulmonary hypertensive crisis. The crisis may appear spontaneously but usually occurs during or shortly after endotracheal tube suctioning, particularly if the endotracheal tube is too far down the trachea and makes contact with the carina. Multiple crises may occur in a single patient. The prevalence of pulmonary hypertensive crises is greatest about 18 hours after operation, but they can occur before or after that time.\(^{1,2,8}\) During an acute hypertensive crisis, atypical cardiac tamponade can result from acute RV dilatation.\(^{13,8,11}\)

Incremental Risk Factors. Although recognized for many years, its precise cause at the time it occurs is unknown.\(^{1,17,22}\) Congenital cardiac defects accompanied by large pulmonary blood flow and relatively low pulmonary vascular resistance
are strong patient risk factors for their development. Chief among them are truncus arteriosus and AV septal defect. The histology of the pulmonary arteries and arterioles is normal or mildly abnormal, with all changes considered to be clearly reversible. The syndrome is not seen in patients with fixed pulmonary hypertension or severe pulmonary vascular disease. Procedural risk factors have not been clearly identified, although absence of pulmonary blood flow during CPB, accumulation of neutrophils in the lung, and damage to pulmonary endothelial cells are known to occur and provide a favorable setting for development of pulmonary hypertensive crises. Release of arachidonic metabolites from some cells in the lung (probably pulmonary endothelial cells), failure of pulmonary endothelial cells to inactivate bradykinin, and release by injured pulmonary endothelial cells of the vasoconstrictive platelet-activating factor are probably all encouraged by events during CPB, perhaps particularly if these cells were preconditioned before operation by a high pulmonary blood flow. Postoperative risk factors nearly certainly include acute hypoxia, which is known to produce acute hypoxic vasoconstriction, probably using some of the mechanisms just described. Catecholamine administration appears to predispose patients to these crises.

Prevention. Because pulmonary hypertensive crisis may be fatal despite intense therapy, its prevention is critical. An important preventive measure in neonates and infants is maintenance of paralysis and sedation (with pancuronium or fentanyl) for at least the first 20 to 24 postoperative hours, and for at least another 24 hours or longer if the patient remains intubated (see Section IV, “General Care of Neonates and Infants,” later in this chapter). Fentanyl has been shown to be a safe agent in neonates and adults, with little adverse effect on cardiac function or systemic and pulmonary circulations. A paralytic agent (see Table 5-4) is given along with fentanyl to prevent rigidity. Fentanyl (in a dose of 25 μg · kg⁻¹), along with pancuronium, should be given before suctioning the endotracheal tube in any neonate or infant who is not already well paralyzed and sedated, because it appears to minimize the possibility of a pulmonary hypertensive crisis. In addition to sedation, aggressive treatment of acidosis, including hyperventilation to PCO₂ = 30 to 34 mmHg, decreases prevalence and severity of pulmonary hypertensive crises. When the monitored pulmonary artery pressure becomes paroxysmally elevated early postoperatively, efforts are made to control and reduce it. A high FiO₂ is maintained because this is as useful an agent as exists for reducing pulmonary vascular resistance. Direct infusion of nitroprusside into the pulmonary artery has also been useful. Many agents have been advanced as being optimal on the grounds that they selectively reduce pulmonary vascular resistance, but few do so, and no clearly superior one has been identified. There are encouraging results from use of inhaled nitric oxide to reduce pulmonary artery pressure in cardiac transplant recipients, patients on LV assist devices, and generally in infants and children prone to pulmonary hypertensive crises. Journis and colleagues found that 15 of 17 children having critical pulmonary hypertension following operation for congenital heart disease responded to inhaled nitric oxide (20 ppm) after failure of conventional medical treatment (Table 5-6). Pulmonary arterial pressure decreased without a change in systemic arterial pressure but with concomitant increase of SaO₂ and SVo₂. Other investigators have also shown an increase in cardiac index and improvement of indices of RV function after nitric oxide treatment. Intra-pulmonary shunt fraction may decrease as well. The response in postoperative patients with valvar heart disease may be less satisfactory.

Nitric oxide inhaled at 20 ppm reduces pulmonary artery pressure and improves SVo₂ within 10 min, while having no effect on systemic arterial pressure when given to a group of patients following operations for defects associated with pulmonary hypertension.

Key: HR, Heart rate; NO, nitric oxide; PPa, systemic arterial pressure; PAo, pulmonary arterial pressure; SaO₂, arterial oxygen saturation; SVo₂, mixed venous blood oxygen saturation.

RENAL SUBSYSTEM

Adequacy

As a guide to the continuing evaluation of the renal subsystem, a urinary catheter is inserted preoperatively in the OR and left for a minimum of 48 hours to monitor hourly urine flow. In some cases, consideration should be given to use of a trocar-introduced suprapubic catheter in adults, rather than a urethral catheter, because this type of catheter is more comfortable, easier to manage, and associated with less urinary tract infection. Serum potassium concentration is measured every 4 hours during the first 24 postoperative hours and, if the patient is still in the ICU, every 8 hours for at least the next 48 hours. Serum creatinine and blood urea nitrogen (BUN) levels are measured each morning for at least the first 48 hours.

Convalescence early after cardiac surgery can, arbitrarily, be considered adequate with regard to urine flow when urine volume is greater than 500 mL · 24 h⁻¹ · m⁻², or 167 mL · 8 h⁻¹ · m⁻², or 20 mL · 1 h⁻¹ · m⁻². Some prefer to use the criterion of 0.5 to 1 mL · h⁻¹ · kg⁻¹ in the case of infants and small children.

In most postoperative patients, CPB induces a diuresis early after operation. Factors responsible for this are hemodilution with a clear fluid prime (lactated Ringer solution, D₅W + ½ NaCl normal saline, or PlasmaLyte A), and often glucose and mannitol additions to increase tubular oncotic load. Low cardiac output therefore can exist early postoperatively even
in the presence of nominally adequate urine flow. Renal function is inadequate when solute excretion is insufficient to keep serum potassium below 5 mEq · L\(^{-1}\), BUN below 40 mg · dl\(^{-1}\), and creatinine below 1.0 mg · dl\(^{-1}\). Convalescence cannot be considered normal when urine is pink but without red blood cells early postoperatively, because this indicates a free plasma hemoglobin greater than 40 mg · dl\(^{-1}\) and an inordinate and potentially dangerous amount of hemolysis.

Acute renal failure requiring dialysis is rare in adults,\(^5\) but postoperative renal dysfunction (doubling or greater of serum creatinine) occurs in approximately 1% of adult patients if preoperative renal function is normal. If any degree of renal dysfunction is present preoperatively, it occurs in 16% to 20% of patients, about one fifth of whom will need dialysis. Acute renal failure occurred in less than 3% of children undergoing open intracardiac operation.\(^6\) Acute renal failure (in patients without preexisting renal disease) after cardiac surgery is nearly always associated with low cardiac output, but rarely may occur when the other criteria of cardiac subsystem performance are satisfactory.\(^3\)\(^,\)\(^4\)\(^,\)\(^1\)\(^9\)

Causes of Acute Dysfunction after Cardiac Surgery

There are no usual intraoperative events during well-conducted cardiac operations that are damaging to renal function and can be considered causes of acute renal failure.

Risk Factors for Acute Dysfunction

**Patient-Specific**

Poor preoperative renal function is intractable to therapy considerably increases the risk of acute renal failure early postoperatively.\(^1\)\(^)\(^9\)\(^,\)\(^1\)\(^2\)\(^0\) Therefore, preoperative evaluation includes assessment of renal function.

The predictive value of serum creatinine and glomerular filtration rate (GFR) on the risk of postoperative dialysis has been quantified by Mehta and colleagues\(^4\)\(^,\)\(^1\)\(^9\)\(^)\(^,\)\(^4\)\(^1\)\(^9\) for adult patients undergoing cardiac surgery (Fig. 5-12). Although traditionally GFR is the standard measure of renal function, its formal measurement is frequently not feasible in the clinical setting. A useful approximation of creatinine clearance can be made with the Cockcroft-Gault equation\(^1\)\(^7\)\(^,\)\(^9\)\(^2\)\(^1\),

\[
Cr \text{ Clearance} = \frac{(140 - \text{age} \times \text{lean body weight [kg]})}{Cr \text{ (mg · dl}^{-1}\text{) \times 72}}
\]

where \(Cr\) = creatinine. For women, multiply the result by 0.85 to account for smaller muscle mass.

Chronic heart failure (preoperative NYHA class IV) considerably increases risk of acute renal failure after operation, as does cyanotic heart disease after cardiac surgery in older patients.\(^3\)\(^1\) A renal lesion is known to exist preoperatively in many such patients. This does not appear to be the case in young patients; for example, renal failure is rare in infants and children undergoing repair of tetralogy of Fallot.\(^3\)\(^2\)\(^1\)

Young age is a risk factor for acute renal failure. When cardiac output is importantly reduced after cardiac surgery in neonates and infants, a prevalence of acute renal failure as high as 8% to 10% has been reported\(^4\)\(^1\)\(^4\)\(^,\)\(^8\) (Srinivasan and colleagues: personal communication; 1981). One reason for this apparently increased prevalence may be that immature kidneys have less ability to concentrate urine in the face of reduced renal blood flow. Compared with older patients, infants may develop more tissue hypoxia during and early after CPB, with a resulting increase in production of potassium, BUN, and other substances, some of which may be nephrotoxic. Uric acid levels, for example, were shown by Hencz and colleagues to rise to nephrotoxic levels (10 mg · dl\(^{-1}\)) in some patients within 24 hours of operation, and the levels were higher (\(P = .001\)) in patients younger than 3 years of age than in older children.\(^3\)\(^1\)\(^5\) At the other end of the spectrum, older age (>70 years) is a risk factor for developing acute renal failure.\(^3\)\(^1\)\(^2\)

Obesity has also been identified as a risk factor for postoperative acute renal failure.\(^3\)\(^4\)

**Procedural**

A long period of CPB increases the risk of acute renal failure.\(^8\)\(^8\) This has been demonstrated by a prospective study\(^8\)\(^1\)\(^8\) and is probably in part related to the damaging effects of CPB. There is an additional risk imposed by a longer duration of hypothermic circulatory arrest, particularly in infants and children.\(^3\)\(^1\)\(^6\) However, a CPB flow of 1.6 L · min\(^{-1}\) (at body temperatures of 28°C or higher) with a mean arterial blood pressure of at least 30 mmHg seems to minimize occurrence of acute renal failure when postoperative cardiac output is good.\(^3\)\(^2\)\(^0\)
Several studies suggest that using a CPB prime of whole blood (rather than hemodilution) increases the risk of acute renal failure, as does high plasma hemoglobin level (>40 mg · dL⁻¹) during and early after CPB.

**Postoperative**

Acute reduction in cardiac output early after operation is the most common and most important risk factor for developing acute renal failure. Yet the prevalence of acute renal failure varies among patients with low cardiac output, in part because of the role played by other risk factors. Picca and colleagues found a 79% mortality in children developing acute renal failure.

Management and Treatment

One important aspect of managing the renal subsystem is a reasonable program of fluid administration (see “Fluid, Electrolyte, and Caloric Intake” in Section II of this chapter) early after open cardiac operations. Its purpose in part is avoidance of fluid overload that can easily develop with even mild impairment of renal function. There is no evidence that larger amounts of fluids reduce the prevalence of acute renal failure in this setting. Maintaining good function in other subsystems, particularly cardiac, is a second important aspect of managing the renal subsystem after cardiac surgery.

When oliguria occurs early postoperatively, cardiac preload and afterload are optimized, and administration of dopamine at 2.5 μg · kg⁻¹ · min⁻¹ is begun (see Appendix 5G). The direct diuretic effect of low-dose dopamine and its subsequent prevention of oliguric renal failure are controversial. At best, dopamine may increase cardiac output, blood pressure, or both, resulting in greater urine volume, but its therapeutic effect on GFR, creatinine clearance, and serum creatinine is doubtful, particularly in high-risk patients. If these measures do not quickly suffice, furosemide (1 mg · kg⁻¹ or up to 40 mg in adults) is administered intravenously. If a good response is obtained, this dosage is repeated every 6 to 12 hours for 3 days. If a response is not obtained within 30 to 60 minutes, the dose is doubled and then quadrupled, and then 8 mg · kg⁻¹ is given. Because of the propensity for increasing osmolarity with mannitol, an alternative recommendation is a pure furosemide infusion at a dose of 1 to 15 mg · h⁻¹ in adults and 0.1 to 0.5 mg · kg⁻¹ · h⁻¹ in infants and children. This technique produces a more consistent urine output, often with a smaller total dose of furosemide than intermittent furosemide administration. This therapy is based on the reasonable hypothesis that maintenance of urine production, even though dilute, is advantageous to renal function. When serum potassium rises above 5.5 mEq · L⁻¹, a glucose and insulin solution is given intravenously, and sodium polystyrene sulfonate enemas are used (see Appendix 5H). These are temporary palliative measures to be used until dialysis can be initiated.

Alternatively, when urine flow does not respond to the first few doses of the furosemide schedule, infusion of a “renal cocktail” may be effective. This consists of a mixture of 400 mg of furosemide in 100 mL of 20% mannitol (both amounts are halved for small patients); it is administered continuously at a furosemide rate of 1 mg · kg⁻¹ · h⁻¹. During infusion of the renal cocktail, the serum osmolarity of the patient is measured every 2 to 4 hours; if it exceeds 310 mOsm · L⁻¹, the infusion is immediately discontinued. Otherwise, it is administered for 4 hours, discontinued for 4 hours, then administered for another 4 hours, and so forth. If a large urine flow develops, the “cocktail” is usually discontinued after 24 hours, or after 3000 mL of urine (in an adult) has been excreted. If a large urine flow does not develop within about 2 hours of beginning this infusion, it is stopped. Occasionally in the absence of a diuretic response to furosemide, intravenous ethacrynic acid (100 mg for an adult) may be effective.

Unless oliguria and hyperkalemia respond to treatment within a few hours, especially in neonates and infants, a considerable probability of death exists. Therefore, peritoneal dialysis or continuous arteriovenous hemodialysis is initiated on an emergency basis; the urgency is in part due to the frequent coexistence of an increased extracellular fluid volume (“fluid overload”) dating back to the time of CPB. More optimally, preventive measures are applied earlier, including (1) ultrafiltration during the closing phases of CPB (see “Components” under Pump-Oxygenator in Section III of Chapter 2); (2) limitation of fluid administration during the early hours after operation; and (3) routine placement, in neonates and infants, of a small silicone peritoneal dialysis catheter through the lower end of the incision used for the median sternotomy. The advantages of this last
technique have been developed and emphasized by Mee.\textsuperscript{M18} His protocol includes using the catheter simply as a drain initially, occasionally the tube drains large amounts of peritoneal fluid with a protein content similar to that of plasma. Should oliguria develop that is unresponsive to furosemide, or should serum potassium rise above 5 mEq $\cdot$ L$^{-1}$, rapid-cycle low-volume peritoneal dialysis is recommended. Dialysates, alternatively isotonic and hypertonic, are used in volumes of 10 mL $\cdot$ kg$^{-1}$. Potassium content depends on serum potassium concentration. Particularly in neonates, infants, and children, dialysis by this or other techniques usually improves cardiac performance and decreases ventilatory requirements.\textsuperscript{M18,Z2} Complications of such protocols are rare; the most frequent error in their use is delay in beginning intervention.\textsuperscript{B20,H4,N14,R8,Z21} At least one study has demonstrated beneficial effects of prophylactic peritoneal dialysis in neonates and infants after complex cardiac operations.\textsuperscript{S7}

In older children and in adults, who more commonly develop nonoliguric renal failure,\textsuperscript{S40} conventional hemodialysis may be appropriate when indicated. However, continuous pumped or unpumped arteriovenous or venovenous hemofiltration is the technique preferred in this setting, with the unpumped technique having advantages in patients who are hemodynamically unstable.\textsuperscript{B6,M28}

**NEUROPSYCHOLOGICAL SUBSYSTEM**

Neuropsychological symptoms and signs after cardiac surgery are difficult to categorize, arguable as to etiology, and often overlooked. Literature concerning them is voluminous, and inferences from the available information are controversial.\textsuperscript{B28}

The neuropsychological sequelae of hypothermic circulatory arrest are described separately in “Brain Function and Structure: Risk Factors for Damage” and “Effects of Brain Damage” under Damaging Effects of Circulatory Arrest during Hypothermia in Section I of Chapter 2. (For a discussion of the emergency treatment of seizures, one sequela of hypothermic circulatory arrest, see Appendix 5I.)

**Generalized (Diffuse) Neuropsychological Function**

Intelligence, problem-solving, concentration, learning, memory, error-free performance, and dexterity are components of the general neuropsychological subsystem, and all or some of these have been included in the term cognitive functions. It is believed that changes in these cognitive functions reflect genuine disturbances in the brain and are testable, usually by psychometric study.

**Adequacy**

Concentration, memory, learning, and speed of visuomotor responses have been reported to be adequate early postoperatively in less than half of patients who undergo cardiac surgery with CPB.\textsuperscript{N7,S14,S15} However, in many patients this inadequacy (or decrease in function) is only mild (and presumably transient); in about 20% of patients it is moderate in severity, and in 5% it is severe.\textsuperscript{S14} By contrast, after peripheral vascular surgery, mild inadequacy is present in 30% of patients, and moderate or severe disturbances in none.\textsuperscript{S14} These findings have been disputed, however, and the early prevalences remain uncertain.\textsuperscript{H3,M25,R12,S26} By 8 weeks after operation, at least 60% of patients have adequate (normal) cognitive functions. Six months to 5 years after operation, more than 80% of patients have adequate (normal) function of this subsystem,\textsuperscript{S31} although Newman and colleagues observed an increase in cognitive decline between 6 months and 5 years.\textsuperscript{S26}

These estimates from objective testing of patients after open cardiac operations have seemed incompatible with the general experience of many physicians and surgeons. The general experience is that patients are not commonly disabled by neuropsychological problems unless they have experienced an overt stroke.\textsuperscript{O1,T16} In no instance among a carefully studied group of 165 patients was neuropsychological dysfunction sufficient to prevent return to work.\textsuperscript{S15}

**Causes of Dysfunction**

Presumably, organic changes in the brain cause disturbances of the general neuropsychological subsystem. Embolization and hypoperfusion, with resultant ischemia, have most generally been considered etiologic to these organic changes. Additional studies have also implicated the inflammatory response to CPB and genetic susceptibility as additional contributors to neuropsychological dysfunction.\textsuperscript{S24} In adults randomized to either pH-stat or alpha-stat acid-base management during CPB, cerebral blood flow was greater using the pH-stat strategy. However, patients with higher cerebral blood flow suffered greater postoperative neurophysiological impairment, suggesting that hyperemia as well as hypoperfusion may be factors in postoperative cerebral dysfunction.\textsuperscript{P11} Speculatively, the causes of both general neuropsychological subsystem dysfunction and localized subsystem dysfunction (e.g., stroke) are the same except in degree, distribution, or both.

Emotions and moods of patients appear to be causally related to cognitive function. For example, patients who sense cognitive deterioration after CPB usually are not found to have it by objective testing; instead, they are found to have more depression postoperatively than preoperatively.\textsuperscript{N8} Also, preoperative depression and lower socioeconomic status appear to appreciably increase risk of deterioration of cognitive function postoperatively.\textsuperscript{P8} In a study of patients randomized to either coronary angioplasty or surgical revascularization, cognitive function was similar in each group after 5 years of follow-up, suggesting no lasting detrimental effect of CPB,\textsuperscript{H21} a finding contrary to that of Newman and colleagues.\textsuperscript{N6}

**Risk Factors for Acute Dysfunction**

Knowledge in this area remains incomplete, in part because of difficulty in defining and measuring the endpoints of acute dysfunction, as well as the variables that are possible risk factors for development of dysfunction. Older age at operation is a mild risk factor for diffuse neuropsychological dysfunction postoperatively.\textsuperscript{T7} Mild or moderate carotid artery stenosis is not a risk factor.\textsuperscript{T7} Longer duration of CPB has been found to be a risk factor for general neuropsychological disturbances after the cardiac operation.\textsuperscript{N7,N9,S6,S26} As has a greater amount of microembolization, both particulate and gaseous.\textsuperscript{B17,F20} Normothermic CPB (used in combination with warm myocardial management) was noted by one group to have a comparatively higher occurrence of central neurologic system events than standard hypothermic perfusion.\textsuperscript{C29} However, other studies have not corroborated these findings.\textsuperscript{B6} Engelman and colleagues\textsuperscript{E4} performed a randomized study to evaluate the effect of perfusion temperature on prevalence of postoperative neurologic dysfunction; 291 patients were divided among perfusion temperatures of 20°,
32°C, and 37°C. In the group as a whole, there was a 36% prevalence of neurologic dysfunction at 1 month postoperatively but no difference in cognitive function, elemental skills, or neurologic functional capacity among the groups. Aside from that for pH-stat regulation, no other correlation has been found between total cerebral blood flow during CPB and prevalence of general neuropsychological dysfunction after operation.\textsuperscript{V3} Oxygenators other than the membrane type and absence of 40-μm arterial blood filtration somewhat increase the risk of this type of dysfunction.\textsuperscript{B16}

Course of Dysfunction
As indicated earlier, the prevalence of general neuropsychological dysfunction declines considerably as time passes after the operation.

Management and Treatment
Management and treatment involve prevention and intelligent counseling and reassurance. The former consists of further improvements in CPB and techniques of cardiac operations. The latter is highly important in determining the final overall result of the operation, because perceived continuing dysfunction can limit quality of life. For example, Bhudia and colleagues performed a randomized clinical trial of 350 adults to evaluate magnesium as a neuroprotector during CPB (780 mg MgSO\textsubscript{4} in 100 mL normal saline intravenously over 15 minutes during anesthesia induction, followed by 3160 mg in 100 mL normal saline over 24 hours; the CPB circuit was primed with MgSO\textsubscript{4} to a concentration of 3.6 mg \textcdot dL\textsuperscript{-1}).\textsuperscript{B15} Magnesium was found to preserve short-term memory and cortical control over brainstem functions (primitiive reflexes).

Mood State

Adequacy
An adequate mood state after a cardiac operation is one without unusual anxiety, depression or euphoria, or delirium. Prevalence of an inadequate mood state has received little study, for reasons similar to those in the case of the general neuropsychological subsystem. In one study of 759 patients undergoing CABG, 7% showed transient confusion without delirium, and in no case did delirium develop thereafter.\textsuperscript{C1}

Causes and Risk Factors for Acute Dysfunction
Preoperative emotional characteristics of the patient play a major role in postoperative mood state. In a study performed during the early era of open cardiac operations, Burgess and colleagues found all patients to have acute preoperative anxiety in varying degrees; a few were frankly depressed. Absence of daily access to an empathetic individual who is not part of the surgical team, both before and after operation, was an important risk factor for increased anxiety and depression postoperatively. These mood states were particularly apparent in the ICU and during the first few days thereafter.

Course of Dysfunction
Most patients have some degree of anxiety during the first few postoperative days, and severe delirium occurs in 2% to 10%; 10% to 20% of patients have hallucinations and frightening dreams late postoperatively, and 10% to 20% of patients may continue to have episodic alterations in mood state after hospital discharge. In some patients, this seems to be related to difficulty in adjusting to the situational demands of life with improved cardiac function.

Management and Treatment
Daily access to an empathetic individual not identified with the surgical team, and attention to the patient as a sensitive and threatened human being by physicians, are the most important methods of prevention. When the mood state becomes severely abnormal, psychiatric assistance is required.

Localized Neuropsychological Function

Adequacy
Most patients recover from open cardiac operations without gross localized neuropsychological subsystem dysfunction (e.g., hemipareses, hemiplegias), and in them the subsystem performs adequately throughout convalescence. Subtle defects occur more frequently. Visual field defects are sometimes perceived by the patient and confirmed by testing, and then usually regress or disappear.\textsuperscript{S26} Difficulty focusing, such as is required for reading, is sometimes experienced in the early postoperative period, but it usually disappears within 2 weeks. Disturbances of memory are nearly always transient but may be noticeable to the patient. Because of the known phenomenon of accentuation and prolongation of the patient's perception of the abnormality by fixation on it, patients and their families are provided supportive care and reassurance. Special diagnostic procedures are rarely indicated, because there is essentially no effective specific therapy (see “Management” later in this section).

Gross neurologic defects, usually hemipareses or hemiplegias, are less common than neuropsychological and mood abnormalities, but they are generally more serious. Prevalence of these abnormalities after open cardiac operations is about 0.5% in relatively young patients, gradually rising with increasing age to around 5% in patients older than about 65, and 8% in those 75 or older.\textsuperscript{C25,G66} In a study of 2108 patients undergoing isolated CABG, adverse cerebral outcomes occurred in 129 (6.1%). Approximately half of these were major deficits; the remainder had deterioration of intellectual function or seizures.\textsuperscript{R9} In a related multicenter study of 271 patients undergoing CABG combined with an intra-cardiac procedure, adverse cerebral outcomes occurred in 43 (16%).\textsuperscript{W25}

Causes and Risk Factors for Acute Dysfunction
These defects probably represent more severe forms of the same kinds of damage (i.e., greater quantities, more sensitive locations) that cause neuropsychological and mood disturbances. Thus, they are probably the result of emboli (e.g., platelet aggregates, clusters of microbubbles, aggregates of fibrin accumulations from pump-oxygenators or tubing surfaces, boluses of air, arteriosclerotic debris or plaques dislodged from the ascending aorta) and other facets of the damaging effects of CPB. When investigated using computed tomography (CT) scans in patients with evidence of stroke after cardiac operations, the defects are typically multiple and posteriorly located in the brain. These findings are most consistent with particulate atheromatous embolization.

Older age is a risk factor for stroke after cardiac operations such as CABG, but this may be only because of the increased prevalence of arteriosclerosis.\textsuperscript{B18,W77} Severe arteriosclerosis of the ascending aorta clearly increases risk of perioperative stroke,
as does known preexisting cerebral vascular disease.66 Duration of CPB and low cardiac output after operation also appear to be risk factors.66,89 Cardiac microbubbles identified by intraoperative TEE have not been a risk factor for diffuse or localized neuropsychological dysfunction; furthermore, such microbubbles can rarely be eradicated by what might appear to be effective surgical maneuvers.79

Management
Precise recommendations for complete prevention of localized neurologic dysfunction remain elusive. However, certain precautions may reduce the frequency of major neurologic events, such as maintaining adequate perfusion pressure, minimizing duration of circulatory arrest, and using blood filters and appropriate de-airing procedures (see Chapter 2). In adults, Blauth and colleagues88 and Wareing and colleagues97 have stressed the importance of ascending aortic atheromatous disease as etiologic in postoperative stroke. Perioperative detection of severe atheromatous disease of the ascending aorta is facilitated by ultrasonographic interrogation by the surgeon.94 Management may consist of (1) modification of the techniques of aortic cannulation or aortic clamping, (2) aortic endarterectomy or resection, (3) grafting of the ascending aorta, and (4) use of an intraaortic filter at the time of aortic clamp removal.115,131,136

The only general therapeutic intervention that seems to be of value is use of hyperbaric oxygenation. This has been demonstrated only in patients with massive air embolization, but even in this setting, evaluation is difficult because spontaneous recovery may occur. The interval from the embolic event (which nearly always occurs in the OR and usually during or at the end of CPB) to hyperbaric therapy plays a major role in outcome; beyond 12 to 24 hours, this therapy probably is not useful.114,115,118 Because these patients, as well as many others without these localized neurologic disorders, are intubated and heavily sedated during this period, localized neuropsychological disturbances are rarely discovered within 24 hours of operation.138 Intense diagnostic efforts, such as lumbar puncture and CT scanning, are generally not indicated in the absence of any therapeutic implication. In addition, CT scanning may fail to be diagnostic.114

Moazami and colleagues have reported the safety and efficacy of intraarterial thrombolysis in a group of 13 patients suffering strokes after cardiac operations.146 A "stroke" team is organized to evaluate all patients with an acute neurologic deficit recognized within 6 hours of operation. Patients with a clinically important stroke (National Institutes of Health [NIH] stroke scale > 10) or isolated disabling symptoms are considered for study. They undergo emergent contrast cranial CT; evidence of hemorrhage or major early signs of infarction preclude thrombolytic therapy. Otherwise, four-vessel arterial angiography is performed using the transfemoral approach. Digital subtraction angiography permits the site of occlusions to be located and collateral circulation evaluated. Patients with middle cerebral, internal carotid, or basilar artery occlusions are considered for thrombolysis. A 2.3F microcatheter is steered to the occlusion by fluoroscopy and embedded within or through the center of the thrombosis. Thrombolysis is attempted at 5- to 10-minute intervals for up to 2 hours. Additional mechanical manipulation of the clot is also used. Among the 13 patients studied, NIH stroke scale improved importantly in 5 (38%; CL 23%-57%) and did not worsen appreciably in the 8 who did not improve.

The prognosis is variable, as is the case with strokes in general. In some patients, the signs and symptoms gradually disappear, whereas in others there is only partial or no recovery from the neurologic defect. At times, the defects are so massive as to be fatal.

GASTROINTESTINAL SUBSYSTEM

Adequacy
Abnormalities of function of the gastrointestinal tract, including the liver and pancreas, are not clinically detectable when convalescence after cardiac surgery is normal; oral intake is usually allowed on the morning after operation. Patients who remain intubated are exceptions. In these cases, fluid intake through a nasogastric tube is begun 12 to 24 hours after operation, gradually progressing to a nutritious one. Evidence of abdominal distention, absence of peristalsis, and hyperperistalsis is sought twice daily. If one of these develops, the gastrointestinal system is not adequate, and alimentation is discontinued, investigations are begun, and intravenously administered hyperalimentation is considered.

Patients with a history of peptic ulcer disease should be given 300 mg of cimetidine (or some other histamine H2-receptor antagonist) every 6 hours by mouth or intravenously during the postoperative hospitalization, beginning 6 to 12 hours after operation. Such a program is worthy of consideration as a routine.

Types of Acute Dysfunction
Acute dysfunction of the gastrointestinal subsystem is uncommon after open cardiac operations, occurring in only about 1% of patients.110,138 However, important dysfunction of the gastrointestinal subsystem is followed by death during the period of hospitalization in more than 50% of those patients. Emergency operations are required for some.

Gastrointestinal Bleeding
Gastrointestinal bleeding after open cardiac operations is usually from the upper part of the gastrointestinal tract.138 The pathology is usually hemorrhagic gastritis or duodenitis.132,136 Occasionally, a previously existing duodenal ulcer is the site of bleeding, and rarely, massive bleeding originates in the colon.139

Acute Cholecystitis
Acute cholecystitis, when it develops after open cardiac surgery, may be noncalculous, but it produces the same clinical syndrome of severe pain, leukocytosis, and right upper quadrant tenderness as when it develops in other patients.110,138 Perhaps because of delay in diagnosis that has been present, mortality among patients who have developed this complication is about 75%.110

Acute Pancreatitis
Some evidence of acute pancreatitis is present in about 25% of patients after open cardiac surgery and presents with hyperamylasemia,133 increased serum lipase, or both. In most cases, the increased level gradually declines, with few if any clinical sequelae. Occasionally (in <5% of patients with elevated amylase) severe pancreatitis develops, with pancreatic abscess or hemorrhagic pancreatitis.140 Indiscriminate
administration of large doses of calcium chloride contributes to development of pancreatic cellular injury after cardiac surgery.\textsuperscript{4}

\textbf{Jaundice}
Convalescence may be complicated by jaundice, with about 20\% of patients having a serum bilirubin concentration of at least 3 mg \cdot dL after cardiac surgery.\textsuperscript{155} Jaundice is moderate or severe (bilirubin concentration > 6 mg \cdot dL) in only about 5\% of patients. Severity of preoperative right atrial hypertension, hypoxia during operation, early postoperative hypotension, duration of CPB, and amount of blood transfused perioperatively all increase the probability of postoperative jaundice.\textsuperscript{155,411,413} Halothane, if used, and duration of CPB may be risk factors.\textsuperscript{415}

Provided postoperative cardiac output is good, hepatic dysfunction can be expected to improve gradually and disappear, but when cardiac output is low, prognosis is poor. Frank hepatic necrosis may develop when cardiac output is acutely and severely reduced. The only useful treatment is that directed at improving cardiac performance and supplying adequate nutritional support.

\textbf{Intestinal Necrosis}
Intestinal necrosis develops uncommonly but insidiously after cardiac operations. Inevitable perforation in the area of necrosis may be overlooked for a number of days because of the multiplicity of problems associated with the causative low cardiac output.

\textbf{Esophagitis}
Esophagitis, when it occurs after a cardiac operation, manifests with dysphagia, which is uncommon. Esophagitis may be related to an intrapericardial accumulation of blood or to pericarditis. When oral candidiasis is present, \textit{Candida esophagitis} is nearly certainly the cause of dysphagia \textsuperscript{421} and can be diagnosed by means of esophagoscopy or radiologic study of the barium-filled esophagus.\textsuperscript{427} When candidal esophagitis appears, antibiotic therapy is stopped unless it is essential. Every 2 to 6 hours, 500,000 to 1 million units of nystatin are given orally, preferably in methylcellulose to increase viscosity.\textsuperscript{422} Treatment is continued for 1 to 3 weeks.

\textbf{Watery Diarrhea}
As a complication of cardiac surgery, watery diarrhea may accompany or follow abdominal distention or appear de novo toward the end of the first week. Should it become frequent and explosive, with passage of mucus and blood, it has ominous implications. Any oral antibiotics should be discontinued when diarrhea develops. The diarrhea may be caused by ischemia of the bowel secondary to a long period of low cardiac output, and this ischemia may lead to small or large bowel infarction,\textsuperscript{435} or it may be a form of ulcerative colitis and proctitis. Diagnosis can be made by sigmoidoscopy and colonoscopy. If the bowel ischemia and ulceration progress, laparotomy and bowel resection are required, but even with such treatment, prognosis is poor.

An important and potentially serious cause of watery diarrhea after cardiac surgery is \textit{Clostridium difficile}, which colonizes the intestinal tract after the normal gut flora has been altered by broad-spectrum antibiotics. Prevalence of this complication is 0.7\% to 1\%.\textsuperscript{428} Risk factors for development of \textit{C. difficile}–associated diarrhea include advanced age, greater cumulative antibiotic days, longer ICU stay, and longer time on ventilator.\textsuperscript{428} \textit{C. difficile} is also the causative organism for antibiotic-associated pseudomembranous colitis. Both pediatric and adult patients who develop watery or persistent diarrhea after cardiac surgery should promptly have a stool specimen examined via a stool toxin assay. If the stool is positive for \textit{C. difficile} toxin, standard therapy is oral metronidazole (alternatively, oral vancomycin) for 14 days, which is usually curative.

\textbf{Abdominal Distention}
Occasionally, gas in the gastrointestinal tract produces abdominal distention within 24 to 48 hours of operation. Bowel sounds can be heard initially. Although not part of normal convalescence, this complication is usually benign and subsides after another day or so in response to fasting, use of glycerin suppositories, and application of heat to the abdomen. A rectal examination should be performed to exclude fecal impaction as a possible cause of distention. If distention does not promptly subside, other causes must be considered; it could be due to oral administration of procainamide or cephalosporins, and these drugs may have to be administered by another route. Mediastinitis and an infected median sternotomy incision may be causative and should be investigated. Abdominal distention may be the first sign of postoperative acute pancreatitis. When combined with marked weakness and fever, particularly in a patient on warfarin, postoperative adrenal insufficiency must be excluded by appropriate tests as a possible cause.

\textbf{Causes of Acute Dysfunction}
Nearly all acute intraabdominal dysfunctions (inadequacies of the gastrointestinal subsystem) result from localized or generalized severe hypoperfusion of either the gastrointestinal tract or the liver, or both.\textsuperscript{431,434,410,413,416,419} However, in neonates and infants, improper position of the inferior vena cava cannula during CPB and thrombosis or infection in umbilical arterial or venous catheters may cause intraabdominal problems early postoperatively.

\textbf{Risk Factors for Acute Dysfunction}
Preoperative \textit{peptic ulcer disease} predisposes patients to upper gastrointestinal bleeding after cardiac operations. Other chronic diseases of the intestinal tract also seem to increase the risk of gastrointestinal complications. \textit{Acute necrotizing enteritis} occurring in neonates who were severely acidic before operation is a risk factor for gastrointestinal dysfunction early postoperatively. \textit{Advanced age} increases the risk of acute dysfunction of the gastrointestinal subsystem after cardiac operations, as does valvar heart disease and congenital heart disease in adults.\textsuperscript{410}

\textit{Long duration of CPB} as a risk factor is arguable, but most believe it to be one. \textit{Low cardiac output} requiring prolonged catecholamine support and IABP increases the risk of serious intraabdominal complications.\textsuperscript{410} Increased prevalence of these complications is also associated with \textit{infection} during the postoperative period, preoperative chronic renal failure, and postoperative acute renal dysfunction.\textsuperscript{438}
Management and Treatment

Encouragement of normal convalescence is the best protection against gastrointestinal dysfunction. Routine administration of cimetidine or some other histamine H₂-receptor antagonist should be considered for any patient at increased risk of gastrointestinal complications.

Once complications appear, their precise nature is determined on an emergency basis, usually by fiberoptic endoscopic examination and with the collaboration of a gastrointestinal specialist. In the absence of massive hemorrhage or gastrointestinal perforation, or both, intense medical treatment rather than surgical intervention is advisable. In the presence of symptoms, however, the possibility of intestinal necrosis must always be entertained, even when symptoms and signs are mild.⁶⁸

ENDOCRINE SUBSYSTEM

Hyperglycemia (in both the OR and ICU) is associated with adverse outcomes after cardiac surgery. Both in diabetics and nondiabetics, serum glucose levels above 200 mg · dL⁻¹ are associated with increased risk for mortality and adverse events.⁵²¹ Insulin therapy is advisable in the ICU to avoid marked hyperglycemia. In patients with type 2 diabetes mellitus, continuous insulin infusion is advisable.⁷¹⁰

Few other abnormalities of the endocrine subsystem have been described as postoperative complications of cardiac surgery. An exception is acute adrenal insufficiency, found by Alford and colleagues in 5, or 0.1%, of 4364 patients.⁴⁶ Its cause is probably hemorrhagic infarction of the adrenal gland.⁴⁶ This can be precipitated by CPB, and the tendency toward it is aggravated by postoperative anticoagulant therapy. Symptoms generally appear between the fourth and tenth postoperative days and consist of abdominal pain and flank pain, abdominal distention, altered mental status, fever, and occasionally shock. When this diagnosis is suspected, a low serum cortisol level is virtually diagnostic. The diagnosis is also highly likely if the serum cortisol level remains low 60 minutes after administration of 25 units of intravenous or intramuscular adrenocorticotropic hormone (ACTH). Later, confirmatory evidence of acute adrenal insufficiency should be obtained.⁴⁶ Prompt treatment with intravenous cortisol and saline solutions results in rapid clearing of symptoms. Lifetime oral treatment is indicated subsequently.

Neither hypo- nor hyperthyroidism has been identified as a complication after cardiac surgery with the aid of CPB. However, an important reduction of plasma free triiodothyronine (T₃), although not of thyroxine (T₄), occurs early after cardiac operations. T₃ remains low for at least 24 hours, leading to the suggestion that its administration at that time is associated with an increase in myocardial function and energy stores.⁴¹⁸ Chronic excessive catecholamine stimulation may depress isometric force development in myocardial muscle. Timek and colleagues⁵⁹ found that exogenous T₃ may improve myocardial fiber shortening amplitude by accelerating Ca²⁺ transients in an in vivo preparation of catecholamine stimulation. There is some clinical evidence that exogenous T₃ (0.6 to 0.8 µg · kg⁻¹) may improve cardiac output immediately after CABG in patients with depressed ejection fraction⁴²² and also in brain-dead organ donors.⁵⁵ However, results have varied. When T₃ was given to patients expected to have an uneventful course, little change in outcome was noted.⁵²⁴ When it was given to adult patients undergoing CABG in a randomized study, improvement in cardiac output and a decreased prevalence of myocardial ischemia compared with controls were noted by Mullis-Jansen and colleagues.⁴⁵³ An increase in cardiac output was also apparent after CABG in patients with depressed LV function.⁴⁵²

HEMATOLOGIC SUBSYSTEM

Adequacy

Function of the hematologic subsystem is assessed in terms of volume of postoperative bleeding, adequacy of clotting, volume restoration, and resistance to infection (see Immune Subsystem later in this section).

Causes of Acute Dysfunction

Excessive blood loss after CPB may result from a variety of causes, either singly or in combination. A surgical (mechanical) cause must always be suspected. Reoperative procedures, complex procedures, and operations on the aorta are those most frequently associated with a mechanical etiology for bleeding. Often if there is excessive bleeding, it is obvious within the first hour after transfer from the OR. It is persistent but may vary in volume over successive hours, depending on hemodynamic status, coagulation status, and patient position and wakefulness. Surgical bleeding occasionally also presents as a delayed increase in chest drainage following an apparently normal early postoperative course, and this usually demands emergency reexploration. Likely causes include suture line leak, chamber rupture, or (in the case of CAGB) graft disruption or mechanical erosion. Occasionally in a patient with a low hourly blood loss persisting over 12 or more hours, a surgical cause is found at reexploration.

Prevalence of reexploration for bleeding varies between 0.5% and 5.0%,¹³ depending on institutional criteria and case mix. Moulton and colleagues⁴³⁰ identified increased patient age, preoperative renal insufficiency, operation other than CABG, and prolonged bypass time as independent risk factors for reexploration. In their series, the prevalence of reexploration was 4.2% (253/6015), and reexploration was strongly associated with increased operative mortality and morbidity, including sepsis, renal failure, respiratory failure, and atrial arrhythmias. Others report little or no increased mortality and morbidity associated with reoperation for bleeding.⁴²

Prevalence of bleeding attributable to nonmechanical (nonsurgical) causes is difficult to estimate, because in many instances reexploration results in cessation of bleeding even though no single site or only a minor site of bleeding can be identified.

Disturbances of coagulation may arise from a myriad of causes. It has long been recognized that the damaging effects of CPB and the magnitude of the resulting inflammatory response are related to postoperative blood loss, presumably via cytokine activation, platelet activation and aggregation, and kallikrein stimulation of neutrophils.¹³⁴,¹³⁸ Platelet abnormalities, both quantitative and qualitative, universally occur during and after CPB. Some consider platelet dysfunction the most common and most important deficit of hemostasis in the postoperative period.¹³¹,¹³⁶,¹³³ The qualitative abnormalities include degranulation and membrane fragmentation
attributable in part to changes in GPIb and GPIIb/IIIa receptor activity.

During CPB, coagulation factors are depleted by dilution, activation, and consumption. These effects center on activation of thrombin, plasmin, and fibrinogen. Antithrombin (AT) III normally inhibits thrombin and factors IV and V. Heparin leads to anticoagulation by enhancing the thrombin-inhibiting ability of AT III by a factor of 2000. Heparin also diminishes activation of factors IX and X and cofactors V and VIII. Residual heparin may lead to excessive bleeding by its effect on thrombin. This has also been characterized as rebound heparin effect.

The rationale for use of heparin-bonded circuits is based partially on the potential to reduce contact activation inherent in the CPB apparatus. Contact activation is due to vibration, blood/gas interfaces, and pericardial aspiration. Simple exposure of blood to tubing may lead to important fibrinolysis, diffuse intravascular coagulation, and various consumption coagulopathies.

Hypothermia that can impair thromboxane synthesis and suppress platelet aggregation may lead to coagulation defects. Thus, adequate rewarming on CPB is essential. Platelet transfusion, although controversial, may be beneficial. Further prevention of coagulation difficulties involves limitation or reversal of hemodilution, efforts to avoid contact activation of platelets and blood proteins, adequate rewarming, and use of pharmacologic agents, all discussed in Chapter 2.

Treatment of Bleeding

There are strong reasons to limit or avoid transfusion of blood products in stable patients. The public, patients, and physicians have become aware of the possibility, although small, of disease transmission from transfusion. The current estimated likelihood of contamination with the human immunodeficiency virus (HIV) is 1 in 440,000 to 640,000 screened units of blood. Hepatitis B is estimated to be present in 1 per 63,000 units, and hepatitis C in 1 per 103,000 units. With routine use of polymerase chain reaction (PCR) testing or nucleic acid testing (NAT), the risk of contamination by HIV and hepatitis B will be even less. The possibility of bacterial contamination is probably slightly greater than the figures just mentioned. Hemolytic reactions occur infrequently and are not generally due to human error, but rather to a delayed reaction from previously undetectable antibody that is activated following a series of transfusions. Finally, the estimated cost for the patient of 1 unit of packed red blood cells (RBCs) is U.S. $250 to $280, and efforts at cost control suggest prudence in transfusion will help lower overall hospital costs. Recent studies have shown a correlation between blood transfusions and greater risk of mortality, infection, and other adverse events.

Strategies to prevent excessive bleeding, or in some cases to treat it, begin with reversal of hypothermia. The importance of remaining on CPB to achieve a core temperature (measured at the tympanic membrane or in the nasopharynx) of 37°C has been stressed elsewhere (Chapter 2). In the ICU, use of warming blankets (or in infants, overhead heaters) supplements this process.

Control of arterial blood pressure using nitroglycerin, nitroprusside, or diazoxide may be helpful. Use of PEEP has been advocated, but its effect on the magnitude of blood loss is controversial. Residual heparin effect or heparin rebound can be diagnosed by a prolonged ACT. Additional protamine can be administered, usually 50 to 75 mg in adults and 5 to 10 mg in children. (There is a remote possibility of a protamine reaction in this setting, which may vary from mild hypotension to anaphylaxis; see “Whole Body Perfusion during Cardiopulmonary Bypass,” in Section II of Chapter 2.)

Use of antifibrinolytic agents in the ICU is controversial. Tranexamic acid, ε-aminocaproic acid (EACA), and aprotinin (now unavailable in the United States) are each more effective when given during CPB than after (see Chapter 2). Transfusion therapies include cryoprecipitate, FFP, platelets, and whole blood or packed RBCs.

Each institution may establish different thresholds for transfusion. As an example, whole blood or packed RBCs could be given for hemoglobin under 7.0 g · dL⁻¹, hematocrit under 20%, or Svo₂ under 65%. This threshold might be raised to hemoglobin under 10 g · dL⁻¹ in severely ill or elderly patients or in those with unstable hemodynamics, because they are unlikely to increase cardiac output in response to acute anemia.

Transfusion of platelets should be considered for patients with a platelet count under 70,000 and excessive bleeding. Similarly, FFP should be administered for an International Normalized Ratio (INR) greater than 1.5 to 1.7 in patients with excessive bleeding and a history of warfarin treatment. Specific treatment with cryoprecipitate, FFP, or other components is indicated in the presence of a consumption coagulopathy reflected by a fibrinogen level less than 200 mg · dL⁻¹, a positive D-dimer assay, or presence of fibrin degradation products.

In recent years, recombinant activated factor VIIa (rFVIIa) has been added to the surgical armamentarium. Originally conceived as therapy for bleeding in patients with hemophilia, rFVIIa promotes hemostasis by increasing generation of thrombin on platelets, producing a more stable fibrin plug that is resistant to fibrinolysis. In the setting of persistent elevation of INR, partial thromboplastin time and/or reduced platelet count/aggregation, rFVIIa has been shown to be effective in treating bleeding associated with postoperative coagulopathy. However, it is expensive (about $7000 per treatment), and concern remains about possible development of a hypercoagulable state that could induce bypass graft or mechanical valve thrombosis. Acute thrombotic complications have been observed in pediatric patients on ECMO support. Thus, it should not be used in the usual postoperative patient, but is an important adjunct in the setting of ongoing bleeding with severe coagulopathy.

Chest drainage tubes must be properly placed in the OR for them to function well early postoperatively and keep the pericardial and pleural spaces free of blood (see “Positioning Chest Tubes” under Completing Cardiopulmonary Bypass in Section III of Chapter 2). During transport to the ICU, chest tubes are connected to an underwater seal. Once the patient is in the unit, the tubes drain into an initially empty container in which a negative pressure of 40 cm H₂O is continuously maintained. Routine “stripping” of the chest tubes by nursing personnel is unnecessary and potentially dangerous, and the technique should be used only for clearing clots. Provisions are made for continuous precise measurement of drainage from the chest tubes; this can be incorporated into
Box 5-1 Indications for Prompt Reoperation for Bleeding

1. Excessive bleeding from the chest tubes, as defined in Table 5-7 for infants and children. Drainage in excess of these criteria means that bleeding will probably continue and reach clearly excessive total amounts (in adults ≥ 1500 mL) within 12 hours. Exceptions to prompt reentry when this criterion is met are rare and are generally limited to patients in whom prolonged efforts at hemostasis have been made already and a bleeding diathesis is present, suture lines are known to be secure, and tamponade is not present.

2. Marked widening of the cardiac silhouette in the portable chest film 8 to 24 hours after operation. Such widening nearly always indicates retention of some clots and blood in the pericardium. Even if the patient's condition is good, elective reoperation and evacuation of blood and clots are usually advisable.

3. Sudden increase (≥300 mL·h⁻¹ in adults) in chest drainage that has been small in the first few postoperative hours. Such an increase usually results from bleeding from an incision in the heart or great arteries.

4. Evidence of acute cardiac tamponade.

*Reoperation is advisable if the patient has bled the amount indicated in any 1 hour (column 1), the lesser amount in column 2 during each of any 2 successive hours, or the still smaller amount (column 3) in each of any 3 successive hours.

*Reoperation is advisable if, by the end of the fourth or fifth postoperative hour, the patient has bled in total the amount indicated.

Heparin Resistance

Heparin resistance may be encountered at operation. It may result from a congenital defect in the coagulation cascade, but usually is the result of chronic heparin therapy. Diagnosis is made by an ACT less than 480 seconds after administration of a minimum of three times the calculated dose of heparin. It is treated by administration of FFP or, more appropriately, antithrombin III concentrate.

Thrombocytopenia

Moderate thrombocytopenia to levels of 100,000 platelets·mL⁻¹ is to be expected following CPB. A level of 70,000 platelets·mL⁻¹ may meet a threshold for transfusion if there is excessive bleeding. Under ordinary circumstances, platelet counts as just noted are decreased by dilution, destruction, and aggregation. Platelet function is diminished by changes in platelet membrane receptor activity, which includes down-regulation of GPIb and GPIIb/IIIa receptors.

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT) is an immuno-mediated syndrome that can occur after prior exposure to...
Heparin products. Unfractionated heparin (and to a lesser degree, low-molecular-weight heparin) binds to circulating platelet factor 4 (PF4), which creates a heparin/PF4 complex that is recognized by immunoglobulin (Ig)G antibodies. The neoepitopes recognized by HIT antibodies are located on PF4 (found in platelet α granules) and are formed by the binding of PF4 to heparin. When IgG antiheparin/PF4 antibody titers are sufficiently elevated, binding of the heparin/PF4/IgG complexes to platelet receptors induces platelet activation and aggregation. Clinical diagnosis of HIT syndrome requires presence of antiheparin/PF4 antibodies and a 30% to 50% decrease in platelet count or absolute platelet count of less than about 80,000. HIT syndrome can also be identified by skin lesions or necrosis at the site of heparin injections in the presence of HIT antibodies. The full-blown syndrome (HIT with thrombosis [HITT]) includes additional presence of arterial or venous thrombotic events, most commonly deep vein thrombosis, but can include pulmonary embolism, disseminated intravascular coagulation, stroke, limb ischemia, renal failure, intestinal ischemia, or coronary thrombosis. Mortality of HITT following cardiac surgery exceeds 25%. Laboratory diagnosis, clinical implications, and management strategies remain without consensus, related to several important observations. Of primary importance is the absence of specificity of current serologic testing. The serologic enzyme-linked immunoabsorbent assay (ELISA) that is commercially available and used in most hospitals is not specific for IgG antibodies (which are responsible for HIT) and does not differentiate among IgG, IgM, and IgA antibodies. As a result, this ELISA is very sensitive (>95% of clinical HIT patients have a positive ELISA for antiheparin/PF4 antibodies) but not highly specific (75%-85%). Furthermore, the predictive value of the ELISA is directly related to the strength of the test result, which is measured in optical density (OD) values. Based on a threshold positive OD value of 0.40, Zwicker and colleagues noted a sixfold increase in the likelihood of a thrombotic event in patients with HIT who had an OD > 1.0 compared with those with an OD of 0.4 to 0.99. When considering all patients with a positive ELISA test (OD > 0.4), 5% or more of patients have evidence of antiheparin/PF4 antibodies before cardiac surgery, and more than 20% are reported to form HIT antibodies following cardiac surgery. The prevalence is somewhat higher with bovine lung heparin than with heparin derived from porcine gut mucosa. Given the low occurrence of clinical HIT after cardiac surgery with heparin (1%-2%), it is not surprising that some studies indicate that positive anti-HIT antibodies preoperatively predict an increased risk of postoperative thrombosis, whereas others show no such relationship.

Functional assays measure platelet activation and detect heparin-dependent IgG antibodies capable of binding to and activating the Fc receptors on platelets. Serotonin Release Assay, which measures serotonin release from activated platelets, has high specificity but is not widely available. Thus, immunoassays are the mainstay of current laboratory diagnosis.

HIT syndrome is most likely to occur 5 to 14 days after exposure to heparin during cardiac surgery and is more likely to occur with repeated or prolonged exposure, including heparin flushes in pressure transducers and prophylactic subcutaneous heparin for preventing deep vein thrombosis. Rarely, HIT presents days to several weeks after hospital discharge. The relationship of falling platelet counts to HIT after cardiac surgery is confounded by the usual decline in platelet count that occurs with hemodilution and platelet aggregation related to CPB. The decreasing platelet count usually reaches its nadir by about the second postoperative day. HIT is uncommon in the first 4 days after cardiac surgery, but is much more likely in the setting of new-onset decreasing platelet count after about postoperative day 4. In this setting, prompt laboratory testing for HIT antibodies is advisable.

Treatment of HIT initially involves prompt discontinuation of unfractionated or low-molecular-weight heparin. In patients who can tolerate systemic anticoagulation, continuous infusion of a direct thrombin inhibitor (argatroban, bivalirudin, or lepirudin) is advisable with appropriate anticoagulation monitoring. Limbs should be routinely screened for clinically silent deep vein thrombosis. Platelet transfusions should be avoided. This therapy should be continued until the platelet count has substantially recovered and there is resolution of any arterial or venous thrombosis events. Anticoagulation should then be gradually transitioned to oral warfarin therapy, with an overlap of at least 5 days and achieving target INR before discontinuing the direct thrombin inhibitor infusion.

In patients who are diagnosed with HIT before planned cardiac surgery, elective operations should be delayed until HIT antibody titers are no longer detectable. In most cases, HIT antibodies disappear within 3 to 4 months. If urgent operation is needed, standard heparinization is recommended during CPB, but a direct thrombin inhibitor is likely preferable for “off-pump” procedures. Although its benefit is unproven, plasmapheresis may be a valuable adjunct for patients with positive HIT antibody titers (OD > 1.0) who cannot safely defer operation. Whether a strategy of repeated plasmapheresis treatments until ELISA OD is less than 1.0 is more protective than a single pre- or intraoperative treatment is unknown. When the ELISA OD is weakly (0.4-0.99) positive, no special pre- or intraoperative therapy is probably necessary. The HIT ELISA should be followed serially after surgery, beginning at 24 to 48 hours. If the OD exceeds 1.0 or platelet count falls with a positive ELISA, early plasmapheresis should be considered until it is deemed safe to begin anticoagulation with a direct thrombin inhibitor.

IMMUNE SUBSYSTEM

Some have suggested that the immune subsystem is mildly depressed for several weeks after CPB. In general, however, specific immunologic responses (in contrast to general responses such as those expressed in the whole body inflammatory response) in nonsensitized patients are weak ones. Interleukin levels are increased after CPB, and some believe this to be responsible for the hyperthermia frequently present early after operation (see “Body Temperature” under Special Considerations after Cardiac Surgery in Section II of this chapter). In adult patients, the number of helper/inducer T-lymphocyte subsets (CD4+) is decreased after CPB, and suppressor/cytotoxic T cells (CD8+) are elevated. This possible overall depression of the immune response can be modulated by pretreatment with indomethacin and thymopentin. Ultrafiltration, glucocorticoids, or lymphocyte...
depletion may even further complicate the immune response by their salutary effects on the whole body inflammatory response.

Section II Special Considerations after Cardiac Surgery

FLUID, ELECTROLYTE, AND CALORIC INTAKE

**Children and Adults**

Because of the increase in extracellular fluid and total exchangeable sodium and the decrease in exchangeable potassium that develop during cardiopulmonary bypass (CPB), postoperative fluid administration early after cardiac operations should be precise. Based on pioneering work by Sturtz and colleagues, a standardized approach to fluid administration has been developed that meets the requirements. For approximately 48 hours after operation in children and adults, no sodium is administered, and minimal amounts of water (as 5% glucose in water) are given intravenously (see Appendix 5K). Larger amounts of water are disadvantageous because they result in higher urine volumes and an increased potassium loss if renal function is good, and fluid overload if renal function is impaired. A modest amount of potassium (10 mEq · m⁻² · 24 h⁻¹) is given on the day of operation, because large amounts generally are not needed in normally convalescing patients, despite the decrease in total exchangeable potassium; larger amounts simply escape in the urine. Exceptions to this are patients receiving digitalis preparations, in whom serum potassium is kept at 4.0 mEq · L⁻¹ or more. In the presence of ventricular ectopic beats, the level is increased to 4.5 to 5.0 mEq · L⁻¹.

Liquids are taken orally a few hours after extubation, and intravenous administration can then cease by the second postoperative day. Ability of the kidneys to excrete sodium may be impaired for some days after operation even in normally convalescing patients, so a diet low in sodium is needed until the patient’s weight (measured daily) falls below preoperative level.

When extubation is delayed beyond the second postoperative day, adequate caloric intake must be ensured. Once bowel sounds are present, caloric needs can be met through nasogastric tube feedings using an appropriate high-calorie formula. Rarely, intravenous hyperalimentation is required.

**Neonates and Infants**

In neonates and infants, more exacting management is required. Care is taken to avoid fluid overload from the solution used to keep the pressure-recording catheters patent. Because the infant’s energy requirements are relatively large, 10% glucose is more appropriate than 5%. Small amounts of sodium are administered from the beginning because of the requirements of infants; a special protocol that includes 250 mL · m⁻² · 24 h⁻¹ of a balanced salt solution is used (see Appendix 5K).

In infants, oral feeding is not begun until 8 hours after extubation. Small feedings of glucose water are then given every 4 hours; if well tolerated, an appropriate formula low in sodium is started after two or three feedings. Mothers who are breastfeeding may resume nursing their infant once he or she is strong enough. The infant must be picked up and held for the feedings and burped thereafter. If the infant is too weak to suck, gavage feedings of the mother’s milk are given through a nasogastric tube.

Placement of a transpyloric feeding tube and initiation of feeding by continuous infusion is started in infants who have been intubated longer than about 2 days. If enteral feeding is necessary for more than a few days, the baby’s caloric and other metabolic needs must be calculated and a determined effort made to meet them. If this does not become possible within 48 to 72 hours, or if abdominal distension or excessive diarrhea persists, intravenous hyperalimentation is begun.

During the first 48 postoperative hours, hypoglycemia may develop, particularly in neonates and infants less than 3 months old. Therefore, blood glucose is routinely measured twice daily in these patients, and as a precaution against hypoglycemia, 10% dextrose in water is used in maintenance fluids (see Appendix 5K). When hypoglycemia (blood glucose level < 80 mg · dL⁻¹) occurs, 50 mg · kg⁻¹ of glucose is given (1 mL · kg⁻¹ of 50% dextrose mixed with an equal amount of 5% glucose in water and administered intravenously over a 15-minute period). Blood glucose levels are measured 30 minutes later and at 4-hour intervals for 24 hours.

**Special Problems**

As indicated earlier, some metabolic acidosis (base deficit of 2 mEq · L⁻¹ or greater) may be present during the early hours after cardiac surgery even when the patient is convalescing normally. It is left untreated if arterial pH is 7.4 or greater and PaCO₂ is 30 mmHg or above. When PaCO₂ is less than 30 mmHg, the base deficit is treated before adjusting PaCO₂ appropriately upward. When pH is less than 7.4, the base deficit is treated (see Appendix 5L). However, if convalescence is otherwise normal, treatment is delayed for 4 to 8 hours in adults and for 2 to 4 hours in infants, by which time the base deficit may have cleared spontaneously. In infants particularly, it is best to avoid an additional sodium load whenever possible.

A mild metabolic alkalosis may be present 24 hours after operation in normally convalescing patients, probably related in part to the citrate load contained in the anticoagulant solution of banked blood. Metabolic alkalosis is self-correcting under these circumstances and is not treated. When large amounts of homologous blood containing sodium citrate have been transfused, important metabolic alkalosis can occur. Metabolism of the citrate leaves bicarbonate as the only anion available to balance sodium ions. This situation may be exacerbated after 2 to 4 days by migration of hydrogen ions from the cells, because hydrogen ions are replaced by potassium ions, and serum potassium falls, sometimes precipitously, in association with potassium loss in urine. Relatively large amounts of potassium chloride must be given under such circumstances (up to 200 mEq in 24 hours), but the dose should be titrated against 4-hourly serum potassium measurements. The alkalosis is associated with a fall in serum chloride and a compensatory rise in PaCO₂. Provided renal function is adequate, the situation will correct itself. If it
continues to worsen, the carbonic anhydrase inhibitor acetazolamide is administered, usually intravenously at a dose of 5 mg · kg⁻¹ up to 250 mg in adults once or twice a day as needed until the alkalosis is corrected.

**BODY TEMPERATURE**

The most frequently misunderstood phenomenon after cardiac surgery is abnormality in body temperature. Most normally convalescing patients are febrile for at least 4 to 5 days after operation, and in some the hyperthermia persists 2 weeks or longer️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️️езды Mountains.ма,
Clinical signs and symptoms may be subtle, but one or more of the following are usually present: progressive and unexplained weakness and lethargy; progressive dyspnea on exertion or orthopnea; unexplained hepaticomegaly, ascites, or peripheral edema; elevated jugular venous pressure; pulsus paradoxus; widening of the cardiac silhouette on chest radiography; and unexplained prerenal azotemia.\[K17\] A chest radiograph (which should be taken routinely the day before hospital discharge or the seventh postoperative day, whichever comes first) usually shows enlargement of the cardiac silhouette before symptoms appear. Cardiac tamponade may, however, not become apparent until as late as 4 months after operation.\[O4\]

Treatment consists of pericardial decompression by either pericardiotomies or surgical drainage. If performed surgically, the subxyphoid portion of the incision is reopened, and the pericardial space is entered at the diaphragm. When a week or more has elapsed from surgery, great care is required to gently dissect along the diaphragmatic surface until the fluid collection is entered. Undue haste can result in inadvertent entry into the right ventricle, which can be friable and soft. Mortality has occurred under such circumstances. After drainage of the fluid with a surgical sucker, a flexible drain is generally left in the pericardial space for 24 hours to drain any residual fluid.

## INFECTION

### Prevalence

Fortunately, important wound complications are uncommon after cardiac surgery. These complications are usually caused in the form of mediastinitis and sternal dehiscence. In a prospective study by Breyer and colleagues, prevalence was 0.8%,\[B26\] but it has been reported to be 1.5% by Culliford and colleagues and as high as 8% when bilateral internal thoracic artery–to–coronary artery bypass grafting is performed.\[C35\] Reported mortality after this complication varies widely, from 6% to 70%.\[C11\] With early effective treatment, it is 5% to 10%.\[J9\]

Although edema and some hematomas are common in a leg from which a saphenous vein has been removed, infection occurs infrequently (1%-2% of cases).\[W26\]

### Risk Factors

Imperfect aseptic technique in the OR is the cause of infected median sternotomy wounds. An undrained retrosternal hematoma is an incremental risk factor.\[C55\] This is one reason for leaving the pericardium open as a routine after cardiac operations; retrosternal bleeding falls into the pericardial space and is aspirated by the pericardial drainage tubes. Prolonged operative time is also a risk factor for development of mediastinal infections.\[F10\,W26\] Inaccurate and insecure sternal closure increases the occurrence of important sternal infections.\[H34\] Reoperation for bleeding is not a risk factor.

Obesity is clearly a risk factor for infection in the median sternotomy wound.\[W26\] The combination of diabetes, obesity, and harvesting of both internal thoracic arteries has been associated with increased prevalence of wound infections.\[K32\] Intraoperative hyperglycemia has been correlated with more postoperative infections in adults\[H17\] and children\[O2\] after cardiac surgery. Among pediatric patients, hyperglycemia (>130 mg · dL\(^{-1}\)) during the first 24 hours after operation has been identified as a risk factor for mediastinitis.\[G8\]

Chronic obstructive lung disease predisposes patients to sternal dehiscence and infection. Male gender is a risk factor, probably related to the common practice of shaving the patient the day before operation when hair is present.

Prolonged mechanical ventilation after operation also increases risk of infection in the median sternotomy,\[N25\] as does need for postoperative dialysis.\[C6\] Corticosteroids greatly increase the risk of sternal wound infection. These drugs must therefore be discontinued completely or reduced to the lowest possible dose for several weeks (ideally, 6 or more) before operation. Despite the clear association between steroids and depressed wound healing, cardiac transplantation (with nearly routine use of pre- and postoperative steroids) has been performed with a low occurrence of mediastinal infection in many centers (see Chapter 21).

### Prevention

A precise aseptic technique by the surgical, anesthetic, and perfusionist team is an essential part of prophylaxis against infection in open cardiac operations. The many people involved and the length and complexity of the operations make bacterial contamination more likely than in shorter and simpler procedures. It has been demonstrated that control of the surgical and ICU environment and awareness of the problem among personnel importantly reduce the prevalence of infection.\[S3\] Preoperative shaving should be done immediately before the operation, if at all.\[T1\]

Infection inside or around the heart, particularly when prostheses have been used, is a major threat to the patient’s life. Therefore, prophylactic antibiotic therapy is recommended for cardiac operations.\[F6\,M35\] Adequate blood levels of antibiotics should be present immediately before and during operation and while any intravascular or endotracheal device is in place.\[R29\] Administration is therefore commenced at induction of anesthesia, an additional dose is given before CPB, and a dose is given immediately after CPB. An appropriate intermittent dosage schedule is continued through the second postoperative day or 24 hours after removal of the last intravascular or endotracheal device.\[B29\] Drug and dosage vary according to prevalence of organisms and their susceptibility.

For many reasons, including to minimize the risk of infection, all intravascular and endotracheal devices should be removed as early postoperatively as possible. Infection is also minimized by simplifying postoperative care, early transfer out of the ICU, early ambulation and oral alimentation, and early hospital discharge.

### Treatment

Occasionally a small, localized, subcutaneous collection of serum or necrotic fat may suggest a wound infection when in fact none is present. These minor complications occur in about 2% of patients.\[B26\] Such collections should be left alone until it becomes clear that a wound infection is present. Even when a small amount of frank pus drains from the wound, mediastinitis should not be assumed to be present unless the sternum has become unstable, a retrosternal collection of fluid is demonstrated by CT, or drainage can be shown to be coming through the sternum from the retrosternal area. Even
sternal dehiscence is not unequivocally diagnostic of infection; occasionally the dehiscence is sterile.

Unusual fever and malaise, sternal tenderness, and persistent severe central chest pain not relieved by usual analgesics suggest the possibility of an important sternotomy infection despite absence of obvious inflammatory changes in the skin. Under these circumstances, the wound is examined twice daily for evidence of sternal instability or drainage coming through the sternum, and repeated blood and wound cultures are taken. Antibiotics are generally not begun until infection is confirmed, but should be initiated with suspected infection in the presence of prosthetic material in or around the heart. As soon as possible, the antibiotic regimen should be tailored to the cultures and microbial sensitivities in order to be specific for the organisms involved.

Diagnosis of an infected wound should be made before there is extensive breakdown of the wound skin edges. CT scans may be helpful and should be obtained when diagnosis is uncertain, but it must be remembered that at least edema and some hemorrhage in the anterior mediastinum are usually present in normally convalescing patients and are visible on CT. However, the diagnosis through CT scanning of retrosternal fluid with air pockets or sternal disruption is usually indicative of mediastinitis.\(^{110}\)

As soon as the diagnosis of an infected median sternotomy incision is made, the patient is returned to the OR and anesthetized, and a formal operation is undertaken.\(^{110}\) The entire median sternotomy incision is reopened, and all the sternal wires, other suture material, and necrotic tissue are removed. Usually the infection is most marked immediately in front of and behind the sternum, and minimal around the heart itself. In this situation, although a few small fragments of sternum may be removed, extensive débridement of the sternum is not performed. The wound is thoroughly irrigated first with warm saline solution and then with dilute povidone-iodine solution. Two small (16F) chest tubes are left anteriorly for the postoperative continuous infusion of dilute povidone-iodine or antibiotic solution, and two larger tubes (20F or 24Fr) are left posteriorly for aspiration of fluid. Generally, the sternum is closed by rewiring, and the tissues anterior to it, including the skin, are closed en bloc by vertical mattress sutures.

The wound is irrigated continuously with 1 to 2 mL · kg\(^{-1}\) · h\(^{-1}\) of dilute (0.5%) povidone-iodine or antibiotic solution through the anterior tubes, and suction is continuously applied to the dependent tubes.\(^{116}\) Full-strength povidone-iodine must be avoided because it injures tissue.\(^{115}\) When an antibiotic solution is used for irrigation, the level of the agent in the solution should be the same as the level in blood during maximal parenteral treatment. An input/output chart must be maintained. If the balance becomes positive, infusion is stopped until the fluid is recovered. Irrigations are not effective after 3 to 4 days, because by then the tubes have become sequestered from the retrosternal space. They are therefore removed at that time.

If the infection is extensive, more rapid recovery occurs when the wound is closed with musculocutaneous flaps\(^{14,110,55,537}\) or, when needed, omental transfer\(^{101,512}\) after débridement. In most cases, the most rapid recovery is accomplished with initial débridement and irrigation, followed by early planned pectoralis flaps and partial or complete sternectomy within several days. Generally, it is prudent to perform this with the plastic surgeon. Rarely, the infection is so extensive the wound is left open 3 to 5 days, with a bulky dressing and drainage tubes, and then the closure accomplished.\(^{76}\) These techniques are useful in infants and children as well as adults. With these protocols, most patients survive this potentially lethal complication and experience good long-term functional results.\(^{327,29}\)

### CHYLOTHORAX

Effused chyle may be present in the thoracic cavity after repair of coarctation of the aorta, after placement of Blalock-Taussig or (less frequently) PTFE interposition shunts, or (rarely) after repair of patent ductus arteriosus.\(^{37,518}\) In such instances, chylothorax probably results from cutting large tributaries of the thoracic duct or, less frequently, from injury to the thoracic duct itself. More complex and difficult to manage are the chylothoraces (and on occasion, pericardial accumulations of chyle with tamponade) that follow operations through a median sternotomy, such as atrial switch procedures for transposition of the great arteries, superior vena cava–right pulmonary artery anastomoses, and the Fontan procedure. Chylothorax probably results from the combination of inevitable transection of small lymph channels (probably in the thymus gland) and elevation of superior vena caval pressure that follows these procedures.

In these patients, the lipid content in chylothorax consists of triglycerides that enter the pleural space as chyle, originating from large lymphatics that have been divided or from generalized lymphatic leakage, presumably from elevated right atrial pressure. Chyle contains a high content of triglycerides in the form of chylomicrons, which produces a milky appearance of the lymphatic fluid. The potential for relative immunodeficiency developing during prolonged chylothoraces relates to the high content of lymphocytes (primarily T lymphocytes) in chyle. In addition, chyle is rich in immunoglobulins and fat-soluble vitamins absorbed from the intestines. Chyle flow increases with dietary intake of fat, particularly long-chain triglycerides, which are absorbed into the lymphatic system from the intestines.

Chylothorax may develop immediately after operation, in which case it may not be recognized initially because the fluid may appear to be serous. In most such cases, chylosus drainage subsides spontaneously, and continuation of effective tube drainage is all that is necessary. However, chylothorax may not develop for a week or more. In that case, needle aspirations repeated every 3 to 4 days usually constitute adequate treatment. Late-appearing chylothoraces after closed operations are particularly likely to subside without operation, and the aspirations can be continued on an outpatient basis.

In early-appearing and persistently large chylothorax, such as may occur after open cardiac operations, the outlook with conservative treatment is less favorable. Malnutrition resistant to therapy rapidly develops. When the chylothorax is a complication of the Fontan operation, its management is part of the overall management of the patient (see Chapter 41). The general strategy includes strong suction (40 cm H\(_2\)O) on the pleural chest tubes while maintaining nutrition with a low-fat diet and supplemental medium chain triglycerides. Octreotide may be a useful adjunct. If the drainage is persistent over about 7 days, surgical pleurodesis, thoracic duct ligation, and/or doxycycline installation into the chest tube is advisable. The tube is then returned to suction. Doxycycline is very irritating to the pleura, so pain control is important.
When chylothorax has developed as a complication of an operation performed through a lateral thoracotomy, surgical intervention is indicated if such drainage persists for more than about 7 days. The hemithorax in which the chyle is accumulating is entered through a posterolateral thoracotomy incision. Chylous leakage is sometimes easily seen and is oversewn. Unfortunately, the source is often not found, and watertight oversewing is not always possible. Under such circumstances, the thoracic duct can be sought behind the esophagus; if identified, it is doubly ligated, and this usually solves the problem. Even if these procedures are apparently successful, and certainly if they cannot be accomplished, the pleural space is scarified, and three properly placed intrapleural tubes are left for at least 96 hours to ensure the lung remains expanded and becomes adherent to the chest wall. Fibrin glue placed on the parietal pleura may enhance adherence. A good result is usually obtained from a combination of these maneuvers.

Rarely, after cardiac operations other than the Fontan operation, chyle accumulates in the pericardial space, with or without chylothorax. This problem was first reported after operations with CPB by Thomas and McGoon and has subsequently been reported by others. It has been reported after the Waterston anastomosis, in which, of course, the pericardium is opened. It has also been reported after a Blalock-Taussig shunt in which the pericardium was not opened. This is a difficult problem, and initial management consists of wide and prompt operative drainage of the pericardium into the pleural spaces by making large pericardial windows and then draining both pleural spaces with chest tubes. Following this, the measures just described are used.

Careful attention to nutrition is important during the period of chylous drainage. Fortunately, chylothoraces have never been reported to become infected.

Although the benefit is unproven, it is generally prudent to restrict oral intake of fats and initiate a low-fat diet with oral supplementation of medium chain triglycerides, which are not taken up by lymphatics. Octreotide is the synthetic polypeptide that mimics natural somatostatin by inhibiting the release of multiple intestinal enzymes. The end result is a decrease in lymph flow by reducing splanchic, hepatic, and portal blood flow, decreasing gastrointestinal motility, and inhibition of intestinal secretion of water and electrolytes. Octreotide is initiated at 1 to 2 µg · kg⁻¹ · h⁻¹, with a maximum dose of 10 µg · kg⁻¹ · h⁻¹ once a persistent chylothorax is identified. Efficacy has been reported in the pediatric cardiac surgical population with this intervention.

In situations in which an infant or child with persistent chylothorax is either too unstable to tolerate a thoracotomy with open pleurodesis or persistent drainage occurs following pleurodesis, chemical pleurodesis is carried out with doxycycline installation through the chest tubes. A standard dose of 20 mg · kg⁻¹ (up to a maximum dose of 1 g) diluted in saline at a concentration of 1 to 8 mg · mL⁻¹ is injected through a chest tube. A standard dose is 20 mL · kg⁻¹, and the chest tubes are clamped for 4 to 6 hours following installation of doxycycline. The patient is turned from side to side to promote even distribution of this irritating agent, and the chest tubes are then reopened and placed to high suction. Installation of doxycycline is irritating to the pleura and is accompanied by considerable pain, so adequate analgesia is of major importance during installation. The dose can be repeated every 1 to 2 days. Reported success exceeds 90% by 4 days.

For refractory cases, some success has been reported with lymphangiography followed by percutaneous coiling of large lymphatics.

### POSTPERFUSION AND POSTCARDIOTOMY SYNDROMES

Postperfusion syndromes are complex and not yet fully understood. Whether they are totally attributable to the body’s response to the damaging effects of CPB (see Chapter 2, Section II) or have multiple etiologies is uncertain.

A cytomegalic postperfusion syndrome has been described that consists of an infection with cytomegalovirus transmitted in homologous blood. The larger the volume of blood used, the greater the chance of infection. It produces moderate pyrexia beginning around the end of the first week, associated with a “flulike illness”; the patient complains of weakness, malaise, muscle pains, and sweating. Differential white blood cell count shows lymphocytosis and atypical mononuclear cells. The disease can be confirmed by demonstrating a rise in complement-fixing special antibody, and the virus can be isolated from the urine, although this is technically difficult. The Paul-Bunnell test is negative, excluding infectious mononucleosis (which can present an identical clinical picture) as a possible diagnosis. Although fever and symptoms usually persist for about 2 weeks, the disease is self-limiting, and no treatment is required. Depression is a common sequela.

Postcommissurotomy syndrome was described by Soloff and colleagues in 1953 when it was noted to follow closed mitral valve surgery. Although they interpreted the syndrome as reactivation of rheumatic fever, it subsequently became clear it was not related to rheumatic fever and could occur after any operation that involved opening the pericardium—hence the name postpericardiotomy syndrome, also called postcardiotomy syndrome. When Ito and colleagues coined the term postpericardiotomy syndrome, they suggested the syndrome was due to an immunologic reaction to damaged autologous tissue in the pericardial cavity. Subsequent work at the same institution confirmed an autoimmune theory of etiology. Apparently, heart-reactive antibodies appear in significant titers in most patients undergoing cardiac surgery, but the titer is much higher in patients who develop this syndrome.

Whether there are single or multiple etiologies, it is a fact that in many patients, symptoms appear a few weeks to a few months after cardiac operations. Nishimura and colleagues found the median postoperative time of onset to be 4 weeks. The most striking symptom is chest pain, both a central ache from pericarditis and severe pain from pleuritis. There may be no associated fever, but pericardial and pleural friction rubs are usually present, and often pericardial and pleural effusions. These are usually minor but may be major, and delayed pericardial tamponade can occur. There are no specific changes in the formed blood elements. Although the disease is self-limiting, its duration is highly variable, with a median of 22 days and a range of 2 to 100 days in the study by Nishimura and colleagues. Recurrences are common, appearing in 21% of patients in the Mayo Clinic series. In some of these patients, recurrence was as long as 30 months.
after a previous episode. The syndrome usually recurs should reoperation be required.

Pain and effusions are often relieved by bed rest and aspirin or nonsteroidal antiinflammatory drugs. Although these symptoms are quickly resolved by prednisone, steroids should be avoided whenever possible because of their side effects. However, when symptoms persist, and once the diagnosis is secure and infection has been excluded, prednisone may be given initially in high doses (40 mg · day⁻¹), gradually reduced, and completely discontinued within 4 to 8 weeks. Subsequent courses may be necessary.

An Italian multi-institutional randomized, double-blind placebo-controlled trial of colchicine for preventing postpericardiotomy syndrome (COPPS trial) enrolled 360 patients with a primary endpoint of reducing occurrence of the syndrome within 12 months of surgery. In the treatment arm, 1 mg of colchicine was given twice on the day of operation and followed by 1.5 mg twice daily for 30 days. The syndrome occurred less frequently (8.9% vs. 21%, P = .002) among treated patients. Most events occurred within 30 days.

Section III General Care of Children and Adults

General management of older children and adults after cardiac surgery, in the absence of specific complications, is relatively simple. This section describes general aspects of care, leaving many of the details and documentation to preceding discussions of subsystems.

Patients leave the OR with an arterial catheter in place and, optimally, pressure-monitoring catheters to reflect central venous pressure and, if desirable, left atrial or capillary wedge pressure. When elevated pulmonary artery pressures are anticipated, direct measurement of pulmonary artery pressure is also advisable. One or more routes of access to large central veins are in place. Risks associated with these devices are extremely low, but care is necessary in placing them, caring for them, and removing them. Proper placement of devices (see “Completing Operation” and “Left Atrial Pressure Monitoring” in Section III of Chapter 2) is key to preventing bleeding intraoperatively or at the time of their removal. Infection is a potential risk, but only 1.5% of such catheters have positive cultures when removed postoperatively. Use of antibiotic or antiseptic gels around the site of emergence of these catheters is nonetheless a prudent precaution. Sterile technique in their management is essential.

Patients often come to the ICU intubated, still anesthetized, and with a nasogastric tube in place. They are attached to a ventilator (usually a volume-controlled one), as described in “Management and Treatment” under Pulmonary Subsystem in Section I. Fluids to be administered until 7 AM of postoperative day 1 (the day after operation) are calculated (“calculated fluids”), and these are begun as described in “Fluid, Electrolyte, and Caloric Intake” in Section II. The urinary catheter placed in the OR (usually a typical Foley catheter, although at times a suprapubic catheter) is connected to a drainage system that permits hourly urine flow to be measured conveniently. Chest tubes are attached to a container in which there is a negative pressure of about 30 to 40 cm H₂O. Arrangements are made for measuring chest drainage at 30- to 60-minute intervals.

Many adult patients who are convalescing normally have systemic hypertension, at least in the early period after operation. Even when cardiac performance is good, prudence dictates controlling this hypertensive tendency. This is usually managed with sedation or a continuous infusion of nitroglycerin or nitroprusside (see Appendix 5A). If the hypertensive state continues, an oral hypertensive agent is usually started at the time of transfer out of the ICU. The dosage should be decreased, at least temporarily, at the time of hospital discharge; symptomatic arterial hypotension may otherwise develop. Finally, patients with impaired ventricular function and reasonable renal function may benefit from addition of afterload-reducing agents such as ACE inhibitors, Ca²⁺ channel blocking agents, or both. Ultimately, this can positively affect ventricular remodeling and benefit cardiac performance.

Chest tube drainage may be reinfused into the patient by an automated system. The system may be “instructed” as to the level of left (or right) atrial pressure above which automatic reinfusion of shed blood is not to be performed. When this limit is not violated, the system automatically reinfuses chest tube drainage at a prescribed rate. At the direction of the surgeon or intensivist, automatic chest tube drainage reinfusion is stopped 6 to 12 hours after the patient comes to the ICU. At times, infusion of shed blood appears to perpetuate a bleeding tendency; in this circumstance, reinfusion is promptly discontinued.

When chest tube drainage is sufficiently small that reoperation will clearly not be indicated, and when all subsystems give evidence of functioning well, consideration is given to extubating the patient. When patients are convalescing normally with appropriate cardiac and pulmonary reserves, the vast majority can be extubated either on the day of operation or the following morning. In concert with the anesthesiologist, many CPB operations in adults and children can be conducted using short-acting drugs that allow extubation within 1 to 4 hours following transfer to the ICU. It is thought this shortens ICU stay and decreases overall costs.

The nasogastric tube is removed just before extubation, and as before extubation, the head of the bed is elevated to about 30 degrees. Deep breathing exercises and spontaneous coughing are encouraged, and chest vibropercussion is carried out on a regular basis. Sips of water are allowed as well as other clear liquids, but no effort is made to attain a prescribed fluid intake by mouth, the intravenous route being relied upon for another 24 hours. In children, the urinary catheter may be removed, but in many of them and in adults it can remain in place another day.

Chest tubes are usually removed early on the morning of the first postoperative day, because appreciable chest drainage has usually ceased by then. When chest tubes are in the pleural space, the lower posterior tubes are removed first, and those in the upper and anterior parts of the thorax a few minutes to a few hours thereafter. This sequence allows for evacuation of air that may have been introduced with removal of the posterior tubes. Often it is most appropriate to remove the chest tubes before extubating the patient, but this is not necessary. Intracardiac monitoring devices generally may be removed on the morning after operation in older children and adults. It is advantageous but not necessary that they be removed before removing chest tubes. In neonates and young
infants, monitoring devices should be removed before the chest tubes, and this is usually not on the first day postoperatively. Some surgeons recommend leaving a soft, malleable drainage catheter in the mediastinum of children and adults for several days (attached to a negative pressure bulb) to drain any residual pericardial fluid while the patient is ambulatory.

After extubating the patient and removing intracardiac catheters and chest tubes, a final portable chest radiograph is obtained. If this is satisfactory, the arterial catheter is removed and the patient transferred to either the pediatric or adult cardiac surgical unit for continuation of convalescence. Because mild vasomotor instability is common after cardiac operations, adult patients frequently experience light-headedness on initial standing the day after surgery. Some surgeons recommend routine assessment of orthostatic blood pressure changes (lying, sitting, standing) prior to transfer out of the patient so that any orthostasis can be corrected before the patient begins ambulating in the hospital room. If the urinary catheter is still in place on the morning of postoperative day 2, it is removed; when a suprapubic catheter is used, the patient’s ability to void can be tested before removing the catheter. When normal convalescence to this point is confirmed, all intravenous catheters are removed. Patients are urged to ambulate and begin self-care to the extent possible.

When progress continues to be satisfactory, the patient is generally discharged from the hospital on the fourth or fifth postoperative day. Some institutions discharge on the third postoperative day, finding this management protocol highly satisfactory for some adult patients. Early hospital discharge implies daily follow-up in an outpatient facility or by a responsible physician for at least 2 to 3 more days. A final chest radiograph and ECG are obtained in the outpatient facility. Appropriateness of all medications and postoperative advice is ascertained at that time, and the patient is carefully instructed as to these matters. All information is conveyed to the patient’s general physician, cardiologist, or pediatric cardiologist, who then assumes responsibility for the patient.

At discharge, children may still be somewhat withdrawn and ill at ease, even with parents. Every effort is made to help parents understand the normality of this situation, and they are advised of ways the child’s return to an entirely normal relation with them can be expedited.

A program of daily exercise should be started as soon as the patient leaves the hospital and should emphasize regular walking for progressively longer periods. Patients who were active and gainfully employed before operation are urged to return to full activity (and employment in the case of adults) as soon as possible and, except under unusual circumstances, no later than 2 to 3 months after the procedure.

Section IV General Care of Neonates and Infants

Neonates, infants, and some small young children present postoperative care problems that differ in some ways from those of adults. Principles of subsystem and overall care remain the same, but the internal milieu of even normal neonates and infants is different in certain respects from adults. The cardiac operation has generally been more urgently indicated, and therefore these young patients often have more preoperative derangements and require more extensive operations. Cardiac reserve of neonates and infants is often less than that of adults after cardiac surgery because of the nature and seriousness of their preoperative cardiac condition. Their small airways are more apt to be suddenly obstructed by secretions, and they are subject to special problems such as episodes of pulmonary arterial hypertensive crises. Serum potassium level rises much more rapidly during oliguria in small patients than it does in older children and adults. These considerations do not necessarily indicate that young age per se is a risk factor for death after cardiac surgery; they do indicate that special attention must be given to them. As in Section III, we provide the general aspects of postoperative care of neonates and infants here, with details presented in the discussions of the various subsystems.

If the endotracheal tube has not been inserted through the nose initially, a nasotracheal tube may be substituted for the orotracheal tube before the patient leaves the OR. A urinary catheter, intracardiac recording devices, epicardial myocardial wires, and intravenous access to large central veins are in place when the patient leaves the OR, just as in adults. In the ICU, the patient is placed on a ventilator specifically designed for small patients. Often, 2.5 to 5 µg · kg⁻¹ · min⁻¹ of dopamine is infused, even in patients convalescing normally, and this is generally continued until the morning of postoperative day 1.

Because measuring devices and infusion of medications require some fluid, and because it is desirable to limit the total fluid intake in neonates and infants just as it is in adults, all continuously infused medications are mixed in sufficient concentration that the infusion rate does not exceed 2 to 3 mL · h⁻¹, the minimal rate at which reasonably accurate infusions can be given. No “calculated fluids” are planned for the day of operation, and this can be reconsidered early on the morning of postoperative day 1. Calculations are made as to the amount of fluid administered not only by the intravenous route but also in flushing pressure-measuring devices, and at 7 AM of postoperative day 1, consideration is given to beginning administration of “calculated fluids” or continuing without them (see Appendix 5K).

Once the patient is settled on the ventilator, the status of anesthetic and sedating medication is assessed. The goal in general is to keep the patient paralyzed and sedated at least until the morning of postoperative day 1. For paralysis, appropriate doses of pancuronium (or a comparable agent) are administered intravenously. This is insufficient to overcome many possibly deleterious reflexes. Therefore, fentanyl is also given as a continuous infusion of about 10 µg · kg⁻¹ · h⁻¹, and at times at the increased dose of 15 to 25 µg · kg⁻¹ · h⁻¹, not only for sedation but also for control of sympathetic activity. Particularly when the nasotracheal tube is suctioned, the patient must be under the influence of fentanyl. Ventilation is arranged to keep arterial PaCO₂ at about 30 mmHg, arterial PaO₂ above 120 mmHg, and if possible, pH at 7.45 or higher. This minimizes the tendency for pulmonary vascular resistance to rise paroxysmally (see
“Pulmonary Hypertensive Crises” under Pulmonary Subsystem in Section I).

We recommend irrigating the endotracheal tube with saline and suctioning every 2 hours, although some who do not use fentanyl favor no suctioning of the endotracheal tube. Whatever the policy, it must be recognized that this is a potentially hazardous procedure, and it should be undertaken only by skilled nurses with adequate backup should an emergency develop during or within a few minutes after suctioning.

Early on the morning of postoperative day 1, consideration is given to extubating the patient. If all subsystems appear to be functioning satisfactorily, the protocol leading to extubation is begun. A dose of dexamethasone (0.3 mg · kg⁻¹) is administered about 1 hour before extubation, for its presumed effect in minimizing laryngeal edema, and then 0.1 mg · kg⁻¹ is given 2 hours later and another dose 2 hours thereafter. Then, if the patient is awake and active, extubation is accomplished. After extubation, the baby is maintained in a humidified oxygen-enriched environment for at least another 24 hours in the ICU, although care is taken to avoid excessively high PaO₂.

If all subsystems are not functioning well on the morning after operation, there should be no hesitancy to continue control of ventilation as well as paralysis and sedation for another 24 hours. However, about 70% of normally convalescing neonates and small infants can be extubated the morning after operation and the remainder usually on the morning of postoperative day 2.

Following extubation and the passage of a few hours, oral feedings can be started. For the feedings, the patient is held at least in a semi-upright position, observing the usual precautions necessary in feeding small babies (see Appendix 5N). Neonates and young infants have little nutritional reserve. When oral intake is not possible on postoperative day 1 or 2, nasogastric tube feeding is begun. If this is not promptly effective, intravenous hyperalimentation is begun (see “Fluid, Electrolyte, and Caloric Intake” in Section II).

To avoid bleeding after their removal, intracardiac catheters should not be removed before postoperative day 2. It is prudent but not mandatory to leave all chest tubes in place until after intracardiac devices have been removed.

When convalescence is not normal for any reason, management is altered appropriately, generally as described in the earlier parts of this chapter.

A special situation is presented early postoperatively by neonates and young infants when the operation leaves pulmonary blood flow coming solely from a surgically created systemic–pulmonary artery shunt (see Special Features of Postoperative Care in Chapter 49). In these intubated patients, magnitude of pulmonary blood flow is largely determined by the relation of systemic to pulmonary vascular resistance. When pulmonary resistance is low, pulmonary blood flow tends to be excessive and systemic blood flow small. Should pulmonary vascular resistance gradually or suddenly rise, pulmonary blood flow declines, sometimes rapidly, and hypoxia develops. In this setting, pulmonary vascular resistance is largely determined by arterial PaCO₂ and arterial pH. Manipulation of PaCO₂ is the best method for regulating pulmonary vascular resistance. When pulmonary blood flow appears to be too high and systemic blood flow too low, arterial PaCO₂ is deliberately elevated modestly (to 40 to 45 mmHg) to increase pulmonary vascular resistance, decrease pulmonary blood flow, and increase systemic blood flow. When pulmonary blood flow seems too low and hypoxia too prominent, pulmonary arteriolar resistance is lowered by lowering the arterial PaCO₂ appropriately, usually to 25 to 35 mmHg.

Alterations in arterial PaCO₂ are conveniently accomplished by altering tidal volume and respiratory rate. The adjustments required are usually sufficiently small that they produce no change in other important variables. Alternatively, ventilatory variables are set so that arterial PaCO₂ is 25 to 30 mmHg; if subsequent pulmonary blood flow seems excessive or systemic blood flow too low, or both, PaCO₂ is increased by simply increasing the fractional concentration of carbon dioxide in the inspired air.

Because most treatment decisions in the ICU are based on use of numeric data and an orderly set of rules and logic, automation can be used for making, displaying, and storing observations and for intervening in some situations via a closed-loop computer system. These concepts were described in 1968, but bedside hardware and computers have been continuously modified since. Computers can be cost-effective, prevent rules-based errors (see “Human Error” in Chapter 6), serve as “cognitive prostheses” to simplify presentation of complex multidimensional data, and provide strategic decision support to the surgical faculty, house staff, and nurses. Although there are studies and opinions to the contrary, these reflect a difference in orientation and goals and thus a different method of using automated care. The ICU computer may do the following:

1. Using the patient’s age, height, weight, and hemoglobin level, the computer calculates and prints out surgeon-specific preoperative orders, directions for assembly and priming the pump-oxygenator, and postoperative orders.
2. At designated intervals (e.g., every 2 minutes), the computer can automatically measure, numerically display, and record systemic and pulmonary artery systolic, diastolic, and mean blood pressures; right and left atrial pressures; heart rate; chest tube drainage; urine flow; and temperature. Plots of these data can be displayed on command.
3. The computer, continually sensing drainage from the chest, automatically reinfuses all the shed blood and uses the desired atrial pressure limit to interrupt infusions when the limit is exceeded.
4. Using computer logic and the rules described under “Bleeding” in Section II, messages can be displayed suggesting reoperation.
5. Arterial blood gas and hemoglobin levels are stored and displayed. The base excess or deficit is calculated. When metabolic acidosis is present, the recommended dose of bicarbonate is calculated using the rules and logic in Appendix 5L.
6. The appropriate concentration and drip rate of infusion of any inotropic agent can be calculated and displayed using the rules and logic in Appendix 5B.

7. The computer regulates infusion of nitroprusside by a closed-loop system, having been programmed with the desired mean arterial blood pressure and other relevant information, using the rules and logic in Appendix 5A.\(^{516,517}\) Studies indicate that this method of continuously maintaining a desired blood pressure is more effective than manual methods in avoiding sudden under- or overdosage.

8. The type and amount of fluid to be given intravenously after surgery is calculated according to the rules and logic in Appendix 5H and can be printed out.

9. The computer can generate surgeon-specific antibiotic orders, including dosages, accounting for the presence of drug allergies.

10. On request, the computer displays all recent data in a tabular or plotted form for review, with the time interval between measurements (e.g., 5 minutes, 15 minutes, 30 minutes, 1 hour) being selected by the reviewer.

### Section VI  Body Surface Area

Because cardiac output has traditionally been normalized according to body surface area ([BSA] as cardiac index), other variables related to cardiac surgical patients are optimally normalized in the same way. The computation of BSA by the classic Boyd formula (a more general statement of the original DuBois formula) requires knowledge of height and weight, and height is not always available in clinical studies. A nomogram (Fig. 5-15, A) can be used to estimate BSA from weight, but in some situations, not even weight is available. In these circumstances, a nomogram (Fig. 5-15, B) can be used to estimate BSA based on age alone.
**5A Protocol for Reducing Arterial Blood Pressure and Afterload**

*Sodium nitroprusside* is administered intravenously (IV) continuously or intermittently as required. It acts directly on arterial (and to a lesser extent, venous) smooth muscle and thus decreases systemic and pulmonary vascular resistance and systemic venous tone. Its onset and end of action are immediate. The dose is 1 to 10 µg · kg⁻¹ · min⁻¹ (doses larger than this are not used), regulated in most cases to maintain a mean arterial blood pressure 10% above the normal value for the patient’s age. In patients with thick left ventricular walls or coronary artery disease, concern about coronary perfusion pressure makes a mean arterial blood pressure 20% above normal desirable (or 150 mmHg in adults). Fifty or 100 µg of sodium nitroprusside are dissolved in 150 mL of 5% glucose in water. The drug may be administered with a servo-pump using a closed-loop system or with a slow-infusion pump. When nitroprusside is being administered, methods should be available for measuring blood thiocyanate levels, because values of >10 g · dL⁻¹ are potentially toxic. Toxity is manifested by signs of intracellular suppression of oxygen consumption (elevation of mixed venous oxygen levels, narrowing of arterial/venous oxygen difference, and metabolic acidosis) and by anorexia, muscular spasms, disorientation, and convulsions. Toxicity is due largely to the formation of cyanide, the major metabolic product of sodium nitroprusside. Toxicity is treated by IV infusion over 15 minutes of 150 µg · kg⁻¹ of a 25% solution of sodium thiosulfate (10 µg · kg⁻¹ · min⁻¹).

*Nitroglycerin* decreases venous tone but also decreases coronary resistance. It is therefore particularly useful when myocardial ischemia is present. Infusion rates of 0.5 to 3 µg · kg⁻¹ · min⁻¹ are recommended. Nitroglycerin is absorbed into polyvinyl tubing used for IV infusion, and the concentration reaching the patient is less than planned until the tubing becomes saturated. Nitroglycerin is not as effective as nitroprusside in lowering arterial pressure.

A single-dose longer-acting drug, *diazoxide*, is available although seldom used. The dose is 3 to 5 µg · kg⁻¹. *Phentolamine* (Regitine) is another vasodilator used on occasion. It has an α-adrenergic receptor blocking effect, produces direct smooth muscle relaxation, and reduces pulmonary vascular resistance. Its recommended infusion rates are 1.5 to 2 µg · kg⁻¹ · min⁻¹.

*Phenoxybenzamine* is a noncompetitive blocker of α-receptors with a prolonged (12- to 24-hour) effect and a delayed (30- to 60-minute) onset. It acts on both arterial and venous vessels and has no important side effects. It is administered IV in a dose of 1 mg · kg⁻¹, with the solution diluted in 20 to 50 mL of normal saline solution and infused slowly over about 15 minutes. The disadvantage of phenoxybenzamine is that its α-blocking effect is complete for at least 12 hours; thus, the drug is not used until the need for prolonged afterload reduction has been established by the patient’s response to a sodium nitroprusside infusion over about 12 hours. Rather than continue infusing sodium nitroprusside at a high rate, phenoxybenzamine may be substituted and the dose repeated in 12 to 15 hours when it is clear its effect is wearing off. The *phosphodiesterase inhibitors* milrinone and amrinone may also produce a salutary vasodilatory effect.

5C Protocol for Managing Some Aspects of Ventricular Electrical Instability

Early Interventions for Ventricular Electrical Instability

1. Give lidocaine as an intravenous (IV) bolus injection (the dose is 1 mg · kg\(^{-1}\) for adults and children, although in adults the usual dose is 50 mg) if the arrhythmia is premature ventricular contraction (PVC) or ventricular tachycardia (VT) with a good hemodynamic state. If there is VT and reduction of cardiac output, use immediate DC cardioversion (100 and then 200 J).

2. Draw a blood sample for determination of serum K\(^+\); when the result is available, treat hypokalemia (K\(^+\) concentration < 4.0 mEq · L\(^{-1}\)) if present:
   a. Administer 5 mEq K\(^+\) as an IV bolus.
   b. Administer 20 mEq K\(^+\) in 50 mL of 5% glucose over 1 hour; then obtain repeat serum K\(^+\) level measurement and repeat treatment until serum level is satisfactory (at least 3.5 mEq · L\(^{-1}\) and preferably 4.0 mEq · L\(^{-1}\)).
   c. Double the IV maintenance K\(^+\) dose.
   d. Recheck serum K\(^+\) level. If it is <4.0 mEq · L\(^{-1}\), order oral K\(^+\) supplement as 20% KCl, 10 mL twice a day in orange juice (60 mEq approximate daily dose).

3. If the ventricular rate is <80 to 90 beats/min, initiate pacing. If basic rhythm is sinus or atrioventricular (AV) junctional, use atrial pacing. When cardiac rhythm is other than sinus or AV junctional, or atrial pacing fails to result in 1:1 AV conduction, use ventricular pacing (with the ventricular wire electrode attached to negative pole of pacer). In the presence of second- or third-degree AV block, consider AV sequential pacing.

Interventions after Control of the Urgent Situation

If the arrhythmia recurs promptly or is not controlled by these simple measures, begin continuous IV lidocaine infusion in a dose of 20 to 50 µg · kg\(^{-1}\) · min\(^{-1}\), or 0.02 to 0.05 mg · kg\(^{-1}\) · min\(^{-1}\).

5D Protocols for Acute Management of Postoperative Atrial Fibrillation

- In hemodynamically stable adult patients, intravenous verapamil, diltiazem, esmolol, propranolol, or amiodarone are effective alternative therapies:
  - **Ibutilide**: after pretreatment with intravenous magnesium (1g), 1 mg infused over 10 minutes; repeat once if no conversion
  - **Verapamil**: 5-10 mg IV as bolus; may repeat after 10-15 minutes
    Adverse effect: infrequently hypotension, later increase of heart rate
  - **Diltiazem**: 20 mg IV over 2 minutes, may repeat × 1
    Adverse effect: infrequently hypotension
  - **Esmolol**: 0.5 mg · kg\(^{-1}\) · min\(^{-1}\) IV infusion
    Adverse effect: hypotension, bronchospasm
  - **Propranolol**: 0.05 mg · kg\(^{-1}\) or 5-mg bolus IV
    Adverse effect: hypotension

- **Amiodarone**: 150 mg IV over 10 minutes
  Adverse effect: rarely hypotension

- **Unstable hemodynamics**
  Digoxin has classically been recommended, but it may be slow to act (3-8 hours) and relatively ineffective at decreasing heart rate in postoperative patients with increased sympathetic activity. In the elderly or in the presence of compromised renal function, the therapeutic window is narrow and toxicity may occur. An estimated digitalizing dose of digoxin provides a convenient guideline for the cardiac surgeon. The estimated dose of digoxin, when no digitalis has been given in the past 10 days, may be considered to be 0.9 mg · m\(^{-2}\) intravenously and 1.6 mg · m\(^{-2}\) orally. The digitalizing dose in infants may be considered 50 µg · kg\(^{-1}\) intravenously, and the maintenance dose 10 to 15 µg · kg\(^{-1}\) · day\(^{-1}\).
DC cardioversion

Amiodarone

■ Recurrent atrial fibrillation
  Procainamide: 500-1000 mg orally, every 6-8 hours
  Sotalol: initially 80 mg twice daily

■ Anticoagulation
  The prevalence of stroke attributable to postoperative atrial fibrillation is unknown. It seems justifiable to initiate anticoagulation if atrial fibrillation persists longer than 48 hours or is recurrent. In these instances, warfarin is recommended. If elective cardioversion is planned, IV heparin is recommended and is prescribed in therapeutic doses.

---

5E Protocol for Rapid Atrial Pacing via Atrial Wires

Rapid Atrial Pacing

The technique of rapid atrial pacing is applied to atrial flutter, defined as a general atrial rate of 250 to 350 beats · min\(^{-1}\) with a constant beat-to-beat cycle length that can be interrupted by rapid atrial pacing. This is rarely possible in atrial flutter-fibrillation, a more rapid type of atrial flutter with a rate > 350 beats · min\(^{-1}\), and is not possible in atrial fibrillation.

ECG limb leads are placed on the patient for monitoring, and the two atrial wires are connected to the rapid atrial pacer. Because the atrial pacing threshold is usually high during atrial flutter, output is set at 10 to 20 mA. Bipolar atrial pacing is used because the stimulus artifact then rarely distorts the ECG tracing, and the atrial complex in the ECG is clearly seen so that atrial capture can be verified.

A relatively slow pacing rate is used first, because occasionally, immediate one-to-one conduction occurs with rapid ventricular tachycardia, which is to be avoided. After this, there are several possible maneuvers for control of atrial flutter and its rapid ventricular response, as described by Waldo and MacLean.\(^{91}\)

Ramp Technique

Atrial pacing is begun at a rate 10 beats · min\(^{-1}\) faster than the atrial flutter rate. The rate of atrial pacing is then gradually increased. When the typical negative atrial complex in lead II changes to a positive atrial complex, indicating capture by pacing, atrial pacing is either abruptly stopped or gradually slowed until the ventricular rate is considered satisfactory.

Constant Rate Technique

Pacing is initiated at a rate 10 beats · min\(^{-1}\) faster than the spontaneous atrial flutter rate. After pacing at this rate for about 30 seconds, pacing is either abruptly stopped or the pacing rate quickly slowed until the ventricular rate is considered satisfactory. If these maneuvers are unsuccessful in interrupting the atrial flutter, they are repeated, with the initial atrial pacing rate increased in increments of 10 beats · min\(^{-1}\).

Continuous Rapid Atrial Pacing

When atrial flutter is interrupted by the procedures just described but recurs with unacceptable frequency, continuous atrial pacing at 400 to 600 beats · min\(^{-1}\) is used. This results in continuing atrial fibrillation with variable atrioventricular block. The ventricular rate can then be controlled by digoxin.

When premature atrial beats are continuous or recurrent despite pharmacologic treatment, continuous atrial pacing at about 200 to 230 beats · min\(^{-1}\) usually results in their suppression and a 2:1 atrioventricular conduction ratio with an acceptable ventricular rate.
Protocol for an Intubated Patient

1. The ventilator is used with its air heating and humidifying devices and the valves for intermittent mandatory ventilation and positive end-expiratory pressure (PEEP) functioning.

2. The patient has a well-positioned and well-secured orotracheal tube in place or, in infants and young children (for greater security and comfort) and adults in whom postoperative ventilation for more than 24 hours is likely, a well-positioned and well-secured nasotracheal tube in place (see Chapter 4).

3. Initially the fractional concentration of oxygen ($FIO_2$) is set at 0.6, tidal volume ($VT$) at 12 to 20 mL · kg$^{-1}$, and intermittent mandatory ventilation (IMV) at 12 to 14 breaths · min$^{-1}$ in adults, 20 to 25 breaths · min$^{-1}$ in older children, 30 breaths · min$^{-1}$ in young children, and 30 to 40 breaths · min$^{-1}$ in infants. End-inspiratory pressure should normally be $<40$ cm H$2$O. In all situations, visual, palpatory, and auscultatory observation of the patient’s chest must be used to confirm that $VT$ is adequate for good air movement in and out of the lungs. These observations must be made whenever the patient becomes restless or agitated or there is any other reason to suspect inadequate gas exchange. Except in patients with chronic obstructive lung disease and those in whom the Glenn or Fontan operation has been performed, PEEP of 5 to 10 cm H$2$O (4 cm H$2$O in patients < 4 years old) may be used.

4. When the patient is admitted to the ICU, baseline blood gas analysis is obtained and ventilatory parameters are adjusted accordingly. Continuous monitoring of oxygen saturation by use of a digital infrared sensor is advisable in most patients. In adults, additional arterial blood gas analyses are not done routinely thereafter unless there is a change in clinical status. In neonates and children, more frequent arterial blood gas analyses are usually necessary.

5. A supine portable chest radiograph is obtained upon arrival in the ICU and reviewed by a physician for placement of the tip of the endotracheal tube; the presence of pneumothorax, atelectasis, vascular congestion, or gastric distention; and size of the mediastinal silhouette. The chest radiograph is routinely repeated the first postoperative morning.

6. Turning of the patient and sterile suctioning of the airway are performed each hour to clear retained secretions and minimize atelectasis. Suctioning is performed after hand bagging with 100% oxygen, hyperventilation for several breaths, and instillation of 1 to 5 mL of sterile saline solution down the endotracheal tube (see Section IV, “General Care of Neonates and Infants,” for discussion of endotracheal tube suctioning in these patients). Suctioning is followed again by hand bagging with 100% oxygen. The length of the endotracheal tube must be known so that the suctioning catheter can be passed with certainty beyond the tube into the trachea.

7. In patients without severe preoperative pulmonary dysfunction, criteria for extubation include:
   a. Patient awake and alert, indicating recovery from anesthesia and ability to protect his or her airway
   b. Satisfactory hemodynamic state
   c. Absence of important drainage from chest tubes
   d. Arterial $P_O_2$ $\geq$ 70 mmHg or $S_{A_O_2}$ $>90\%$ to $92\%$ (in the absence of intracardiac right-to-left shunting) on IMV of 6 breaths · min$^{-1}$ and $FIO_2$ of 0.40
   e. Spontaneous respiratory rate $<25$ breaths · min$^{-1}$ in adults, $<40$ breaths · min$^{-1}$ in young children, and $<50$ breaths · min$^{-1}$ in infants
   f. Absence of increased work of breathing (use of accessory respiratory muscles)
   g. Normal Pa$CO_2$ and pH (Pa$CO_2$ may be somewhat elevated with a normal pH, if metabolic alkalosis is present)
Protocol for Oliguria

**Indication**

Urine output in the early postoperative period of <0.5 to 1.0 mL · kg\(^{-1}\) · h\(^{-1}\) in infants and children and <0.5 mL · kg\(^{-1}\) · h\(^{-1}\) (30-35 mL · h\(^{-1}\)) in adults.

**Rationale**

To reverse the nearly universal occurrence of fluid retention following cardiopulmonary bypass.

**Treatment**

1. Exclude low cardiac output as the cause of the oliguria.
2. Insert a urinary catheter if not already in place.
3. Administer a diuretic:
   a. *Furosemide*: 1 mg · kg\(^{-1}\) for infants and children and 20 to 40 mg for adults administered intravenously (IV) as a bolus. Usually, no greater diuretic response is elicited with higher doses. However, doses of up to 180 to 240 mg may be necessary in patients with chronic heart failure, cirrhosis, and the nephrotic syndrome.
   i. The expected result is at least a doubling of the urine output over 2 to 3 hours.
   ii. If the diuresis is inadequate, other diuretics may be used in adults.
   b. *Ethacrynic acid*: 50 to 100 mg IV in 50 mL of solute over 30 minutes; ototoxicity occurs in 2% to 3% of patients.
   c. *Bumetanide*: 0.5 to 2 mg IV over 1 to 2 minutes
   d. *Torsemide*: 10 to 20 mg IV as a bolus
e. A continuous infusion of the diuretics just mentioned may be safer and more effective in some patients. This is usually given after a bolus if the diuretic effect is not sustained. Furosemide is given at an initial infusion rate of 5 mg · h\(^{-1}\), increasing to 20 mg · h\(^{-1}\) if necessary. The equivalent dose of bumetanide is 0.5 mg · h\(^{-1}\), increasing to 1 mg · h\(^{-1}\); and for torsemide, 5 mg · h\(^{-1}\), increasing to 10 mg · h\(^{-1}\).

Protocol (Interim Measures) for a Serum K\(^+\) Level > 5.5 mEq · L\(^{-1}\) from Acute Renal Failure

1. Give glucose and insulin solution intravenously (IV). For adults, mix 20 units of regular insulin in 50 mL of 50% dextrose and give IV over 10 minutes. For children and infants, mix 0.5 mL of regular insulin per kilogram of body weight in 2 mL of 25% dextrose per kilogram and give IV over 10 minutes.
2. Administer a sodium polystyrene sulfonate enema. For adults, mix 50 g in 200 mL of sorbitol or 20% dextrose, and give as a retention enema; hold for 30 minutes, then remove; repeat hourly as necessary. For children and infants, give 1 g · kg\(^{-1}\) and 10 to 50 mL of sorbitol as a retention enema (total volume of sorbitol may be increased up to about 150 mL for children up to about 10 years of age).
3. Give 1 mEq · kg\(^{-1}\) sodium bicarbonate IV for infants and children. For adults, give 1 ampule (44 mEq) IV.
4. If potassium levels exceed 6.5 mEq · L\(^{-1}\) and the patient is not receiving digoxin, give 10 mg · kg\(^{-1}\) of IV calcium chloride for infants and small children, and about 200 mg · kg\(^{-1}\) for adults, to decrease the cardiovascular effects of hyperkalemia.
5. If these measures do not result in a potassium level < 5.5 mEq · L\(^{-1}\), nephrology consultation should be obtained.
Protocol for Seizures in Infants and Children

General Comments

Generalized or focal seizures are an infrequent but potentially serious occurrence following cardiac surgery in infants and children. In such cases a number of etiologies are possible (e.g., metabolic; infectious; cerebral edema, embolism, or hemorrhage; decreased cerebral perfusion), but in most patients no specific causative factor is identified. The following protocols outline initial evaluation to identify possible correctable causes and describe an initial treatment regimen. In most cases, a consultation is obtained with a neurologist knowledgeable about cardiac surgical patients. A few generalizations are useful:

1. In infants and small children, whether the seizure is generalized or focal is not helpful diagnostically.
2. Respiratory arrest, discoordinate respiratory activity, or sudden inability to adequately mechanically ventilate can be an indication of seizure activity in infants. Additional evidence of seizures is usually present on detailed evaluation.
3. After initial control of seizures, anticonvulsant therapy should be continued through the recovery period. Decisions regarding long-term therapy are made by the neurologist or pediatric cardiologist before hospital discharge.
4. Most children having a seizure in the early postoperative period will not have a chronic seizure disorder.
5. Choreiform movements are more serious symptoms than are seizures and are more apt to persist.
6. Because of its potential to cause cardiorespiratory depression and its short duration of action, diazepam is best avoided as an anticonvulsant unless the patient is being artificially ventilated.

Initial Evaluation and Treatment

1. At the onset of a seizure, arterial blood gases and pH; serum glucose, calcium, and electrolytes; cardiac index; and body temperature are determined.
2. Interventions are made in an attempt to correct:
   a. pH < 7.25 or > 7.50; PaCO₂ < 25 mmHg; PaO₂ < 80 mmHg; and base deficit > 10 to 15 mEq · L⁻¹. (In some patients, prompt control of seizures will correct low values.)
   b. Serum glucose level < 40 mg · dL⁻¹ in infants and < 60 mg · dL⁻¹ in older children (see “Fluid, Electrolyte, and Caloric Intake” in Section II)
   c. Serum calcium level < 7 mg · dL⁻¹ in infants and < 8 mg · dL⁻¹ in older children
   d. Serum sodium level < 125 mEq · L⁻¹. Usual management in this situation is restriction of salt and water intake.
   e. Cardiac index < 2.0 L · min⁻¹ · m⁻²
   f. Body temperature > 38.6°C (>101.5°F)

Initial Anticonvulsant Therapy

When seizures are first noted, steps are taken to terminate them or, if they are no longer present, prevent their recurrence while the chemical and other variables are being determined.

1. Give:
   a. 0.1 to 0.2 mg · kg⁻¹ of diazepam intravenously (IV) and
   b. 15 mg · kg⁻¹ of phenobarbital IV over 5 to 10 minutes as a loading dose.
2. If seizures are not controlled by these measures, additional doses of diazepam (if the patient is being ventilated) may be used. (The full effect of the loading dose of phenobarbital may not be apparent for several hours, but if problems continue at this stage, consider giving a further 5 mg · kg⁻¹.)
3. If there has been spontaneous termination of seizure activity and prevention of recurrence is desired, omit step la and proceed to step 1b.
4. Continuing major seizures will rarely be a problem. If they are, a loading dose of phenytoin (20 mg · kg⁻¹ orally) is given, followed by maintenance with 3 to 4 mg · kg⁻¹ · day⁻¹ given orally.
5. An alternative, especially when seizures interfere with effective ventilatory support, is paralysis with pancuronium.

Maintenance Anticonvulsive Therapy

Administration of phenobarbital (2.5 mg · kg⁻¹ · 12 h⁻¹) can be instituted 12 to 24 hours after giving the initial loading dose.
Protocol for Autotransfusion

1. Several commercial chest drainage systems that accommodate autotransfusion are available. The two general types are (1) those that transfuse shed blood directly from the drainage system and (2) those that contain a drainage receptacle (a collapsible bag) that is manually transferred as an independent infusion setup.
2. A filter is optional.
3. Often there is a threshold for autoinfusion (i.e., drainage > 100 mL in adults).
4. A time limit for duration of autotransfusion is set for 4 to 6 hours.
5. Reinfusion of shed blood is governed by:
   a. Amount of drainage
   b. Atrial pressure limits

6. With either system, the total volume of chest drainage must be noted. This is a simple arithmetic sum of volume currently occupying the chest drainage reservoir plus the amount of chest drainage autotransfused. This total is noted hourly.
7. Contraindications to autotransfusion include:
   a. Infectious endocarditis or other infection
   b. Exogenous chemicals in the mediastinum
      i. Disinfectants
      ii. Topical antibiotics
      iii. Hemostatic agents
      iv. Biological glue
   c. Hematologic abnormalities (e.g., sickling, diffuse intravascular coagulation, hemolysis)

Protocol for Intravenous Fluids

In adults and children (>2 years of age or >13 kg in weight):

1. Day of operation:
   a. 500 mL of 5% glucose in water · m⁻² · 24 h⁻¹
   b. 10 mEq of K⁺ · m⁻² · 24 h⁻¹
2. First and second postoperative days:
   a. 750 mL of 5% glucose in water · m⁻² · 24 h⁻¹
   b. 20 mEq of K⁺ · m⁻² · 24 h⁻¹
3. Third postoperative day:
   a. 750 mL of 5% glucose in water · m⁻² · 24 h⁻¹ or 1100 mL of 5% glucose in one-quarter-strength saline solution · m⁻² · 24 h⁻¹
   b. 350 mL of 5% glucose in saline solution · m⁻² · 24 h⁻¹
   c. 10 mEq of K⁺ · m⁻² · 24 h⁻¹
4. If oral intake has not been established on the third postoperative day, consider gavage feeding or intravenous (IV) hyperalimentation.

In infants and small children (<2 years old or <13 kg in weight):

1. Day of operation:
   a. Calculate patient’s saline requirement.
      i. 250 mL · m⁻² · 24 h⁻¹ are required.
   ii. If this is 75 mL or less for the individual patient, use only balanced salt solution for flushing the arterial catheter; if it is 75 to 150 mL, use balanced salt solution for flushing the arterial and left atrial catheters; if it is >150 mL, flush the arterial, left atrial, and right atrial (and, if present, pulmonary artery) catheters with balanced salt solution.
      iii. Give no additional sodium-containing fluids if step ii supplies the patient’s needs. Otherwise, subtract the amount in step ii from the requirement and give the difference.
   b. Calculate the patient’s water requirement.
      i. 500 mL · m⁻² · 24 h⁻¹ of 10% glucose in water are required.
      ii. Subtract 72 mL · the number of intracardiac recording catheters being flushed with 10% glucose solution

---

4 An automatic, very slow (3 mL · h⁻¹ or 72 mL · 24 h⁻¹), continuous infusion system for all devices attached to pressure transducers is used. The solution flushing the arterial needle must be a heparinized balanced salt solution to prevent arterial spasm and pain. When salt restriction is important, as in infants, a glucose solution can be used for flushing the other pressure lines.
2. Days thereafter:
   a. Calculate patient’s saline requirement.
      i. $250 \text{ mL} \cdot \text{m}^{-2} \cdot 24 \text{ h}^{-1}$ are required.
   b. Calculate patient’s water requirement.
      i. $750 \text{ mL} \cdot \text{m}^{-2} \cdot 24 \text{ h}^{-1}$ of 10% glucose are required.
      ii. Subtract 72 mL · the number of intracardiac catheters being flushed with 10% glucose in

   Note that when medications such as lidocaine, catecholamines, and sodium nitroprusside are administered, the amount of fluid thereby infused must be determined and subtracted from the daily fluid requirement.

---

### Protocol for Metabolic Acidosis

**Indication**
Metabolic acidosis exists if the base deficit is $>2 \text{ mEq} \cdot \text{L}^{-1}$ and pH is $<7.35$ or $\text{PaCO}_2$ is $<30 \text{ mmHg}$.

**Rationale**
Treatment is directed only at the extracellular fluid, and a conservative dose of $\text{NaHCO}_3$ is given because more can easily be administered if needed.

\[
\text{Extracellular fluid volume} = 30\% \text{ body weight (kg)}
\]

\[
\text{Base deficit (mEq} \cdot \text{L}^{-1}) \cdot 0.3 \cdot \text{body weight (kg)}
= \text{total extracellular base deficit}
\]

**Treatment**
1. Administer $\text{NaHCO}_3$ so that the amount of $\text{Na}^+$ (mEq) equals half the total extracellular base deficit.
2. Remeasure base deficit in 30 to 60 minutes and repeat treatment if indicated.

Note that in acute reduction of cardiac output or cardiac arrest, much larger doses of $\text{NaHCO}_3$ are indicated (44 mEq for adults, 1 mEq · kg$^{-1}$ for infants and children).

---

### Protocol for Hyperthermia

**Indication**
Hyperthermia exists if rectal temperature is $\geq 38.3^\circ\text{C}$ ($\geq 101^\circ\text{F}$).

**Rationale**
Hyperthermia increases metabolic demands and thus myocardial oxygen consumption. Severe hyperthermia (central temperatures $\geq 41.1^\circ\text{C}$ [$\geq 106^\circ\text{F}$]) may permanently and severely damage the brain.

**Treatment**
1. If rectal temperature is $\geq 38.3^\circ\text{C}$ ($\geq 101^\circ\text{F}$), give acetaminophen as a rectal suppository every 4 hours. The dose in infants and children is 10 mg · kg$^{-1}$ (rounded to the nearest 30 mg), and in adults, 650 to 1300 mg.
2. Consider using a cooling blanket or cold syringing and a fan or ice bags applied to the body.
3. If rectal temperature is $\geq 39.4^\circ\text{C}$ ($\geq 103^\circ\text{F}$):
   a. Insert esophageal temperature probe for continuous monitoring of central temperature and intensify efforts...
to improve cardiac output. Check for possible transfusion reaction.

b. If esophageal temperature is ≥39.4°C (≥103°F):
   i. Make preparations for peritoneal dialysis with room temperature or cooled dialysate, to be initiated if simpler measures do not promptly control hyperthermia.
   ii. Give acetaminophen as in step 1.
   iii. Give dexamethasone, 0.25 mg · kg⁻¹ IV, then 0.1 mg · kg⁻¹ IV every 6 hours.

4. Give sodium nitroprusside, 1 µg · kg⁻¹ · min⁻¹, to increase peripheral heat loss if arterial pressure remains acceptable with this drug; if inotropic agents are necessary, give preference to amrinone and isoproterenol.

5. Abolish muscular heat production, particularly when an infant is restless, by paralyzing with pancuronium (0.1 mg · kg⁻¹).

6. Continue efforts to improve cardiac output.

5N

Protocol for Infant Feeding

Infants can rapidly develop a profoundly catabolic state after major surgery. Caloric intake should be raised to adequate levels as soon as possible after operation.

When respiratory assistance via an endotracheal tube continues into the third postoperative day, gavage feeding is begun unless specific contraindications exist. In extubated infants, weakness and underdevelopment may prevent proper feeding and result in aspiration, making intermittent gavage feeding necessary. The steps are as follows:

1. As a precaution, prepare the endotracheal suction catheter for immediate use.
2. Check to be certain that the nasogastric tube is in the stomach; if intermittent gavage is to be used, a feeding catheter is inserted for each feeding and then removed.
   a. Aspirate the tube. If stomach contents are not obtained or if large quantities of air with a little mucus are obtained, the tube is probably in the trachea.
   b. While listening over the stomach with a stethoscope, inject a little air and listen for the typical noise.
   c. Persistent coughing suggests that the tube is in the trachea.
   d. Absence of a normal cry suggests the tube is in the trachea (steps a, b, and d apply to patients without an endotracheal tube).
3. If these checks indicate the tube is in the stomach, and if aspiration does not reveal >10 to 15 mL of fluid in the stomach, initial feedings can be begun. Feedings are injected slowly over 2 to 3 minutes or allowed to enter by gravity, preferably with the infant sitting upright. Otherwise, the infant is placed on his or her right side, with the head inclined to at least a 15-degree angle.
4. Gavage feeding is given every 3 hours on the following schedule:
   a. Give sterile water, 10 to 15 mL × 1.
   b. If well tolerated, give 10% dextrose in water, 30 mL × 1.
   c. If well tolerated and residual is <5 mL, give SMA-20 or equivalent formula, 30 mL × 8; if well tolerated, give SMA-20 in increasing amounts.
5. If needed:
   a. Consider giving SMA-27 (27 calories per ounce) if diarrhea is not present.
   b. Consider continuous drip infusion to avoid a bolus effect (residual fluid in the stomach is aspirated and measured every 2 hours).

INTRODUCING THE CHAPTER

What It Is About

Cardiac surgical procedures, particularly coronary artery bypass grafting (CABG), are the most quantitatively studied therapies in the history of medicine. These studies reveal a complex, multifactorial, and multidimensional interplay among patient characteristics, variability of the heart disease, effect of the disease on the patient, conduct of the procedure, and response of the patient to treatment. Because cardiac surgeons were “data collectors” from the beginning of the subspecialty, it is understandable that efforts to improve the quality of medical care while containing costs found cardiac surgical results (outcomes) an easy target. The dawn of medical report cards made it evident that multiple factors influencing outcome must be taken into account to make fair comparisons of outcomes (see “Risk Stratification” and “Risk Adjustment” in Section VI). This scrutiny of results, often by the media, reveals that variability in performing technical details of operations, coupled with environmental factors often not under direct control of cardiac surgeons, contribute to differences in results.

Propensity toward data collection in cardiac surgery was reinforced in the 1970s and early 1980s by challenges from cardiologists to demonstrate not simply symptomatic improvement from operative procedures, but improved survival and long-term quality of life (appropriateness). This resulted in one of the first large-scale, government-funded registries and an in-depth research database (Box 6-1) of patients with ischemic heart disease, as well as a rather small, narrowly focused randomized trial (Coronary Artery Surgery Study). It stimulated subsequent establishment by the Society of Thoracic Surgeons (STS) of what is now the largest non-governmental registry of cardiac surgical data.

Thus, it is important for all in the subspecialty of cardiac surgery, not just those engaged in bench, translational, or clinical research, to (1) understand how information generated from observations made during patient care is transformed into data suitable for analysis, (2) appreciate at a high level what constitutes appropriate analyses of those data, (3) effectively evaluate inferences drawn from those analyses, and (4) apply new knowledge to better care for individual patients.

It is our desire that the reader realize these goals and not conclude prematurely that this chapter is simply a treatise on biostatistics, outcomes research, epidemiology, biomathematics, or bioinformatics.

Who Should Read It

This chapter should be read in whole or in part by (1) all cardiac surgeons, to improve their comprehension of the medical literature and hone their skills in its critical appraisal; (2) young surgeons interested in becoming clinical investigators, who need instruction on how to pursue successful research (see Technique for Successful Clinical Research later in this section); (3) mature surgeon-investigators and other similar medical professionals and their collaborating statisticians, mathematicians, and computer scientists who will benefit from some of the philosophical ideas included in this section, and particularly from the discussion of emerging analytic methods for generating new knowledge; and (4) data managers of larger clinical research groups who need to fully

---

"In its narrowest definition, bioinformatics is a collection of methods devised to process genomic data, representing the reality that advances in genomics require sophisticated and often new computer algorithms. Some would say bioinformatics is the next frontier for statistics, others for machine learning. This is the narrow view. The National Institutes of Health (NIH) in the United States has provided a broader view. The NIH Biomedical Information Science and Technology Initiative Consortium agreed on the following definition of bioinformatics, ‘recognizing that no definition could completely eliminate overlap with other activities or preclude variations in interpretation by different individuals and organizations’: Bioinformatics is research, development, or application of computational tools and approaches for expanding the use of biological, medical, behavioral or health data, including those to acquire, store, organize, archive, analyze, or visualize such data (http://grants1.nih.gov/grants/bioc/CompuBioDef.pdf). They go on to define computational biology in a broader context than genomics as ‘the development and application of data-analytical and theoretical methods, mathematical modeling and computational simulation techniques to the study of biological, behavioral, and social systems.’ Thus, to lead from information to new knowledge, they envision bringing together quantitative needs in structural biology, biochemistry, molecular biology, and genomics at the microscopic level, and medical, health services, health economics, and even social systems disciplines at the macroscopic level, with analytic tools from computer science, mathematics, statistics, physics, and other quantitative disciplines. This vision transcends current restrictiveness of traditional biostatistics in analysis of clinical information. This is why we emphasize in this chapter that the material is not simply for surgeons, their clinical research team, and consulting and collaborating biostatisticians, but also for a wider audience of professionals in a variety of quantitative disciplines."
appreciate their pivotal role in successful research (Appendix 6A), particularly as described in Sections I, II, and III of this chapter.

The potential obstacle for all will be language. For the surgeon, the language of statistics, mathematics, and computer science may pose a daunting obstacle of symbols, numbers, and algorithms. For collaborating statisticians, mathematicians, and computer scientists, the Greek and Latin language of medicine is equally daunting. This chapter attempts to surmount the language barrier by translating ideas, philosophy, and unfamiliar concepts into words while introducing only sufficient statistics, mathematics, and algorithms to be useful for the collaborating scientist.

Because this chapter is intended for a mixed audience, it focuses on the most common points of intersection between cardiac surgery and quantitative science, with the goal of establishing sufficient common ground for effective and efficient collaboration. As such, it is not a substitute for statistical texts or academic courses, nor a substitute for the surgeon-investigator to establish a collaborative relationship with biostatisticians, nor is it intended to equip surgeons with sufficient statistical expertise to conduct highly sophisticated data analyses themselves.

How It Has Evolved
At least three factors have contributed to evolution of Chapter 6 from edition to edition of this book: increasing importance of computers in analyzing clinical data, introduction of new and increasingly appropriate and applicable methods for analyzing those data, and growing importance of nontraditional machine learning methods for mining medical data.

Thus, the title of this chapter in Edition 1 was “Surgical Concepts, Research Methods, and Data Analysis and Use.” Its sections highlighted (1) surgical success and failure, (2) incremental risk factors, (3) research methods, (4) methods of data presentation and analysis and comparison, (5) decision making for individual patients, and (6) improving results of cardiac surgery. All remain important, but progress in each of these areas warrants a fresh approach. In the first edition, formulae were provided for surgeons to implement on a new generation of programmable calculators. These programs provided confidence limits and simple statistical tests that continue to be valuable, particularly in reading and evaluating the literature; however, with the passage of time, increasing sophistication and complexity of programmable calculators have taken implementation of the programs out of the reach of most surgeons. Therefore, we have eliminated those appendices.

In Edition 2, an organizing schema for clinical research was developed, and the name of the chapter was changed to reflect it: “The Generation of Knowledge from Information, Data, and Analyses.” But this schema did not lead to a matching organizational format for the chapter; it paved the way for one. At the time of its writing, there was explosive progress in techniques for analyzing time-related events, so an important portion of the chapter was devoted to this topic. Effective analysis of time-related events was no longer possible with programmable calculators; they demanded powerful computer resources.

In Edition 3, the progression from information to data to analyses to knowledge became the explicit organizing schema for the chapter. Sophisticated methods for longitudinal data analyses and comparative effectiveness assessment were...
introduced. Whereas the statistician was once the surgeon’s primary collaborator in data analysis, that edition introduced computer scientists and mathematicians as partners in collaborative research.

In this edition we introduce other collaborators in the fields of artificial intelligence, ontology, and machine learning. In doing so, we expand themes hinted at in the third edition and hint at new techniques on the horizon. This edition is also strongly influenced by the Institute of Medicine’s (IOM) Learning Healthcare System initiative and comparative effectiveness emphases of the IOM and NIH. Undoubtedly, evolution of this chapter will continue in subsequent editions, because new methods are constantly being developed to better answer clinical questions.

How It Is Organized

The organizational basis for this chapter is the Newtonian inductive method of discovery. It begins with information about a microcosm of medicine, proceeds to translation of information into data and analysis of those data, and ends with new knowledge about a small aspect of nature. This organizational basis emphasizes the phrase, “Let the data speak for themselves.” It is that philosophy that dictates, for example, placing “Indications for Operation” after, not before, presentation of surgical results throughout this book.

Information

In health care, information is a collection of material, workflow documentation, and recorded observations (see Section II). Information may be recorded in paper-based medical records or in electronic (computer) format.

Data

Data consist of organized values for variables, usually expressed symbolically (e.g., numerically) by means of a controlled vocabulary (see Section III). Characterization of data includes descriptive statistics that summarize parts or all of the data and express their variability.

Analysis

Analysis is a process, often prolonged and repeated (iterative), that uses a large repertoire of methods by which data are explored, important findings are revealed and unimportant ones suppressed, and relations are clarified and quantified (see Sections IV and VI).

Knowledge

Knowledge is the synthesis of information, data, and analyses arrived at by inductive reasoning (see Section V). However, generation of new knowledge does not occur in a vacuum; an important step is assimilating new knowledge within the body of existing knowledge.

New knowledge may take the form of clinical inferences, which are simple summarizing statements that synthesize information, data, and analyses, drawn with varying degrees of confidence that they are true. It may also include speculations, which are statements suggested by the data or by reasoning, often about mechanisms, without direct supportive data. Ideally, it also includes new hypotheses, which are testable statements suggested by reasoning or inferences from the information, data, and analyses.

New knowledge can be applied to a number of processes in health care, including (1) generating new concepts, (2) making individual patient care decisions, (3) obtaining informed consent from patients, (4) improving surgical outcomes, (5) assessing the quality and appropriateness of care, and (6) making regulatory decisions (see Section V).

How to Read This Chapter

Unlike most chapters in this book, whose various parts can be read somewhat randomly and in isolation, Section I of this chapter should be read in its entirety before embarking on other sections. It identifies the mindset of the authors; defends the rationale for emphasizing surgical success and failure; contrasts philosophies, concepts, and ideas that shape both how we think about the results of research and how we do research; lays out a technique for successful clinical research that parallels the surgical technique portions of other chapters; and for collaborating statisticians, mathematicians, and computer scientists engaged in analyzing clinical data, lays the foundation for our recommendations concerning data analysis.

Much of the material in this introductory section is amplified in later portions of the chapter, and we provide cross-references to these to avoid redundancy.

THE DRIVING FORCES OF NEW KNOWLEDGE

Many forces drive the generation of new knowledge in cardiac surgery, including the economics of health care, need for innovation, clinical research, surgical success and failure, and awareness of medical error.

Economics

The economics of health care are driving changes in practice toward what is hoped to be less expensive, more efficient, yet higher quality care. Interesting methods for testing the validity of these claims have become available in the form of cluster randomized trials. In such trials (e.g., a trial introducing a change in physician behavior), patients are not randomized, physicians are (patients form the cluster being cared for by each physician)! This leads to inefficient studies that nevertheless can be effective with proper design and a large enough pool of physicians. It is a study design in which the unit of randomization (physician) is not the unit of analysis (individual patient outcome). Such trials appear to require rethinking of traditional medical ethics.

Innovation

Just when it seems that cardiac surgery has matured, innovation intervenes and drives new knowledge, both from proponents and opponents. Innovation occurs at several levels. It includes new devices; new procedures; existing procedures performed on new groups of patients, such as the elderly and the fetus; simplifying and codifying seemingly disparate anatomy, physiology, or operative techniques; standardizing procedures to make them teachable and reproducible; and introducing new concepts of patient care (the intensive care unit, automated infusion devices, automated care by computer-based protocols). Many of these innovations have had applications beyond the boundary of cardiac surgery.
Yet, innovation is often at odds with cost reduction and is perceived as being at odds with traditional research. In all areas of science, however, injection of innovation is the enthral that prevents entropy, stimulating yet more research and development and more innovation. Without it, cardiac surgery would be unable to adapt to changes in managing ischemic heart disease, potential reversal of the atherosclerotic process, percutaneous approaches to valvar and congenital heart disease, and other changes directed toward less invasive therapy.

What is controversial is (1) when and if it is appropriate to subject innovation to formal clinical trial and (2) the ethics of innovation in surgery, for which standardization is difficult.

Reducing the Unknown

New knowledge in cardiac surgery has been driven from its inception by a genuine quest to fill voids of the unknown, whether by clinical research or laboratory research (which we do not emphasize in this chapter, although the principles and recipe for success are the same as for clinical research). This has included research to clarify both normal and abnormal physiology, but also to characterize the abnormal state of the body supported on cardiopulmonary bypass.

Clinical research has historically followed one of two broad designs: randomized clinical trials and nonrandomized studies of cohorts of patients (“clinical practice”), as detailed later in this section under “Clinical Trials with Randomly Assigned Treatment” and “Clinical Studies with Nonrandomly Assigned Treatment,” respectively. Increasing emphasis, however, is being placed on translational research—that is, bringing basic research findings to the bedside. John Kirklin called this the “excitement at the interface of disciplines.” Part and parcel of the incremental risk factor concept (see “Incremental Risk Factor Concept” in Section IV) is that it is an essential link in a feedback loop that starts with surgical failure, proceeds to identifying risk factors, draws inferences about specific gaps in knowledge that need to be addressed by basic science, generates fundamental knowledge by the basic scientists, and ends by bringing these full circle to the clinical arena, testing and assessing the value of the new knowledge generated for improving medical care.

Surgical Success and Failure

Results of operative intervention in heart disease, particularly surgical failure, drive much of the new knowledge generated by clinical research. In the late 1970s and early 1980s, a useful concept arose about surgical failures. That is, in the absence of natural disaster or sabotage, there are two principal causes of failure of cardiac operations (or other treatments) to provide a desired outcome for an individual patient: (1) lack of scientific progress and (2) human error.

The utility of this concept is that it leads to the programmatic strategies of research on the one hand and development on the other. Thus, lack of scientific progress is gradually reduced by generating new knowledge (research), and human error is reduced in frequency and consequences by implementing available knowledge (development), a process as vital in cardiac surgery as it is in the transportation and manufacturing sectors.

Error

Increased awareness of medical error is driving the generation of new knowledge, just as it is driving increasing regulatory pressure and medicolegal litigation. The UAB group was one of the first to publish information about human error in cardiac surgery and place it into the context of cognitive sciences, human factors, and safety research. This interface of disciplines is essential for facilitating substantial reduction in injury from medical errors.

Surgical Failure

Surgical failure has been a strong stimulant of clinical research aimed at making scientific progress. With increasing requirements for reporting both outcomes and process measures in the United States (with “pay for performance”), there is now also an economic stimulus to reduce human error. The term “human error” carries negative connotations that make it difficult to discuss in a positive, objective way in order to do a root-cause analysis of surgical failures. It is too often equated with negligence or malpractice, and almost inevitably leads to blame of persons on the “sharp end” (caregivers), with little consideration of the decision making, organizational structures, infrastructures, or other factors that are remote in time and distance (“blunt end”).

Human Error

As early as 1912, Richardson recognized the need to eliminate “preventable disaster from surgery.” Human errors as a cause of surgical failure are not difficult to find, particularly if one is careful to include errors of diagnosis, delay in therapy, inappropriate operations, omissions of therapy, and breaches of protocol.

When we initially delved into what was known about human error in the era before Canary Island (1977), Three Mile Island (1979), Bhopal (1984), Challenger (1986), and Chernobyl (1986), events that contributed enormously to knowledge of the nature of human error, we learned two lessons from the investigation of occupational and mining injuries. First, successful investigation of the role of the human element in injury depends on establishing an environment of non-culpable error. The natural human reaction to investigation of error is to become defensive and provide no information that might prove incriminating. An atmosphere of blame impedes investigating, understanding, and preventing error. How foreign this is from the culture of medicine! We take responsibility for whatever happens to our patients as a philosophical commitment. Yet cardiac operations are performed in a complex and imperfect environment in which every individual performs imperfectly at times. It is too easy when things go wrong to look for someone to blame. Blame by 20/20 hindsight allows many root causes to be overlooked.

Second, we learned that errors of omission exceed errors of commission. This is exactly what we found in ventricular septal defect (VSD) repair (Table 6-1), suggesting that the cardiac surgical environment is not so different from that of a gold mine, and we can learn from that literature.

These two lessons reinforced some surgical practices and stimulated introduction of others that were valuable in the early stages of growth of the UAB cardiac surgery program:
using hand signals for passing instruments, minimizing distractions, replying simply to every command, reading aloud the protocol for the operation as it proceeds, standardizing apparently disparate operations or portions thereof, and focusing morbidity conferences candidly on human error and lack of knowledge to prevent the same failure in the future. To amplify, these practices might be enunciated as a “culture of clarity”—in today’s terms, a culture of transparency—the end result of which is a reproducible and successful surgical endeavor. In the operating room, each individual on the surgical team is relaxed but alert:

- Hand signals serve to inform assistants and the scrub nurse of anticipated needs for a relatively small number of frequently used instruments or maneuvers.
- Spoken communication is reserved for those out of the field of sight (i.e., the anesthesiologist and perfusionist). When verbalized, “commands” are acknowledged with a simple reply: “thank you,” “roger,” “yes.” Even those individuals out of the field learn to anticipate these events or commands.
- Anticipated deviations from the usual are presented a few minutes to a day or two before the event. (In teaching settings, residents are encouraged to write an operative plan in the preoperative note.) Unexpected deviations are acknowledged to all concerned as soon as possible.
- Successful routines are codified. These include chronology for anticoagulation and its reversal, myocardial management routines (induction of cardioplegia, intervals of cardioplegia reinfusion, controlled myocardial reperfusion before aortic clamp removal), and protocols controlled by the surgeon for commencing and weaning the patient from cardiopulmonary bypass.
- Technical intuitive concepts are articulated. For example, some think the VSD in tetralogy of Fallot is a circular hole. Thus, closing such a hole would simply involve running a suture circumferentially to secure a patch. Kirklin and Karp were able to describe the suture line as having four different areas of transition in three dimensions and precisely articulated names for those transitions. Each had a defined anatomic relationship to neighboring structures, so the hole became infinitely more interesting!
- Discussion of surgical failure is planned for a time (e.g., Saturday morning) when distractions are minimal. The stated goal is improvement, measurable in terms of reproducibility and surgical success. The philosophy is that events do not simply occur but have antecedent associations, so-called root-cause analysis. An attempt is made to determine if errors can be avoided and if scientific knowledge exists or does not exist to prevent future failure.

A major portion of the remainder of this chapter addresses acquisition and description of this new knowledge.

**Categories of Human Error**

**Slips** are failures in execution of actions and are commonly associated with attention failures (Box 6-2). Some external stimulus interrupts a sequence of actions or in some other way intrudes into them such that attention is redirected. In that instance, the intended action is not taken. **Lapses** are failures of memory. A step in the plan is omitted, one’s place in a sequence of actions is lost, or the reason for what one is doing is forgotten. **Mistakes** relate to plans and so take two familiar forms: (1) misapplication to the immediate situation of a good plan (rule) appropriate for a different and more usual situation and (2) application of the wrong plan (rule).

Slips and lapses constitute active errors. They occur at the physician-patient interface. Mistakes, in addition, constitute many latent errors. These are indirect errors that relate to performance by leaders, decision makers, managers, certifying boards, environmental services, and a host of activities that share a common trait: planning, decisions, ideas, and philosophy removed in time and space from the immediate healthcare environment in which the error occurred. (blunt...
end). These are a category of error over which the surgeon caring for a patient (sharp end) has little or no control or chance of modifying because latent errors are embedded in the system. It is claimed by students of human error in other contexts that the greatest chance of preventing adverse outcomes from human error is in discovering and neutralizing latent error.8,7

Inevitability of Human Error
If one considers all the possibilities for error in daily life, what is remarkable is that so few are made. We are surrounded with unimaginable complexity, yet we cope nearly perfectly because our minds simplify complex information. Think of how remarkably accident-free are our early-morning commutes to the hospital while driving complex machines in complex traffic patterns.1,14

When this cognitive strategy fails, it does so in only a few stereotypical ways.3 Because of this, models have been developed, based largely on observation of human error, that mimic human behavior by incorporating a fallible information-handling device (our minds) that operates correctly nearly always, but is occasionally wrong.20 Central to the theory on which these models are based is that our minds can remarkably simplify complex information. Exceedingly rare imperfect performance is theorized to be the price we pay for being able to cope, probably nearly limitless, with complexity. The mechanisms of human error are purported to stem from three aspects of “fallible machines”: downregulation, upregulation, and primitive mechanisms of information retrieval. In the text that follows, we borrow heavily from the human factors work of James Reason.8,7

Downregulation We call this habit formation, skill development, and “good hands.” Most activities of life, and certainly those of a skillful surgeon, need to become automatic. If we had to think about every motion involved in driving a car or performing an operation, the task would become nearly impossible to accomplish accurately. It would not be executed smoothly and would be error prone. It is hard to quantify surgical skill. It starts with a baseline of necessary sensory-motor eye-hand coordination that is likely innate. It becomes optimized by aggregation of correct “moves” and steps as well as by observation. It is refined by repetition of correct actions, implying identification of satisfactory and unsatisfactory immediate results (feedback). Then comes individual reflection and codification of moves and steps by hard analysis. Finally, motor skills are mastered by a synthesis of cognition and motor memory. The resulting automaticity and reproducibility of a skillful surgeon make a complex operation appear effortless, graceful, and flawless.1,14 However, automaticity renders errors inevitable.

Skill-based errors occur in the setting of routine activity.3
They occur when attention is diverted (distraction or preoccupation) or when a situation changes and is not detected in a timely fashion.3 They also occur as a result of overattention. Skill-based errors are ones that only skilled experts can make—beautiful execution of the wrong thing (slip) or failure to follow a complex sequence of actions (lapse). Skill-based errors tend to be easily detected and corrected.

Rule-based errors occur during routine problem-solving activities.3 Goals of training programs are to produce not only skillful surgeons but also expert problem solvers. Indeed, an expert may be defined as an individual with a wide repertoire of stored problem-solving plans or rules. Inevitable errors that occur take the form of either inappropriate application of a good rule or application of a bad rule.

Upregulation Our mind focuses conscious attention on the problem or activity with which we are confronted and filters out distracting information. The price we pay for this powerful ability is susceptibility to both data loss and information overload. This aspect of the mind is also what permits distractions or preoccupations to capture the attention of the surgeon, who would otherwise be focused on the routine tasks at hand.3 In problem solving, there may be inappropriate matching of the patient’s actual condition to routine rules for a somewhat different set of circumstances. Some of the mismatch undoubtedly results from the display of vast quantities of undigested monitored information about the patient’s condition. Errors of information overload need to be addressed by more intelligent computer-based assimilation and display of data.

Primitive Mechanisms of Information Storage and Retrieval The mind seems to possess an unlimited capacity for information storage and a blinding speed of information retrieval unparalleled by computers. In computer systems, there is often a trade-off between storage capacity and speed of retrieval; not so for the mind. The brain achieves this, apparently, not by storing facts but by storing models and theories—abstractions—about these facts (i.e., it stores meaning rather than data behind the meaning). Furthermore, the information is stored in finite packets along with other, often unrelated, information. (Many people use the latter phenomenon to recall names, for example, by associating them with more familiar objects such as animals.) The implications for error are that our mental image may diverge importantly from reality.

The mind’s search strategy for information achieves remarkable speed by having apparently just two tools for fetching information. First, it matches patterns. Opportunity for error arises because our interpretation of the present and anticipation of the future are shaped by patterns or regularities of the past. Second, if pattern matching produces multiple items, it prioritizes these by choosing the one that has been retrieved most often. This mechanism gives rise to rule-based errors, for example, in a less frequently occurring setting.

Conscious Mind When automatic skills and stored rules are of no help, we must consciously think. Unlike the automaticity we have just described, the conscious mind is of limited capacity but possesses powerful computational and reasoning tools, all those attributes we ascribe to the thought process. However, it is a serial, slow, and laborious process that gives rise to knowledge-based errors.3 Unlike stereotypical skill- and rule-based errors, knowledge-based errors are less predictable. Furthermore, there are far fewer opportunities in life for “thinking” than for automatic processes, and therefore the ratio of errors to opportunity is higher. Errors take the form of confirmation bias, causality vs. association, inappropriate selectivity, overconfidence, and difficulties in assimilating temporal processes.

The unusual ordering of material presented in the clinical chapters of this book was chosen by its original authors to provide a framework for thinking with the conscious mind about heart disease and its surgical therapy that would assist in preventing knowledge-based errors. For example, an algorithm (protocol, recipe) for successfully managing mitral valve regurgitation is based on knowledge of morphology,
etiology, and detailed mechanisms of the regurgitation; preoperative clinical, physiologic, and imaging findings; natural history of the disease if left untreated; technical details of operation; postoperative management; both early and long-term results of operation; and from all these considerations, the indications for operation and type of operation. Lack of adequate knowledge results in inappropriate use of mitral valve repair, too many mitral valve replacements, or suboptimal timing of operation.

Reducing Errors

We have presented this cognitive model in part because it suggests constructive steps for reducing human error and, thus, surgical failure. It affirms the necessity for intense apprentice-type training that leads to automatization of surgical skill and problem-solving rules. It equally suggests the value of simulators for acquiring such skills. It supports creation of an environment that minimizes or masks potential distractions. It supports a system that discovers errors and allows recovery from them before injury occurs. This requires a well-trained team in which each individual is familiar with the operative protocol and is alert to any departures from it. In this regard, deLeval and colleagues’ findings are sobering. Major errors were often realized and corrected by the surgical team, but minor ones were not, and the number of minor errors was strongly associated with adverse outcomes. It was also sobering that self-reporting of intraoperative errors was of no value. Must there be a human factors professional at the elbow of every surgeon and physician?

James Reason suggested that other “cognitive prostheses” may be of value, some of which are being advocated in medicine. For example, there is much computers can do to reduce medication errors. A prime target is knowledge-based errors. Reducing these errors may not be achievable through computer artificial intelligence, but rather through more appropriate modes of information assembly, processing, and display for processing by the human mind. Finally, if latent errors are the root cause of many active errors, analysis and correction at the system level will be required. A cardiac surgery program may fail, for example, from latent errors traceable to management of the blood bank, postoperative care practices, ventilation systems, and even complex administrative decisions at the level of hospitals, universities with which they may be associated, and national health system policies and regulations within which they operate.

Lack of Scientific Progress

A practical consequence of categorizing surgical failures into two causes is that they fit the programmatic paradigm of “research and development”: discovery on the one hand and application of knowledge to prevent failures on the other. The quest to reduce injury from medical errors that has just been described is what we might term “development.” The remainder of this chapter focuses mainly on the portion of the paradigm that is research, but also more narrowly on clinical research.

PHILOSOPHY

Clinical research in cardiac surgery as emphasized in this chapter consists largely of patient-oriented investigations motivated by a serious quest for new knowledge to improve surgical results—that is, to increase survival early and long term; to reduce complications; to enhance quality of life; to extend appropriate operations to more patients, such as high-risk subsets; and to devise and evaluate new beneficial procedures that have been generalized into a strategy of managing not so much individual malformations as a physiologic situation (e.g., the Fontan operation and its variants [see Chapter 41] and the Norwood operation [see Chapter 49]).

This inferential activity, aimed at improving clinical results, is in contrast to pure description of experiences. Its motivation also contrasts with those aspects of “outcomes assessment” motivated by regulation or punishment, institutional promotion or protection, quality assessment by outlier identification, and negative aspects of cost justification or containment. These coexisting motivations have stimulated us to identify, articulate, and contrast philosophies that underlie serious clinical research. It is these philosophies that inform our approach to analysis of clinical experiences.

Deduction versus Induction

“Let the data speak for themselves.”

Arguably, Sir Isaac Newton’s greatest contribution to science was a novel intellectual tool: a method for investigating the nature of natural phenomena. His contemporaries considered his method not only a powerful scientific investigatory tool, but also a new way of philosophizing applicable to all areas of human knowledge. His method had two strictly ordered aspects that for the first time were truly systematically expressed: a first, and extensive, phase of data analysis whereby observations of some small portion of a natural phenomenon are examined and dissected, followed by a second, less emphasized, phase of synthesis whereby possible causes are inferred and a small portion of nature revealed by the observations and analyses. This was the beginning of the inductive method in science: valuing first and foremost the observations made about a phenomenon, then “letting the data speak for themselves” in suggesting possible natural mechanisms.

This represented the antithesis of the deductive method of investigation that had been so successful in the development of mathematics and logic (the basis for ontology-based computer reasoning today). The deductive method begins with what is believed to be the nature of the universe (referred to by Newton as “hypothesis”), from which logical predictions are deduced and tested against observations. If the observations deviate from logic, the data are suspect, not the principles behind the deductions. The data do not speak for themselves.

Newton realized that it was impossible at any time or place to have complete knowledge of the universe. Therefore, a new methodology was necessary to examine just portions of nature, with less emphasis on synthesizing the whole. The idea was heralded as liberating in nearly all fields of science.

As the 18th century unfolded, the new method rapidly divided such diverse fields as religion into those based on deduction (fundamentalism) and those based on induction (liberalism), roughly Calvinism vs. Wesleyan-Arminianism. This philosophical dichotomy continues to shape not just the scientific but the social, economic, and political climate of the 21st century.
Collectivism versus Individualism

To better convey how new knowledge is acquired from observing clinical experiences, we look back to the 17th century to encounter the proverbial dichotomy between collectivism and individualism, so-called lumpers and splitters or forests and trees.846

In 1603 during one of its worst plague epidemics, the City of London began prospective collection of weekly records of christenings and burials. In modern language, this was an administrative database or registry (see Box 6-1). Those “who constantly took in the weekly bills of mortality made little use of them, than to look at the foot, how the burials increased or decreased; and among the casualties, what has happened rare, and extraordinary, in the week current,” complained John Graunt.311 Unlike those who stopped at counting and relating anecdotal information, Graunt believed the data could be analyzed in a way that would yield useful inferences about the nature and possible control of the plague.

His ultimate success might be attributed in part to his being an investigator at the interface of disciplines. By profession he was a haberdasher, so Graunt translated merchandise inventory dynamics into terms of human population dynamics. He described the rate of goods received (birth rate) and the rate of goods sold (death rate); he then calculated the inventory (those currently alive).

Graunt then made a giant intellectual leap. In modern terms, he assumed that any item on the shelf was interchangeable with any other (collectivism). By assuming, no matter how politically and sociologically incorrect, that people are interchangeable, he achieved an understanding of the general nature of the birth-life-death process in the absence of dealing with specific named individuals (individualism). He attempted to discover, as it were, the general nature of the forest at the expense of the individual trees.

Graunt then identified general factors associated with variability of these rates (risk factors, in modern terminology; see Multivariable Analysis in Section IV). From the City of London Bills of Mortality, he found that the death rate was higher when ships from foreign ports docked in the more densely populated areas of the city, and in households harboring domestic animals. Based on these observations, he made inferences about the nature of the plague—what it was and what it was not—and formulated recommendations for stopping its spread. They were crude, nonspecific, and empirical: avoid night air brought in from foreign ships (which we now know is not night air but rats), flee to the country, separate people from animal vectors, and quarantine infected individuals.823 Nevertheless, they were effective in stopping the plague for 200 years until its cause and mechanism of spread were identified.

Lessons based on this therapeutic triumph of clinical investigation conducted more than 300 years ago include the following: (1) empirical identification of patterns of disease can suggest fruitful directions for future research and eliminate some hypothesized causal mechanisms, (2) recommendations based on empirical observations may be effective until causal mechanisms and treatments are discovered, and (3) new knowledge is often generated by overview (synthesis), as well as by study of individual patients.836

When generating new knowledge about the nature of heart disease and its treatment, it is important both to examine groups of patients (the forest) and to investigate individual therapeutic failures (the trees). This is similar to Heisenberg’s uncertainty principle in chemistry, thermodynamics, and mechanics, in which physical matter and energy can be thought of as discrete particles on the microhierarchical plane (individualism, splitting, trees), and as waves (field theory) on the macrohierarchical plane (collectivism, lumping, forests). Both views give valuable insights into nature, but they cannot be viewed simultaneously. Statistical methods emphasizing optimum discrimination for identifying individual patients at risk tend to apply to the former, whereas those emphasizing probabilities and general inferences tend to apply to the latter.83,847

Continuity versus Discontinuity in Nature

When we turn our focus from named individuals experiencing surgical failure to groups of patients, data analysis becomes mandatory to discover relationships between outcome and items that differ in value from patient to patient (called variables). A challenge immediately arises: Many of the variables related to outcome are measured either on an ordered clinical scale (ordinal variables), such as New York Heart Association (NYHA) functional class, or on a more or less unlimited scale (continuous variables), such as age. Three hundred years after Graunt, the Framingham Heart Disease Epidemiology Study investigators were faced with this frustrating problem.820,821 Many of the variables associated with development of heart disease were continuously distributed ones, such as age, blood pressure, and cholesterol level. To examine the relationship of such variables to development of heart disease, it was then accepted practice to categorize continuous variables coarsely and arbitrarily for cross-tabulation tables. Valuable information was lost this way. Investigators recognized that a 59-year-old’s risk of developing heart disease was more closely related to
that of a 60-year-old’s than to that of the group of patients in the sixth vs. seventh decade of life. They therefore insisted on examining the entire spectrum of continuous variables rather than subclassifying the information.

What they embraced is a key concept in the history of ideas—namely, *continuity in nature*. The idea has emerged in mathematics, science, philosophy, history, and theology.

In our view, the common practice of stratifying age and other more or less continuous variables into a few discrete categories is lamentable because it loses the power of continuity (some statisticians call this “borrowing power”). Focus on small, presumed homogeneous groups of patients also loses the power inherent in a wide spectrum of heterogeneous but related cases. After all, any trend observed over an ever-narrower framework looks more and more like no trend at all! Like the Framingham investigators, we therefore embrace continuity in nature unless it can be demonstrated that doing so is not valid, useful, or beneficial. (Modern methods of machine learning that use classification methods may seem to stumble at this point, but repetition of analyses over thousands of sampled data sets combined with averaging achieves a close approximation to continuity in nature; see Classification Methods in Section VI.)

**Single versus Multiple Dimensionality**

The second problem the Framingham investigators addressed was the need to consider multiple variables simultaneously. Univariable (one variable at a time) statistics are attractive because they are simple to understand. However, most clinical problems are multifactorial. At the same time, clinical data contain enormous redundancies that somehow need to be taken into account (e.g., height, weight, body surface area, and body mass index are highly correlated and relate to the conceptual variable “body size”).

Cornfield came to the rescue of the Framingham investigators with a new methodology called *multivariable logistic regression*¹²⁰ (see “Logistic Regression Analysis” in Section IV). It permitted multiple factors to be examined simultaneously, took into account redundancy of information among variables (covariance), and identified a parsimonious set of variables for which the investigators coined the term “factors of risk” or *risk factors*²² (see “Parsimony versus Complexity” later in this section and Multivariable Analysis in Section IV).

Various forms of multivariable analysis, in addition to logistic regression analysis, have become available to clinical investigators. Their common theme is to identify patterns of relationships between outcome and a number of variables considered simultaneously. These are not cause–effect relations, but associations with underlying causal mechanisms (see discussion of surrogates under Multivariable Analyses in Section IV). The relationships that are found may well be spurious, fortuitous, hard to interpret, and even confusing because of the degree of correlation among variables. For example, women may be at a higher risk of mortality after certain cardiac procedures, but female gender may not be a “risk factor,” because other factors, such as body mass index, may be the more general variable related to risk, whether in women or men. Even so, it is simultaneously true that (1) being female is not per se a risk factor, but (2) women are at higher risk by virtue of the fact that on average they are smaller than men.

This means that a close collaboration must exist between statistical experts and surgeons, particularly in organizing variables for analysis.

**Linearity versus Nonlinearity**

Risk factor methodology introduced another complexity besides increased dimensionality. The logistic equation is a symmetric S-shaped curve that expresses the relationship between a scale of risk, called *logit units*, and a corresponding scale of absolute probability of experiencing an event¹¹⁶,k⁹ (Fig. 6-1). Because the relationship is not linear, it is not possible to simply add up scores for individual variables and come up with a probability of an event, a technique that has been attempted in other settings¹¹¹,p² (see Risk Stratification in Section VI).

The nonlinear relationship between risk factors and probability of outcome makes medical sense. Imagine a risk factor with a logit unit coefficient of 1.0 (representing an odds ratio of 2.7; Box 6-3 and see Fig. 6-1). If all other things position a patient far to the left on the logit scale, a 1-logit-unit increase in risk results in a trivial increase in the probability of experiencing an event. But as other factors move a patient closer to the center of the scale (0 logit units, corresponding to a 50% probability of an event), a 1-logit-unit increase in risk makes a huge difference. This is consistent with the medical perception that some patients experiencing the same disease, trauma, or complication respond quite differently. Some are medically robust because they are far to the left (low-risk region) on the logit curve before the event occurred. Others are medically fragile because their age or comorbid conditions place them close to the center of the logit curve. For the latter, a 1-logit-unit increase in risk can be “the straw that breaks the camel’s back.” It is this kind of relation that makes it hard to demonstrate, for example, the benefit of bilateral internal thoracic artery grafting in relatively young adults followed for even a couple of decades, but easy in patients who have other risk factors.¹³² The same has been demonstrated for risk of operation in patients with aortic regurgitation and low ejection fraction.²²⁴

This type of sensible, nonlinear medical relation makes us want to deal with absolute risk rather than relative risk or risk ratios²²² (see Box 6-3). Relative risk is simply a translation of the scale of risk, without regard to location on that scale. Absolute risk integrates this with the totality of other risk factors.

**Raw Data versus Models of Data**

Importantly, the Framingham investigators did not stop at risk factor identification. Because logistic regression generates an equation based on raw data, it can be solved for a given set of values for risk factors. The investigators devised a cardboard slide rule for use by lay persons to determine their predicted risk of developing heart disease within the next 5 years.

Whenever possible and appropriate, results of clinical data analyses should be expressed in the form of mathematical models that become equations. These can be solved after “plugging in” values for an individual patient’s risk factors to estimate absolute risk and its confidence limits. Equations are compact and portable, so that with the ubiquitous computer,
they can be used to advise individual patients\textsuperscript{44,13,20,30} (see “Decision Making for Individual Patients” in Section V).

Nihilism versus Predictability

One of the important advantages of generating equations is that they can be used to predict future results for either groups of patients or individual patients. We recognize that when speaking of individual patients, we are referring to a prediction concerning the probability of events for that patient; we generally cannot predict exactly who will experience an event or when an event will occur. Indeed, whenever we apply what we have learned from clinical experience or the laboratory to a new patient, we are predicting. This motivated us to develop statistical tools that yield patient-specific estimates of absolute risk as an integral byproduct.\textsuperscript{844} These were intended to be used for formal or informal comparison of predicted risks and benefits among alternative therapeutic strategies.

Of course, the nihilist will say, “You can’t predict.” However, in a prospective study of 3720 patients in Leuven, Belgium, we generated evidence that predictions from
Box 6-3 Expressions of Relative Risk

Proportion
Consider two groups of patients, A and B. Mortality in group A is 10 of 40 patients (25%); in B, it is 5 of 50 patients (10%). For the sake of illustrating the various ways these proportions (see Box 6-13), 0.25 and 0.10, can be expressed relative to one another, designate a as the number of deaths (10) in A and b as the number of deaths (30) in A and b as the number alive (30). The total in A is a+b (40) patients, nA. Designate c as the number of deaths (5) in B and d as the number alive (45). The total in B is c+d (50) patients, nB. Designate P as the proportion of deaths in A, a/(a+b) or a/nA, and P as the proportion in B, c/(c+d) or c/nB.

Relative Risk (Risk Ratio)
Relative risk is the ratio of two probabilities. In the example above, relative risk of A compared with B is P/P = [a/(a+b)]/[c/(c+d)] = 0.25/0.10 or 2.5. Equivalently, one could reverse the proportions, P/P = 0.10/0.25 = 0.4. If P were to exactly equal P, relative risk would be unity (1.0). Another way to express relative risk when comparing two treatments is by relative risk reduction, which for relative risks greater than 1 is 1 minus relative risk. This is mathematically identical to dividing the absolute difference in probabilities by the higher of the two: (P − P)/P.

Odds and Gambler’s Odds
The odds of an event is the number of events divided by non-events. In the example above, the odds of death in A is a/b = 10/30 = 0.33; in B, it is c/d = 5/45 = 0.11. The mathematical interrelation of probability (P) of an event and odds (O) are these: O = P/(1 − P) and P = O/(1 + O). A probability of 0.1 is an odds of 0.11, but a probability of 0.5 is an odds of 1, of 0.8 an odds of 4, of 0.9 an odds of 9, and of 1.0 an odds of infinity. Often, it is interesting to examine the odds of the complement (1 − P) of a proportion, (1 − P)/P, which is gambler’s odds. Thus, a P value of .05 is equivalent to an odds of .053 and a gambler’s odds of 19:1. A P value of .1 has a gambler’s odds of 99:1, and a P value of 2 has a gambler’s odds of 4:1.

Odds Ratio and Log Odds
The odds ratio is the ratio of odds. In the above example, the odds ratio of A compared with B is (a/b)/(c/d) = ad/bc, which is either (10/30)/(5/45) = 3 or (10 · 45)/(30 · 5) = 3. Note that the logistic equation is Ln[P/(1 − P)]. For A, P/(1 − P) is a/b, the odds of A. Thus, Ln[P/(1 − P)] is log odds. Logistic regression can then be thought of as an analysis of log odds. Exponentiation is useful for dichotomous (yes/no) risk factor from such an analysis re-expresses it in terms of the odds ratio for those with versus those without the risk factor (see Box 6-5).

When the probability of an event is low, say less than 10%, relative risk (RR) and the odds ratio (OR) are numerically nearly the same. The mathematical relation is RR = [1−P]/[1−P] · OR. In the above example, the relative risk was 2.5, but the odds ratio was 3, and the disparity increases as the probability of event increases to 50%.

Relative risk is easier for most physicians to grasp because it is simply the ratio of proportions. It is unusual to encounter a physician without an epidemiology background who understands the odds ratio.

Expressing Relative Risk and Odds Ratios
Both relative risk and odds ratios are expressed on a scale of 0 to infinity. However, all odds ratios less than 1 are squeezed into the range 0 to 1, in contrast to those greater than 1, which are spread out from 1 to infinity. It is thus difficult to visualize that an odds ratio of 4 is equivalent to one of 0.25 if a linear scale is used. We recommend that a scale be chosen to express these quantities with equal distance above and below 1.0. This can be achieved, for example, by using a logarithmic or logit presentation scale.

Risk Difference (Absolute Risk Reduction) and Number to Treat
The risk difference is the difference between two proportions. In the above example, P − P is the risk difference. In many situations, risk difference is more meaningful than risk ratios (either relative risk or the odds ratio). Consider a low probability situation with a risk of 0.5% and another with a risk of 1%. Relative risk is 2. Yet risk difference is only 0.5%. In contrast, consider a higher-probability situation in which one probability is 50% and the other 25%. Relative risk is still 2, but risk difference is 25%. These represent the proverbial statement that “twice nothing is still nothing.” They reflect the relation between the logit scale and absolute probability (see Fig. 6-1, A), recalling that the logit scale is one of log odds.

An alternative way to express a difference in probabilities when the difference is arranged to be positive (e.g., P − P), and thus expresses absolute risk reduction, is as the inverse, 1/(P − P). This expression of absolute risk reduction is called number to treat. It is useful in many comparisons in which it is meaningful to answer the question, “How many patients must be treated by A (compared with B) to prevent one event (death)?” In our example, absolute risk reduction is 25% − 10% = 15%, and number needed to treat is 1/0.15 = 6.7. Number needed to treat is particularly valuable for thinking about risks and benefits of different treatment strategies. If it is large, one may question the risk of switching treatments, but if it is small, the benefit of doing so becomes more compelling.

Hazard Ratio
In time-related analyses, it is convenient to express the model of risk factors in terms of a log-linear function (see Box 6-5 and “Cox Proportional Hazards Regression” in Section IV): Ln(λ) = β0 + β1X1 + … + βXk, where ln is the natural logarithm and λ is the hazard function. The regression coefficients, β, for a dichotomous risk factor thus represent the logarithm of the ratio of hazard functions. Hazard ratios, as well as relative risk and the odds ratio, can be misleading in magnitude (large ratios, small risk differences) in some settings. Hazard comparisons, just like survival comparisons, are often more meaningfully and simply expressed as differences.

multivariable equations are generally reliable (see “Residual Risk” in Section VI). We compared observed survival, obtained at subsequent follow-up, with prospectively predicted survival. The correspondence was excellent in 92% of patients. However, it was poor in the rest (Fig. 6-2 and Table 6-2; see also “Residual Risk” in Section VI). A time-related analysis of residual risk identified circumstances leading to poor prediction and revealed the limitations of quantitative predictions: (1) When patients have important rare conditions that have not been considered in the analysis, risk is underestimated. (2) When large data sets rich in clinically relevant variables are the basis for prediction equations, prediction should be suspect in only a small proportion of patients with unaccounted-for conditions (see “Residual
of risk in patients with them.

Data from Sergeant and colleagues.\textsuperscript{39} July 1987 to 1992; n = 3720.

A related use of predictive equations is in comparing
alternative therapies. Some would argue that the only believ-
able comparisons are those based on randomized trials,
and that documented clinical experiences are irrelevant and
misleading.\textsuperscript{875,877} However, many randomized trials are
homogeneous and focused and are analyzed by blunt instru-
ments, such as an overall effect. On the other hand, real-
world clinical experience involves patient selection that is
difficult to quantify, may be a single-institution experience
with limited generality except to other institutions of the
same variety, is not formalized unless there is prospective
gathering of clinical information into registries, and is less
disciplined. Nevertheless, analyses of clinical experiences can
yield a fine dissecting instrument in the form of equations
that are useful across the spectrum of heart disease for com-
paring alternative treatments and therefore for advising
patients.\textsuperscript{829} (see “Clinical Studies with Nonrandomly Assigned
Treatment” later in this section).

Parsimony versus Complexity

Although clinical data analysis methods and results may
seem complex at times, as in the large number of risk factors
that must be assessed for comparing treatment strategies
in ischemic heart disease, an important philosophy behind
such analysis is parsimony (simplicity). We have discussed two
reasons for this previously. One is that clinical data contain
inherent redundancy, and one purpose of multivariable analy-
ysis is to identify that redundancy and thus simplify the dimen-
sionality of the problem. A second reason is that assimilation
of new knowledge is incomplete unless one can extract the
essence of the information. Thus, clinical inferences are
often even more digested and simpler than the multivariable
analyses.

We must admit that simplicity is a virtue based on philo-
sophical, not scientific, grounds. The concept was introduced
by William of Ocken in the early 14th century as a concept

Risk” in Section VI for details). Except for these limitations,
multivariable equations appear capable of adjusting well for
different case mixes.

This analysis has important implications for “report card” registries used in institutional comparisons.\textsuperscript{106}
Surgeons often object to these comparisons on the basis
that risk adjustment (see Risk Adjustment in Section VI)
accounts for neither risk stratification (see Risk Stratification
in Section VI) nor rare combinations of risk factors that
defy prediction. They may be correct. Unfortunately, in
advising patients about operation, we find that these are
the very individuals whose risk is difficult to predict on
clinical grounds and for whom we wish we had good
prediction equations.

The amount of data necessary to generate new knowledge
is much larger than that needed to use the knowledge in a
predictive way. To generate new knowledge, data should be
rich both in relevant variables and in variables eventually
found not to be relevant. But for prediction, one needs to
collect only those variables used in the equation (see Risk
Adjustment in Section VI) unless one is interested in inves-
tigating reasons for lack of prediction (see Residual Risk in
Section VI).

Blunt Instruments versus Fine Dissecting Instruments

A related use of predictive equations is in comparing
alternative therapies. Some would argue that the only believ-
able comparisons are those based on randomized trials,
and that documented clinical experiences are irrelevant and
misleading.\textsuperscript{875,877} However, many randomized trials are
homogeneous and focused and are analyzed by blunt instru-
ments, such as an overall effect. On the other hand, real-
world clinical experience involves patient selection that is
difficult to quantify, may be a single-institution experience
with limited generality except to other institutions of the
same variety, is not formalized unless there is prospective
gathering of clinical information into registries, and is less
disciplined. Nevertheless, analyses of clinical experiences can
yield a fine dissecting instrument in the form of equations
that are useful across the spectrum of heart disease for com-
paring alternative treatments and therefore for advising
patients.\textsuperscript{829} (see “Clinical Studies with Nonrandomly Assigned
Treatment” later in this section).
Clinical data may be used as a form of advertising. Innovation stems less from purposefulness than from aesthetically motivated curiosity, frustration with the status quo, sheer genius, fortuitous timing, favorable circumstances, and keen intuition. With innovation comes the need to promote. However, promotional records of achievement should not be confused with serious study of safety, clinical effectiveness, and long-range appropriateness.

Of growing importance is the use of clinical information for regulation or to gain institutional competitive advantage. Using clinical outcomes data to rank institutions or individual doctors has become popular in the United States (see Risk Stratification and Risk Adjustment in Section VI). Many surgeons perceive clinical report cards as a means for punishment or regulation. What is troubling is that their use is based on a questionable quality-control model of outlier identification. Because doctors are people and not machines, this approach generates counterproductive ethical side effects, including defensiveness and hiding the truth. It hinders candid, non-accusatory (non-culpable), serious examination of medical processes for the express purpose of improving patient care (see “Human Error” earlier in this section).

Critics of clinical report cards charge that their rankings, some institutions refuse to operate on sicker patients. In several studies of community hospitals by the UAB group, it was shown that they could indeed improve their risk-unadjusted rankings by restricting surgery to low-risk cases. However, their results in such patients were often inferior to those of institutions of excellence operating on similar low-risk patients. That is, their risk-adjusted mortality was higher even for low-risk cases.

With the intense focus on institutional performance, another undesirable side effect of data analysis decreed years ago has crept back in: undue emphasis on hospital mortality and morbidity. Studies of hospital events have the advantage of readily available data for extraction, but early events may be characterized incompletely. After repair of many congenital and acquired heart diseases, early risk of mortality and morbidity. Studies of hospital events have the advantage of readily available data for extraction, but early events may be characterized incompletely. After repair of many congenital and acquired heart diseases, early risk of surgery extends well beyond the hospital stay. This has led to reflection on the effect of time frame on studies of clinical experiences. Use of intermediate-term data is likely to characterize the early events well, but requires cross-sectional patient follow-up. Long-term follow-up is essential to establish appropriateness of therapy, but it is expensive and runs the risk of being criticized as being of historical interest only.

Yet another reason for interest in clinical information is to use it for profit or corporate advantage. At present, the philosophies of scientific investigation and business are irreconcilable. One thrives on open dissemination of information, the other on proprietary information offering a competitive advantage. In an era of dwindling public resources for research and increasing commercial funding, we may be seeing the beginning of the end of open scientific inquiry.

New Knowledge versus Selling Shoes

The philosophies described so far focus on the challenge of generating new knowledge from clinical experiences. However, other uses are made of clinical data.
The second edition reflects data and outcomes from an era of largely unregulated medical care, and similar data may be impossible to gather and freely analyze when care is largely regulated. This is not intended as an opinion as to the advantages or disadvantages of regulation of health care; indeed, as regulation proceeds, the data in this book, along with other data, should be helpful in establishing priorities and guidelines.

As already noted in both the first and second editions, the last section of each chapter is on indications for operation. In the future, regulations of policymakers may need to be added to the other variables determining indications.

On the horizon is the promise that medicine will become decreasingly empirical and more deterministic.62 However, as long as treatment of heart disease requires complex procedures, and as long as most are palliative in the life history of chronic disease, there will be a need to understand more fully the nature of the disease, its treatment, and its optimal management. This will require adoption of approaches to data that are inescapably philosophical.

**CLINICAL RESEARCH**

In response to the American Medical Association’s Resolution 309 (1-98), a Clinical Research Summit and subsequently an ongoing Clinical Research Roundtable (IOM) have sought to define and reenergize clinical research.10 The most important aspects of the definition of clinical research are that (1) it is but one component of medical and health research aimed at producing new knowledge; (2) the knowledge produced should be valuable for understanding the nature of disease, its treatment, and prevention; and (3) it embraces a wide spectrum of types of research. Here we highlight only two broad examples of that spectrum: clinical trials with randomly assigned treatment and clinical studies with nonrandomly assigned treatment—both of which are interrelated with clinical effectiveness research.7

**Clinical Trials with Randomly Assigned Treatment**

Controlled trials date back at least to biblical times when casting of lots was used as a fair mechanism for decision making under uncertainty (Numbers 33:54). Solomon noted, “The lot causeth disputes to cease, and it decideth between the mighty” (Proverbs 18:18). An early clinical trial took place in the Court of Nebuchadnezzar, king of Babylon (modern Iraq). He ordered several gifted Hebrew youths (“well favored, skillful in all wisdom, cunning in knowledge, and understanding science”) to reside at his palace for 3 years as if they were his own children. He proposed to train them in Chaldean knowledge and language. Among them were Daniel and the familiar Shadrach, Meshach, and Abednego. Daniel objected to the Babylonian diet, and so proposed a 10-day clinical trial: The Hebrews would be fed a vegetarian diet with water, while the children of the king would be fed the king’s meat and wine. After 10 days, the condition of the Hebrews was determined to be better than that of the king’s children, and they received permission to continue to eat their own diet (Daniel 1:1-15).99 (This is remarkably reminiscent of the contemporary controversy surrounding carbohydrate-rich vs. protein-rich diets.)

The first modern placebo-controlled, double-blinded, randomized clinical trial was carried out in England by Sir Austin Bradford Hill on the effectiveness of streptomycin vs. bed rest alone for treatment of tuberculosis,835 although 17th- and 18th-century unblinded trials have been cited as historical predecesors.5,21,22

Clinical trials in which cardiac surgical procedures and medical therapy have been randomly assigned have made major contributions to our knowledge of treatment and outcomes of heart disease.73 Notable examples are the Veterans Administration (VA) study of CABG,912 the Coronary Artery Surgery Study (CASS) trial of CABG,93 the European Coronary Surgery Study trials,16 and the PARTNER trial of percutaneous aortic valve replacement.119 Trials of CABG vs. percutaneous coronary intervention have also been important (e.g., the Balloon Angioplasty Revascularization Investigation [BARI]).720,511

Randomization of treatment assignment has three valuable and unique characteristics:

- It eliminates selection factors (bias) in treatment assignment (although this can be defeated at least partially by enrollment bias).
- It distributes patient characteristics equally between groups, whether they are measured or not, known or unknown (balance), a well-accepted method of risk adjustment.825,874,877,87
- It meets assumptions of statistical tests used to compare end points.877

Randomized clinical trials are also characterized by concurrent treatment, excellent and complete compilation of data gathered according to explicit definitions, and proper follow-up evaluation of patients. These operational byproducts may have contributed nearly as much new knowledge as the random assignment of treatment.

Unfortunately, it has become ritualistic for some to dismiss out of hand all information, inferences, and comparisons relating to outcome events derived from experiences in which treatment was not randomly assigned.876 If this attitude is valid, then much of the information now used to manage patients with cardiac disease would have to be dismissed and ignored! Investigations concerning differences of outcome among different physicians, different institutions, and different time periods would have to be abandoned. However, moral justification may not be present for a randomized comparison of procedures and protocols that clinical experience strongly suggests have an important difference.825 (The difficulty of recruitment in BARI reflects this problem.) In fact, when Benson and Hartz811 investigated differences between randomized trials and observational comparisons over a broad range of medical and surgical interventions, they found “little evidence that estimates of treatment effects in observational studies reported after 1984 are consistently larger than or qualitatively different from those obtained in randomized controlled studies.”811 (See, however, the

---

1In the United States, the Federal Council for Comparative Effectiveness Research has defined this type of research as “The conduct and synthesis of research comparing the benefits and harms of different interventions and strategies to prevent, diagnose, treat and monitor health conditions in ‘real world’ settings.” The purpose of this research is to improve health outcomes by developing and disseminating evidence-based information to patients, clinicians, and other decision makers, responding to their expressed needs about which interventions are most effective for which patients under specific circumstances.71
rebuttal by Pocock and Elbourne.\textsuperscript{914} These findings were confirmed by Concato and colleagues.\textsuperscript{921} Nevertheless, we acknowledge a hierarchy of clinical research study designs, and the randomized trial generates the most secure information about treatment differences.\textsuperscript{937}

Trials in which treatment is randomly assigned are testing a hypothesis, and hypothesis testing in general requires a yes or no answer unperturbed by uncontrollable factors. Thus ideally, the study is of short duration, with all participants blinded and a treatment that can be well standardized. However, in many clinical situations involving patients with congenital or acquired heart disease, the time-relatedness of freedom from an unfavorable outcome event is important and can jeopardize interpretation of the trial.\textsuperscript{95} This is because individual patients assign different values to different durations of time-related freedoms, in part because differing severities of disease (and corresponding differences in natural history) affect different time frames and in part because the longer the trial, the more likely there will be crossovers (e.g., from medical to surgical therapy).\textsuperscript{915,916} Also, the greater the number of risk factors associated with the condition for which treatment is being evaluated, the greater the potential heterogeneity (number of subsets) of patients with that condition and the greater the likelihood that a yes/no answer will apply only to some subset of patients. In such situations, a randomized trial may have the disadvantage of including only a limited number of subsets. It may in fact apply to no subset, because the “average patient” for whom the answer is derived may not exist except as a computation. Trials have addressed this problem by basing the randomization on subsets\textsuperscript{96} or by later analyzing subsets by stratification (but see concerns raised by Guillemin\textsuperscript{939} or by multivariable analysis).\textsuperscript{981}

These considerations, in addition to ethical concerns,\textsuperscript{955,957,958} have fueled the debate about whether surgery is an appropriate arena for randomized trials of innovation, devices, and operations.\textsuperscript{911,929,927,934,935,937,1,29} Some argue strongly that randomization should be required at the outset of every introduction of new therapy.\textsuperscript{935} In three related articles arising from the Balliol Colloquium held at the University of Oxford between 2007 and 2009, clinicians and anesthesiologists sought to clarify the issues surrounding surgical clinical trials.\textsuperscript{941,955,957} They recognized important stages in developing a surgical technique, starting with innovation, progressing through development and exploration, to assessment and long-term outcomes. They then explore options for evaluative studies and barriers to each, including sham operations and nonoperative treatment alternatives.\textsuperscript{915} They end with an IDEAL model for surgical development (idea, development, exploration, assessment, long-term study) and the role of feasibility-randomized trials in exploration, and definitive trials in assessment, and registries in long-term surveillance.\textsuperscript{951,913}

Steven Piantadosi of Johns Hopkins University describes a number of important methodological problems with conducting successful surgical trials, however (personal communication; November 2001):

- Operations are often not amenable to blinding or use of placebos (sham operations), although there is growing acceptance of this in some cases of surgery, in part because of the huge placebo effect of surgery.\textsuperscript{983,958,912,913,916,981,900} This can introduce bias that may be impossible to control; however, thoughtful and creative study designs can often produce substantial blinding, such as of those assessing outcome.
- Selection bias is difficult to avoid. He notes that it is insufficient to compare patients undergoing operation with those who do not, no matter how similar the groups appear, unless every patient not undergoing operation is completely eligible for surgical intervention.\textsuperscript{926} Judgment is a characteristic of a good surgeon, and the better the surgical judgment, the more likely bias will enter any trial of surgical vs. nonsurgical therapy, even if it is the bias of selecting patients for the trial.
- Surgical therapy is skill-based. Therefore, any result obtained from a trial consists of the inextricable confounding of (1) procedure efficacy and (2) surgical skill.
- Surgery is largely unregulated. Every operation is different, and particularly in treatment of complex congenital heart diseases, tailoring operations to the specific anomaly is expected and often necessary for patient survival. There is little uniformity from patient to patient to provide a basis for randomizing therapy.

Given these potential obstacles to adequate evaluation of surgical procedures ever occurring, McCulloch has proposed a hybrid strategy that begins with a prospective but nonrandomized surgical study during the dissemination phase of development (phase II) that progresses to a phase III randomized clinical trial.\textsuperscript{912} During the phase II study, learning curves are determined, a likely treatment effect is identified for sample-size calculation, consensus is built, and quality measures to confirm delivery of intended operations are drawn up. Failure of these preliminary steps is perhaps what has stirred much of the controversy over the STICH trial of the Dor procedure.\textsuperscript{988,989,962}

Moses\textsuperscript{928} and others\textsuperscript{929,934,935,938,937} present the case for a balance between randomized clinical trials and observational clinical studies. However, observational studies are beset with these same problems of selection bias and skill variance; thus, not to be overlooked are the development and rapid introduction of powerful new methods for drawing causal inferences from nonrandomized trials\textsuperscript{921,929} (see “Causal Inferences” later in this section).

Clinical Studies with Nonrandomly Assigned Treatment

General Comments

Clinical studies with nonrandomly assigned treatment produce little knowledge when improperly performed and interpreted. Because this is often the case, many physicians have a strong bias against studies of this type. However, when properly performed and interpreted, and particularly when they are multinstitutional or externally validated, clinical studies of real-world experience can produce secure knowledge (see Comparative Effectiveness footnote on page 266).

This statement would be considered a hypothesis by some, a fact by others.\textsuperscript{911,914} For those who consider it a hypothesis, the hypothesis could be tested as a separate project in a large randomized trial. Hypothetically, such a trial could have two parts: (1) a trial with randomly assigned treatment and (2) a registry with nonrandomly assigned treatment (a registry usually contains many more patients than a trial). For the test, multivariable analyses would be performed of patients in the registry, with propensity adjustment or matching.\textsuperscript{921,929}
“Propensity Score” later in this section). The resulting multivariable equations for various unfavorable events would then be used to predict the now-known outcomes of the patients randomly assigned to the alternative forms of therapy. Predicted outcomes would be compared with observed outcomes (see Residual Risk in Section VI); if they were the same, the validity of the technique of properly performed and analyzed studies with nonrandomly assigned treatment would, in that instance and clinical setting, be established. If they were not the same, the reason should be investigable.

Causal Inferences

The fundamental objection to using observational clinical data for comparing treatments is that many uncontrolled variables affect outcome.\(^2\) Thus, attributing outcome differences to just one factor—alternative treatment—stretches credibility. Even a cursory glance at the characteristics of patients treated one way vs. another usually reveals that they are different groups. This should be expected because treatment has been selected by experts who believe they know what is best for a given patient. The accusation that one is comparing apples and oranges is well justified.\(^3\)

Indeed, a consistent message since Graunt is that risk factors for outcomes from analyses of clinical experience (and these include treatment differences) are associations, not causal relations.\(^4\) Multivariable adjustment for differences in outcome is valuable but not guaranteed to be effective in eliminating selection bias as the genesis of a difference in outcome (a form of confounding).\(^5\) Indeed, developers of balancing score methods claim that the difference in outcome between patients who have similar balancing scores but receive different treatments provides an unbiased estimate of the effect attributable to the comparison variable of interest.\(^6\) That is technical jargon for saying that the method can identify the apples from among the mixed fruit of clinical practice variance, transforming an apples-to-oranges comparison into an apples-to-oranges comparison.\(^7\)

Randomly assigning patients to alternative treatments in clinical trials balances both patient characteristics (at least in the long run) and number of subjects in each treatment arm. In a nonrandomized setting, neither patient characteristics nor number of patients is balanced for each treatment. A balancing score achieves local balance in patient characteristics at the expense of unbalancing \(n\). Tables 6-3 and 6-4 illustrate local balance of patient characteristics achieved by using a specific balancing score known as the propensity score (see “Propensity Score” later in this section for details on how it is derived from patient data). Table 6-3 demonstrates that patients on long-term aspirin therapy have dissimilar characteristics from those not on this therapy. Unadjusted comparison of outcomes in these two groups is invalid—an apples-to-oranges comparison.\(^8\) Therefore, multivariable logistic regression analysis (see “Logistic Regression Analysis” in Section IV) was performed to identify factors predictive of treatment received (long-term aspirin vs. not).\(^9\) The resulting logistic equation was solved for each patient’s probability of being on long-term aspirin therapy. This probability is one expression of what is known as a propensity score (in this case, the propensity to be on long-term aspirin therapy). Patients were then sorted

Data from Gum and colleagues.\(^a\)

\(^a\)Table shows that patient characteristics differ importantly, making direct comparisons of outcome invalid. As shown in original article, many other patient characteristics differed between the two groups.

Key: ASA, Long-term aspirin use; SD, standard deviation.
The most widely used balancing score is the propensity score. It provides for each patient an estimate of the probability of belonging to one group vs. another (group membership). Here we describe (1) designing the nonrandomized study, (2) constructing a propensity model, (3) calculating a propensity score for each patient using the propensity model, and (4) using the propensity score in various ways for effecting a balanced comparison.

Designing the Nonrandomized Study

The essential approach to a comparison of treatment outcomes in a nonrandomized setting is to design the comparison as if it were a randomized clinical trial and to interpret the resulting analyses as if they emanated from such a trial. This essential approach is emphasized in Rubin’s 2007 article, “The Design versus the Analysis of Observational Studies for Causal Effects: Parallels with the Design of Randomized Trials.”

As noted by Rubin, “I mean all contemplating, collecting, organizing, and analyzing data that takes place prior to seeing any outcome data.” He emphasizes by this statement his thesis that a nonrandomized set of observations should be conceptualized as a broken randomized experiment… with a lost rule for “patient allocation, and specifically for the propensity score, which the analysis will attempt to use.”

Key: AF, Atrial fibrillation; MV, mitral valve; OPCAB, off-pump coronary artery bypass grafting.
construct.” For example, the investigator should ask, “Could each patient in all comparison groups be treated by all therapies considered? If not, this constitutes specific inclusion and exclusion criteria. If this were a randomized trial, when would randomization take place? One must only use variables to construct a propensity score that would be known at the time randomization would have occurred, not after that; this means that variables chosen in the propensity score analysis are not those that could possibly be affected by the treatment.

**Constructing a Propensity Model** For a two-group comparison, typically, multivariable logistic regression is used to identify factors predictive of group membership (see “Logistic Regression Analysis” in Section IV). In most respects, this is what cardiac surgery groups have done for years—find correlates of an event. In this case, it is not risk factors for an outcome event, but rather correlates of membership in one or the other comparison group of interest.

We recommend initially formulating a parsimonious multivariable explanatory model that identifies common denominators of group membership (see Multivariable Analysis in Section IV). Once this traditional modeling is completed, a further step is taken to generate the propensity model, which augments the traditional model by other factors, even if not statistically significant. Thus, the propensity model is not parsimonious. The goal is to balance patient characteristics by whatever means possible, incorporating “everything” recorded that may relate to either systematic bias or simply bad luck, no matter the statistical significance. (However, this is not to say that the addition of nonsignificant variables is done carelessly; the same rigor in variable preparation described in Multivariable Analysis in Section IV is mandatory.) It is important to use as many continuous variables as possible to represent these patient characteristics, because it produces a fine, as opposed to coarse, set of values when the propensity score is calculated.

When taken to the extreme, forming the propensity model can cause problems because medical data tend to have many variables that measure the same thing. The solution is to pick one variable from among a closely correlated cluster of variables as a representative of the cluster. An example is to select one variable representing body size from among height, weight, body surface area, and body mass index.

**Calculating a Propensity Score** Once the propensity modeling is completed, a propensity score is calculated for each patient. A logistic regression analysis, such as is used for the propensity model, produces a coefficient or numeric weight for each variable (Box 6-5). The coefficient maps the units of measurement of the variable into units of risk. Specifically, a given patient’s value for a variable is transformed into risk units by multiplying by the coefficient. If the coefficient is 1.13 and the variable is “male” with a value of 1 (for “yes”), the result will be 1.13 risk units. If the coefficient is 0.023 for the variable “age” and a patient is 61.3 years old, 0.023 times 61.3 is 1.41 risk units.

One continues through the list of model variables, multiplying the coefficient by the specific value for each variable. When finished, the resulting products are summed. To this sum is added the intercept of the model (see Box 6-5), and the result is the propensity score. Note that technically, the intercept of the model, which is constant for all patients, does not have to be added; however, in addition to using the propensity score in logit risk units as described here, it may be used as a probability, for which the intercept is necessary.

**Using Propensity Score for Comparisons** Once the propensity model is constructed and a propensity score is calculated for each patient, three common types of comparison are employed: matching, stratification, and multivariable adjustment.

The propensity score can be used as the sole criterion for matching pairs of patients (Table 6-6). Although a number of matching strategies have been used by statisticians for many years, new optimal matching algorithms have arisen within computer science and operations research. These have been motivated by the need to optimally match volume of Intranet and Internet traffic to computer network configurations. In addition, Rubin (personal communication, 2008) has suggested matching with replacement vs. the usual “greedy” matching, which removes matched patients from further consideration. Indeed, matching can be bootstrapped, creating multiple matched comparison groups over which outcome can be averaged.

Rarely does one find exact matches. Instead, a patient is selected from the control group whose propensity score is nearest to that of a patient in the case group. If multiple patients are close in propensity scores, optional selection among these candidates can be used. (Remarkably, problems of matching on multiple variables disappear by compressing all patient characteristics into a single score (compare Table 6-6 with unmatched data in Table 6-3).)

Tables 6-4 and 6-6 demonstrate that such matching works astonishingly well. The comparison data sets have all the appearances of a randomized study! The average effect of the comparison variable of interest is assessed as the difference in outcome between the groups of matched pairs. However, unlike a randomized study, the method is unlikely to balance unmeasured variables well, and this may be fatal to the inference.

Once patients are matched, it is important to diagnostically test the quality of matching. This can be accomplished visually by graphs of standardized differences (Fig. 6-3). Differences that were substantial should virtually disappear. If they do not, it is possible that interaction terms (multiplicative factors rather than additive factors) may be required.

A graph of propensity scores for the groups is instructive (Fig. 6-4). The scores for two treatments may nearly overlap, as they would for a randomized trial. On the other hand, there may be little overlap, as in Fig. 6-5, and the comparison focuses on the center part of the spectrum of propensity score where there is substantial overlap (virtual equipoise).

Outcome can be compared within broad groupings of patients called strata or subclasses, according to propensity score. After patients are sorted by propensity score, they are divided into equal-sized groups. For example, they may be split into five groups, or quintiles (see Tables 6-4 and 6-5), but fewer or more groups may be used, depending on the size of the study. Comparison of outcome for the comparison variable of interest is made within each stratum. If a consistent difference in outcome is not observed across strata, intensive investigation is required. Usually, something is discovered about the characteristics of the disease, the patients, or their clinical condition that results in different outcomes across the spectrum of disease. For example, in their study of ischemic mitral regurgitation, Gillinov and colleagues discovered that the difference in survival between those
undergoing repair vs. replacement progressively narrowed as complexity of the pattern of regurgitation increased and condition of the patient worsened (Fig. 6-6). Apparent anomalies such as this give important insight into the nature of the disease and its treatment.

The propensity score for each patient can be included in a multivariable analysis of outcome. Such an analysis includes both the comparison variable of interest and the propensity score. The propensity score adjusts the apparent influence of the comparison variable of interest for patient selection differences not accounted for by other variables in the analysis.

Logistic Regression

Sir Francis Galton, cousin of Charles Darwin, explored the relation between heights of adult children and average height of both parents (midparent height). He found that children born to tall parents were in general taller than their parents, and children born to short parents, shorter. He called this “regression towards mediocrity.” He even generated a “forecaster” for predicting son and daughter height as a function of father and mother height. It is presented in an interesting way as pendulums of a clock, with chains around two different-sized wheels equivalent to the different weights (regression coefficients) generated by the regression equation!

Today, any empirical relation of an outcome or dependent variable to one or more independent variables (see later Box 6-18) is termed a regression analysis. Several of these are described below.

**Linear**

The form of a linear regression equation for a single dependent variable \( Y \) and a single independent variable \( x \) is:

\[
Y = a + bx
\]

where \( a \) is called the intercept (the estimate of \( Y \) when \( x \) is zero), and \( b \) is the slope (the increment in \( Y \) for a one-unit change in \( x \)). More generally, when there are a number of \( x \)'s:

\[
Y = \beta_0 + \beta_1 x_1 + \cdots + \beta_k x_k
\]

where \( \beta_0 \) is the intercept, \( x_1 \) through \( x_k \) are independent variables, and \( \beta_1 \) through \( \beta_k \) are weights, regression coefficients, or model parameters (see later Box 6-13) that are multiplied by each \( x \) to produce an incremental change in \( Y \).

It would be surprising if biological systems behaved as a series of additive weighted terms like this. However, this empirical formulation has been valuable under many circumstances in which there has been no basis for constructing a biomathematical model based on biological mechanisms (computational biology).

An important assumption is that \( Y \) is distributed in Gaussian fashion (see Box 6-15), and this may require the scale of the raw data to be mathematically transformed.

**Log-Linear**

A log-linear regression equation has the following form:

\[
\ln(Y) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \cdots + \beta_k x_k
\]

where \( \ln \) is the logarithm to base \( e \). Such a format is used, for example, in the Cox proportional hazards regression model (see Section IV). However, in studies of events (see “Logistic Regression Analysis” and Time-Related Events in Section IV), the estimation procedure does not actually use a \( Y \). Rather, just as in finding the parameter estimates called mean and standard deviation of the Gaussian equation (see Box 6-15), parameter estimation procedures use the data directly. Once these parameters are estimated, a predicted \( Y \) can be calculated.

**Model**

A model is a representation of a real system, concept, or data, and particularly the functional relationships within these; it is simpler to work with, yet predicts real system, concept, or data behavior.

**Mathematical Model**

A mathematical model consists of one or more interrelated equations that represent a real system, concept, or data by mathematical symbols. These equations contain symbols that represent parameters (constants) whose values are estimated from data and an estimating procedure.

A mathematical model may be based on a theory of nature or mechanistic understanding of what the real system, concept, or data represent (biomathematical models or computational biology). It may also be empirical. The latter characterizes most models in statistics, as depicted previously. The Gaussian distribution is an empirical mathematical model of data whose two parameters are called mean and standard deviation (see Box 6-15). All mathematical models are more compact than raw data, summarizing them by a small number of parameters in a ratio of 5 to 10 or more to 1.

**Nonlinear Equation**

When applied to mathematical models, it is an equation that can be solved directly with respect to any of its parameter values by simple mathematical manipulation. A linear regression equation is a linear model.

Occasionally the propensity score remains statistically significant in such a multivariable model. This constitutes evidence that adjustment for selection factors by multivariable analysis alone is ineffective, something that cannot be ignored. It may mean that not all variables important for bias reduction have been incorporated into the model, such as when one is using a simple set of variables. It may mean that an important modulating or synergistic effect of the comparison variable occurs across propensity scores, as noted previously (e.g., the mechanism of disease may be different within quintiles). It may mean that important interactions of the variable of interest with other variables have not been
accounted for, leading to a systematic difference identified by the propensity score. The collaborating statistician must investigate and resolve these possibilities. Understanding aside, this statistically significant propensity score has performed its intended function of adjusting the variable representing the group difference.

In some settings in which the number of events is small, the propensity score can be used as the sole means of adjusting for the variable representing the groups being compared.

Figure 6-3 Covariable balance plot before and after propensity score matching on selected covariables. Symbols depict percent standardized differences for covariables between patients in less invasive and conventional groups. Key: BMI, Body mass index; BUN, blood urea nitrogen; COPD, chronic obstructive pulmonary disease; Dysfunct., dysfunction; HTN, hypertension; LV, left ventricular; Regurg., regurgitation; TV, tricuspid valve.

Figure 6-4 Distribution of propensity scores for conventional and less invasive approaches for aortic valve replacement.

Figure 6-5 Mirrored histogram of distribution of propensity scores for conventional (bars above zero line) and less invasive (bars below zero line) approaches for aortic valve replacement. Darkened area represents matched patient pairs, showing that they cover the complete spectrum of cases but predominate in the central area (area of “virtual equipoise”).

The propensity score may reveal that a large number of patients in one group do not have scores close to patients in the other. Thus, some patients may not be matched. If stratification is used, quintiles of patients may have hardly any matches at one or the other, or both, ends of the propensity spectrum, and these remaining may not be well matched.

The knee-jerk reaction is to infer that these unmatched patients represent, indeed, apples and oranges unsuited for direct comparison. However, the most common reason for lack of matches is that a strong surrogate for the comparison group variable has been included inadvertently in the propensity score. This variable must be removed and the propensity model revised. For example, Banbury and colleagues studied blood use with vacuum-assisted venous return (VAVR) by comparing two sequential VAVR configurations with gravity drainage. Because the three groups represented consecutive sequences of patients, date of operation was a strong surrogate for group membership. Furthermore, physical configuration and size of tubing and cannulae varied systematically among groups. Thus, priming volume also was a strong surrogate for group. Neither could be used in forming propensity scores (multiple scores in this instance).

Figure 6-4 Distribution of propensity scores for conventional and less invasive approaches for aortic valve replacement.
If this is not the case, the analysis may indeed have identified truly unmatchable cases (mixed fruit). In some settings, they represent a different end of the spectrum of disease for which different therapies have been applied systematically.\textsuperscript{G14} Often the first clue to this “anomaly” is finding that the influence of the comparison variable of interest is inconsistent across quintiles.\textsuperscript{G14} Indeed, this emphasizes the nature of comparisons with balancing score methodology: the comparisons relate only to the subset of patients who are truly apples-to-apples. Comparing these apples to the remaining oranges with respect to outcomes is not valid. The oranges result from systematic selection of patients for one vs. the other treatment. The area of broad overlap of propensity scores, in contrast, can be thought of as the area of virtual equipoise (see Fig. 6-5).

Thus, when apples and oranges (and other “mixed fruit”) are revealed by a propensity analysis, investigation should be intensified rather than the oranges simply being set aside. After the investigations are complete, comparisons among the well-matched patients can proceed with known boundaries within which valid comparisons are possible.

**Limitations**

Some investigators tell us that balancing score methods are valid only for large studies, citing Rubin.\textsuperscript{R28} It is true that large numbers facilitate certain uses of these scores, such as stratification. Case-control matching is also better when a large group of controls far exceeding cases is available. However, we believe there is considerable latitude in matching that still reduces bias; the method seems to “work” even for modest-sized data sets.

Another limitation is having few variables available for propensity modeling. The propensity score is seriously degraded when important variables influencing selection have not been collected.\textsuperscript{D23} A corollary to this is that unmeasured variables cannot be reliably balanced. If these are influential on outcome, a spurious inference may be made.\textsuperscript{D8}

The propensity score may not eliminate all selection bias.\textsuperscript{R18} This may be attributed to limitations of the modeling itself imposed by the linear combination of factors in the regression analysis that generates the balancing score (see Box 6-5). If the comparison data sets are comparable in size, it may not be possible to match every patient in the smaller of the two data sets, simply because closely comparable patients have been “used up,” unless bootstrap sampling with replacement has been used.

Perhaps the most important limitation is inextricable confounding. Suppose one wishes to compare on-pump CABG with off-pump operations. One designs a study to compare the results of institution A, which performs only off-pump bypass, with those of institution B, which performs only on-pump bypass. Even after careful application of propensity score methods, it remains impossible to distinguish between an institutional and a treatment difference, because they are inextricably intertwined (confounded); that is, the values for institution and treatment are 100% correlated.

**Extension**

At times, one may wish to compare more than two groups, such as groups representing three different valve types. Under this circumstance, multiple propensity models are formulated.\textsuperscript{R26} We prefer to generate fully conditional multiple logistic propensity scores\textsuperscript{R28} (see “Polytomous and

---

**Figure 6-6** Demonstration of changing risk across propensity score for mitral valve repair vs. replacement. Because of small numbers of patients with mitral valve replacement in quintiles III through V, these quintiles are grouped together. Patient profiles are similar in each quintile but differ across quintiles. Each symbol represents a death according to the Kaplan-Meier estimator. Vertical bars enclose asymmetric 68% confidence limits (CL); solid lines enclosed within dashed 68% CLs represent parametric survival estimates; numbers in parentheses are numbers of patients traced beyond that point. \( P \) values are for log-rank test. A, Quintile I. B, Quintile II. C, Quintiles III through V. (From Gillinov and colleagues.\textsuperscript{G14})
Ordinal Logistic Regression” in Section IV), although some believe this “correctness” is not essential.

Most applications of balancing scores have been concerned with dichotomous (yes/no) comparison group variables. However, balancing scores can be extended to a multiple-state ordered variable (ordinal) or even a continuous variable. An example of the latter is use of correlates of prosthesis size as a balancing score to isolate the possible causal influence of valve size on outcome.

Logistic regression is not the only way to formulate propensity scores. A nonparametric machine learning technique—random forests (see Classification Methods in Section VI)—can be used and has been found by Lee and colleagues to better balance groups, with reduced bias. We have formulated a generalized theorem as an extension of the work of Imai and van Dyk for propensity scores and devised a data-adaptive, random-forest nearest-neighbor algorithm that simultaneously matches patients and estimates the treatment effect from thousands of bootstrap samples, while simultaneously refining the characteristics of “true” oranges—noncomparable patients.

TECHNIQUE FOR SUCCESSFUL CLINICAL RESEARCH

Marbán and Braunwald, in reflecting on training the clinician-investigator, provide guiding principles for successful clinical research. Among these:

- Choose the right project.
- Embrace the unknown.
- Use state-of-the-art approaches.
- Do not become the slave of a single technique.
- Never underestimate the power of the written or spoken word.

In this subsection, we emphasize these principles and suggest ways to operationalize them.

Because of increasingly limited resources for conducting serious clinical research, a deliberate plan is needed to successfully carry a study through from inception to publication. Here we outline such a plan for study of a clinical question for which clinical experience (a patient cohort) will provide the data. This plan appears as a linear workflow (Fig. 6-7); in reality, most research efforts do not proceed linearly but rather iteratively, with each step being more refined and usually more focused right up to the last revision of the manuscript. As is true of most workflow, there are mileposts at which there need to be deliverables, whether a written proposal, data, analyses, tables and graphs, a manuscript, or page proofs.

Research Proposal

Because of the necessity for Institutional Review Board (Ethics Committee) oversight, but also because it is good science, every serious clinical study needs a formal proposal (Box 6-6). This proposal serves to clarify and bring into focus

---

2 Although the technique described is aimed at clinical studies of cohorts of patients, many aspects apply to randomized clinical trials, retrospective clinical studies, and even laboratory research.
is to collect data for too many variables, with little thought given to how they might be used. This wastes scarce resources and compromises the quality of collecting relevant variables.

Dr. John Kirklin called this “the Christmas tree effect.”

Sample Size
For any study, a minimum sample size is needed to detect an effect reliably. For events (e.g., death), sample size is dependent on the number of events, not size of the study group (see Box 6-4).

Feasibility
Successful projects are built on ascertaining that (1) the study population can be identified reliably (ideally from electronic databases), (2) the values for variables required are either already in electronic format (but may need to be verified) or can be obtained readily by review of medical documents, (3) the sample size is sufficient to answer the question (see Box 6-4), (4) clinical practice is not completely confounded with the question being asked (one cannot compare two techniques if only one is performed; one may not be able to unravel confounding of two techniques if one surgeon performs one and another the other), and (5) institutional resources are available (one cannot assess PET scans if they are not performed). If the project is not feasible, the study should be abandoned or a long-range plan devised for prospectively obtaining and recording the needed data.

Limitations and Anticipated Problems
Every study has limitations and anticipated problems. These can be identified by a brief but serious investigation of the state of all the above. If any appear insurmountable or present fatal flaws that preclude later publication, the study should be abandoned. There are always more questions than can be addressed in cardiac surgery, so not being able to answer some specific research question is not an excuse to abandon the search for new knowledge!

Data Analysis
Details of analytic methodology should be formulated in collaboration with a statistician or other quantitative analyst (see Section IV). The surgeon-investigator often does not recognize or know the most appropriate analytic methodology. Collaboration with a statistician or other quantitative professional should reveal appropriate methodology and whether the proposed manner in which data are to be collected will meet the requirements of the methodology. Unfortunately, the surgical literature is not a good resource for determining appropriate methods.

Institutional Review Board (IRB)
Any proposal that does not use existing data already approved for use in research by an IRB requires study-specific IRB approval before any research is commenced.

Timetable and Deliverables
Develop a timetable for data abstraction, data set generation (see Fig. 6-7), data analysis, and reporting, all deliverables at various milestones in the study. If the timetable is beyond that tolerable, abandon the study. It is rare for a study to be completed in a year from start to finish. This emphasizes both the bottlenecks of research and the need for lifelong commitment. Although abstract deadlines often drive the timetable, this is a poor milepost (see “Presentation” in Section V).
the question being asked. A common mistake is to ask questions that are unfocused, or uninteresting, or overworked, or that do not target an area of importance. Marbán and Braunwald say, “Ask a bold question...about which you can feel passionate.”

Brainstorming with fellow surgeons and collaborators is essential. The first deliverable is the research question, well debated.

The next step is to define clearly the inclusion and exclusion criteria for the study group (see “Identify Study Group” in Section III). A common mistake is to define this group too narrowly, such that cases “fall through the cracks” or an insufficient spectrum is stipulated (see “Continuity versus Discontinuity in Nature” earlier in this section). The inclusive dates should be considered carefully. Readers will be suspicious if the dates are “strange”; did you stop just before a series of deaths? Whole years or at least half years dispel these suspicions. Similarly, suspicion arises when a study consists of a “nice” number of patients, such as “the first 100 or 1000 repairs.”

In defining the study group, particular care should be taken to include the denominator. For example, a study may be made of postoperative neurologic events, but it is also important to have a denominator to put these events into context. Or one may study a new surgical technique but be unable to compare it with the standard technique without a comparison group. A study of only numerators is the true definition of a retrospective study; if the denominator is included, it is a prospective or cohort study (Box 6-7).

End points (results, outcomes) must be clearly defined in a reproducible fashion. Generally, every event should be accompanied by its date of occurrence. A common failing is that repeated end points (e.g., thromboembolism, assessments of functional status) are recorded only the first or most recent time they occur. This should never be done. Techniques to analyze repeated end points are available (see Longitudinal Outcomes in Section IV).

Careful attention must be paid to the variables that will be studied. They should be pertinent to the study question (purpose, objective, hypothesis). A common failing is to collect values for too many variables such that quality suffers. This error usually arises in a reasonable and understandable way. The surgeon-investigator reasons that because the patient records must be reviewed, a number of other variables may as well be abstracted “while there.” Or realizing the full complexity of the clinical setting, the surgeon-investigator feels compelled to collect information on all possible ramifications of the study, even if it is quite peripheral to the focus of the study. This is termed the “Christmas tree effect,” meaning adding ornament upon ornament until they dominate what once was “just” a fine tree. There needs to be a balance between so sparse a set of variables that little can be done by way of risk factor identification or balancing characteristics of the group, and so rich a set of variables that the study flounders or insufficient care is given to the quality and completeness of relevant variables.

Study feasibility must then be assessed. A common failing is forgetting that if an outcome event is the end point, the effective sample size is the number of events observed (see Box 6-4). A study may have 1000 patients, but if only 10 events are observed, one cannot find multiple risk factors for those events.

It is wise at the outset to plan the data analysis. Often, for example, the setup for the analysis data set is specific to the methods of analysis. This has to be known by the data managers (see Appendix 6A).

A necessary step is review of the literature. Sifting through articles is often painful, but it should result in identifying those few key papers that are absolutely pertinent to the study. Unfortunately, the search is too often confined to recent literature, and this may result in “reinventing the wheel.”

For executing the study, some realistic time frame with deliverables should be established with collaborators. A common failing is not providing sufficient time for data verification and other aspects of data management that are the heart of a high-quality study. Actual analysis of data may consume one tenth the time of high-quality data preparation.

**Box 6-7 Retrospective, Prospective**

When clinical data are used for research, some term this retrospective research (e.g., the National Institutes of Health). Epidemiologists also perform what they call retrospective studies that bear no resemblance to typical clinical studies. Thus, confusion has been introduced by use of both the word retrospective and prospective to designate interchangeably two antithetical types of clinical study. The confusion is perpetuated by institutional review boards and government agencies that believe one (prospective), but not the other (retrospective), constitutes “research” on human subjects. The confusion can be eliminated by differentiating between (1) the temporal direction of study design and (2) the temporal direction of data collection for a study, as did Feinstein.

**Temporal Direction of Study Design**

The temporal pursuit of patients may be forward. That is, a cohort (group) of patients is defined at some common time zero, such as operation, and this group is followed for outcomes. Some call this a cohort study. It is the most typical type of study in cardiac surgery: A group of patients is operated on and outcome is assessed. Statisticians have called this a prospective clinical study design; it moves from a defined time zero forward (which is what the word prospective means).

In contrast, temporal pursuit of patients may be backward. Generally in such a study, an outcome event occurs, such as death from a communicable disease. Starting from this event (generally, a group of such events), the study proceeds backward to attempt to ascertain its cause. Feinstein suggests calling such a study a “trohoc” study (cohort spelled backwards). For years, many epidemiologists called this a retrospective clinical study design because of its backward temporal direction of study.

**Temporal Direction of Data Collection**

Increasingly, retrospective is used to designate the temporal aspect of collecting data from existing clinical records for either a cohort or trohoc study. If charts or radiographs of past patients in a cohort study must be reviewed or echocardiographic features measured, the data collection is retrospective. Feinstein has coined the term “retrolective” for this to avoid use of the word retrospective because of the previously well-understood meaning of the latter in study design. If registry data are collected concurrently with patient care, this process is surely prospective data collection. Feinstein suggests calling such data collection “prolective” data collection.
The completed formal research proposal becomes the second deliverable of a study. It is likely to be updated throughout the course of a study, and we advocate online tracking of each study, with periodic updates of the protocol as one of the tasks in project management.

Database Development and Verification

The next step for successful research is careful attention to the data themselves (see “Extract Values for Variables” in Section III). If electronically available data are to be used, every variable must be defined both medically and at the database content level (see Section II). If data are to be collected de novo, an appropriate database must be developed (see Fig. 6-7). Every variable must be in a format of one value per variable. These variables must follow a controlled vocabulary for analysis, not free text. The deliverable at this stage is a database ready for data to be collected and entered.

Data Collection

Research on existing databases for which blanket IRB approval has been secured may not require separate approval of each study. However, before any de novo data are gathered from medical records or by patient follow-up, separate IRB approval may be required.

There is generally a core set of variables (core data elements) that should be collected for each patient (Box 6-8). In many cardiac surgical settings, these data elements are stipulated by regulatory agencies (e.g., the state of New York) or surgical societies (e.g., Society of Thoracic Surgeons National Database). They include demographics (note that it is essential to record patients’ date of birth rather than age because age can be calculated from date of birth to any chosen “time zero”), the cardiac procedure and possibly clinical symptoms and status at time of operation, past cardiac medical history (particularly prior cardiac procedures), disease etiology, coexisting cardiac defects, coexisting noncardiac morbidity (e.g., diabetes), laboratory measurements known to be consistently associated with clinical outcomes, findings of diagnostic testing, intraoperative findings, support techniques during operation, and factors related to experience (e.g., date of operation).

Beyond these core variables, there will likely be a need for variables specific to a particular study. These should be identified and reproducibly defined. The danger is specifying too many variables; however, a thoughtfully compiled list adds depth to a study. Further, experienced investigators realize that in the midst of a study, it occasionally becomes evident that some variables require refinement, others collecting de novo, others rechecking, and others redefining. It is important to understand that when this occurs, the variables must be refined, collected, rechecked, or redefined uniformly for every patient in the study.

Clinical studies are only as accurate and complete as the data available in patients’ records. Therefore, cardiac surgeons and team members seriously interested in scientific progress must ensure their preoperative, operative, and postoperative records are clear, organized, precise, and extensive, so that information gathering from these records can be complete and meaningful. The records should emphasize description, and although they may well contain the conclusions of the moment, it is the description of basic observations that becomes useful in later analyses.

Verification

The first step in data verification is to enter values for each data element (variable) for 5 to 10 patients only. These reveal problems of definition, incomplete “pick lists,” missed variables, difficult-to-find variables that may not be worth the effort to locate, poor-quality variables/incomplete recording, lack of good definition, inconsistent recording, and questionable quality of observations. Once these issues are addressed, general data abstraction may proceed (see “Verify Data” in Section III).
When all values for variables are in a computer database, formal verification commences. This can take three general forms: (1) value-by-value checking of recorded data against primary source documents, (2) random quality checking, and (3) automatic reasonableness checking. If a routine activity of recording core data elements (see Section III, Data) is used, it is wise to verify each element initially to identify those that are rarely in error (these can be “spot checked” by a random process) and those that are more often in error. The latter are usually a small fraction of the whole and are often values requiring interpretation. These may require element-by-element verification.

When it is believed that data are correct (this is an iterative process with the above), they are checked for reasonableness of ranges, including discovery of inconsistencies among correlated values. For example, the database may indicate that a patient had a quadrangular resection of the mitral valve, but someone had failed to record that the posterior leaflet was prolapsing and had ruptured chordae, or the database records that a patient is 60 cm tall and weighs 180 kg; this is likely a problem of confused units of measurement (inches and pounds).

Data Conversion for Analysis
An often underappreciated, unanticipated, and time-consuming effort is conversion of data elements residing in a database to a format suitable for data analysis (see Analysis Data Set in Section III). Even if the day comes that all medical information is recorded as values for variables in a computer-based patient record (see Section II, Computer-Based Patient Record), this step will be unavoidable. Statistical procedures require data to be arranged in “columns and rows,” with each column representing values for a single variable (often in numeric format), and each row either a separate patient or multiple records on a single patient (as in repeated-measures longitudinal data analysis). Unfortunately, this conversion process may involve redundancy, such as the necessity to again document all variables and provide a key to the possible values for each.

This process nearly always involves creating additional variables from a single variable, such as a separate variable for each mutually exclusive etiology of cardiomyopathy. These polytomous variables (lists) are then converted to a series of dichotomous variables (best expressed as 0 for absence and 1 for presence of the listed value).

Some categorical variables are ordinal, such as NYHA functional classes. These may have to be reformulated as an ordered number sequence (e.g., 1-4). Variables recorded with units (e.g., weight in kilograms, weight in pounds) must be converted to a common metric.

Calculated variables are also formed. These include body surface area and body mass index from height and weight, e values (see Chapter 1) from measured cardiac dimensions, ejection fraction from systolic and diastolic ventricular volumes, intervals between date and time variables for which event indicator variables are created, and many other calculations. Because data conversion, creation of derived variables, and formation of calculated variables is time consuming and error prone, groups that conduct a large number of studies often store trusted, well-verified computer code to perform these operations on a repetitive basis.

Often information is coalesced from multiple databases, and these queries, concatenations, and joining functions transpire in this phase of the process. These otherwise arduous functions can, under some circumstances, be automated. Alternatively, a data warehouse composed of multiple disparate electronic data sources can be implemented and maintained and appears to the investigator as a single data source.

An important activity is managing sporadic missing data. If too much data are missing, the variable may be unsuitable for analysis (see “Impute Values” in Section III). Otherwise, missing value imputation is necessary so that entire patients are not removed from analyses, the default option in many analysis programs.

Data Analysis
Specific data analysis methods will be described in Section IV. Here, we simply indicate how this aspect of the research process leads to success.

First, the analysis process leads to understanding of the “raw data,” often called exploratory data analysis. This understanding is gleaned from such analyses as simple descriptive statistics, correlations among variables, simple life tables for time-related events, cumulative distribution graphs of continuously distributed variables (see “Descriptive Statistics” in Section III), and cluster analyses whereby variables with shared information content are identified.

Second, the analytic process attempts to extract meaning from the data by various methods akin to pattern recognition. Answers are sought for questions such as: Which variables relate to outcome and which do not? What inference can be made about whether an association is or is not attributable to chance alone? Might there be a causal relationship? For what might a variable associated with outcome be a surrogate?

What will be discovered is that answering such questions in the most clinically relevant way often outstrips available statistical, biomathematical, and algorithmic methodology! Instead, a question is answered with available techniques, but not the question. Some statisticians, because of insufficient continuing education, lack of needed statistical software, lack of awareness, failure of communication, or lack of time, may explore the data less expertly than required. One of the purposes of this chapter is to stimulate effective collaboration between cardiac surgeons and data analysis experts so that data are analyzed thoroughly and with appropriate methodology.

Interpreting Analyses
It is one thing for a statistician to provide a statistical inference; it is quite another for the cardiac surgeon, using that information, to draw meaningful interpretations that affect patient care.

Kirklin and Blackstone empirically found that the most successful way to embark on this interpretive phase of clinical research is to write on a clean sheet of paper the truest two or three sentences that capture the essence of the findings (and no more!). This important exercise produces an un mini abstract for a paper (whether or not it is required by a journal) and provides the roadmap for writing the manuscript (see Scientific Paper in Section V).
Communicating the Findings

A common error of the surgeon-investigator is to simply summarize the data instead of taking the important step of drawing meaningful clinical inferences from the data and analyses. He or she has not taken the vital step of asking (1) What new knowledge has been gleaned from the clinical investigation? (2) How can this new knowledge be incorporated into better patient care? (3) What do the data suggest in terms of basic research that needs to be stimulated? (4) How can I best communicate information to my local colleagues? (5) How can I best present this information to the cardiac surgical and cardiologic world at large?

Meaningful new knowledge may not be generated because the statistical inferences from data analyses are accepted as the final result. Instead, the results must be studied carefully and many questions asked. Often this will lead to additional analyses that increasingly illuminate the message the data are trying to convey. Graphical depictions are of particular importance in transforming mere numbers on computer printouts to insight. Depictions must lead beyond statistical inference to clinical inference. What have the data revealed about how to better care for patients? This question is the one best linked to the original purpose of the study. If the study has suggested ways to improve patient care, the next step is to put what has been learned into practice (see Section V).

Most studies generate more new questions than they answer. Some of these new questions require additional clinical research. Others require the surgeon-investigator to stimulate colleagues in the basic sciences to investigate fundamental mechanisms of the disease process.

Because most surgeon-investigators are part of a group, an important facet of generating new knowledge is discussing with colleagues the results, statistical and clinical inferences, and implications of a study. Multiple points of view nearly always clarify rather than obscure their interpretation.

Finally, clinical research is not a proprietary activity. Yet, too often manuscripts fail to elucidate from research. One reason may be that an abstract was not accepted for a meeting, perhaps because the data were not thoroughly digested before its submission. Although abstract deadlines may be important mechanisms for wrapping up studies, they too often stifle a serious and contemplative approach to generating new knowledge. A second reason manuscripts do not get written is that the surgeon-investigator views the task as overwhelming. Possibly he or she has not developed an orderly strategy for writing. We provide some guidance for this in Section V. A third barrier to writing is time demands on the surgeon-investigator. Usually, this results from not making writing a priority in one’s professional life. This is a decision that should be made early in one’s surgical career. If dissemination of new knowledge is a desire, then writing must be made a high-priority part of one’s lifestyle.

Section II  Information

Information is a collection of facts. The paper medical record is one such collection of facts about the health care of a patient. In it, observations are recorded (clinical documentation) for communication among healthcare professionals and for workflow (e.g., plan of care, orders). However, perhaps as much as 90% of the information communicated in the care of a patient is never recorded. The attitude of health insurers—“If it is not recorded, it did not happen”—thus represents a sobering lack of appreciation of the way information about patient care is used and communicated. However, it is also an indictment of the way medical practice is documented. Too much is left out of written records, and too many operative reports are poorly organized and incomplete. Too often this reflects the kind of imprecise thinking that gives rise to medical errors (see “Human Error” earlier in this section). If important clinical observations are not recorded during patient care, preferably in a clear, complete, and well-organized (structured) fashion, they are unavailable subsequently for clinical research.

COMPUTER-BASED PATIENT RECORD

In 1991, the IOM (Institute of Medicine) recognized the need not only for computerizing the paper medical record (as the electronic medical record [EMR]) but also for devising a radically different way to record, store, communicate, and use clinical information. They coined the term “computer-based patient record,” or CPR, and distinguished it from the EMR by the fact that it would contain values for variables using a highly controlled vocabulary rather than free text (natural language).

Two decades have passed. Still, there is no universally accepted definition of the CPR beyond that it contains electronically stored information about an individual’s lifetime health status and health care. There is no accepted information (data) model, catalog of data elements, or comprehensive controlled medical vocabulary, all of which are fundamental to developing and implementing the envisioned CPR. There is little movement to capture every health encounter in a patient-owned record; rather, data are siloed within institutions.

These issues aside, for the cardiac surgical group interested in serious clinical research, a CPR with a few specific characteristics could enormously facilitate clinical studies. Furthermore, it could transform the results into dynamic, patient-specific, strategic decision-support tools to enhance patient care.

First and foremost, the CPR must consist of values for variables, selected from a controlled vocabulary. This format for recording information is necessary because analysis now and in the foreseeable future must use information that is formatted in a highly structured, precisely defined fashion, not uncontrolled natural language. Extracting structural information from natural language is a formidable challenge and one that should be unnecessary. Second, the CPR must accommodate time as a fundamental attribute. This includes specific time (date/time stamps), inexact time (about 5 years ago), duration (how long an event lasted, including inexact duration), sequence (second myocardial infarction [MI], before, after), and repetition (number of times, such as three MIs). Third, the CPR must store information in a fashion that permits retrieval not only at the individual patient level but also at the group level, according to specified characteristics. Fourth, the CPR will ideally incorporate mechanisms for using results of clinical studies in a patient-specific fashion for decision support in the broadest sense of the term,
such as patient management algorithms and patient-specific predictions of outcome from equations developed by research.\textsuperscript{12, 14, 20} (see “Use of Incremental Risk Factors” in Section V).

There are many other requirements for CPRs, from human-user interfaces, to administrative and financial functions, to healthcare workflow, to human error avoidance systems, that are beyond the scope of the clinical research theme in this section.

**Ontology**

If medical information is to be gathered and stored as values for variables, a medical vocabulary and organizing syntax must be available.\textsuperscript{14} A technical term for this is *ontology*.

In Greek philosophy, *ontology* meant “the nature of things.” Specifically, it meant what actually is (reality), not what is perceived (see “Human Error” in Section I) or known (epistemology). In medicine of the 17th and 18th centuries, however, it came to mean a view of disease as real, distinct, classifiable, definable entities. This idea was adopted by computer science to embrace with a single term everything that formally *specifies the concepts and relationships* that can exist for some subject, such as medicine. An ontology permits sharing of information, such as a vocabulary of medicine (terms, phrases), variables, definitions of variables, synonyms, all possible values for variables, classification and relationships of variables (e.g., in terms of anatomy, disease, healthcare delivery), semantics, syntax, and other attributes and relationships.

An ontology for all of medicine does not yet exist. Efforts to develop a unified medical language, such as the Unified Medical Language System (UMLS) of the National Library of Medicine, are well underway and becoming increasingly formalized linguistically as ontologies.\textsuperscript{15}

Ontology is familiar to clinical researchers, who must always have a controlled vocabulary for values for variables, well-defined variables, and explicit interrelations among variables. Without these, there is no way to accurately interpret analyses or relate results to the findings of other investigators. However, a clinical study is a microscopic view of medicine; scaling up to all of medicine is daunting.

Perhaps, then, the simplest way of thinking about an ontology for the researcher is as dictionaries of variables and values and their organizational structure, and some mechanism to develop and maintain them. These attributes have collectively been called *metadata* (data about data) or a *knowledge base*, and metadata-base or knowledge-base management systems, respectively.\textsuperscript{21}

**Information (Data) Model**

An information (data) model is a specification of the arrangement of the most granular piece of information according to specific relationships and the organization of all of these into sets of related information. The objective of an information model is to decrease entropy—that is, to decrease the degree of disorder in the information and thereby increase efficiency of information storage and retrieval (performance).

**Object-Oriented Information Model**

In 1993 at UAB, John Kirklin led a team effort to develop a CPR that would be ideal for clinical care as well as clinical research.\textsuperscript{21} The first step was an attempt to develop an object-oriented information model. These efforts failed. In object technology, only a few formal relationships can be established easily. Failure of the object data model was attributed to the realization that in medicine, “everything is related to everything” on multiple hierarchical (polyhierarchical) levels. Indeed, medical linguistics forms a semantic network.\textsuperscript{51}

**Relational Information Model**

The most ubiquitous information model in business, the relational database model, was found to be even more unsuitable as a medical information model,\textsuperscript{17} just as it is now being found to be unsuitable in complex, rapidly changing, multidimensional businesses such as aircraft building and repair. In relational database technology, variables are arranged as columns of a table, sets of columns are organized as a table, individual patients are in rows, and a set of interrelated tables constitute the database. However, in medicine, information is multidimensional. A given value for a variable must carry with it time, who or what machine generated the value, the context of obtaining the value (“documentation”), format or units of measurement, and a host of attributes and relationships—indeed ontology—that give the value meaning within the context of healthcare delivery. Simply storing a set of values is insufficient. Furthermore, when data must be analyzed, information relevant to the values, such as described earlier, may importantly affect the analysis and must be present even if it seems ancillary. The relational data model also poorly represents and retrieves sequences (in which retention of order is vital) and is difficult to maintain for complex data, because every change (addition, subtraction) in data structure requires the database to be updated.

Popularity of the relational model among clinical researchers stems from its simplicity in handling a microscopic corner of medical information. As soon as a new topic is addressed or new variables must be collected, the typical behavior of the research team is to generate a new specific database. Rarely do these multiple, independent, and to some extent redundant databases communicate with one another across studies. This attests to the inappropriateness of such a simplistic data model for a CPR, and even for a busy cardiac surgery research organization.\textsuperscript{18}

**Semistructured Information Model**

A different kind of information model emerged from an important conference at UAB of leaders in the development of several different types of database as part of the CPR project. After review of the strengths and profound limitations of various information models, a novel approach was suggested by Kirklin and then formalized. He proposed that all information that provided context and meaning to a value for a variable be packaged together. He envisioned that such a complex data element should be able to reside as an independent self-sufficient entity.\textsuperscript{21} (In computer science terminology, this would be called a completely flattened data model.)

This idea has several meritorious implications. First, an electronic container for a collection of complex data elements could consist of a highly stable, totally generic repository for a CPR because it would be required to possess no knowledge of content of any data element. It could therefore manage important information storage and retrieval functions, implement data encryption for privacy and
confidentiality, store knowledge bases used to construct the complex data elements and retrieve them, maintain audit trails, and perform all those functions of database management systems that are independent of data content. The second implication is that as medical knowledge increases, new entries would be made in the knowledge-base dictionaries. These would be updated, not the database structure. Not only would this case database maintenance, it would enforce documentation in the knowledge base. The third implication, and the one most important for clinical research, is that no a priori limitations would be placed on relations; they could be of any dimensionality considered useful at the time. These data elements were retrieved for analysis. Thus, the electronic container is a single variable value-pair augmented with contextual documentation and capable of being modified as new or more knowledge accrues.

Essential characteristics of such an information repository are:

- Self-documentation at the level of individual values for a variable (complex data element)
- Self-reporting at the time of data element retrieval and potential
- Self-displaying in a human-computer interface
- Self-organizing

The latter is an important attribute for future implementation of what might be called “artificial intelligence” features of a CPR. These may be as simple as self-generation of alerts, solution of multivariable equations for decision support at the individual patient level, or intelligent data mining for undiscovered relations within the information. B42

About 1995, at the time these ideas were being developed at UAB, similar thinking was going on among computer scientists at Stanford University and the University of Pennsylvania, arising from different stimuli. B71,M17 They termed an information model of complex data elements that carried with them all attributes intended for self-documentation, self-reporting, and self-organizing semistructured data. This phrase meant that the data elements were fully structured, but no necessary relation of one data element to another was presupposed. The culmination of these efforts was a database for storing complex data elements called Lore M17 and a novel query language for retrieving complex data elements called Lorel. A1

In the 1990s, it was recognized that the information structure suggested by Kirklin and the University of Pennsylvania and Stanford computer scientists could be conceptualized as a directed acyclic graph (Fig. 6-8). At that time, another entity was also rapidly coming into existence with similar properties, but of global proportions: the World Wide Web (WWW, or simply the Web). A Web page is analogous to a complex data element, with an essential feature being that it is self-describing, so it can be retrieved. The Web is the infrastructure for these pages. It has no need to be aware of Web page content. The subject matter has no bounds. Not surprisingly, then, the tools developed for retrieving semistructured data were quickly adapted to what has become known as search engines for the Web. Like Dr. Kirklin’s vision of complex data elements, information retrieved by a search engine can become related in ways never envisioned by the person generating it, because full structure is imposed only at the time of retrieval, not at the time of storage.

In 1998, the Lore scientists realized that the information model for semistructured data could be implemented in XML (extensible markup language). XML is a textual language for information representation and exchange, largely developed for document storage and retrieval but adaptable to values for variables. D6,G16

At least on a conceptual basis, we believe a CPR can be formulated using a semistructured information model that will facilitate clinical research by not imposing restrictions at the time of storage, as relational and object models do.

Subsequently at Cleveland Clinic, investigators have been both harnessing and developing “Semantic Web” tools for data storage and manipulation, in part within the framework of the World Wide Web Consortium (W3C) and in part through ontologies built by Douglas Lenat of Cycorp. B42 W3C is an international community that works with the public to develop Web standards. It is developing a suite of technologies that build on standards associated with the World Wide Web and provide a formal model for representing information in a manner that emphasizes the meaning of terms rather than their structure. B32 It is a vision of how the existing infrastructure of the Web can be extended in such a way that machines can interpret the meaning of data involved in interactions over the Web.

This particular collection of standards is commonly referred to as Semantic Web technologies. They are built on a graph-based data model known as the Resource Description Framework (RDF), as well as a framework for describing conceptual models of RDF data in a particular domain known as the Ontology Web Language (OWL). It also includes a standard querying language called SPARQL.

RDF captures meaning as a collection of triples consisting of components analogous to those of an elementary sentence in natural language: subject, verb, object. Typically, terms in these sentences are resources identified by Uniform Resource Identifiers (URIs). URIs are global identifiers for items of interest (called resources) in the information space of the Web. B32 Collections of RDF triples constitute an RDF graph.

Many requirements outlined by the IOM as crucial for CPR systems are addressed by using RDF as a data format for patient record content. In particular, our ability to link with other clinical records can be facilitated when RDF is used in this way. B32 Use of URIs as syntax for the names of concepts in RDF graphs is the primary reason for this. The meaning of terms used in a patient record (as well as the patient record itself or some part of it) can be made available over the Web in a (secure) distributed fashion for on-demand retrieval.

A judicious application of Semantic Web technologies can also lead to faster movement of innovation from the research laboratory to the clinic or hospital. B32 In particular, it is envisioned that use of these technologies will improve productivity of research, help raise quality of health care, and enable scientists to formulate new hypotheses, inspiring research based on clinical experience. B41

TIME

The ability to manage that ubiquitous attribute of all medical data—time—is not part of any widely available information retrieval system (generally called query languages). Some proposals have been tested in a limited fashion, such as the
Figure 6-8 Comparison of relational information model with a semistructured one presented as a directed acyclic graph. A, Relational. Tables are related by ID and source. Note that second table is many-to-one; that is, many postoperative echocardiograms were performed on one patient. B, Semistructured. (From Jonathan Borden, www.jonathanborden-md.com).

Tzolkin system developed at Stanford University, but the software is not generally available. The reason for needing to consider time is readily apparent. Whenever we think about retrieving medical information along some time axis (e.g., sequence, duration, point in time), new logical relations must be generated to obtain reasonable results. For example, if we ask for all patients younger than 80 years who have undergone a second coronary artery bypass operation followed within 6 months by an MI, a number of time-related logical steps must be formulated. What is meant by patients younger than 80? Younger than 80 when? At the time of initial surgery, second surgery, MI, or at the time of the inquiry? The sequence of coronary artery bypass grafting (CABG) must be ascertained from data elements about each procedure a patient has undergone. Information about the MI and its relation to the date of the second CABG must be retrieved. The process is even more complex if only approximate dates are available.
Perhaps a growing interest pertaining to the time axis in business may stimulate development of better tools for managing queries related to time in medical information.

Section III  Data

Data consist of organized information. We add the following further constraints.

First, data consist of values for variables. These values have been selected from a list of all possible values for a variable, and this list is part of a constrained vocabulary. Natural language processing is too primitive at present to allow values to consist of free text, and that will not change in the foreseeable future. Our exploration with linguistics experts of the needed lexical parsing rules to determine from dictated medical notes whether a person experienced a hospital death after cardiac operation produced multiple pages of daunting logic. In part, the complexity arises because of the richness of language that includes euphemisms, synonyms, and misspellings; in part it is because one must also identify negating (“did not expire”), adjudicate probabilities (“may have died”), and examine indirect evidence (no mention of death in available dictated notes, but an autopsy was reported).

Second, data consist of values for variables that have been accurately and precisely defined both at the level of the database and medically. One of the important benefits of multicenter randomized trials, concurrent observational studies, or national registries is that these activities require establishing agreed-upon definitions at the outset. Coupled with this is often intensive and ongoing education of study coordinators and other data-gathering personnel about these definitions, exceptions, and evolution of definitions and standards. There is a mechanism to monitor compliance with these definitions and standards throughout the study, and the same should hold true for any registry. However, a mechanism to ensure similar adherence to definitions is essential even for individual clinical studies. Further, documentation must be in place to identify dates on which changes in definition have occurred, and these must be communicated to the individuals analyzing the data (generally, indicator variables are created that “flag” cases for which definitions of an individual variable have changed). The rigor of establishing good definitions is considered distasteful by investigators who are impatient to collect data, but it is essential for successful research. It is also somewhat of an iterative process, which is why we suggest extracting data on the basis of initial definitions for a few patients scattered over the entire time frame of the study, then refining the definitions. One must also be aware of standards developed by national and international groups of cardiac surgeons and cardiologists assembled for this purpose.

Third, data consist of values for variables that have been organized, generally using a database management system, into a database or data set(s) suitable for analysis. There is an essential translation step in going from even organized information into data in a format compatible with the analytic technique to be employed. For example, if one is analyzing survival after a cardiac surgical procedure, one must define “time zero,” construct the interval from time zero to occurrence of the event of interest from date-time data, generate an indicator variable for whether by the end of follow-up a patient has or has not experienced the event, impute values for additional variables if some of the data are known only inexactly, and manage the problem of possible missing values for some of these variables (see Time-Related Events in Section IV). These details will not be part of the medical information system but must be created at the time of analysis (see “Analysis Data Set” later in this section). This is because at the present time and for the foreseeable future, data analysis procedures presume that data will be organized in a fully structured format, generally a relational one (tables with columns for each variable and rows for each separate observation, which may be a single patient or multiple measurements for a single patient). It is our view that the fully structured organization of data, probably in relational database format (see “Relational Information Model” in Section II), should be imposed only at the point of extraction of values for variables from information (often called the “export” phase in a process termed rectangularization). This allows the input of data to be semistructured (see “Semistructured Information Model” in Section II), maximally flexible, and with few imposed organizational constraints (outside of retrievability), so that relations among variables are imposed by the research question being asked and not by a priori database constraints.

INFORMATION TO DATA

An idealized, linearized perspective on the process of transforming clinical information to data suitable for analysis requires three broad steps (see Fig. 6-7): (1) formulating a clinical research proposal that leads to identifying a suitable study group, (2) gathering proposed variables and values that lead to an electronic data set, and (3) manipulating the values and variables to create a data set in a format suitable for analysis. This is a linear process in theory only. In reality, it contains checks that cause the investigator to retrace steps.

Identify Study Group

The clinical research proposal (see Box 6-6) provides detailed specifications for the study group of interest. The medical specification must be translated into a formal query, generally using a query language that will be used to identify patients in the study group. Query engines include the now-familiar Bing and Google, and the search engines of the National Library of Medicine, including PubMed. For data managers familiar with relational databases, the Structured Query Language (SQL) is a universal query language.

It is frequently true that electronic sources of registry data do not narrow the study group as much as desired. This may require investigating a larger group of candidate patients and selecting by medical records review those who meet the study specifications.

If the semistructured information model is adopted (see “Semistructured Information Model” in Section II) as we advocate, then at the present time, experts in query languages specific to this type of information must be consulted. However, because such information is stored in the same format as Web documents, the increasing sophistication, accuracy, and usability of Internet search engine technology will simplify this process.

The end result of a query is identification of a group of patients (or candidate patients) for the study. The major
checks here are whether the patients indeed meet criteria for inclusion and exclusion and whether a sufficient number of patients (or a sufficient number of outcome events, as will be found in subsequent steps; see Box 6-4) are retrieved for a meaningful analysis.

**Extract Values for Variables**

A source, or sources, for obtaining values for the set of variables specified in the clinical research proposal must now be identified for the study group (see Fig. 6-4 and Box 6-6). Currently these are contained either in some electronic format (e.g., hospital information system) or in the paper record.

**Export from Electronic Information Sources**

If some or all the variables specified are in electronic format, sources must be identified and a query made for patients in the study to extract values for the variables. This often time-consuming step is facilitated by three factors. First, at the time the information system is created, procedures can be built in to ease extracting, formatting, and exporting values for variables. This is particularly feasible in a so-called metadata-driven system, in which “data about data” drives not only the data entry process but the data extraction process as well.\(^\text{621}\)

It is also particularly feasible for relational databases that are electronically linked (e.g., portals) to the analysis system. Second, “standard” groups of core data elements can be identified that form the basis for at least a major portion of the variables needed for most studies. The advantage of this strategy is that queries can be assembled carefully and refined over time. Third, successful, accurate ad hoc queries can be stored so that when the same variables are again specified, these queries can be reused.

Often more than one electronic data source must be used. In this case, values for variables in common may need to be adjudicated if they do not match in value or in variable nomenclature. Ultimately, unique variables must be joined into a common database.

**Extract from Medical Records**

Even if the majority of information is available electronically, there are nearly always some variables new to the study that must be gathered from paper records if a CPR is not available. A more arduous process must be put into place for extracting data from original documents.\(^\text{33}\) A precise methodology is necessary for assembling information to prevent repetitious handling of both the patient’s record and the extracted information, as well as to ensure complete and accurate data retrieval while preserving the patient’s privacy and confidentiality.\(^\text{4}\)

All information should be recorded in clearly defined, objective terms. There may be a preference for using descriptive terms that have been clearly defined (e.g., absent, trivial, mild, moderate, severe). Alternatively, numeric coding may be used,\(^\text{367,33}\) with each numeral clearly defined. Pedal pulses, for example, may be recorded as 0, 1, 2, 3, or 4, with 4 indicating normal. Either method is equally rigorous as long as values are picked from a controlled vocabulary.

Accuracy of data entry is improved by recording only primary information (e.g., date of birth, date of operation) and not indices derived or calculated from them (e.g., patient age at operation, body surface area). Such indices can later be calculated quickly and reproducibly by computer. Data should also be coded in a way that is simple and self-documenting (using words or phrases from a constrained list of possible values for a variable, sometimes called “pick lists”).

A key concept is to record core data elements that can be logically combined in multiple ways to form derived variables (see Box 6-8). For example, for analysis one may want to use only the variable “current smoker.” If this were the variable gathered primarily, one would be unable later to derive other data about smoking, such as pack-years, duration of smoking, or when a previous smoker quit. Core data elements would instead relate to dates of smoking and intensity, from which all others could be derived.

The process of gathering data is the most time-consuming step in a study. It is not unusual for it to consume months or years of work. Even if electronic sources of information are used, if values for variables were not entered at the point of care, the expense can be enormous. This is why the CPR, as the repository of all patient data and patient care workflow, is essential to increase the efficiency of clinical research.

For many institutions, identifying patients using a simple registry (e.g., Society of Thoracic Surgeons Database) and extracting more detailed ancillary data for a specific study is the cost-effective method for clinical research. Although review of the medical record in this way is often considered a thankless chore, it has the benefit of an investigator gaining valuable in-depth insight into the patient cohort that is generally not captured by typical “case report forms” or routine registry capture. Indeed, the clinical importance of the research and the clinical inferences and practical recommendations coming from the research are often greatly enhanced by careful review of all or at least a substantial sampling of the medical records.

**Verify Data**

No matter what method of data export or extraction is used, experience dictates that one or more iterative data verification steps must be inserted before any analyses are performed. This process is long and tedious and can be boring. It usually reveals many errors, but it also allows review of each patient’s record to detect missed information. Data are then checked for reasonableness, a process greatly aided by computer. This can be accomplished quite simply by looking at the maximum, minimum, and average of each variable (although sometimes more sophisticated univariable analyses must be done, as described later in this section under Descriptive Data Exploration) by making simple scatter plots of related variables (e.g., age, height, and weight form a smooth scatter plot against one another), cumulative distribution plots of

——

\(^1\)Regulations regarding patient privacy and confidentiality are pertinent to how clinical data can be used for research. Some generalities can be made, however. First, during analysis of data, informative patient identifiers are unnecessary and should be eliminated from the analysis data set. Second, those who must verify data values for medical records, perform patient follow-up, and join disparate databases will need patient identifiers to accomplish these tasks. Because these activities take place within the confines of an institution, it is generally agreed at the present time that use of patient identifiers is appropriate under the purview of an institutional review board (IRB). Third, communication with patients by IRB-approved mailed questionnaires or IRB-approved telephone scripts must begin with obtaining patient consent. Fourth, communication with medical professionals about follow-up status or documentation of events requires patient consent. Fifth, databases should conform to regulatory (Health Insurance Portability and Accountability Act [HIPAA]) standards.
Follow-up

Time-related events occurring after hospital discharge are often extracted opportunistically simply from clinic visit records rather than by systematic patient contact. Patients not appearing for clinic visits are said to be untraced. This is an unacceptable method of follow-up.

Even with systematic methods, however, some patients cannot be traced, and in the United States, privacy and confidentiality regulations are making this task increasingly difficult. It has been demonstrated that untraced adult patients have a high probability of being dead. In contrast, in the UAB experience, untraced infants usually were doing well; their parents, generally young and often highly mobile, have simply dropped contact with the pediatric cardiologist. Either way, a high prevalence of untraced patients potentially introduces bias into the time-related analysis, leading to overestimating or underestimating survival or freedom from other events, and reduces effective sample size.

Follow-up may be active (direct patient contact) or passive (use of government death indices). In either case, most institutions require IRB (ethics committee) approval of the follow-up process, and patient consent at each contact as well.

It is possible that the movement toward IRB reform may remove some of the variability in IRB handling of follow-up studies. In addition, patients, like families, can be invited to consent for follow-up by a centralized group, such as has been employed by the Congenital Heart Surgeons Society. Yet another interesting development is PatientsLikeMe (www.patientslikeme.com), a highly monitored and sophisticated Web-based research site focused primarily on neurologic diseases with moment-to-moment updates of real-world side effects of medications. It is uncertain how representative the sample of patients might be, but it illustrates our experience that with rare exceptions, patients want to be contacted. PatientsLikeMe has found that with rare exceptions, patients want to be contacted by opportunities the sample of patients might be, but it illustrates our experience that with rare exceptions, patients want to be contacted.

Active Follow-up

Active follow-up means that patients or their families are contacted directly by mailed questionnaire, telephone, or electronic means (e-mail, Internet). Active follow-up is essential for discovering time-related events and longitudinal clinical condition, perhaps with the exception of vital status, which may be available from government sources. Active follow-up data, and particularly the date of last active follow-up, must be kept separate from any augmentation of these data from passive sources. If a patient is found to have died, nearest relatives are contacted in a sensitive, sympathetic fashion to document the circumstances of death and ascertain all other pertinent cardiac events that occurred between the date of last active contact and death.

There are two general methods of active follow-up: anniversary and cross-sectional.

Anniversary Method In the anniversary method, the patient is contacted yearly on the anniversary of his or her entry into the study (or periodically if not yearly) or is given a set of forms to send to the investigators on the anniversary of entry. This method is ideal for sampling the time-varying condition of the patient (e.g., functional status, freedom from angina, growth and developmental patterns). It has the added advantage of maintaining yearly contact with the patient, an important consideration in a mobile society. It has also been
demonstrated that nonlethal morbid events such as thromboembolism and hemorrhage after heart valve replacement are forgotten unless there is at least yearly contact.\textsuperscript{B52} Yearly active contact also makes it more likely patients will report events to their physicians during the course of the year.

**Cross-sectional Method** In the cross-sectional method, a specific follow-up inquiry of the patient cohort is initiated on a specific calendar date (called the common closing date), with the goal of obtaining the status of all patients at a specific instant in time. In practice, of course, finite time is necessary to conduct the follow-up. For example, a cross-sectional follow-up may be initiated on August 1 and questionnaires returned over the ensuing 2 months. During this time, telephone calls may be made to nonresponders or those whose questionnaires have been returned as undeliverable.

Two techniques are then used to manage the cross-sectional data. The best method is to choose a common closing date. In the example stated, this would be August 1, the date follow-up began. For this method, the status of the patient, including all events observed, is that as of the common closing date. For patient condition (longitudinal data), a decision must be made about condition as of the closing date. This can be made clear on the follow-up form or via the telephone script. Alternatively, all events reported during follow-up are used, with the date of follow-up taken as the date the questionnaire was signed or the telephone call completed. This method, called date of last report,\textsuperscript{B13} was suggested by the Mayo Clinic group; we do not recommend it.

Note that if a patient responds to the questionnaire but shortly thereafter experiences an event and contacts those performing the follow-up study, the new information is recorded but disregarded. Restriction to initially reported events emphasizes a property of active follow-up: it is systematic. In contrast, any other method, be it physician office visits or voluntary contact, is opportunistic and nonsystematic. The problem with nonsystematic follow-up is that it captures numerators but not the denominator of a patient cohort, so analyses of time-related events are distorted.

**Goodness of Follow-up** In performing active follow-up, particularly in cross-sectional follow-up studies conceived after considerable experience has accumulated, every effort should be made to contact every patient in as short a time as possible.\textsuperscript{B54} Special assistance may be required to achieve a high level of follow-up under these circumstances. In the past, we advised using cross-reference indices to former neighbors or contact of relatives and former physicians, churches, and other agencies.\textsuperscript{B54} However, in the United States this is now prohibited.

There is no perfect way to describe and quantify goodness of follow-up. Traditionally, the mean and standard deviation of follow-up duration, including either all patients or only living patients, are given, as well as total patient-years of follow-up. Various percentiles of follow-up are also useful (see “Descriptive Statistics” later in this section), such as the 10th, 50th, and 90th. Alternatively, the percentage of patients traced beyond certain intervals (e.g., 5, 10, 15 years) may be given. We then recommend stating what percentage of patients have not been traced beyond hospital discharge (lost to follow-up) and how many could not be contacted by active follow-up at the latest inquiry.

Grunkemeier and Starr have described a patient-year method for estimating goodness of follow-up based on observed vs. potential follow-up duration.\textsuperscript{G32} For each patient, the duration of potential follow-up is computed (this is the interval from study entry until death or, for the patient still alive at follow-up, common closing date or response date, anniversary date, or analysis date, depending on the type of follow-up study performed). The measure of goodness of follow-up is the ratio of total observed follow-up duration to total potential follow-up duration.

Neither of these methods of reporting adequately indicates the degree of information lost by incomplete follow-up. The traditional reporting method may be overly optimistic, and the Grunkemeier and Starr method has the same drawback as all patient-year methods in that it reflects loss of information accurately only when the hazard function for the event is reasonably constant. For example, if a patient has been traced for 10 years but has been lost for the past 5 years, the contribution to the goodness of follow-up statistic would be the same as that of five individuals who were lost just after study entry (e.g., after hospital discharge) 1 year ago. If the hazard function is steeply declining in the first year (as it often is), then is very low after 10 to 15 years, the information lost by failure to trace the five recent patients is greater than the information lost by failure to trace further the patient with a follow-up duration of 10 years.

It may be possible to devise a better expression of goodness of follow-up. For example, if a parametric estimate of the cumulative hazard function is made, the difference in potential vs. observed cumulative hazard experienced (expressed as a percentage) may better account for the time-related loss of information. However, the important thing is to expend great effort to obtain complete follow-up information.\textsuperscript{B54} Failure to trace a substantial number of patients, however expressed, makes even the most sophisticated analysis suspect.

**Follow-up Instrument** The follow-up instrument may be a simple questionnaire mailed to the patient (with one or two remailings followed by telephone contacts to nonresponders). If so, it is wise to not exceed a single sheet in length, relying on the telephone or personal contact to obtain more details if events have occurred. Alternatively, the inquiry may be completely by telephone, using well-trained individuals, a script, and a form that is filled out during the conversation.

Patients rarely resent being followed up; to the contrary, periodic follow-up is useful not only in detecting medical trends in individual patients who may need attention, but also in generating good will between the patient and the medical system.

**Passive Follow-up** If vital status is the only outcome of interest, date of death may be obtainable from government vital statistics offices or a death registry. In passive follow-up, only death and date of death (which may be approximate) are identified, not whether each individual in the study is alive or dead at the time of inquiry.\textsuperscript{T1} Usually there is a lag between death and reporting, so methods must be employed to determine the status of living patients at any given time. At Cleveland Clinic, investigators have available a large registry of patients who are actively followed. When passive follow-up is used, patients known by active follow-up to be dead or alive are purposely included. It is then determined when most of these actively followed patients were identified as dead by the passive government death indices. A common closing date is thereby selected for all passively followed patients in the study.
 Manipulate Variables and Values

To interpret patient information meaningfully, an index time for study entry must be established for every patient. The reason is the central place of date-time in medicine. In a system of longitudinal data entry at the time of patient care, past, present, and future are defined in terms of this index time. For surgeons, fortunately, this is often the time of an operative procedure. It is more difficult in medical situations to define, say, onset of disease; often, date of diagnosis or patient encounter is used. Once index time for study entry has been determined, then, using dates for each data element, one can determine if there have been previous events, such as MRIs, how many of these have occurred, and the interval from the most recent to the index time. All items in what we commonly think of as “past medical history” are defined in terms of this index time for study entry.

One of the most common requirements is to compute intervals between dates. For example, the age of a patient at index time is calculated from index time and date of birth. Follow-up intervals are similarly computed from dates. A common error is attempting to manually calculate intervals between dates and index time. This is rarely accurate and should be done by computer.

Indicator variables are always required (an exception is described in Classification Methods in Section VI). These may simply be the translation of a variable whose value has been coded as YES or NO into the numbers 1 and 0, respectively. A cardinal rule to avoid ambiguity, human error, and misinterpretation is that the computer variable name of an indicator variable must always be the one indicated by a YES or 1. Thus, in forming an indicator variable from a primary variable called SEX with values of MALE and FEMALE, one would name the indicator variable MALE with values of 0 for female and 1 for male. An indicator variable called SEX or GROUP is ambiguous and should rarely be used as an analysis variable, because it is not self-documenting.

Another common requirement is to form multiple indicator variables from a single variable containing values from a non-ordered list. These list variables often are represented by a set that allows selection of multiple items from the list. Typical list variables are diagnoses or type of operation. A non-ordered (polytomous) list variable is not interpretable in many types of data analysis (the exception is mutually exclusive lists, for which polytomous methods are useful; see “Polytomous and Ordinal Logistic Regression” in Section IV and Classification Methods in Section VI). Generally, a variable useful for data analysis from such list variables must take on at least one of three values: 0 (NO), 1 (YES), or blank (MISSING). However, in many cases the medical pick list can be so long that in general clinical practice, only positive findings are recorded and all the rest (e.g., thousands of possible diagnoses) “dismissed” (Kirklin called these “dismissal lists”).

When it comes to data analysis, however, we often need indicator variables for all list items that identify more than YES (or 1). Generally, the assumption is made that if a list item is not selected, the patient did not have that condition or procedure. However, it is possible that he or she did, but the list item was added recently and so was not collected at index time; (2) the data abstractor could not find the item, forgot to look for it, or was distracted and did not return to find it; or (3) the item was recorded in a previous clinical record that was not retrieved by the criterion used to gather the electronic data set.

Such ambiguities can be avoided to some extent for a particular discipline by gathering important data elements using individual variables. For example, one may wish to have unambiguous information on the comorbidities diabetes (and its treatment); preoperative dialysis for chronic renal failure; history of prior MI (perhaps with date or a count of the number experienced); history of cerebral vascular accident, carotid artery, and often peripheral arterial disease; chronic pulmonary disease, and the like. Rather than making them items in a long list of variables, create individual variables whose values of YES or NO must be explicitly entered. An alternative is to have multiple missing value indicators, representing by default “not yet found,” but then including the extremes of “pending” and “completely absent,” “don’t know,” “lost chart,” “illegible,” “invalid response,” “refused to answer,” and “not applicable” (e.g., child relation of parent fields to which the answer is NO, or all smoking history variables for a person who never smoked).

Screen and Scrub

As intervals and indicator variables are created, data screening is performed. Negative intervals are found, and dates or times corrected in original sources. Impossible combinations of variables may be found, such as a “normal” aortic valve said to have a 100-mmHg gradient and valve area less than 1 cm². Parent-child relations are verified, particularly if the database has inadvertently not been set up properly to manage such relations. For example, specifying an aortic valve prosthesis should be a child variable of a parent variable for “aortic valve replacement.”

Inconsistencies are reported to the investigation team for resolution, and the iterative process is repeated. This process is often discouraging to the unknowledgeable investigator who assumes that all data (particularly those personally extracted) are flawless.

1In a hierarchical data structure, a parent variable (or node) is one level higher and directly associated with one or more child variables (or nodes). Thus, “duration of smoking” is a child variable to the parent variable “history of smoking.” If history of smoking is positive, then duration is a child node associated with that positive response. Likewise, CABG is a child node of “cardiac procedures,” which itself is a child node of “therapeutic interventions.”
Just as important as improving accuracy of the data set is evaluating the quality of each variable by this screening and scrubbing process. One may find that information is too often unavailable in medical records to trust the variable, and it is dropped. One may also find that interpretation of the clinical condition has been so variable that the values gathered are not reproducible. Either a better surrogate has to be found or the data element must be dropped from further consideration.

If an electronic repository of information is maintained by a research enterprise, it is important that corrections discovered in the information anywhere along the way be fed back to the original database and the data re-exported. In this way, database quality will be constantly improved. Ideally, the change in the primary data will be documented (audit trail).

**Impute Values**

In any study, there are likely to be values that have not been recorded. Most statistical procedures eliminate entire observations (e.g., patients) for which any data requested for analysis are missing. In medical data analysis, however, one is more likely to introduce bias by eliminating all data on an entire patient than by substituting a value for the missing data that can be shown not to importantly bias the analysis. The process is called **missing value imputation**.

Although the literature on managing missing data is extensive, much of it is directed toward survey investigations in which entire survey instruments have not been returned. The general directive for such data is to eliminate records for nonresponders. In clinical research, missing data are most commonly sporadic or systematic (block missing) for some specific time segment (e.g., missing magnetic resonance imaging data before the introduction of that technology). These common types of missing data should be managed in a different way from that of surveys.

**Sporadic Missing Values**

For sporadic values missing in a small proportion of patients, it is reasonable to substitute (impute) the mean value for all patients with non-missing data (called noninformative imputation). Thus, if 5% of patients are missing values for ejection fraction, the mean value is substituted.

If there are at least five outcome events associated with patients having sporadic missing values for a variable, a dichotomous (0,1) missing value indicator is created and forced into all models in which the primary variable is incorporated. If the indicator variable is not statistically significant, it is likely that the imputation has been noninformative with respect to outcome. If it is significant, the indicator variable both adjusts for this and serves as a warning that additional work must be done, such as use of informative imputation.

**Informative imputation** capitalizes on redundancy in medical information. A multivariable equation is generated (see Multivariable Analysis in Section IV) for the variable of interest, but using only patients for whom values are not missing. A value is predicted from this equation for the patient with the value missing, and this is the imputed value. Missing value indicators are just as germane for informative as for noninformative imputation.

Yet another strategy is **multiple imputation**. Briefly, a set of randomly chosen values is used for imputing missing values for each patient and analysis is performed, followed by another set of values and analysis. This process may be repeated as many as 200 to 1000 times, and the many analyses summarized. More commonly, an initial investigation data set is constructed and used for preliminary model building (see Multivariable Analysis in Section IV). This is followed by applying that preliminary model to additional imputed data sets (5 to 10) and aggregating the results.

When to impute missing values by whatever method is chosen turns out to be important: transform, then impute. As noted in “Calibration” under “Risk Factor Identification” in the Section IV discussion titled Multivariable Analysis, the scale of continuous variables may have to be transformed to meet model assumptions (linearizing transformations). It is important that transformations first be performed, followed by missing value imputation, as documented by von Hippel.

**Systematic Missing Values**

Systematic missing values occur under two conditions that can be managed similarly. First, a value may be inapplicable. For example, in a study of mitral valve surgery, values for various repair techniques are inapplicable to patients receiving a prosthesis. Second, some test may come into use part way (in calendar time) through a study, or information may not have been collected about some variable until a certain calendar date. For such patients, we suggest that the missing data be managed as “interaction terms.” By this we mean that systematic missing values be set to zero (0). Then a missing value indicator is generated—1 for patients with systematic missing values and 0 otherwise. Both variables are linked in all analyses. This makes interpretation of the models realistic, although it is a strategy that is computationally close to noninformative missing value imputation. A drawback is that the missing value indicator may become an unrecognized surrogate for temporal trends in the data if the block missing data are concentrated among patients early in the study.

**Organize Variables for Analysis**

Once the aforementioned steps have been achieved, often iteratively, the result is a final data set in the format needed for analysis. However, one further step remains: organizing variables deemed suitable for analysis in a medically meaningful way. The reason for this is the importance we place on informed data analysis. Those analyzing the data must “know the data” just as the investigator knows the data. Not every variable has equal importance for analysis. For example, quantitative ejection fraction is “better data” than a qualitative assessment of left ventricular function on a coarsely graded scale; creatinine level at surgery contains more data than a diagnosis of renal failure; individual components of leaflet morphology in atrioventricular septal defect contain higher information content than Rastelli type.

Not every variable is of equal reliability, but medical information tends to be redundant, so more reliable surrogates should be sought and analyzed. Many variables are highly correlated and may be of equal reliability, such as height, weight, body surface area, and body mass index (indeed, the latter two are calculated from the former two). Therefore, if such variables are equally associated with an outcome, one may arbitrarily select the most reliable or easily measured representative of that concept (in this example, body size).

The data management team, in collaboration with the investigator, must then compile a final list of analyzable variables. These should be grouped in a medically meaningful fashion that aids informal data analysis. A suggested
grouping might be as follows, although it will vary from study to study:

- Demographics (age, sex, socioeconomic position, size)
- Symptoms (functional status, angina class)
- Ventricular function (ejection fraction, number of previous MIs, interval from last infarction to surgery)
- Pathophysiology and etiology (grade of mitral valve regurgitation, etiology of valvar regurgitation)
- Coronary artery anatomy and disease (degree of left main disease and that of each coronary system, dominance)
- Other cardiac comorbidity (previous cardiac operations, atrial fibrillation)
- Noncardiac comorbidity (smoking history, creatinine, pulmonary disease, diabetes, albumin level)
- Preoperative management (preoperative intraaortic balloon counterpulsation for hemodynamic instability, intravenous nitroglycerin and heparin for unstable angina)
- Cardiac procedure (coronary artery bypass grafting, bilateral internal thoracic artery grafts, quadrangular resection of mitral valve)
- Support techniques (duration of aortic clamping, use of warm substrate-enhanced induction cardioplegia, duration of circulatory arrest)
- Experience (date of operation, surgeon)
- Outcome, in-hospital events (length of postoperative stay, occurrence of various complications, hospital death)
- Outcome, time-related events (all-cause mortality, interval from surgery to death or censoring)
- Longitudinal data (echocardiographic findings after valve operations, NYHA functional class)
- Missing value indicator variables
- Interaction terms (organized according to above schema)

A practical way to implement this organizational structure is to isolate programming code in the form of a computer macro that contains the list of available variables for analysis and a place for those analyzing the data to insert code for imputing missing values, transforming the scale of variables, forming additional indicator variables, and performing other useful data manipulations. This strategy guards against human error in data analysis by isolating to a single location all data manipulation useful for all analyses.

DESCRIPTIVE DATA EXPLORATION

After the analysis data set has been constructed, data are explored by producing simple descriptive tables (sorting and tallying) and simple statistics about continuous variables, scatter plots of variables, and other exploratory data analyses. To understand this process, some appreciation of numeric data is necessary.

Numbers

Accuracy and Precision

Because both calculators and computers express numbers to many digits (Box 6-9), it is necessary to know a set of rules for compaction and expression (display) of numeric data. The format in which a numeric value is expressed has implications. The number 493, for example, implies that the \textit{truth} is somewhere between 492.5 and 493.5 (accuracy), and that the scatter in repeated measurements of the number (precision) is no greater than that explicitly expressed (Box 6-10). The number 492.8 implies that the result is somewhere between 492.75 and 492.85, and 492.76 implies that the result is somewhere between 492.755 and 492.765. This last numeral to the right (right-most digit) explicitly indicates that the accuracy is much greater and the precision much less than when the number is 493.

Rounding

In computation and computer storage, all available digits of numbers displayed or recorded by measuring devices should be retained. It is only at the last step of numeric presentation that numbers are rounded (Box 6-11). In presenting numeric information, numbers should be rounded in such a way as to reflect their precision or reproducibility, although consistency within tables is also important.

Tabular Presentation

Numbers are often presented in tabular form that indicates distribution of data between the extremes of a continuous variable (e.g., patient age). Such tables should be prepared so that positioning of any point along the continuous variable can be unambiguously determined. In this text, intervals between extremes of a continuous variable are indicated by symbols of inequality (Table 6-7). This method of presentation of tabular information is mathematically conventional (Box 6-12) but not conventional for medical publications, where ambiguity often abounds.

Descriptive Statistics

Descriptive statistics are numbers used to summarize values for a specific variable recorded for a group of patients (sample; nomenclature is given in Box 6-13), such as age, presence or absence of coronary artery disease, and NYHA functional class. Variables fall into two broad categories for which different methods and expression of summarization are appropriate: (1) \textit{categorical} and (2) \textit{continuous}.

Categorical variables take on a small number of values. If they take on just two (e.g., YES, NO), they are called \textit{dichotomous} variables. If they have values that are ordered (e.g., none, mild, moderate, severe), they are called \textit{ordinal} variables. If they are just a list (e.g., type of valve prosthesis), they are called \textit{polytomous} variables.

Continuous variables take on a theoretically limitless number of values, although these values may have natural constraints (e.g., age, which cannot be negative). Their degree of granularity may vary (e.g., age may be calculated in whole years in adults, but in days or even hours [higher granularity] in neonates).

Categorical Variables

Dichotomous

Descriptive statistics for dichotomous categorical variables include simple counts (i.e., a count of the number of times the variable was YES [or 1] or NO [or 0]): How many cases were performed? How many men and women were in the study? How many patients died after operation? Summary counts are of limited value, however, because they do not reflect the size of the sample. Therefore, a summary statistic can be formulated that normalizes the counts to a standard denominator, commonly 100 (percent). This is a probability parameter estimate, so it not only reflects
Accuracy versus Precision

**Accuracy**
Absence of systematic error of measurement (bias) from the “truth.” It is an expression of “rightness.”

**Precision**
Ability to provide the same answer in repeated measurements. It is an expression of “exactness.”

These terms are often interchanged, but in data analysis they are not synonymous. Repeated measurements of PO2 in a blood gas machine may have a great deal of scatter on repeated readings (imprecise), but their average value may reflect faithfully the true PO2 (accurate). Another blood gas machine may yield PO2 with little scatter in repeat readings (precise), but may be uncalibrated, so the readings are inaccurate (biased). There is often a trade-off between accuracy and precision in medical measuring instruments.

Another way to express this number is as the sum of 4 + 30 + 200 + 1,000.

To the right of the decimal point, the first place is called the tenths (1/10) place, the second the hundredths (1/100) place, and the third the thousandths (1/1000) place. Thus, in 0.1234, the 4 is in the tenths place, 3 in the hundredths place, 2 in the thousandths place, and 1 in the ten-thousandths place. Another way to express this number is as the sum of 0.0004 + 0.02 + 0.1.

**Decimal Place**
In the decimal system, decimal place is the position of digits immediately to the right of the symbol designating the decimal point. Location of the decimal point reflects the scale of measurement and is unrelated to significant digits.

**Significant Digit**
Digits of the decimal form of a number beginning with the leftmost nonzero digit and extending to the right, with the implicit implication that all digits to the right are significant digits. That is, they are warranted either by inherent properties of the measuring device used to generate the numbers or by statistical properties of a collection of such numbers.

**Scientific Notation**
A method of expressing (displaying) numbers from 1 to 9, followed by a decimal point, the remaining significant digits, if any, multiplied by a power of 10. For example, 0.00037 in scientific notation is $3.7 \times 10^{-4}$, where $10^{-4} = 0.0001$. In general, the numeric value, here 3.7, is called the mantissa, 10 is called the radix, and $-4$ is called the exponent.

**Leading Zero**
Zero placed before a decimal point that is not considered a significant digit. It is generally used (1) when it is implied that a nonzero significant digit could replace it, or (2) to separate a negative sign (−), a positive sign (+), or a plus or minus sign (±) from the decimal point. Increasingly, numbers that are constrained to the range 0 to 1, such as probabilities (including $P$ values), are expressed (displayed) without a leading zero.
**Box 6-11 Rounding Numbers**

Certain generally agreed-upon conventions for rounding numbers exist, although they are not easily found in print.

**Step 1: Determine the Number of Digits to Save**

This is suggested by precision of the measuring instrument for individual numbers and by the standard error of the mean value or proportion associated with a series of numbers (see Box 6-12). For the latter, the place of the first significant digit of the standard error is found, and the mean or proportion is then rounded to that place. The same place is saved in confidence limits. If the standard error is also being expressed, one additional place is saved in it (because the usual expression of the standard error is a form of shorthand, and saving the extra place helps in using the standard error to calculate confidence limits).

**Step 2: Look for Exceptions**

Exceptions to Step 1 are as follows: (1) if the first significant digit of the standard error is 1, then one additional place may be saved; (2) for percentages with a floor of 0% and ceiling of 100%, if the percentage is between 0% and 10% or between 90% and 100%, keep at least 2 significant digits; and (3) within a single contingency table, consistency in saving digits is desirable, so all numbers may be rounded to the place indicated by the majority of the numbers. In medical data, two significant digits (see Box 6-9) usually suffice.

**Step 3: Round**

Round the number by removing digits from its right side that falsely suggest a high degree of precision or accuracy. This is done as follows:

- If the digit in the first place beyond (to the right of) the digit to be rounded is greater than 5, add 1 to the right-most digit to be retained and drop all other digits to its right. This is called “rounding up.”
- If the digit in the first place beyond the digit to be rounded is less than 5, simply drop it and all other digits to its right. This is called “rounding down.”
- If the digit in the first place beyond the digit to be rounded is exactly 500 … 0, add 1 to the rightmost digit to be retained if the last significant digit is odd (i.e., 1, 3, 5, 7, 9), and leave the digit to be rounded as is if it is even (i.e., 0, 2, 4, 6, 8). This rule results after rounding in a rightmost digit that is always an even number.

---

**Table 6-7 Use of Symbols of Inequality: Illustration with \( P \) Values and Their Interpretation**

<table>
<thead>
<tr>
<th>( P )</th>
<th>Interpretation of Null Hypothesis</th>
<th>Inferences About the Difference</th>
</tr>
</thead>
<tbody>
<tr>
<td>.05</td>
<td>Almost certainly not true</td>
<td>Unlikely to be due to chance</td>
</tr>
<tr>
<td>.05</td>
<td>.1</td>
<td>Probably not true</td>
</tr>
<tr>
<td>.2</td>
<td>Possibly not true</td>
<td>Possibly not due to chance</td>
</tr>
<tr>
<td>.2</td>
<td>Nearly certainly true</td>
<td>Likely to be due to chance</td>
</tr>
</tbody>
</table>

*Each \( P \) value can be unambiguously located in one of the four lines of the table. The top line contains all \( P \) values less than .05. The fourth, or bottom, line contains all \( P \) values greater than or equal to .2. The second line embraces all \( P \) values greater than or equal to .05 but less than .1. A small sample size also could account for this \( P \) value.

---

**Box 6-12 Inequalities**

- Less than; \( 3 < 4 \) means “3 is less than 4.”
- Greater than; \( 5 > 3 \) means “5 is greater than 3.”
- Less than or equal to; systolic blood pressure \( \leq 130 \) means systolic pressure is “less than or equal to 130.”
- Greater than or equal to; diastolic blood pressure \( \geq 80 \) means diastolic pressure is “greater than or equal to 80.”

**30 \( \leq x < 40 \)**

The number represented by \( x \) is greater than or equal to 30 (i.e., 30 is less than or equal to \( x \)) but is less than 40. Note that \( x \) is strictly less than 40 (39.999...), not exactly equal to 40. This statement is unambiguous, whereas the statement that “\( x \) is between 30 and 40” is ambiguous because it is unclear whether 30 or 40 (or both) is included by the word *between*.

---

the counts represent mutually exclusive categories. A list of types of prosthesis used is likely to be mutually exclusive (a patient can fall into only one category), but a table of complications is unlikely to be so (a patient can experience more than one complication). In presenting lists, all categories should be represented, including number of missing values and whether some categories have been coalesced (e.g., under “other”).

List variables are often useful for analysis if they are mutually exclusive (see “Polytomous and Ordinal Logistic Regression” in Section IV). Otherwise, the list should be decomposed into a set of dichotomous variables for each category.

**Continuous Variables**

The other broad category of variables is continuous, for which each patient in a study (sample) may have a different value (e.g., age, weight, ejection fraction). Thus, the raw data are rarely published, because each patient or subject in a study is likely to be unique in regard to continuous variables, making any tabular presentation unwieldy unless the number of patients and number of variables are small. Summarizing statements may be made of the raw data by one of several techniques.

A commonly used summarization of raw data is a simple table with patients grouped into “nice” ordered categories. A histogram is a plot of such a table (see Fig. 6-9, A). Another method of constructing a simple table is to sort patients into several groups of equal number, even if the width of the range of values in each group is different. Because the number of such groups was originally 10, these are called *decile tables*.

Yet another alternative is to divide patients into *percentiles*, stating the value of the variable at these percentiles as follows. Patients or subjects are first sorted by (generally) increasing magnitude of the variable under consideration (e.g., by increasing age). Then the number (or more commonly the proportion) of patients with values less than or equal to each value is calculated. For example, if there are 21 patients and each is a different age at operation, patients are first sorted.
Box 6-13  Words

Piantadosi, Kirklin, and Blackstone provided a glossary of statistical terms in the first edition of Pearson and colleagues' Thoracic Surgery.13

**Population**
The entire set of things with specified attributes. For example, the population of patients with ischemic heart disease encompasses everybody with that disease, not only at the present time, but anyone in the past or future.

**Sample**
One or more things with specific attributes belonging to a population. Thus, my next patient, or a group of patients I have operated on with ischemic heart disease, represents a sample of the population of such individuals.

**Proportion**
A proportion is a part compared with the whole. Specifically, it is the number having some attribute value of interest, divided by the number in the sample. Ten deaths among 30 patients is a proportion of 0.3.

**Percent**
Percent is a part compared with the whole, normalized to a sample size of 100. It is calculated by multiplying a proportion by 100.

**Parameter**
A constant used to characterize some attribute of a population. One generally uses a sample of patients to estimate such constants. These constants are commonly (but not always) designated by letters or symbols in mathematical equations called models (see Box 6-5).

**Variable**
An attribute about a thing that can take on different values from one thing to another. For example, systolic blood pressure is a variable because its value differs from patient to patient. The word *parameter* is often used incorrectly when the word *variable* is meant.

**Prevalence, Incidence, Rate**
*Prevalence*, *incidence*, and *rate* are often used interchangeably. Perhaps common usage should prevail (it rarely leads to confusion), but from the standpoint of correct usage, these are not interchangeable terms. We prefer selecting the specific word whose technical definition matches the context.

**Prevalence**
Frequency of occurrence of some factor, characteristic, event, or incident in a group. Of the three words being considered, it is the least commonly used but the most commonly meant! For example, if 78% of patients are men, the prevalence of males in the sample is 78%; we would not use the phrase, “The incidence of males was….“ Similarly, hospital mortality may be 1%. That is the *prevalence*, or occurrence, of hospital mortality. We would not use the phrase, “Hospital mortality rate was…“ or “Incidence of hospital mortality was….“ The word *occurrence* is often a suitable substitute for *prevalence*.

**Incidence**
Frequency of occurrence *per unit of time*. It is expressed on a scale of inverse time (cases per year, deaths per year) or *rate* of occurrence. The prevalence of mortality across time is expressed as survival; the incidence of mortality is expressed by the hazard function.

**Rate**
Quantity per unit time. Speed is a rate: km · h⁻¹; cardiac output is a blood flow rate: L · min⁻¹. In the context of events, *rate* is synonymous with *incidence*. The hazard function is a rate (mortality · year⁻¹) and incidence.

How, then, can we rephrase such common expressions as the following?
- Incidence of hospital mortality was…
- Hospital mortality rate was…
- Five-year survival rate was…

We could write “Prevalence of hospital mortality was…..” However, in most instances, the words *prevalence*, *incidence*, and *rate* are superfluous. It is better to just write “Hospital mortality was…..” or “Five-year survival was…..”

Box 6-14  Parametric versus Nonparametric

**Nonparametric**
A statistical method that summarizes data in specific ways and by specific procedures that do not use either an empirical or biomathematical model (see Box 6-5). A median value in the distribution of values for age is a nonparametric estimate. Kaplan-Meier survival estimates are nonparametric estimates.

**Parametric**
A statistical method that summarizes data in terms of either an empirical or biomathematical model (see Box 6-5). Numeric estimates of the constants in these models are called *parameter estimates*. Coefficients of a regression equation are parameters (see Box 6-5), as are mean and standard deviation.

**Parameter Estimates**
Parameters in mathematical models (see Box 6-5) are placeholders for numeric values. When the parameters take on specific values, the model becomes an *equation* that can be solved—for example, for an individual patient’s risk. These numeric values are called *parameter estimates*. They are *estimates* because they are based on a finite sample of data. Just as a mean value (a parameter estimate) is associated with uncertainty proportional to both the standard duration (another parameter estimate) and effective sample size, so any parameter estimate is associated with uncertainty.

Parameter values are estimated by means of statistical theory and procedures. The estimation process may be complex or as simple as counting and dividing.
from youngest to oldest. No patient is younger than the youngest one (0/21, 0%, or minimum); 1/21 are as young or younger than the youngest (4.8%), and for these data, this is also the 5th percentile; 2/21 (9.5%) are as young or younger than the second youngest patient, and this is also the 10th percentile. The middle value of age, that of the 11th patient in this list, is called the median or 50th percentile. All (21/21, 100%) are as young or younger than the oldest. A cumulative distribution plot, produced easily by computer but laboriously by hand, presents all the raw data in this percentile format (see Fig. 6-9, B).

Alternatively (and more commonly), a value is found below which a stated proportion of patients have that value or a lesser one (100 times that proportion is the percentile). For example, the median is the 50th percentile. This means that half the patients have a value for the continuous variable below the median, and half have values greater. For consistency, one might also state the 15th and 85th percentiles, as they correspond to 70% confidence limits (CLs; see “Confidence Limits [Intervals]” in Section IV). More commonly, 25th and 75th percentiles (quartiles) or 10th and 90th percentiles are used, which summarize the middle 50% of data.

This method of summarizing data is called nonparametric (see Box 6-14). Beyond such simple counting (percentages and percentiles), more abstract methods are often brought into play to describe continuous data. The methods have in common a process whereby raw data on a sample of patients are used to estimate values of parameters of mathematical equations. The most familiar of these is the arithmetic average, or mean, which is estimated as the summation of all values of the continuous variable (e.g., age, pulmonary artery pressure) divided by the number of people or observations (n). The rationale for using the arithmetic average is that it provides an estimate of the central tendency of the data and a characteristic of the population studied. If the data are distributed perfectly symmetrically in the form of a bell-shaped curve, the arithmetic average is exactly at the midpoint of the data range (Fig. 6-10). It is also the most frequently occurring number (mode), with half the patients above it and half below (median).

The derivation of averages, or means, was begun by astronomers centuries ago. They thought that the scatter in their data was from observational error or imprecision, and they used means, or averages, in an attempt to obtain true values (accuracy). Later, Gauss discussed and described the normal distribution curve, which is estimated as the summation of all values of the continuous variable (e.g., age, pulmonary artery pressure) divided by the number of people or observations (n). The rationale for using the arithmetic average is that it provides an estimate of the central tendency of the data and a characteristic of the population studied. If the data are distributed perfectly symmetrically in the form of a bell-shaped curve, the arithmetic average is exactly at the midpoint of the data range (Fig. 6-10). It is also the most frequently occurring number (mode), with half the patients above it and half below (median).

The mean is the easiest statistic to calculate. Unfortunately, it is not a robust measure of central tendency. If many infants and only one or two adults are in a study, average age is greatly exaggerated by the few adults. A more robust measure of central tendency is the median. Whether or not the sample data are distributed in a Gaussian-type bell-shaped curve (see Fig. 6-10 and Box 6-15) may be tested by such statistics as the Shapiro-Wilk W statistic for small n (e.g., 50 or less) and the Kolmogorov-Smirnov D statistic for larger samples. The skewness of the data (rightward or leftward asymmetric tail) and their kurtosis (unusual peakedness of the distribution of values) are also tested.

Thus, in addition to an estimation of the population mean, some measure of dispersion (variance, spread, scatter) of values is needed. One such measure is the standard deviation, the name of the second parameter of the Gaussian distribution equation (see Box 6-15). It refers to variability from subject to subject or variability of individuals within the sample and is used to determine whether an individual is “within limits of normal.” Standard deviation is necessary for comparison statistics. For example, an individual’s standard deviation from the mean regarding a particular measured variable (commonly called z) is often useful. This is calculated from the difference between the measurement for the individual and the mean normal value divided by the standard deviation. A z may be negative or positive and has no units (see “Standardization of Dimensions” under Dimensions of Normal Cardiac and Great Artery Pathways in Chapter 1).

Standard error is a measure of the reliability with which the population mean is estimated from the sample mean, and it is needed for comparing one group with another. It is more appropriately (but infrequently) called the standard deviation.
### Box 6-15 Gaussian Distribution

The equation of the bell-shaped Gaussian (normal) distribution curve is:

\[
y = \frac{1}{\sigma \sqrt{2\pi}} e^{\frac{-(x-\mu)^2}{2\sigma^2}}
\]

where:
- \( \pi \) is a constant, approximately 3.1415927…, pi
- \( e \) is a constant, approximately 2.7183…, the base of the natural logarithms
- \( \sigma \) is a parameter that represents the standard deviation of the variable
- \( \mu \) is a parameter that represents the mean of the variable \( x \)
- \( y \) represents the probability of occurrence of a particular value of \( x \)

Because in medicine normal has several unrelated meanings, we have used the more technical term Gaussian.

#### Standard Deviation versus Standard Error

Standard deviation is the Gaussian distribution parameter representing the scatter or deviation of individual values from the mean. It is a descriptive statistic, the inflection point of the Gaussian distribution (see Fig. 6-10, B).

Standard error is the standard deviation of the mean, an estimate of the precision of the mean (see Box 6-15). Unlike the standard deviation, which is similar in value for large and small samples of data, the standard error decreases as approximately the square root of \( n \) increases.

Because the Gaussian curve is symmetric around the mean, the two parameters of the Gaussian distribution are expressed by the shorthand mean \( \pm SD \), where SD is 1 standard deviation. This means 68.3% of values for patient age fall between (mean – SD) and (mean + SD). This is one instance, not common in statistics, where the shorthand \( \pm \) is used instead of confidence limits (see Box 6-16).

---

of the mean and is obtained simply by dividing the standard deviation by the square root of \( n \) (see Box 6-15).

Other methods are available for summarizing skewed data. One is to resort to a purely nonparametric (i.e., without equations, coefficients) description (e.g., using the median and its various percentiles). Another is to transform the data into a more normally distributed variable. For example, a logarithmic transformation is often useful; the resultant mean is called the geometric mean.

---

### Section IV Analyses

**HISTORICAL NOTE**

Analysis, as expressed by Sir Isaac Newton, is that part of an inductive scientific process whereby a small part of nature (a phenomenon) is examined in the light of observations (data) so that inferences can be drawn that help explain some aspect of the workings of nature.

Philosophies underpinning methods of data analysis have evolved rapidly since the latter part of the 19th century and may be at an important crossroad. Stimulated in large part by the findings of his cousin Charles Darwin, Sir Francis Galton, along with Karl Pearson and Francis Edgeworth, established at that time what has come to be known as biostatistics. Because of the Darwinian link, much of their thinking was directed toward an empirical study of genetic versus environmental influence on biological development. It stimulated development of the field of eugenics (human breeding) and the study of mental and even criminal characteristics of humans as they relate to physical characteristics (profiling). The outbreak of World War I led to development of statistics related to quality control. Sir Ronald Fisher formalized a methodological approach to experimentation, including randomized designs. The varying milieu of development led to several competing schools of thought within statistics, such as frequentist and Bayesian, with different languages and different methods. Formalization of the discipline occurred, and whatever the flavor of statistics, it came to dominate the analytic phase of inferential data analysis, perhaps because of its empirical approach and lack of underlying mechanistic assumptions.

Simultaneously, the discipline of biomathematics arose, stimulated in particular by the need to understand the growth of organisms (allometric growth) and populations in a quantitative fashion. Biomathematicians specifically attempt to develop mathematical models of natural phenomena such as clearance of pharmaceuticals, enzyme kinetics, and blood flow dynamics. These continue to be important today in understanding such altered physiology as cavopulmonary shunt flow. Many of the biomathematical models came to compete with statistical models for distribution of values for variables, such as the distribution of times to an event.

Advent of the fast Fourier transform in the mid-1960s led to important medical advances in filtering signal from noise and image processing. The impetus for this development came largely from the communications industry, so only a few noticed that concepts in communication theory coincided with those in statistics and mathematics.

As business use of computers expanded, and more recently as genomic data became voluminous, computer scientists developed methods for examining large stores of data (see footnote 1, p. 253). These included data mining in business and computational biology and bioinformatics in the life sciences. Problems of classification (e.g., of addresses for automating postal services) led to such tools as neural networks, which have been superseded in recent years by an entire discipline of machine learning.

In the past quarter century, all these disciplines of mathematics, computer science, information modeling, and digital signal processing have been vying for a place in the analytic phase of clinical research that in the past has largely been dominated by biostatistics. Specifically, advanced statistics and algorithmic data analysis have conquered the huge inductive inference problem of disparity between number of parameters to be estimated and number of subjects (e.g., in genetics, hundreds of thousands of variables for \( n = 1 \)). Advanced high-order computer reasoning and logic have taken the Aristotelian deterministic approach to a level that allows intelligent agents to connect genotype with phenotype. It may be rational to believe that the power of these two divergent approaches to science can be combined in such a way that very “black box” but highly predictive methods can be explored by intelligent agents.
report the logical reasons for a black-box prediction.31 Fortunately for those of us in cardiac surgery, we need not be threatened by these alternative voices, but rather can seize the opportunity to discover how each can help us understand the phenomena in which we are interested.

OVERVIEW

This section highlights (1) the important statistical concept of dealing with uncertainty, illustrating it with CLs and P values, (2) the increasingly important signal processing concept, multivariable analysis, illustrating it with logistic regression of early postoperative events; and (3) analysis of time-related and longitudinal events, which we present in terms of biomathematical concepts. In Section VI, other specialized methods are highlighted, including some that are only peripherally related to serious clinical research but importantly affect cardiac surgeons.

UNCERTAINTY

Publication of an experience with mitral valve repair in 438 patients, among whom 8 (1.8%) died in the hospital, is in isolation a record of past achievement. Assuming honest reporting, there is no uncertainty about this result, but in and of itself, except for inviting applause or criticism, it has only historical value. Yet most persons expect past experience to be useful in predicting what can be accomplished in the present or the future, or in comparing outcome with that of other surgical options or continued medical therapy (see “Nihilism versus Predictability” in Section I). That is, they recognize the future is uncertain, but they are not nihilists; they assume there is continuity in nature (see “Continuity versus Discontinuity in Nature” in Section I). There are well-tested theories and methods that quantify the uncertainty of inferring from the past the probable results in the future (assuming nothing changes), expressed as a degree of uncertainty. Quantifying the degree of uncertainty is a major part of making results of past experience truly useful.

Point Estimates

Point estimates usually represent the central tendency of a set of numbers that describe the characteristics or state of a sample (e.g., group of patients). The previously mentioned 1.8% hospital mortality is a point estimate. So are the mean value of age in a group of patients and percent survival (survivorship) 1 or 20 years after an operation.

Such numbers are generally derived from a study of a sample (see Box 6-13) of all members of a population (e.g., everyone everywhere undergoing mitral valve repair). Yet the clinical study is nearly always performed to generalize beyond the sample examined.

Generalizing from a sample to the population is fraught with uncertainty. For example, recorded, unrecorded, or unrecognized patient characteristics may occur at a different frequency in the sample than in the population (including your future patients). Surgeons use expert clinical judgment in decision making, and this introduces selection bias into the sample. There is well-recognized variance in institutional policies, processes, procedures, skill, and experience that influences outcome in ways that are difficult to dissect and confounded inextricably with both outcomes and interpretation of outcomes. These all suggest that inferences from sample point estimates alone are unlikely to be predictive of results in either the population or future samples.

Despite this admonition over the past quarter century, we have observed fewer and fewer cardiac surgery publications that accompany point estimates with a measure of uncertainty. Although it is speculation, the cause may be in part the complexity of programming the present generation of advanced programmable calculators and handheld computers to generate CLs “on the fly” as one reads journal articles.

Confidence Limits (Intervals)

CLs, the extremes of a confidence interval (Box 6-16), are the fundamental statistics that quantify the uncertainty of point estimates. It is not the underlying data that are uncertain (e.g., how many hospital deaths occurred in a well-defined group of patients), but inferences about the future based on known data from the past.

For example, if there was one hospital death in three operations for postinfarction VSD, the proportion of hospital deaths (hospital mortality) was 0.33 (1/3, 33% hospital mortality). This was the mortality in that experience, looking at it solely as a record of achievement. Likewise, if 10 deaths occurred among 30 such operations, or 100 occurred among 300, the mortality was also 33%. Intuitively, there would be more confidence that the risk in an entire population, not just in the small sample studied, was near 33% on the basis of the experience with 300 operations than on the basis of three operations. Yet, also intuitively, one suspects something has been learned about the risk in an entire population from only three operations. For example, the true risk cannot be exactly 0% or exactly 100%.

Historical Development

The questions “What is the risk of repair of postinfarction VSD in general?” and “Is risk with the method of repair I used higher or lower than that with the method another surgeon is using?” are similar to questions put to Galileo about the nature of chance, and particularly games of chance, by 17th-century gamblers.33,34 From those questions emerged the Laws of Chance, now known as the theory of probability.33 These laws are believed to apply to all things that can have more than one possible result; things with exactly one result are the limiting case of this theory, having a probability equal to 1, or certainty. More and more scientists believe that all natural phenomena, including those of the physical world, behave in accordance with the theory of probability.37,39

Box 6-16 Confidence Limits, Confidence Intervals

Confidence Limits

Numbers at the two extremes of an interval that encompasses a stated percentage of the variability of a point estimate. In this book, we use confidence limits (CL) rather than confidence intervals (CI) to avoid confusion with cardiac index (CI), a familiar abbreviation used by cardiac surgeons.

Confidence Interval

Interval encompassing a stated percentage of the variability of a point estimate.
Events and phenomena of cardiac surgery can also be considered to behave in accordance with this theory.

Galileo showed that there is variability in sample point estimates. To illustrate, if the risk of death in the entire population of patients undergoing repair of postinfarction VSD by a given method is 33%, and samples of 3 patients are taken repeatedly, 0 deaths among the 3 would be experienced in 30% of samples, 1 death in 44% of samples, 2 deaths in 22% of samples, and 3 deaths in 4% of samples. In larger samples, results are less variable. For example, with samples of size 300, although the number of deaths experienced may still be quite variable, the proportion dying will be 30% to 36% in 70% of samples taken.

Because of this random variability in the sample estimates of risk, it is impossible to estimate the population parameter (see Box 6-13) with certainty (i.e., to know the risk in the entire population) from sample information. However, the pattern of variability in repeated sampling is well understood, and in most situations it is possible to derive a formula to calculate the range of values that would contain the parameter for a specified percentage (e.g., 70%) of samples taken.

Users of CLs should be aware that this range of values for all proportions except 0.5 (50%) is asymmetric, in contrast to standard deviations, which are symmetric. Thus, we must report both the point estimate (probability) and lower and upper CLs.

As the sample size increases and more information becomes available, width of the confidence interval decreases (i.e., a more precise estimate is obtained). With a more precise estimate, the investigator is less uncertain where the population parameter lies, or in other words, what the “true” risk is. With a less precise estimate, the investigator is more uncertain.

### Computational Methods

A number of methods have been developed to calculate CLs for proportions. Bootstrapping is a generalized method for obtaining CLs for any statistic. The original sample of data is randomly sampled in such a way that the patient can be sampled again (sampled with replacement) and form a data set equal in size to the original. Because of replacement, some patients will appear more than once in this bootstrap sample, and others will not appear at all. The point estimate (e.g., hospital mortality) is estimated in this sample. Then another sample is drawn in the same fashion, and this process is repeated as many as 1000 times. All the point estimates from each sample are sorted from smallest to largest, as in forming a cumulative frequency distribution (see Descriptive Data Exploration in Section III). The “best” estimate of the point estimate is the median value (50% above and 50% below). If 70% CLs are desired, then the 15th percentile is the lower CL and the 85th percentile is the upper limit (if 68.3% limits are desired, the numbers would be approximately the 16th and 84th percentiles). Approximating formulae are used in most statistical packages.

### What Level of Confidence?

Any desired CL can be derived, such as 50%, 70%, 90%, 95%, or 97.5%. Choice of CLs to be expressed (called the confidence coefficient) depends on (1) use to be made of them, (2) consistency, or (3) convention, in that order of preference.

Most often in cardiac surgery, CLs are used as scanning tools to aid predictions and comparisons, either of proportions or time-related depictions (see “Scanning Tool” later in this section). If great certainty is desired in the inference that there is a difference between two proportions of time-related depictions, 95% confidence intervals may be chosen for the comparisons. If only moderate certainty is required that the evident difference is a true difference and would be found in larger samples, 50% confidence intervals might be chosen.

Most situations in cardiac surgery seem to lie somewhere between these extremes, so use of 70% CLs for most comparisons is reasonable. The interval is relatively narrow (specific), and although it is reasonably certain that lies within the CLs, there is a 15% chance it will be higher and a 15% chance it will be lower.

Seventy-percent CLs (actually 68.3%) are equivalent to 1 standard deviation (SD), and 95% CLs are consistent with 2 SDs. For consistency, if other numeric estimates are presented to 1 SD, 70% CLs should be used, and if 2 SDs are presented, 95% CLs should be used. We emphasize consistency because we believe surgeons should become familiar with using CLs as a scanning tool; to use a tool effectively, it is helpful to be consistent among all measures of uncertainty. Conventionally, many statisticians use 95% CLs, even in the context of using 1 SD for most everything else, and 50% limits for nonparametric statistics. This makes no sense and is simply a habit, not a product of reflective thinking about the inferences or about consistency.

In numeric presentation of differences, such as difference in survival curves (see Box 6-3), 90% CLs are equivalent in comparative inference to individual 70% CLs, a largely empirical finding. The reason is that a one-sided confidence interval of a difference between two estimates is narrower than the sum of the 70% upper and lower CLs that just touch. This narrowness is compensated for by use of somewhat wider CLs (90%) of the difference.

### Scanning Tool

Overlapping or nonoverlapping of CLs around two or more point estimates can be used as a simple and intuitive scanning method for determining whether the difference in point estimates is unlikely to be due to chance alone. Delimit the effect, and because they are accompanied by the magnitude of the effect, there is no confusion between statistical significance and magnitude of the effect, as there may be if P values are used (see “P Values” later in this section). When CLs are not overlapping, the difference is unlikely to be due to chance alone.

Because the phrase “nonoverlapping CLs suggests with a stated degree of uncertainty that a difference exists” is cumbersome, the phrase evident difference may be used to express the same idea (Appendix 6B). Nonoverlapping CLs are easily visualized in a nomogram in which the CLs are displayed around the point estimate expressing the association between variables. Within this context, it can be said with a stated degree of uncertainty that the effect of the independent variable compared with a baseline value becomes evident at the
point at which the CLs just separate. However, in contrast to evident differences in a contingency table, this point is not easily seen in a nomogram, and it does not appear in an equation. The point at which evident differences appear in equations can, however, be calculated mathematically (see Appendix 6B).

We stress that comparing CLs in this way is a scanning tool. The classic method using \( P \) values involves computing the difference between the two proportions and testing the hypothesis that the difference is zero. Experience with scanning and \( P \) value methods has taught that when the lower 70% CL of one estimate just touches the upper 70% confidence of the other, the \( P \) value for the difference is between .08 and .1; when similar 95% CLs just touch, the \( P \) value is about .01.

**\( P \) Values**

The phrase “statistically significant,” generally referring to \( P \) values, has done disservice to the understanding of truth, proof, and uncertainty. This is in part because of fundamental misunderstandings, in part because of failure to appreciate that all test statistics are specific in their use, and in part because \( P \) values are frequently used for their effect on the reader rather than as one of many tools useful for promoting understanding and framing inferences from data.\(^{6,5,13,58}\) In fact, \( P \) values are deemed by some to be unnecessary statistics and not worth the risk of misinterpreting or misusing them. They prefer CLs.\(^{56}\)

**Definition**

In the context of hypothesis (or significance) testing, the \( P \) value is the probability of observing the data we have, or something even more extreme, if a so-called null hypothesis is true.\(^{6,53}\) (Box 6-17).

Historically, hypothesis testing is a formal expression of English common law. The null hypothesis represents “innocent until proven guilty beyond a reasonable doubt.” Clearly, two injustices can occur: a guilty person can go free or an innocent person can be convicted. These possibilities are termed **type I error** and **type II error**, respectively (see Box 6-17). Evidence marshaled against the null hypothesis is called a test statistic, which is based on the data themselves (the exhibits) and \( n \). The probability of guilt (reasonable doubt) is quantified by the \( P \) value or its inverse, the odds \([1/(1/P)]−1\) (see Box 6-3).

Had the originators been raised under a different judicial system, perhaps a different pattern for testing hypotheses might have arisen. Specifically, the system does not judge how innocent a person is (the “alternative hypothesis”; see Box 6-17), nor does it test for equivalence, a very important matter for comparing pharmaceuticals and even alternative surgical therapies.\(^{6,5,12,5,4,7,4,51,8}\)

Some statisticians believe that hypothesis or significance testing and interpretation of the \( P \) value by this system of justice is too artificial and misses important information.\(^{5,3,6,5,2}\) For example, it is sobering to demonstrate the distribution of \( P \) values by bootstrap sampling. Furthermore, the magnitude of the \( P \) value is dependent on two factors: magnitude of difference and sample size. These individuals would prefer that \( P \) values be interpreted simply as “degree of evidence,” “degree of surprise,” or “degree of belief.”\(^{6,7,5}\) We agree with these ideas and suggest that rather than using \( P \) values for judging guilt or innocence (accepting or rejecting the null hypothesis), the \( P \) value itself should be reported as degree of evidence.

### Box 6-17 Hypothesis (Significance) Testing

#### Statistical Hypothesis

A claim about the value of one or more parameters. For example, the claim may be that the mean for some variable (e.g., creatinine) is greater than some fixed value or some value obtained under different conditions or in a different sample of patients.

#### Null Hypothesis

A claim that the difference between one or more parameters is zero or no change (written \( H_0 \)). It is the claim the investigator is arguing against. When a statistician infers that there is “statistical significance,” it means that by some criteria (generally a \( P \) value), this null hypothesis has been rejected. Some argue that the null hypothesis can never be true, and that sample size is just insufficient to demonstrate this fact. They emphasize that the magnitude of \( P \) values is highly dependent on \( n \), so other “measures of surprise” need to be sought.

#### Alternative Hypothesis

This is the “investigator’s claim” and is sometimes called the study hypothesis. Usually the investigator would like the data to support the alternative hypothesis.

#### Test Statistic

A number, computed from the distribution of the variable to be tested in the sample of data, that is used to test the merit of the null hypothesis.

#### Type I Error

Rejecting the null hypothesis when it is true (false negative). The probability of a type I error is designated by the Greek letter alpha (\( \alpha \)).

#### Type II Error

Not rejecting the null hypothesis when it is false (false positive). The probability of type II error is designated by the Greek letter beta (\( \beta \)).

Calculating the \( P \) Value

All methods for calculating \( P \) values have in common one or more point estimates, some measure of variability for each, some comparison statistic related to the point estimates (e.g., the difference or a ratio), an estimate of the variability of the comparison statistic, and size of the groups.

The test to be used is selected. This must be appropriate for the comparison. It is crucial that a biostatistician familiar with the data and desired comparison be the one to select this test and interpret the results. In general terms, this demands that a specific distribution of the difference or ratio be selected. From the difference or ratio, some measure of its variability, \( \sigma \), and \( n \), a number is computed for the particular distribution selected, called the test statistic (see Box 6-17). There are a number of test statistics, which means there are a number of prescribed, defined, specific methods (tests) for calculating the test statistic. The statistician selects the test statistic to be used on the basis of the fit of the data to the assumptions underlying the test.
The magnitude of the computed test statistic among the hypothetically determined distribution of values for the test chosen is determined. The area under the distribution curve (proportion of the total area) occupied by more extreme values of the test statistic is the $P$ value, a number ranging from 0 to 1.

In the case of many test statistics, a family of distribution curves exists, and to determine the $P$ values, one of these must be selected. The selection is based, more or less, on the sample size ($n$). By “more or less,” we mean that some information content in the $n$ may already have been “used up” in other calculations in the process and may not be available for computation of the $P$ value. What is left, called degrees of freedom, determines the distribution curve selected.

The phrases one-tailed $P$ value and two-tailed $P$ value are commonly used. Which is appropriate depends on the research hypothesis being tested. When the hypothesis relates to differences in either direction (“different from zero”), a two-tailed $P$ value is used; when it relates to differences in only one direction (“less than,” for example), a one-tailed $P$ value is used. A two-tailed $P$ value is always the same as or larger than a one-tailed $P$ value. Generally, in the work described in this book, two-tailed $P$ values are used.

Use of Expressions of Degree of Uncertainty

Whether one uses CLs or $P$ values, a decision must be made concerning the degree of certainty desired in the inference that $A$ is different from $B$. Some have a slavish attachment to a certain $P$ value, such as .05, or a certain width of CLs, such as 95%, as the yardstick for all situations. Sir Ronald Fisher wrote, “No scientific worker has a fixed level of significance at which from year to year, and in all circumstances, he rejects hypotheses; he rather gives his mind to each particular case in the light of his evidence and his ideas.”

This discussion would be unnecessary if all sample sizes were moderately large and the number of events ample, providing adequate power (information content) for all computations (see Box 6-4). In many clinical investigations, a large sample is simply not available, yet important decisions must be made on the basis of the inference generated. Then the cost of making a wrong decision based on an analysis, and the risk of overlooking or not finding a relation between two variables that in fact exists, plays importantly in the decision regarding what $P$ value to use (see Table 6-7 and Box 6-17). The greater the cost, the smaller the $P$ value demanded.

An apparent contradiction to the foregoing discussion is the setting of so-called humongous databases of hundreds of thousands or millions of patients. In this setting, the dependence of $P$ values on $n$ becomes glaringly apparent. Essentially in every comparison, no matter how small the clinical difference, $P$ values are small. “All null hypotheses are false.”

In this circumstance, other measures of surprise must be devised for testing differences that take into account the magnitude of the difference.

**MULTIVARIABLE ANALYSIS**

The Necessity

Surgeons have intuitively understood that surgical outcome, such as hospital mortality, may be related to a number of explanatory variables, such as renal and hepatic function. However, when presenting a risk factor analysis of outcome for a group of patients, two reactions are heard, often from the same critic: (1) “Your analyses are much too complex, far beyond the comprehension of ordinary cardiac surgeons,” and (2) “This is a very complex, multifactorial situation, and you have not begun to take all the things that could have influenced outcome into consideration.” This contradiction reflects the cognitive structure of the human mind, as discussed in Section I. On the one hand, we perceive, understand, and store in our brains simplified models of reality; on the other hand, our conscious minds recognize that “things are often less simple than they seem.”

To complicate matters, we generally know neither the cause nor the causal sequence that leads to a surgical failure, and that is what we want to know to make progress toward preventing future failures. The cause may in fact be buried in the clinical record and the data we have extracted therefrom, but we do not know this is true and suspect we are ignorant of the real cause. Extensive cautionary literature on surrogate endpoints for clinical trials and how they can lead us astray fuel this anxiety (Fig. 6-11). We need, perhaps, to be reminded that public health recommendations based on crude risk factors for the plague were effective in halting it and preventing its recurrence for 200 years while the causative organism and vector were being discovered.

Faced with hundreds, perhaps thousands, of variables, the investigator seeks to find simple or dominant or stratospheric comprehension of the data. He or she wants to discover the wood, not necessarily the trees (or branches and leaves, for that matter). Multivariable analysis (Box 6-18) is a set of methods for considering multiple variables simultaneously and for (1) identifying those that by some criteria are associated with an outcome, (2) estimating the magnitude of each variable’s influence in light of all others, (3) quantifying the degree of uncertainty of those estimates, and (4) revealing the relation among the set of variables so identified while (5) dismissing others either as noise or as so correlated with other variables associated with outcome that they either do not contribute further information or are so lacking in information (sparse) that their association cannot be determined.

**Historical Note**

Fisher understood the relation of outcome to possibly multiple explanatory variables when he wrote that the behavior of a sample could be considered characteristic of the population only when no subsets within the population behaved differently. Yet the use of these ideas in a formal way in medicine emerged only during the last half of the 20th century. This is because multivariable analysis, particularly of events after cardiac procedures and more especially time-related outcomes, involves considerable computational power. The mathematical models are nonlinear (see Box 6-5), so solving for their parameters is (1) an iterative process—that is, a series of systematically directed mathematical steps that
follow an algorithm or plan to find the best value of the coefficient and its variability by gradually closing in on it, and (2) a mathematical process in which computations for explanatory variables are performed simultaneously. Because the computational challenge is considerable, use of multivariable analysis had to await development of computers.

The first use of multivariable analysis to identify risk factors for outcome events in humans was probably the Framingham epidemiologic study of coronary artery disease.\textsuperscript{520} Two papers are landmarks in this regard. In 1967, Walker and Duncan published their paper on multivariable analysis in the domain of logistic regression analysis, stating that “the purpose of this paper is to develop a method for estimating from dichotomous (quantal) or polytomous data the probability of occurrence of an event as a function of a relatively large number of independent variables.”\textsuperscript{W2} Then in 1976, Kannel and colleagues coined the term “risk factors” (actually “factors of risk”), noting that (1) “a single risk factor is neither a logical nor an effective means of detecting persons at high risk” and (2) “the risk function…is an effective instrument…for assisting in the search for and care of persons at high risk for cardiovascular disease.”\textsuperscript{K3} In 1979, the phrase “incremental risk factors” was coined at UAB to emphasize that risk factors add in a stepwise, or incremental, fashion to the risk present in the most favorable situation.\textsuperscript{K9}

Before the advent of multivariable analysis, stratification of the values of one or more potential risk factors was often used to search for association of risk with outcome. Although this is still of interest as a scanning method, it has serious disadvantages, including (1) loss of information by coarseness of stratification and (2) possibly erroneous inferences from the necessarily arbitrary nature of stratification. These dangers were well summarized by Kannel and colleagues, who stated that “while there is some convenience in dichotomizing a continuous variable like blood pressure into high and low, one would prefer some method to take into account the exact value.”\textsuperscript{K3}

Figure 6-11  Success and failure of surrogate end points. Success: Setting that provides greatest potential for surrogate end point to be valid. Failure: Four reasons for failure of surrogate end points. A, Surrogate is not in causal pathway of disease process. B, Of several causal pathways of disease, intervention affects only pathway mediated through surrogate. C, Surrogate is not in pathway of intervention’s effect or insensitive to its effect. D, Intervention has mechanisms of action independent of disease process. Dotted lines represent mechanisms of action that might exist. (Redrawn from Fleming and DeMets.\textsuperscript{F2})
Carrier of Risk Factors: Underlying Mathematical Model

Multivariable analysis as described by the Framingham investigators requires a model (equation) that relates a placeholder for explanatory variables (generally one or more of the model parameters) to the dependent (outcome) variable. The equation may be a completely linear one; for these, iterative techniques are not required, but the computations are large and for all practical purposes require a computer. The general term for such a model is a regression equation (see Box 6-5).

Logistic multivariable regression analysis is a special type of nonlinear model that can be used as a prototype to understand the nature of the relation of risk factors to outcome in a medically rational fashion. Fig. 6-1, A illustrates the relation between the absolute probability of an event on the vertical axis and an expression of risk measured in logit units along the horizontal axis. The horizontal axis is the one related to risk factors. The relation is sigmoidal (S-shaped). Notice that an increment of risk along the horizontal axis, if far to the left or right of the curve, is not associated with a perceptible increase or decrement in probability. However, a small increment near 0 logit units is associated with a large change in probability.

To illustrate, imagine two patients. One is a strapping football player who is mugged on his way to a pharmacy late at night. He is stabbed in the abdomen, and his inferior vena cava is lacerated. Fortunately, a trauma center is nearby, and he is rushed to surgery. His anxious parents arrive at the hospital about an hour after the incident and want to know, “What are his chances, doctor?” Let us say that the injury moves the football player’s risk two units to the right on the logit scale. Before the incident, this robust individual was near the center of the logit curve, say at −1 logit units, before the incident. Two logit units of acute risk greatly increase his probability of hospital mortality.

A week later, the second patient, a frail, elderly diabetic man, is walking to the same pharmacy for his insulin when he is stabbed in the abdomen, and his inferior vena cava is lacerated. He too is rushed to the trauma center and into the operating room. An hour later, his anxious daughter arrives at the hospital and wants to know, “What are his chances, doctor?” The fragile patient may already have been sitting near the center of the logit curve, say at −1 logit units, before the incident. Two logit units of acute risk greatly increase his probability of hospital mortality.

These anecdotes emphasize that the models underlying risk make good medical sense. They reflect what we mean by a robust patient, a fragile patient, and an unsalvageable patient. They reflect the reality that the identical risk factor may operate with respect to absolute risk differently, depending on the presence or absence of other risk factors.

Risk Factor Identification

Given a mathematical model to carry risk factors (see Box 6-5), the next task is risk factor identification. It requires (1) screening of candidate variables for suitability in the analysis, (2) calibrating continuous and ordinal variables to outcome, (3) selecting variables related to outcome, and (4) presenting results in the format of incremental risk factors.

Screening

Screening candidate variables has two purposes: (1) to determine whether there are sufficient data (see Box 6-4) to be suitable in the analysis and (2) to understand a variable in relation to other candidate variables. Because for outcome events the effective sample size for analysis is the number of events, not the number of patients, a variable may not be suitable for analysis when it represents a subgroup of patients with too few events to evaluate. This represents a limitation of the study, not of methodology. Indeed, one is generally happy with a therapy associated with few events; however, it then makes sense that risk factors cannot be identified.

We do not screen variables to discover which ones relate individually to outcome. It is a common practice of many groups to ignore variables that are not univariately associated with outcome. However, there is a long history of occurrence of lurking variables (Box 6-19 and Fig. 6-12) that are found to relate to outcome only when (1) other variables that mask their importance are accounted for in the analysis or (2) they are suitably transformed (or coupled with nonlinear rescaling of themselves), indicating a complex association with outcome.

It is valuable to determine the pairwise correlation of variables. This will help one understand why many variables may be associated with outcome, but only a few are selected as risk factors. Medical data are highly redundant, sharing a great deal of information.

Calibration

Continuous variables contain unique values for each patient and so are particularly valuable in analyses. For unclear reasons (statisticians uniformly decry the practice), many investigators stratify continuous variables into two or a few arbitrary categories, throwing away valuable information. This flies in the teeth of a fundamental philosophy of data analysis: continuity in nature (see “Continuity versus Discontinuity in Nature” in Section I). Furthermore, to better understand the phenomenon we are studying, it is important to determine the shape of the relation of continuous variables (e.g., age, birth weight, creatinine) to outcome.

Box 6-19 Lurking Variables

Lurking variables are those found to relate to some outcome or dependent variable (see Box 6-5) only after (1) other variables masking their importance are taken into account either by multivariable analysis or matched-type analyses (e.g., using balancing scores) or (2) the lurking variable (if continuous or ordinal) is properly rescaled (e.g., transformed) so that complex relations are revealed, such as higher risk of mortality at both old and young age.

Fig. 6-12, A shows survival in patients after exercise stress testing stratified according to long-term aspirin use.

Apparently there is no relation to survival. However, Table 6-3 shows that there are multiple differences in patient characteristics between these two groups of patients, with those taking aspirin being older, for example. Indeed, in multivariable analysis, the moment age is taken into account, a beneficial effect of long-term aspirin is revealed. Fig. 6-12, B shows survival in propensity-matched pairs of patients (see “Clinical Studies with Nonrandomly Assigned Treatment” in Section I). The lurking benefit of long-term aspirin use is clearly revealed.
However, the scale on which a continuous variable has been measured or expressed may not coincide with the outcome. Therefore, the appropriate calibration of the variable to outcome must be discovered. One method to accomplish this is to examine various linearizing transformations (Fig. 6-13). However, the “perfect” transformation of scale may not coincide with the best one after other factors have been considered in a multivariable model. Thus, we rely on graphical methods, as in the figure, to obtain a set of similar transformations, and then include all transformed variable candidates in the selection process to be described. A promising offshoot of nonparametric machine learning techniques, such as random forests technology, is the generation of risk-adjusted coplots that can suggest the shape of the relationship of these continuous variables with risk (Fig. 6-14).

**Variable Selection**

A seminal contribution of the Framingham Study investigators was the idea that in the absence of identified mechanisms of either disease or treatment failure, useful inferences for medical decision making, lifestyle modification, and programmatic decisions about avenues of further research can be gleaned by nonspecific risk factor identification. A direct consequence of the idea, however, is that for any set of potential variables that may be associated with outcome, there is no unique set of risk factors that constitute the best common denominators of disease or treatment failure. Therefore, different persons analyzing the same data may generate different sets of risk factors.

As a consequence, multivariable identification of risk factors has become an art that depends on expert medical knowledge of the entity being studied, understanding the goals of the research, knowledge of the variables and how they relate to the study goals as well as to one another, identification of the quality and reliability of each variable, and development of different, often sequential, analysis strategies appropriate to each research question. Not all these issues of art or expertise will disappear, but there are substantial aspects of multivariable analysis that are yielding to science.

Nafteil, of UAB, in an important 1994 letter to the editor of the Journal of Thoracic and Cardiovascular Surgery, addressed nine aspects of multivariable analysis that contribute to obtaining different models (sets of risk factors). He called these “steps and decisions that may influence the final equation”:

- Differing statistical models. For example, if time-related events are being modeled, results using a Cox proportional hazards model (see “Cox Proportional Hazards Regression” later in this section) will differ from those using a multiphase nonproportional hazards model (see “Parametric Hazard Function Regression” later in this section).
- Differing approaches to missing data (see “Impute Values” in Section III).
- Differing approaches to minimal information (see Box 6-4).
- Differing approaches to correlated data. Variables with similar information content should be chosen for maximal insight by the clinical investigator, not necessarily the statistician.
- Differing coding of data. Some may pay more attention than others to linearizing transformation of continuous variables, to whether continuous or ordinal variables should be dichotomized or in other ways collapsed, or to management of interaction (multiplicative) variables.
- Differing approach to apparently incorrect data. Variables with similar information content should be chosen for maximal insight by the clinical investigator, not necessarily the statistician.
- Differing variable selection methods and $P$-value criteria. This area is undergoing complete change through introduction of machine learning algorithmic methods.\cite{561} Even with new methods, however, a criterion must be arbitrarily established to differentiate what is signal from what is noise ($P$ values, for example).
- Differing computer resources. Although even desktop computers rival the computational capacity of large-scale computers of a decade ago, computer-intensive methods may require large networks of computers.
- Differing appreciations of the science. Unless data analysts work collaboratively with the surgeon-investigator, analysis may be uncreative. One cannot divorce the underlying clinical science from data analysis.

In all these areas but one, new knowledge has been generated that is beginning to differentiate inadequate techniques from reasonable techniques and optimal techniques. That one area remaining is “differing variable selection methods,” and it is an important one.

Part of the challenge is that variables may be thought to be risk factors because they are associated with a small $P$ value, and other factors may be thought not to be risk factors because of larger $P$ values, but both opinions may be erroneous (type I and type II statistical errors, respectively; see Box 6-17). There is therefore a need for a method that balances these two types of error. Closely coupled with this is the need for a statistic that measures the reliability with which a risk factor has been identified. Because one is analyzing only a single set of data rather than many sets of data about the same subject, determining this reliability has been elusive.

There is new thinking about what risk factor identification is. In thinking anew, we leave traditional statistical methodology out of the picture, and risk factor identification becomes an attempt to find signal (risk factors) in noise (other candidates). Important advances in pure mathematics (logical analysis)\cite{53,54} and machine learning (algorithmic analysis)\cite{561} are proving valuable for such diverse signal detection challenges as handwriting identification, genomic identification, and now risk factor identification. These techniques are
Chapter 6  Generating Knowledge from Information, Data, and Analyses

Bootstrap bagging belongs to a class of new methods that has developed over the past 30 years. In 1983, an astonishing article entitled “Computer-Intensive Methods in Statistics” appeared in the popular scientific literature. Its authors, Persi Diaconis and Bradley Efron from Stanford University, indicated that “most statistical methods in common use today were developed between 1800 and 1930, when computation was slow and expensive. Now, computation is fast and cheap…. The new methods are fantastic computational spendthrifts…. The payoff for such intensive computation is freedom from two limiting factors that have dominated statistical theory since its beginnings: the assumption that the data conform to a bell-shaped curve and the need to focus on statistical measures whose theoretical properties can be analyzed mathematically.”

Efron and his group demonstrated that random sampling with replacement from a data set to create a new data set, resampling to produce perhaps thousands of new data sets, and combining the information generated from these many data sets can produce robust and accurate statistics without assumptions. His group called this technique bootstrapping, after the expression “pulling yourself up by your own bootstraps,” because it reflected the fact that one could develop all the statistical testing necessary directly from the actual data simply by repeatedly sampling them (see footnote 7, p. 296).

These techniques have been applied to entire analytical processes, including multivariable analysis. In fact, one still has to pay attention to appropriate models, missing data, variable considerations, correlated variables, appropriate strategy, and so forth, that remain part of a disciplined, informed approach to the data. However, the variable selection process is bootstrapped.

In practice, a carefully crafted set of variables is formulated that will be subjected to simple automated variable selection, such as forward stepwise selection, whereby the most significant variables are entered one by one into a multivariable model. Specific $P$ value criteria for entering and retaining these variables are specified. Then a random bootstrap sample of cases is selected, generally of the same sample size as the original $n$. A complete automated analysis is performed, and its results are stored. Then another random bootstrap set of cases is drawn from the original data set, and analysis is performed. This resampling of the original data set, followed by analysis, continues perhaps hundreds and even thousands of times, then the frequency of occurrence of risk factors among these many models is summarized. Frequency of occurrence generally stabilizes after about 100 bootstrap analyses. The many models are also analyzed by cluster techniques to detect closely related variables that in the final model will be represented by the most commonly occurring representative. All this information is used to select variables for the final multivariable model.

Of interest, the variables identified for every bootstrap data set are usually different, a sobering revelation. However, it becomes evident that some variables never are selected and others are seldom selected; these constitute “noise.” Variables that appear in 50% or more of models are claimed to be reliable and are considered “signal” for inclusion in the final model.

This phenomenon is illustrated in Table 6-8 and Fig. 6-15. Fifteen variables were selected from among many being analyzed for the late hazard phase of death following mitral valve repair or replacement for degenerative disease. In analysis of the first bootstrap sample, 8 of these 15 variables were selected (only 5 were ultimately found to be reliable risk factors). By 100 analyses, although every variable had been identified as a risk factor in at least 2 analyses, 5 variables dominated the analyses (we considered these reliable risk factors), 8 rarely appeared, and 2 appeared in 22% to 32% of analyses.

What happens in bootstrap bagging is similar to what is seen in signal averaging, such as in visual evoked potentials. Noise becomes canceled out, and signal becomes amplified. In the same way, many variables appear rarely in models, but a few show up time and time again (see Fig. 6-15). One can therefore express the reliability of identification of a given risk factor.

Bootstrap bagging, although demanding a huge number of computer cycles, removes much of the human arbitrariness from multivariable analysis and provides another important statistic: a measure of reliability of each risk factor. Thus, increasingly we have been reporting not only the magnitude of the effect, its variance, and its $P$ value, but also its bootstrap reliability. The technique appears to provide a balance between selecting risk factors that are not reliable (type I error) and overlooking variables that are reliable (type II error).

Machine learning technologies, often used to avoid the issue of variable selection, are being harnessed in interesting ways by either embedding traditional parametric models (which are emphasized in this chapter) or extending nonparametric analytic strategies. For example, results of traditional variable selection are highly dependent on the order in which variables are entered or eliminated. One can instead imagine forming thousands of bootstrap models with clusters of randomly chosen variables forced into each, and aggregating the results. One can apply learning theories to model development. One can examine “variable importance” (often revealing that many variables actually degrade predictive power). Splitting algorithms can be averaged to reveal the most common splits (Fig. 6-16). Research in variable selection is extremely brisk, and important new methods are developing quickly.

Verification

The ideal verification of a multivariable analysis is to demonstrate its accuracy in predicting results of a new set of patients,

---

Footnote 7: Sampling with replacement: Imagine a data set having 869 patients and 30 variables. A uniform random number generator produces at random a number between 0 and 1 (the numbers chosen at random are, in the long run, equally likely across that range). The random number is multiplied by 869, and the product is rounded to the nearest integer from 1 to 869. All the variables and their values for the patient with that observation number are copied to a new data set. Importantly, the patient is not removed from the original data set and is available to be selected at random again. This is what is meant by “sampling with replacement”; the patient is chosen but not removed from the possibility of being chosen again.

In bootstrapping, random selection continues until a new data set is built with the same $n$ as the original. However, because patients were never removed from the original data set, the new data set contains many duplicate observations and does not contain on average 37% of patients who were never chosen. When hundreds or even thousands of such data sets are built by this sampling with replacement mechanism, it is rare that any two are alike; it is also extremely rare that one of the data sets will, by chance, have the exact composition of the original data set (each patient selected only once).

Key: BUN, Blood urea nitrogen; NYHA, New York Heart Association.

preferably extramurally. Another popular method, if the data set or number of events is large, is to split the data set randomly into training and testing data sets. Modeling is performed on the former and verification on the latter. Whether this is an efficient and effective strategy has been debated. One of the first applications of bootstrapping was to address this issue by generating multiple training and testing sets. Within the domain of the primary multivariable analysis itself, there are, as it were, internal validity diagnostics. For example, in linear regression (see Box 6-5), a measure of explained scatter is the \( r^2 \) value (square of the familiar correlation coefficient). It is desirable that the value of \( r^2 \) be high (closer to 1 than 0); however, if a model is overdetermined by having in it either too many factors or surrogates for the outcome-dependent variable, a high \( r^2 \) may be spurious.

In logistic regression (see “Logistic Regression Analysis” later in this section), there are a number of diagnostic tools available. One of the earliest was the decile table, often attributed to Hosmer and Lemeshow but used much earlier by the Framingham investigators and others. By solving the multivariable equation for each patient, patients are ordered with respect to their estimated probability of experiencing an event. They are then stratified in up to 10 groups (thus “decile”), and within each group the estimated probabilities summed. This sum represents expected events; it is compared with observed events in each decile. The Hosmer-Lemeshow statistic is a general test of the differences between observed and predicted events.

Borrowing from classification theory, which deals with false and true positives and false and true negatives, an analysis of sensitivity and specificity can be performed, varying the cut point from 0 to 1 of what probability is considered predictive of an event’s occurring. The number of correctly predicted events (true positives) divided by the number of true positives plus false negatives is sensitivity. The number of correctly predicted nonevents (true negatives) divided by the number of true negatives plus false positives is specificity. A graph of 1-specificity on the horizontal axis and sensitivity on the vertical axis is then constructed—the receiver operating characteristic (ROC) curve (Fig. 6-17). The area beneath this curve is a measure of goodness of fit. (Harrell and colleagues called this the c index of concordance.) It varies from .5 to 1. A concordance index between .8 and .9 is desirable for prediction purposes.

In addition, for all varieties of multivariable models, a number of regression diagnostic procedures are used, including formal testing of goodness of fit, identification of observations that particularly influence the results, and analysis of residuals (difference between observed and predicted values) in linear regression.

A validation technique that holds future promise is “out-of-bag” (OOB) prediction error assessment. As noted earlier in this section, a bootstrap sample or average does not
select about a third of patients. These nonselected patients are known as the OOB sample. A model developed on the two thirds of data can be applied to the OOB sample, and prediction error calculated.

Presentation

A multivariable parametric model analysis generates an enormous amount of information, including:

- The structure of the model and estimates of parameters related to that structure
- A list of risk factors identified
- Magnitude of association of each risk factor with outcome as adjusted for all other variables in the model (these multipliers may be expressed either as the parameter estimates themselves—called model coefficients—or as some reformatted relative risk expression; see Box 6-3)
- Direction of each relation, positive or negative
- Uncertainty of the associations, generally expressed as standard deviations of the coefficients
- A statistical score on which a \( P \) value is based
- \( P \) values

---

**Figure 6-15** Example of automated variable selection by bootstrap aggregation (bagging). Fifteen variables labeled A through O are depicted as potential predictors of death after mitral valve surgery. In column A, analyses of five bootstrap samples are shown. Tall bars indicate the variable was selected at \( P < .05 \), and gaps represent variables not selected. In all cases, variables A and D were selected, but otherwise analyses appear to be unique. Panel B shows a running average of these five analyses. Variables A, D, I, and J were selected more often than others. Panel C shows averages of 10, 50, 100, 250, and 1000 bootstrap analyses. Notice that no variable was selected 100% of the time, and all 15 were selected at one time or another. But if we consider variables appearing in 50% or more analyses as reliable risk factors, variables A, C, D, I, and J fit that criterion of “signal” and the rest are “noise.” (From Blackstone and colleagues.\(^{842}\))
Figure 6-16 Use of random forests for variable selection. **A,** Example of a random tree. A bootstrap sample of patients from original data set is used to create a random tree. At the root node, a random set of variables are chosen to be candidates, and the most predictive variable for survival among those is identified. Node levels are numbered based on their relative distance to top of tree (i.e., 0, 1, 2). Splitting of nodes to create trees continues until terminal nodes have a few distinct events (e.g., deaths). **B,** Illustration of minimal depth of a variable in a random tree from a 2000-tree forest. Highlighted are three top variables: peak VO₂ (violet), blood urea nitrogen (BUN, aqua), and exercise time (tan). Depth of a node is indicated by numbers 0, 1, 2, 3-8. Minimal depths are 0, 1, 2 for exercise time, peak VO₂, and BUN, respectively.
Figure 6-16, cont’d  

C, Illustration of six random trees from a 2000-tree forest. Three most important variables among these trees are color coded blue for treadmill exercise time, violet for peak \( \dot{V}O_2 \), and green for serum BUN.  

D, Minimal depth (variable importance) from random survival forests analysis. Dashed blue line is threshold for filtering variables: all variables below line are predictive. Diameter of each circle is proportional to forest-averaged number of maximal subtrees for that variable. (From Hsich and colleagues.)
Incremental Risk Factor Concept

An incremental risk factor is a variable identified by multivariable analysis that is associated with an increased risk of an adverse outcome (surgical failure). Surgical failure may be an event, such as early postoperative stroke, and risk is expressed in terms of probability. It may be a time-related event, and risk is expressed in terms of a shorter interval to the event, such as premature death. It may be a longitudinal outcome, and risk is expressed as increased prevalence, higher grade of failure, or elevated or lowered quantitative level. In the context of other simultaneously identified factors, the magnitude (strength) and certainty (P value) of an incremental risk factor represent its contribution over and above those of all other factors. Thus, it is incremental in two ways: (1) with respect to being associated with increased risk and (2) with respect to other factors simultaneously incorporated into a risk factor equation.

There are a number of possible interpretations of an incremental risk factor, all of which should be assessed in drawing inferences:

- Incremental risk factors are variables that reflect increased difficulty in achieving surgical success. This original definition addressed the reality of surgical complexity. Complexity may be expressed in terms of morphologic features (e.g., atrioventricular septal defect). It may also relate to duration of operation (e.g., longer myocardial ischemic time); to both the operation and components of it; to presence of associated cardiac or noncardiac diseases; to demographics (e.g., young age, low birth weight, gender, socioeconomic position); or to conditions that increase difficulty of access (reoperations) or add a potential for complication (e.g., religious preference that precludes administration of blood products, administration of thrombolytics shortly before operation).

- Incremental risk factors are common denominators of surgical failure. The Framingham originators of the risk factor concept were initially disappointed that they did not discover mechanistic (deterministic) causes of heart disease, only weak associations. These weak associations are what we call common denominators. They are general factors associated with increased or decreased risk of an outcome. Sufficient data (see Box 6-4) are necessary to keep them from becoming identifiers of specific patients.

- Some incremental risk factors reflect disease acuity. Need for emergency or urgent operation in patients with severely impaired functional status, such as NYHA class IV or V (the latter designating severe hemodynamic instability or cardiogenic shock), low pH, or short interval from MI to ruptured ventricular septum, represent risk factors that increase acuity.

- Some incremental risk factors reflect immutable conditions that increase risk. These include extremes of age or body size, genetic disorders, gender, and race.

- Some incremental risk factors reflect influential coexisting noncardiac diseases that shorten life expectancy in the absence of cardiac disease. These include chronic renal disease, diabetes, malignancies, arteriosclerosis, and infectious diseases.

- Incremental risk factors are usually surrogates for true, but unmeasured or unrecognized, sources of surgical failure. It is tempting to misinterpret associations as causes. Studies of surrogate end points to decrease sample size for randomized clinical trials are instructive.

A set of numbers indicating quantitative interrelation of all parameter estimates in the model (the variance-covariance matrix)

Bootstrap reliability of each risk factor identified

Figure 6-17 Illustration of receiver operating characteristic (ROC) curves. These are for renal failure after either coronary artery bypass grafting or cardiac valve procedures in 15,844 patients operated on at Cleveland Clinic from 1986 to 2000. Three ROC curves are shown. One is based on preoperative laboratory measurements alone, the second on extensive clinical data alone, and the third combines the two. Diagonal dashed line is the line of random prediction.

There is some controversy about which of these nine sets of numbers should be reported in a manuscript. It may be sufficient for understanding the relations to simply list the risk factors and place in an appendix some of the numeric data. If the model is intended to be used for prediction, including CLs, the entire list must be reported or provided electronically, as has been done for Society of Thoracic Surgeons National Cardiac Database models.

None of the nine, however, directly addresses the way a final multivariable model is formulated to reveal incremental risk factors (see “Incremental Risk Factor Concept” later in this section). The incremental risk factor concept was developed to facilitate medical interpretation of a multivariable analysis. Any dichotomous risk factor in a multivariable analysis can be complemented to allow it to have a positive sign. This is desirable because we think of variables in the model as risk factors, and usually we consider risk to be increasing (positive value) with increasing value of the risk factor. Generally, continuous and ordinal variables cannot be formulated this way, so we recommend that each of these be accompanied by an indication of the direction of greater risk (younger age, lower ejection fraction, greater functional impairment, higher bilirubin).

Incremental Risk Factor Concept

This is desirable because we think of variables in the model as risk factors, and usually we consider risk to be increasing (positive value) with increasing value of the risk factor. Generally, continuous and ordinal variables cannot be formulated this way, so we recommend that each of these be accompanied by an indication of the direction of greater risk (younger age, lower ejection fraction, greater functional impairment, higher bilirubin).
They demonstrate a number of circumstances under which such surrogates may be misleading (see Fig. 6-11). On the other hand, if unknown cause and measurable surrogate are strongly mechanistically linked, interim neutralization of the surrogate may neutralize the cause (Appendix 6D). The Framingham investigators classified most risk factors as rather general, insensitive, but useful surrogates for underlying mechanisms.  

- Incremental risk factors may be spurious associations with risk. One of our motivations to base risk factor identification on algorithmic methods such as bootstrap bagging is that in simulations, these methods balance very nearly 50:50 the probability of overlooking a risk factor and identifying a spurious association.

- An incremental risk factor may be a cause or mechanism of surgical failure. It is difficult to establish a causal mechanism outside the scope of a randomized, well-powered, and well-conducted generalizable clinical trial. This is due to confounding between selection factors influencing treatment recommendations and decisions and outcome. Balancing score methods (e.g., propensity score) attempt to remove such confounding and approach more closely causal inferences (818) (see “Balancing Scores” in Section I).

In addition, we must acknowledge that “association,” “cause,” and “mechanism” may simply be levels of granularity in the pathway of cause to effect. As more becomes known at the molecular level, it may be assumed that at that level of fine granularity, a clear understanding of mechanisms may emerge. However, a macroscopic event such as death or a complication after a cardiac operation may not be completely understood by knowledge of the many individual events taking place at the microscopic level, which probably interact in a complex fashion.

- Some incremental risk factors reflect temporal experience. The “learning curve” idea is intended to capture variables relating to experience of the surgical team, but also those representing temporal changes in approach or practice (e.g., addition of retrograde cardioplegia to myocardial management, preservation of chordae in mitral valve replacement). It is more helpful to identify specific temporal changes in management as separate variables than to lump them into a “date of operation” variable. To do so may require initially suppressing date of operation in the analysis to allow entry of such identifiers of management changes.

- Some incremental risk factors reflect quality of care and, as such, “blunt end” ramifications of institutional policies and practices, healthcare systems, and national and political decisions. Just like temporal experience, however, it is more helpful to identify the specific factors reflected in institutional variance than simply to state that some institutions are high risk and others low risk. If these can be identified and institutions no longer enter an analysis as risk factors, it becomes important to quantify their frequency of occurrence in each institution. If the prevalence is high, and if associations are strongly linked to mechanisms of failure, then institutional protocols to lower the prevalence are warranted. Although quality of care is measured by outcomes, factors influencing it are identified in risk factor assessment and serve as important information for quality monitoring, quality improvement, quality comparison, and assessment of strategies implemented. (Institutional variance is addressed in more detail under Risk Stratification in Section VI.)

- Incremental risk factors reflect individual patient prognosis. They cannot be used to identify which patient will suffer a surgical failure, but they can be used to predict the probability of failure. Surgeons make recommendations and decisions every day that reflect conscious or unconscious assessment of probabilities. Patient selection requires weighing the probabilities of risks and benefits (value) of intervention vs. nonintervention or an alternative management strategy. Indications for operation is the same. Analysis of clinical experience transforms generalities of patient selection and indication guidelines into quantitative probabilities for an individual patient’s characteristics (see “Decision Making for Individual Patients” in Section V).

**EARLY EVENTS**

**Method of Expression**

Early mortality is often expressed as hospital mortality, which includes all deaths that occur after operation but before hospital discharge. The disadvantage of using hospital mortality is that the relatively high but rapidly declining early phase of risk after cardiac operation nearly always extends beyond the hospital period, often out to 3 months and occasionally 6. The degree of extension, even after such safe operations as CABG, appears to increase as risk factors increase. Thus, hospital mortality underestimates the true early risk of operation and gives an incomplete picture of this measure of quality of care. It also covers a variable time period.

An alternative is to use 30-day mortality, but this requires patient follow-up, either active (and expensive) or passive (and delayed). The hybrid of these, operative mortality, is all hospital deaths plus those that occur in the first 30 days. Actually, the most appropriate way to depict early mortality (or any other outcome event) after a procedure or decision is in a time-related manner beginning at time zero (see Time-Related Events later in this section).

If simple percentages are used, at least the confidence intervals around that percentage have to be stated (see Uncertainty earlier in this section), and ideally some information about characteristics of the patient group. Often the patient group is stratified in some manner to demonstrate the effects of heterogeneity of risk factors on outcomes.

**Logistic Regression Analysis**

Logistic regression is used for multivariable analysis of hospital outcomes (events) that are dichotomous (yes/no).

**Historical Note**

The logistic equation was introduced by Verhulst between 1835 and 1845 to describe population growth in France and Belgium. Thus, it belongs to a large class of growth equations. The logistic equation is the simplest of these, resulting in a symmetric S-shaped curve when plotted (see Fig. 6-1, A). The model reappeared in the work of Pearl and Reed at Johns Hopkins University in 1920. They recognized the
pattern of an autocatalytic reaction in the characteristic pattern of the logistic equation for populations; this was earlier suspected by Pearl in 1909 from his reflections on the relation of these curves to organic laws of change. The equation is characterized by an initial phase of increasingly rapid chemical conversion catalyzed by the products produced, followed by a decelerating phase as reactants are consumed (e.g., hydrolysis of ethyl acetate to acetic acid and ethyl alcohol).

Also at Johns Hopkins University during the late 1920s, Berkson and colleagues found that the logistic equation represented kinetics between enzymes and certain substrates. Later at the Mayo Clinic in the 1940s, Berkson found a logistic relationship between dosage of drug and proportion of small experimental animals killed (bioassay). In his studies, the outcome variable was a probability. Unlike population or biochemical kinetics in which not only the rate but also the initial (base) level and the final (asymptotic, limiting) level must be estimated, when the logistic equation is used to estimate the probability of an event, values are constrained within a base of 0 and asymptotic level of 100% (or unity), simplifying the equation and leaving a single parameter to estimate from the data, z.

In 1955, Berkson dubbed the units of the logistic nomogram logit units, parallel to the probit units of another method of bioassay. Thus, certain aspects of the nature of population behavior, enzyme kinetics, lethality of drugs, and risk factors for human outcomes found common ground in this fundamental logistic expression. The logistic equation was made multivariable in the 1960s by Cornfield and colleagues and Walker and Duncan, as described under Multivariable Analyses earlier in this section.

Logistic Regression Equation
Multivariable logistic regression generalizes the discriminant analysis of Fisher by embedding it within the logistic equation. Thus z, the logistic parameter expressed in logit units, is assumed to be related to a logit-linear combination of incremental risk factors (see Box 6-5):

\[ z = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \ldots + \beta_k x_k \]  

(6.1)

where \( \beta_0 \) is the intercept term (logit units when all \( x = 0 \)), \( x_i \) through \( x_k \) are the numeric values for the independent variables, and \( \beta_i \) through \( \beta_k \) are coefficients, estimated from the data, that translate the values of the independent variables (see Box 6-18) to logit units. Logit units are related to probabilities \( P \) by the logistic relationship:

\[ z = \ln \left( \frac{P}{1-P} \right) \]  

(6.2)

where \( \ln \) is the natural logarithm. This form of the logistic equation makes clear why “log” is part of its name. Notice, also, that \( z \) is a function of the ratio of \( P \), the probability of an event, and \( 1-P \), the complementary probability of the event’s not occurring. This ratio is the odds ratio (see Box 6-3), and Equation 6-2 is referred to as log odds. Equation 6-2 is not computationally applicable to raw clinical data for which \( P \) is exactly 0 or 1 for each patient (e.g., analysis of a dichotomous variable like mortality; see Box 6-5). Thus, the computational form is a nonlinear equation obtained by exponentiating Equation 6-2:

\[ P = \frac{1}{1+e^{-z}} \]  

(6.3)

where \( P \) is the estimated probability using the maximum likelihood principle, and \( e \) is the base of the natural logarithms. In practice, the dependent variable is a dichotomous variable with value 0 (no event) or 1 (event), and the independent variables are potential incremental risk factors (see Box 6-18). In this form, no restrictions are made on the distribution of the risk factors \( x_i \); they may be any mix of continuous, dichotomous, or ordinal variables.

Polymorphic and Ordinal Logistic Regression
Polymorphic Logistic Regression
The “event” whose probability is being calculated does not always take the simple form of 0 and 1; sometimes it is a list of possible dichotomous outcomes. Consider hospital mortality. It may occur in a multiplicity of modes (e.g., acute cardiac failure, death from hemorrhage, death in renal failure). The data may need to be analyzed for more than one mode of death. Such analysis leads to the coding of multiple so-called competing events (bioassay), alive, acute cardiac failure, death in renal failure, and so forth. These are unordered lists of modes of death for which polymorphic logistic regression might be considered.

One option for polymorphic variables is to analyze each event category independently, determining its incremental risk factors using logistic regression for dichotomous outcomes as previously described. It is important to note that for such analyses, the entire data set is used.

Another option is to analyze each variable in the same fashion as time-related competing risks (see “Competing Risks” under Time-Related Events later in this section). The assumption is that all items in the list are independent. As in temporal competing risks analysis, patients experiencing events in any other category are eliminated (e.g., all patients dying in other modes) in these separate analyses. Thus, the data set used to analyze each event in the list contains all patients experiencing each successive event in the list. The entire data set is not used. The analysis is performed and the results interpreted as a conditional probability; that is, the probability of an event of one type, conditional on the absence of another type (e.g., the probability of cardiac death given the absence of any other mode of death.)

An important feature of this type of conditional probability analysis is that event categories must be strictly mutually exclusive. This means that a patient can be assigned only one mode of death, for example. If one were analyzing morbid events such as hospital complications, this should be the earliest occurring complication (in which case one would normally use time-related techniques, of course). This introduces a certain arbitrariness into the analysis. Furthermore, if one adds another category of morbid event to the list, the probabilities of the remaining new ones will not be the same, because the “denominator” (all those not experiencing an event) plus the patients in each successive category will change.

On the other hand, if one then uses the logistic regression equation to predict the occurrence of each event category, the method of conditional probability guarantees these will add to 100% (including the category “no event”) as long as the same risk factors are used for each analysis, and approximately so if a different set is used. This property of polymorphic logistic regression, then, distinguishes it from ordinary logistic regression. In ordinary logistic regression in which
Figure 6-18 Illustration of ordinal longitudinal outcomes. Diagram illustrates the assumption that aortic regurgitation across stented bovine pericardial aortic valve prostheses progresses from grade 0 to grade 1+, then to grade 2+, and finally to grades 3+ and 4+. (Redrawn from Blackstone.823)

Chapter 6 Generating Knowledge from Information, Data, and Analyses

the entire patient sample is used for each event, it is unlikely that the probabilities for a list of events will add to 100%.

This leads us to reflect that ordinary logistic regression examines an event in isolation of any other kind of event. It is ideal for answering the question, “What is the nature of this outcome phenomenon?” Polytomous logistic regression, by considering the entire list of events that make up a more global event (e.g., death, complications), answers the question, “What are the probabilities of each kind of event conditional on none of the others occurring?” All these will add up to the total probability of the overall event.

Although used in data analysis by others before them, Hosmer and colleagues described the equations and programmed the software for performing a multiple (polytomous) logistic regression simultaneously on multiple events.829 and these algorithms are incorporated into the most modern logistic regression computer software. Generally, all items in the polytomous list are analyzed simultaneously, with multiple streams of the same set of risk factors. This allows assessment of the sometimes complex interplay of risk factors among the various list items.

An important limitation of polytomous logistic regression is that the number of risk factors must be such that the category with the fewest events does not become overdetermined. When there is wide difference among the categories in number of events, perhaps one or two orders of magnitude, this can limit the model considerably, permitting little insight into the most commonly occurring category and jeopardizing the least commonly occurring. Some coalescence of categories may be necessary.

Assumptions of polytomous logistic regression include noninformative censoring (just as for time-related events)—that is, occurrence of one item in the list is unrelated to the possible occurrence of another, had the first not happened first. In cardiac operations, in which multiorgan system failure often leads to death, independence of modes of death such as from renal failure or hepatic failure is hard to accept.

**Ordinal Logistic Regression.** A generalization of logistic regression is to an ordinal response (dependent) variable such as NYHA functional status after operation.828,829 The logistic equation, by means of multiple intercept terms, then predicts the probability for each ordinal level, all of which sum to 100%. We have found the widest application of this method in examining repeated assessment of time-related patient status (NYHA class or degree of regurgitation of a cardiac valve after repair),831 so this topic is discussed in more depth under Longitudinal Outcomes later in this section.

The primary assumption of ordinal logistic regression is that there is an orderly relation between increasing risk and increasing ordinal level of the outcome variable.832 Patients “flow,” as it were, into states of greater severity, and states of lesser severity empty (Fig. 6-18). This assumption may be violated, so testing the proportional odds assumption is mandatory during analysis. The most common reason for violation of the proportional odds assumption is too few patients in some categories. This requires coalescence of categories until the proportional odds assumption is met.

A practical note is that a naive solution of an ordinal logistic equation generates cumulative probabilities. What one generally is interested in is the actual probabilities of each level of the ordinal variable. These must be obtained by subtraction and the CLs calculated for each such conditional probability.

**Diagnostics.** Upon completion of a logistic regression analysis, it is important to perform a variety of diagnostics to determine the quality of the results obtained.821 Pregibon has presented a number of helpful logistic regression diagnostics.816 Harrell has incorporated a number of diagnostics into his R-based package.812 These substantially extend more typical Hosmer-Lemeshow diagnostics.

**TIME-RELATED EVENTS.** The interval between an intervention such as a cardiac procedure and an unfavorable outcome event such as death is of obvious importance.

The usual outcome events considered, such as death, are called terminating events; that is, they can occur only once. Other morbid events, such as thromboembolism and transplant rejection, may occur a number of times and are called repeated morbid events.828 Yet others are not dichotomous events but events associated with a severity scale; these are called weighted morbid events. Terminating, repeated, and weighted events have in common one attribute or assumption: They occur instantly in time distant from some starting time (e.g., cardiac operation).

Depictions of time-related events have been called by many names that reflect their origin in the discipline from which they arose (economics, government, industrial reliability testing, biologic sciences).831 In this book, estimates based on counting theory alone (nonparametric estimates, see Box 6-14) are termed actuarial estimates or life-table estimates, for which there is strong historical precedence.831 These terms do not imply for us the specific theoretical underpinnings or method of calculation, of which there are many.
Historical Note

The word actuarial comes from the Latin actuarius, meaning “secretary of accounts.” The most notable actuarius was the Praetorian Prefect Domitius Ulpianus, who produced a table of annuity values in the early 3rd century AD. This table continued to be used in Europe into the early 19th century. With emergence of both definitive population data and the science of probability, modern actuarial tables arose, produced first by Edmund Halley (of comet fame) in 1693. He was motivated, as was Ulpianus, by economics related to human survival, because governments sold annuities to finance public works. Workers in this combined area of demography and economics came to be known as actuaries in the late 18th century. Importantly for this discussion, the methodology of the actuary varied widely. In the 19th century, the actuary of the Alliance Assurance Company of London, Benjamin Gompertz, developed mathematical models of the dynamics of population growth (birth and death) to characterize survival. This model-based, completely parametric (equations with constants estimated from data) methodology (see Box 6-14) was substantially different from the simple empirical counting methodology (nonparametric) of Halley.

In the more than 300 years since Halley, a multitude of methods have been developed (and often reinvented) in actuarial science, demography, statistics, industry, and medical science. They all have the common goal of estimating the distribution of intervals between a designated time zero and occurrence of an event. In medicine, an ad hoc direct method of survival estimation was developed in which nth-year survival (e.g., 5-year survival) excluded all patients whose follow-up interval was less than n years. Life tables constructed in this fashion were not guaranteed to be monotonically decreasing, nor did they use all patients with all available information for each time-related estimate.

The direct method highlights a unique problem with time-related events data: incomplete (not missing) data (Box 6-20). Rarely are we patient enough to observe a group of patients until all have died. Rather, at a given point in time we know the duration of survival for some patients and therefore have complete data with respect to vital status; for others we know only that they are still living after a certain interval of time. We know something (they have not died within that interval), but information about when they will eventually die is incomplete. A method was needed to use both complete and incomplete data; we call this censored data (see Box 6-20).

In 1950, Berkson and Gage published their landmark medical paper on the life-table (actuarial) method for censored data, which they stated was no different from that used by others as early as at least 1922. Estimates of percent survival and censoring were made at arbitrarily determined intervals (e.g., yearly), although the original papers Berkson cites also address a method of generating a new estimate at every unique death interval that went unrecognized even after the work by Kaplan and Meier.

In 1952, Paul Meier at Johns Hopkins University and, in 1953, Edward Kaplan at Bell Telephone Laboratories submitted to the Journal of the American Statistical Association a new method for survival analysis, the product-limit method, that used more of the data. Estimates were generated at the time of each occurrence of an event. Furthermore, the basis for the estimates was grounded in sound statistical theory.
and assumptions, such as the effect of informative censoring. Much of the development was in the field of medicine.

Important developments also took place in industrial reliability. Wayne Nelson\textsuperscript{66} at General Electric developed a method for analyzing time-related events in the \textit{cumulative hazard function} rather than the survivorship domain (see "Fundamentals" under Time-Related Events later in this section) because he was interested in the rate at which events occurred (hazard function). The estimation procedure differed, therefore, from that of Kaplan and Meier, but the two methods converge as the number of events increases (see "Repeated Events" and "Weighted Events" later in this section). Importantly, by not "thinking" in the probability domain but rather the hazard function domain, he extended his method to repeated events, and then extended this further to weighted events.\textsuperscript{N7,N8} He called the latter \textit{time-related cost functions}, recognizing that recurrence of the same event, such as a machine repair, may be associated with different costs. (We have used this, for example, to analyze the grade of medical impairment from repeated episodes of thromboembolism following heart valve replacement.\textsuperscript{B27,B28})

Fundamentals

Time-related events are those presumed to occur at an instant in time after a defined starting time. Time of occurrence generally differs from patient to patient. Information about occurrence of the event and when it occurred is obtained by patient follow-up, as detailed under "Follow-up" in Section III.

Essential Data

Successful analysis of time-related events requires answers to three fundamental questions:

- What is the event?
- When is time zero?
- Who is at risk?

\textbf{Event} Defining the \textit{event} for an analysis may be straightforward, such as death from any cause. Events that are not uniformly fatal are called \textit{nonterminating} or \textit{morbid events}. Examples include brain abscesses, reoperations, and development of angina. A clear, uniformly applied definition of the event is vital and has two components: (1) It defines an \textit{uncensored} patient who experiences the event, and (2) it defines a \textit{censored} patient who at some point in time becomes untraced as regards the event.

Caution must be exercised in considering the time-relatedness of some events. For example, degeneration of a xenograft heart valve is a time-related \textit{process}, not an event. Timing of reoperation for structural valve deterioration of a xenograft, therefore, depends on the rate of a process, the patient’s response to that process, and medical decision making. Processes that can be measured at multiple times are best studied by the methods described under \textit{Longitudinal Outcomes} later in this section.

\textbf{Time Zero} The moment a patient becomes at risk of experiencing the event of interest is called \textit{time zero} (Fig. 6.19). For patients who undergo interventions such as a cardiac procedure, time zero is often the time of the procedure. Under many circumstances, however, defining time zero is not so simple. For example, it is not easy to date the

![Figure 6.19: Right-censored time-related-events data. Conceptual graph of incomplete data in a group (cohort) of patients followed after operation cross-sectionally (see Follow-up in Section III). A, Calendar date is along horizontal axis, and each patient enters at a different date, ordered from earliest date of operation to most recent, top to bottom. Systematic active follow-up has a common closing date. Patients still alive at follow-up are depicted by arrowheads indicating that they will continue to be followed. Terminated lines are deaths. B, Patients are now aligned at \textit{time zero}, when operation was performed. They have also been sorted from shortest interval to longest (called \textit{rank order}). Patients who are still alive are depicted by lines with arrowheads. Time of their death is unknown and in the future, but we at least know they have lived as long as is indicated by the length of their follow-up line. This is called \textit{incomplete data} with respect to death, or \textit{censored data}. Because the arrow of time is presumed to proceed from left to right, data are called \textit{right censored}. The four lines that terminate without an arrow are deaths. C, Basic counting needed to estimate survival. Along the left is number of patients at risk; at time of shortest follow-up, all eight patients were at risk. Number decreases progressively as patients either die or are no longer traced. On right is the count of deaths at that interval (here, as is usually the case, the number is 1).
onset of ischemic heart disease, although it may be easy to identify the date of a first MI.

At Risk Patients remain at risk of experiencing the event from time zero to either the occurrence of the event or the time at which they no longer can experience the event (censoring; see Box 6-20). Defining who is at risk demands thought. For example, if the event is reoperation for bioprosthetic structural valve deterioration, then patients receiving a mechanical prosthesis are never at risk. This distinction may not be obvious to a statistician asked to analyze structural valve deterioration unless the surgeon-investigator explains it in detail. In this example, patients receiving a bioprosthesis also become no longer at risk of this event the moment the bioprosthesis is explanted for other indications. They are permanently censored at that point. Note that if a repeated morbid event is being analyzed, such as transplant rejection or thromboembolism, patients continue to remain at risk after each occurrence of the event until they are censored by death, end of follow-up, or, for these examples, retransplantation or removal of the valve prosthesis.

Granularity of Time
The basic data required for the simplest time-related analyses are (1) the interval from time zero to either occurrence of the event or censoring (usually the interval to end of follow-up) and (2) an indicator variable specifying that the event occurred (uncensored) or did not (censored). Granularity of this interval is important, particularly for parametric models (see “Parametric Survival Estimation” later in this section). The shorter the interval from time zero to the event, the finer the granularity required. In cardiac surgery, calculating the interval for a patient dying on the day of operation or experiencing a complication may require use of clock time (hours and minutes) of time zero (generally the first time that an attempt is made to wean the patient from cardiopulmonary bypass or that the operation is declared to be completed) and clock time of death or the complication. When the interval is long, simply subtracting the calendar date of the event from that of surgery is sufficiently granular.

Time-to-Event Model
There are two distinctly different ways to think about time-related events, and this difference must be understood for effective communication between the surgeon-investigator and the statistician. First, time-to-event data may be thought of as simply the distribution of intervals to an event (martingale or counting theory). This will be the framework with which most statisticians are familiar. Second, time-to-event data may be thought of in terms of the mathematics of mass transport from one state (e.g., alive) to another (death) (Markov process theory). This is the framework more familiar to a surgeon, who has training in such mass transport phenomena as diffusion, heat transfer, blood flow, and other dynamic transport processes involving rates.

Distribution Framework (Counting Process) Intervals to event are thought of like any other continuous, positive-valued variable. They can be expressed as a cumulative distribution graph (see Fig. 6-9, B), just like age. The only nuance is that by convention, the graph is turned upside down (its complement) so that it starts at 100% and falls as the interval lengthens. This is called the survivorship function. A common alternative expression for a cumulative distribution function is its slope (derivative), the probability density function, which is analogous to an ordinary histogram (see Fig. 6-9, A). Typically this function is not useful in survival analysis. What is useful is the ratio of the probability density function to the survivorship function (the conditional probability density function), because it represents the risk of the event in patients who have not yet experienced it. This ratio is the hazard function in survival analysis.

If \( S(t) \) is the survivorship function across time \( t \), \( b(t) \) the probability density function, and \( \lambda(t) \) the hazard function, the following mathematical equations express the above relations:

\[
b(t) = \frac{\partial S(t)}{\partial t} \tag{6-4}
\]

where \( \partial S(t)/\partial t \) is the slope (derivative) of \( S(t) \), and:

\[
\lambda(t) = b(t)/S(t) \tag{6-5}
\]

Mass Transport Framework (Hazard Function) A force of mortality called the hazard function, or \( \lambda(t) \), transports patients from the state of being alive, \( S(t) \), to the state of death \( F(t) \) (Fig. 6-20). This framework of thinking was initially suggested by John Graunt in the mid-1600s.\(^{6,23}\) Exactly the same equations, 6-4 and 6-5, hold for this dynamic process.

Useful Mathematical Relations
The area beneath the hazard function accumulates exposure to risk across time and is called the cumulative hazard function, \( \Lambda(t) \):

\[
\Lambda(t) = \int_0^t \lambda(u)du \tag{6-6}
\]

This relation yields other useful relationships:

\[
S(t) = e^{-\Lambda(t)} \tag{6-7}
\]

where \( e \) is the base of the natural logarithms, and

\[
-\ln[S(t)] = \Lambda(t) \tag{6-8}
\]

where \( \ln \) is the natural logarithm. Thus, the cumulative hazard function is easily calculated from estimates of \( S(t) \), and its slope reflects the shape of \( \lambda(t) \).

Nonparametric Survival Estimation
The nonparametric Kaplan-Meier method\(^{24}\) is the most commonly used method for estimating the survivorship function in medicine, although a number of others have been
Each Kaplan-Meier estimate incorporates the number of patients experiencing an event since the last event occurred and the number of patients at risk in that interval, taking into account censoring (see Fig. 6-19, C). Computing Kaplan-Meier survival estimates is relatively straightforward. The basic idea is to first calculate the probability of surviving (being event-free) in the interval since the last event occurred (the ratio of events, generally 1, to number at risk). This probability is then multiplied by the probability of surviving up to that time, a product called a conditional probability. This successive multiplication of individual probabilities by preceding ones is what gave rise to the generic description of this method, the product-limit method. It also guarantees that the estimates of survival decrease monotonically.

As can be imagined, at the longest intervals, few patients remain at risk and individual survival estimates make large jumps. For example, if four patients are alive and one dies, the probability of survival in that interval is only 75%. This phenomenon results in systematic bias downward, underestimating the survivorship function. This is called the completion effect.

Each Kaplan-Meier estimate has an expressed degree of uncertainty. Often this is reported as the standard error (essentially the 68% symmetric confidence intervals). Preferably, however, the degree of uncertainty is expressed using asymmetric confidence units. When plotted, a symbol positioned on the horizontal axis at the time of each event and on the vertical axis at the Kaplan-Meier estimate graphically displays the information (Fig. 6-21, A).

There is controversy about (1) whether or not Kaplan-Meier estimates should be connected and (2) if they are connected, in what fashion. If parametric estimates are also generated, the obvious solution is to compare nonparametric and parametric estimates, with nonparametric estimates unconnected (Fig. 6-21, B). If this is not the case and connection is desired, most statisticians connect estimates with a horizontal straight line at the level of the previous estimate. This is technically called “zero order” interpolation with a left step. It can be proven that this practice is the worst possible means of connecting estimates. Therefore, some statisticians connect the estimates by straight line segments (first-order interpolation), as did Berkson and Gage, but others use yet higher-order interpolation methods that approach the smoothness of parametric estimates. Kaplan-Meier and other nonparametric life-table estimates are not “raw data” (descriptions of actual events). The time of death actually “happened,” but the proportion, or percentage, is a computation and thus an estimate.

**Parametric Survival Estimation**

Unlike nonparametric survival estimation that arose from the theory of counting, model-based or parametric survival estimation (see Box 6-14) arose out of biomathematical considerations of the force of mortality, the hazard function. Unlike survival, which depicts prevalence of an event (or freedom therefrom) across time, the hazard function depicts the rate of occurrence, or incidence, of an event across time (see Box 6-13).

**General Comments**

During the Great Plague, John Graunt assumed a constant risk of mortality (the mortality rate or force of mortality). He called it the hazard function after a technical term for a form of dicing that had, by the mid-17th century, come into common usage to mean “calamity,” much as “crap shoot” has taken on the connotation of the losing throw in craps. Because a constant hazard rate presumes a mathematical model of survival, his was a parametric method. Graunt’s colleague, William Petty, believed instead that the hazard rate was age related (time varying).

Thereafter, the hazard function essentially disappeared from the medical world until the 1980s, although it remained in use in industry and in government depictions of population behavior. This is possibly because the hazard function, unlike the survivorship function, appears to have no well-understood statistical counterpart, as do the Kaplan-Meier estimator and death density function. It may also be related to the difficulty of understanding intuitively a series composed of almost an infinite number of instantaneous estimates of risk to the easily perceived accumulated risk expressed as freedom from the event. Also, the inherently mathematical nature of the hazard function makes it difficult and
forbidding to many physicians whose statistical collaborators may not have thought to introduce it to them in terms of biochemical reaction rates or other familiar physiologic rates. For those who need a visceral sense of the hazard function, think of its magnitude in terms of the sudden change from a sense of well-being to one of danger when screeching tires are heard close by.

Linearized Rate The most common expression of hazard is the linearized rate. It was linearized rates that John Graunt used when exploring risk factors for the plague. A linearized rate means the hazard function is constant across time. The analogy is radioactive decay: a constant rate of decay leads to exponential decrease in radioactivity. Likewise, a constant hazard leads to an exponentially decreasing survivorship function. When hazard is constant, the cumulative hazard is linearly increasing: \( A(t) = at \); that is, it increases linearly with increasing time with constant hazard slope \( a \). Then \( S(t) = \exp(-at) \), where \( \exp \) is the exponential function, and thus survival decreases exponentially.

The linearized rate is easily computed by simply counting the number of events and dividing by the total follow-up time of a group of patients:

\[
\hat{\lambda} = \frac{n_d}{\sum t_i} \tag{6-9}
\]

where \( \hat{\lambda} \) is estimated constant hazard, \( n_d \) is number of events, \( n \) is total number of patients, and \( t_i \) is individual \( i \) time to the event.

Importantly, if there are multiple events per patient, such as thromboembolic events, all occurrences are counted. CLs of linearized rates are also easily calculated (see “Repeate Events” later in this section). However, there are a number of different, although roughly equivalent, formulae for these CLs. For example, Cox and Oakes present a simple formula:

\[
\text{SD} \left[ \ln(\hat{\lambda}) \right] = \frac{1}{\sqrt{n_d}} \tag{6-10}
\]

and the upper CL of \( \hat{\lambda} \), \( \hat{\lambda}^+ \), is:

\[
\hat{\lambda}^+ = e^{\ln(\hat{\lambda}) + z\sqrt{n_d}} \tag{6-11}
\]

and the lower CL, \( \hat{\lambda}^- \), is

\[
\hat{\lambda}^- = e^{\ln(\hat{\lambda}) - z\sqrt{n_d}} \tag{6-12}
\]

where \( z \) is the confidence coefficient (1 for 68% CL, 1.96 for 95% CL), and \( e \) is the base of the natural logarithms.

Time-Varying Rate Although linearized rates have frequently been used for cardiac surgery data, particularly by regulatory agencies, it is uncommon for hazard to be constant. Rather, cardiac procedures, perhaps more than many other therapies, impose on patients a time-related course composed of highly variable and sometimes rapidly changing instantaneous risks of death modulated by multiple risk factors of varying strength and times of influence. Certainly the hazard function is greater 1 hour after operation than it is 1 week, 1 month, or 1 year after operation. Thus, a great deal of practical importance is attached to the time-varying hazard function after operation.

Visual examination of life-table depictions of events after cardiac operation in cohorts of well-followed patients reveals simple, smoothly time-varying patterns (see Fig. 6-21). These patterns suggest that the intervals between events are closely spaced immediately after the operation (usually time zero) and become more widely spaced in the hours and days that follow. Some days, weeks, or even months later, they merge into a sparse, random spacing of events. If follow-up evaluation is extended considerably, the time interval between events may again begin to shorten, representing accelerated risk. Nevertheless, under most circumstances, the majority of patients are free of the event even after many years, making censoring prevalence high in the cardiac surgical setting.

The stereotypical patterns observed in analysis of several thousand life tables of freedom from an unfavorable outcome event after cardiac operation led the UAB group, at the urging of D.R. Cox, to believe that a mathematical model for time-related events could be developed. In this development, it was thought likely that risk factors for late-occurring events would differ at least in strength, if not qualitatively, from those in the acute phase of recovery after operation, and that their prevalence might be different in different time frames. Further, the ability to graph patient-specific risk and survival estimates became increasingly important to development of new knowledge in cardiac surgery. Finally, these depictions required CLs. Therefore, the UAB group introduced a hazard function modeling method that produced not only time-related freedom from an event but also time-varying risk (hazard function) for an event, complete with CLs. The method is analogous to using a prism to decompose white light into its various colors. It decomposes time-varying hazard into as many as three simple additive hazard phases as shown in Fig. 6-22 (a more generalized method would allow more than three phases for unusual situations as has been done for longitudinal outcomes described later in this section).

The mathematical model is as follows:

\[
A(t, x) = \sum_{j=1}^{k} \mu_j(x, \beta_j) \cdot G_j(t, \Theta_j) \tag{6-13}
\]

where \( A(t,x) \) is the cumulative hazard function, \( \mu_j(x,\beta_j) \) is a function of risk factors for the \( j \)th phase, \( G_j(t,\Theta_j) \) is a shaping function unique for each phase, and \( \Sigma \) is the sum of the individual components (phases) \( 1 \) through \( k \). Such a formulation places Equation 6-13 into the class of mixture distributions and competing risk models (see “Competing Risks” later in this section), with each hazard phase competing for the event.

The shaping functions \( G_j(t,\Theta_j) \) are based on a collection of biomathematical models of risk that were assembled into generic expressions. They permit great flexibility in shape of the short- and long-term hazard. Shape of the early hazard phase of short-term risk originated as an assembly of a large number of nested mathematical models describing biochemical reactions, ecology, and population growth. The early hazard function can begin at infinity after time zero, it can start at zero and peak, or it can start at a finite value and decline from there. Shape of the constant hazard phase, as its name implies, is a constant value (horizontal line) across time. Shape of the late hazard function is based on a
generalization of the Weibull model of risk used widely in industrial settings.\textsuperscript{10}

Although early and late hazard phases can have several of their shaping parameters estimated, in practice they usually reduce from four down to one or two parameters, resulting in simple, special-case forms of their respective generic mathematical constructs.

Each phase also has a scaling function \( \mu_t \) that can carry risk factors. This parameter was selected by sensitivity analyses and was not arbitrary. The form of the regression model may be either logit-linear or log-linear (see Box 6-5); they yield nearly identical coefficients and shapes.

All phases of the model are defined from time 0 to infinity. The phases are overlapping and additive across time (see Fig. 6-22, B), but the nature of the shaping functions allows a phase to predominate more at one time than another (see Fig. 6-22, C). This property permits the model to accommodate risk factors not displaying proportional hazard properties across all time (see “Cox Proportional Hazards Regression” later in this section).

A computer software program interfaced to the SAS system\textsuperscript{44} is available at http://my.clevelandclinic.org/professionals/software/hazard/default.aspx.

**Estimating Time-Related Hazard Function**  The first step in developing a model specific to a set of event-time data is to determine the overall hazard function across time (without considering risk factors). This is the step, sometimes a time-consuming one, that differs from the work required in using the Cox model described later in this section. The work is best done in the cumulative hazard domain by taking minus the logarithm of the life-table estimates\textsuperscript{36} (Fig. 6-23). This depiction makes evident the early phase of hazard, the duration of its predominance, and the point at which it levels off (its asymptotic value). Slope of the intermediate phase of risk yields an estimate of the constant hazard scaling parameter. Departures late from the constant hazard slope yield information about the late rising phase of hazard if it is present. Such plots also reveal whether one or two of the three phases may be completely absent, given the duration of follow-up and distribution of observed events.

The method of maximum likelihood is used to estimate values for the parameters of the proposed model, which includes exploring various mathematical forms of the early and late generic shaping equations, defined by the sign of their exponents, and reducing the model to its simplest form (parsimony).\textsuperscript{31} The only input to this process is the sequence of event and censoring intervals. No arbitrary assignment of events to early, constant, or late hazard phase is required. The model simply attempts to best represent the distribution over time of these intervals. An iterative (optimization) procedure is used to estimate the parameter values. Once estimated, these values can be used to solve the resulting equation for

\[ \text{cumulative hazard function, and hazard function (time-related instantaneous risk of event and slope of cumulative hazard).} \]

\[ \text{Box 6-5} \]

\[ \text{Fig. 6-22, } B \]

\[ \text{Relative influence} \]

\[ \text{Fig. 6-23} \]

\[ \text{under most circumstances, the late hazard phase equation is constrained such that hazard increases monotonically (i.e., without decreasing at any point). In reality, the equation is more flexible than this and can conform to late hazards that may at some point diminish. For example, the hazard function for the population of the United States has an early declining hazard phase reflecting infant mortality, a constant hazard phase that over the past century has practically disappeared, and a generally rising late hazard phase. However, this phase is interrupted by a small peaking hazard phase during late teenage and early adulthood years, representing, among other causes, accidental deaths. Furthermore, at the extreme of old age, hazard may not increase to the extent predicted by a Weibull relation, perhaps because these elderly individuals are a highly select robust group.} \]
time-related freedom from the event and the hazard function (Fig. 6-24).

Absence of some phases may be related to duration of follow-up or number of events observed and their intervals, which may make it difficult to identify statistically the existence of a phase. Most commonly, one or two phases are found.

At this juncture, investigation is made of model validity. The calculated (parametric) event-free curves are superimposed on the Kaplan-Meier estimates and examined for lack of correspondence (see Figs. 6-21 and 6-23).

Multivariable Analysis

Feigl and Zelen introduced multivariable analysis of constant hazards using a log-linear model (see Box 6-5). This formalized the method used 300 years earlier by Graunt, but it is inapplicable to data with time-varying hazards that typically characterize risk after interventions.

A number of methods were used in a limited way in demographics and industry, but in 1972 everything changed. That year, D.R. Cox proposed a multivariable method that did not require estimating the hazard function as in Fig. 6-21. A, Nonparametric estimates. B, Superimposed nonparametric and parametric estimates. Note good correspondence between the two sets of estimates. (From Studer and colleagues.)

Figure 6-24  Death after coronary artery bypass grafting (CABG), illustrating survivorship and hazard functions and decomposition of hazard into phases. A, Survival. Solid blue line is survival estimate, and dashed lines enclose confidence limits (CL) equivalent to ±1 standard error. Numbers are percent survival at 30 days, 5, 10, 15, and 20 years after operation. Red line is survival in an age-sex-race–matched population life table. B, Hazard. Solid blue line is hazard estimate, and dashed lines enclose CLs equivalent to ±1 standard error. Red line is hazard in an age-sex-race–matched population life table. C, Components of instantaneous risk of death (hazard). Three are depicted: (1) an early rapidly falling hazard phase, (2) a constant hazard phase, and (3) a late-rising hazard phase. These components sum across time to overall hazard function shown by dotted line. (From Sergeant and colleagues.)
function. Rather, it assumed that an unspecified underlying hazard function of any shape was modulated in a regular way by a set of risk factors. This is called a semiparametric method because the model for risk factors was parametric, but the underlying hazard was unspecified.

Cox Proportional Hazards Regression

The log-linear (see Box 6-5) form of the Cox model of risk factors is:

\[
\ln[\Lambda(t)] = \ln[\Lambda_0(t)] + \beta_1 x_1 + \beta_2 x_2 + \ldots + \beta_k x_k \tag{6-14}
\]

where \(\Lambda_0(t)\) is the underlying unspecified hazard that is modified by risk factors \((x)\) that are weighted by coefficients \((\beta)\); \(\ln\) is the natural logarithm. The importance of the log-linear form is that the scale of both \(\beta\) and \(x\) can span the entire number line, and still the hazard function will be positive when \(\ln[\Lambda(t)]\) is exponentiated, which must be the case.

Another way to express the Cox model is in the cumulative hazard domain. Let us say there is one dichotomous risk factor, \(x_1\), and coefficient, \(\beta_1\). Then:

\[
\Lambda(t) = \Lambda_0(t)e^{\beta_1 x_1} \tag{6-15}
\]

where \(\Lambda(t)\) is the cumulative hazard function, \(\Lambda_0(t)\) is the underlying cumulative hazard, and \(e\) is the base of the natural logarithms. The ratio of cumulative hazard with the factor present \((x_1 = 1)\) to that with it absent \((x_1 = 0)\) is:

\[
\frac{\Lambda(t, x_1 = 1)}{\Lambda(t, x_1 = 0)} = e^{\beta_1} \tag{6-16}
\]

Taking logarithms and rearranging:

\[
\beta_1 = \ln[\Lambda(t, x_1 = 1)] - \ln[\Lambda(t, x_1 = 0)] \tag{6-17}
\]

Notice that the logarithm of the two cumulative hazard curves is separated across all time by a constant distance \(\beta_1\) (Equation 6-17), and the exponential of \(\beta_1\) (Equation 6-16) represents a constant ratio of cumulative hazards. This idea of a constant distance of separation or constant ratio is known as the proportional hazards assumption of the Cox method. Recall that cumulative hazard is estimated from the survival curve \(S(t)\) by taking minus its logarithm (Equation 6-8). Therefore, if logarithms are taken of cumulative hazard using either Kaplan-Meier or Nelson estimates (or a single logarithm of Nelson cumulative hazard estimates), the proportionality assumption can be checked. If the proportional hazards assumption does not hold, nonproportional hazard methodology must be used.

Often \(\beta\) is expressed in a fashion to reflect relative risk as hazard ratios and their CLs (see Box 6-3). This can be seen from Equation 6-16, where the \(\beta_1\) is exponentiated, showing a ratio of hazards with and without the risk factor. CLs are asymmetric, obtained from the variance of \(\beta\). The hazard ratio makes sense for dichotomous variables, but less sense for continuous ones, particularly if transformation of scale has been necessary.

Parametric Hazard Function Regression

Multivariable analysis of risk factors is no more (or less) difficult in the totally parametric hazard function domain than in the logistic or Cox regression domain (see “Multivariable Analysis” earlier in this section). The only intellectual (not computational) complexity is that risk factors are estimated simultaneously in all phases of hazard. Within each hazard phase, risk factors are assumed to obey a proportional hazards assumption (see “Cox Proportional Hazards Regression” earlier in this section). However, the entire model need not (and generally does not) obey the proportional hazards assumption. It therefore has been classified as a model of nonproportional hazards.

The main additional work in using a multiphase hazard method is obtaining the underlying specified hazard function. Among the diagnostics for such a model is the general depiction of the time frame during which each hazard phase dominates (see Fig. 6-22, C). The data can be examined within these separate time frames for screening and for transformations that may be necessary for continuous and ordinal variables.

After risk factors have been identified in each hazard phase, a final check on which phase a risk factor properly belongs to is performed. Occasionally a risk factor will be found with similar strength in each hazard phase, and such a variable indeed meets the proportional hazards assumption across the entire span of follow-up represented in the data. This suggests that the entire sum in Equation 6-13 could be multiplied by another scaling function consisting of proportional hazards variables.

A complete description of the final equation that emerges from the hazard function multivariable analysis includes a model specification, coefficients for all variables (incremental risk factors) in each phase of the equation (recall that a risk factor can occur in more than one phase), intercept for each phase, shaping parameter estimates, and a variance-covariance matrix. Because the equation is by definition completely parametric, prediction of an event-free curve and its corresponding hazard function, each accompanied by CLs, is possible for any desired combination of values for the risk factors by substituting values for each variable in the equation and solving it for any time interval(s) desired.

Validating the Multivariable Analysis

Validation of the multivariable analysis in a specific study is accomplished by comparing the computed time-related survival of a stratified life-table depiction of the entire study group with that predicted by the multivariable equation (Fig. 6-25). This process can be extended to subgroups to check the adequacy of modeling efforts. The process is similar to that for risk adjustment (see “Risk Stratification” in Section VI) and is accomplished in the following manner. For each patient, the survivorship function is estimated across time \(\hat{S}(t; x_i, \Theta, \beta)\) from each individual’s specific values for the risk factors in the equation. In the above notation, \(t\) is the time interval after time zero, \(\Theta\) is the vector (column of numbers) of shaping parameter estimates, \(\beta\) is the vector of regression coefficient estimates, and \(x_i\) is the corresponding vector of risk factor values for individual \(i\). For clarity, this is abbreviated to notation \(\hat{S}(t; x_i)\). In addition, the upper and lower CLs for \(\hat{S}(t; x_i)\) are calculated using the variance-covariance matrix from the multivariable analysis. The predicted value of time-related survival in a group of \(n\) individuals is then calculated as the average at each point in time of the individual survival estimates:

\[
\hat{S}(t) = \frac{\sum_{i=1}^{n} \hat{S}(t; x_i)}{n} \tag{6-18}
\]

The theoretical justification for this is that the individual \(\hat{S}(t; x_i)\) represents proper cumulative distribution functions.
and these should sum to another proper cumulative distribution function.\textsuperscript{116} On the other hand, specific theory underlying the formulation of CLs for this estimate in a straightforward manner has not been available. A conservative estimate has been made, however, by averaging the upper CLs for each individual to form an upper CL for \( \hat{S}(t) \), and similarly for the lower CL. The error, if present, is that the confidence intervals are too wide. These confidence intervals have been found to be roughly equivalent to those obtained by averaging the variance of the logistic transform of \( \hat{S}(t) \), but they are somewhat more stable.

For the validation, time-related freedoms from the event of stratified groups of the cohort are determined nonparametrically as well and plotted according to the Kaplan-Meier estimator. For example, Fig. 6-26 shows tetralogy data stratified according to presence or absence of a transanular patch. This variable was not identified as a “significant” risk factor in the multivariable analysis. Nonetheless, averaged parametric survival values for the patients in the subset compare well with stratified Kaplan-Meier survival. (This validation study also indicates that difference in prevalence of risk factors in patients with and without transanular patching, not the patching itself, appears to account for the difference in mortality.) Propensity score matching would provide the most reliable support for this inference (see “Propensity Score” in Section I).

In a fashion akin to the logistic model, an overall assessment of validity within each stratum also may be obtained by calculating the number of expected events and comparing that with the number of observed events in the domain of time-related events, conservation of events is attributed to the cumulative hazard function rather than to the probability domain. Thus, for each individual’s specific follow-up interval \( (t) \), the cumulative hazard, \( \Lambda(t; x_i) \), is calculated. These are summed to estimate the expected number of events \( (E) \):

\[
E = \sum_{i=1}^{n} \Lambda(t; x_i)
\]

(6-19)

The expected number of events is compared with the observed number of events by a chi-square goodness-of-fit test.

Expressing Degree of Uncertainty in Time-Related Depictions of Freedom from an Event

There is conflict (or at least difference of opinion) between (1) those who focus on a single overall \( P \) value for the difference between two time-related freedom-from-event depictions (life tables) and (2) those who use time-related depictions as a consideration when recommending therapy for individual patients (see “Time-Related Events” earlier in this section). This stems from their differing needs. Studies involving testing hypotheses, such as clinical trials in which

\begin{table}
\centering
\begin{tabular}{|c|c|c|c|}
\hline
Interval (months) & Life table & Parametric & Life table & Parametric \\
\hline
1 & 97% & 97% & 92% & 93% \\
3 & (97%) & 96% & 90% & 90% \\
6 & (97%) & 95% & 88% & 89% \\
12 & (97%) & 95% & 87% & 89% \\
36 & (97%) & 95% & (87%) & 89% \\
72 & (97%) & 95% & (87%) & 89% \\
\hline
\end{tabular}
\caption{Simple repair (\( n=81 \)) versus transanular patching (TAP) (\( n=92 \)).}
\end{table}
treatment is randomly assigned, usually require a yes/no (true/false) answer to a hypothesis, and a single overall P value may be appropriate. The clinician, on the other hand, lives daily with the reality that for an individual patient, occurrence of an unfavorable outcome event at one point in time (interval after time zero) is often considerably less disadvantageous than occurrence of the same event at another point in time; the clinician also understands that there is considerable variability among patients as to the time of greatest disadvantage.

Mantel recognized in 1966, as no doubt did others, that time-related variability occurs in the relation between survival curves of two different treatments or between groups of patients. He noted that in some cases the difference may be similar throughout time; that in others the relation between the two may be similar at some times but not at others; and that in still others one survival curve may cross another. He also recognized that varying hazard phases are present after surgical procedures, and he understood the variability in the “utility function,” or value, ascribed by different individuals to the same survival curve.

These matters posed difficulties for those seeking a simple yes/no answer to a hypothesis. In response to this, Mantel and others set about to devise tests that would generate a single overall P value. These tests make different assumptions, each attempting to overcome some difficulty posed by the differing patterns of survival. In contrast, clinicians wish to compute, examine, and understand the variability in the time-related comparisons between curves in order to best inform and advise patients. Thus, they wish to know the time-related certainty of differences that may exist.

The scanning method of comparing confidence intervals, as well as methods involving P values, can be applied to develop time-related estimates of the degree of uncertainty in comparing survival and other event-free curves. A depiction of time-related survival is in actuality a series of proportions; the proportions are discrete when determined by the Kaplan-Meier life-table method and are continuously variable when determined by the parametric hazard function regression analysis method. Thus, the overlapping or non-overlapping of confidence intervals around each of two survival curves can be used to scan the possibility, at various specific intervals after time zero, that the difference between the curves is or is not likely to be due to chance alone (Fig. 6-27, A). Also, based on classic statistical principles, the time-related confidence intervals around the difference between the two proportions can be determined and their relation to zero computed and visualized in a continuous, time-related depiction (Fig. 6-27, B). An equivalent expression of absolute difference is absolute risk reduction, the inverse of this difference, often expressed as number to treat to save one life (see Box 6-3). The time-related relation of the difference compared to zero difference can be depicted continuously in terms of the P value (Fig. 6-27, C). The time-related relation of the difference compared to zero difference can be depicted continuously in terms of the hazard function (Fig. 6-27, D). They may also be compared using the CLs around the hazard ratio (Fig. 6-27, E). Alternatively, the area between survival curves—the lifetime function—can be computed (Fig. 6-27, F). We prefer the lifetime function to the alternative statistic, expected lifetime, because the complete hazard function beyond the follow-up information available affects the value of this extrapolated statistic, and its trajectory may not be well characterized.

Repeated Events

Unlike death, morbid events such as thromboembolism or important bleeding after heart valve replacement may recur. Furthermore, the consequences of these events may be variable, from apparently “no functional residual” from a transient ischemic attack to a fatal outcome (Fig. 6-28).

If the hazard function is truly constant, the method of linearized rates, as described earlier in this section under “Parametric Survival Estimation,” may be used. The estimation procedure is simple but rarely appropriate, because most hazard functions are not constant.

When the hazard function is not constant, three general approaches to display and analysis of morbid events have been used: analysis as a terminating event, repeated events analysis, and modulated renewal process analysis.

Terminating Events Approach

The most common method of display and analysis of repeated morbid events is to focus only on the first occurrence, ignoring any further information beyond that point for the patients experiencing the event. It thus becomes a terminating events analysis, with Kaplan-Meier estimation of freedom from occurrence of the event. This is the least informative approach.

Repeated Events Approach

True repeated events analysis can be performed, but generally this requires abandoning the Kaplan-Meier estimator and turning to the Nelson estimator. The Nelson method is formulated in the cumulative hazard domain (see “Fundamentals” under Time-Related Events earlier in this section). Patients continue to be followed after each occurrence of the event until end of follow-up or death or some other appropriate censoring mechanism (see Fig. 6-28). Estimates are made at the time of each occurrence, with the hazard estimated as 1/number at risk, and the cumulative hazard as the sum of all these hazards. Graphical depiction of Nelson estimates is as cumulative hazard across time, with the vertical axis being the number of repetitions of the event expected per patient (Fig. 6-29). Thus:

\[
\Lambda(t) = \sum_{i=1}^{n} \frac{n_{\text{end}}}{n_{\text{start}}} \tag{6-20}
\]

where \( n_{\text{end}} \) is the number experiencing the event (generally 1) at time \( t \), and \( n_{\text{start}} \) is number at risk.

\(^{11}\) Comparison of Kaplan-Meier and Nelson estimators. The Kaplan-Meier estimator for survival at time \( t \), \( S(t) \), is:

\[
S(t) = \prod_{i=1}^{n} \left(1 - \frac{n_i}{n_{\text{start}}}\right)
\]

Transforming \( S(t) \) to cumulative hazard:

\[
\Lambda(t) = -\sum_{i=1}^{n} \ln \left(1 - \frac{n_i}{n_{\text{start}}}\right)
\]

If \( n_{\text{start}} = 100 \) and \( n_{\text{end}} = 1 \), the logarithmic term \( 1 - \frac{n_i}{n_{\text{start}}} \approx 0.99 \) and its logarithm is 0.01005. Compare this with the Nelson estimate of cumulative hazard, \( n_{\text{end}}/n_{\text{start}}, \) which in this case is 1/100 = 0.01. For all practical purposes, the two estimates are equivalent. The advantage of the Nelson estimator is that it can be extracted from the probability domain \( S(t) \) so that repeated and weighted events can be evaluated, neither of which has a probability domain counterpart.
Figure 6-27  Survival estimates for a cachectic diabetic man with unstable angina according to different initial treatment strategy for his ischemic heart disease. This set of graphs depicts the decision-making challenge of intervention versus continued medical therapy (or natural history of a chronic disease) versus one alternative intervention. There are “crossing lines”: an initial higher risk of surgery is traded for a longer-term survival benefit. A patient might prefer to delay surgery or accept an alternative therapy if there are matters of short-term importance that are higher in priority than short-term risk of mortality of medical therapy. Another similar patient may want to undergo immediate high-risk surgery because of importance of long-term goals. Therefore, the decision by patients concerning timing of surgery, if at all, must take into account these crossing lines and their personal short- and long-term goals (preferences). 

A, Survival. Solid lines enclosed within dashed confidence limits (CL) are point estimates for (1) natural history (medical), (2) percutaneous coronary intervention (PCI), and (3) coronary artery bypass grafting (CABG). These predictions are based on patient-specific solutions of the multivariable equations presented in reference. 

Within the first year, procedure mortality results in a survival advantage for medical therapy, but after 2 years, nonoverlapping CLs indicate an advantage for intervention. 

B, Difference in predicted percent survival (solid curve) between CABG and natural history (medical) with dashed 90% CLs. Initially, there is a medical benefit (negative difference), but after 1 year, a CABG benefit. P value for difference in predicted percent survival between CABG and natural history (medical). Difference in benefit shown by overlap and nonoverlap of CLs in B is depicted in terms of P value; note that P value is shown symmetrically above and below 1, reflecting a change in direction of benefit. 

C, Hazard function (solid curves) for death from natural history (medical), PCI, and CABG with dashed 70% CLs. Note that instantaneous risks diverge considerably earlier than survival estimates (A) and lifetime estimates (F), because rates must both change and remain changed sufficiently long to produce a survival or lifetime difference. 

D, Hazard ratio (solid curve) of CABG and natural history (medical) with dashed 90% CLs. Initially, the hazard ratio favors medical therapy, but then CABG. Note that hazards become proportional after about 6 months (flat portion of ratio), but are nonproportional before then. Vertical axis has been arranged to give equal weight to a twofold increase in risk and a 0.5-fold decrease in risk. 

F, Difference in predicted lifetime (solid curve) between CABG and natural history (medical) with dashed 90% CLs. Lifetime difference is the area between the two corresponding survival curves depicted in A.
The Blackstone-Naftel-Turner parametric hazard methodology is designed to analyze repeated morbid events. An interesting but useful technical detail of such an analysis is that each patient’s follow-up history is recorded as a sequence of interevent segments: time zero to first event, first event to second (etc.), last event to censoring mechanism. Each segment has a beginning and ending time. Kalbfleisch and Prentice point out that this approach to the data simplifies what might otherwise appear to be a daunting analytical challenge.\(^1\)

**Modulated Renewal Process Approach**

The hazard function for repeated events such as cardiac rejection episodes may follow a similar pattern after each repeated episode, only modulated to some degree (higher or lower) in its intensity. Such a phenomenon, commonly observed in the industrial setting, is called a modulated renewal process (see Fig. 6-28, D).\(^1\)

The idea behind a modulated renewal process is that the industrial machine (or patient) is restarted at a new time zero each time the event occurs. This permits (1) ordinary Kaplan-Meier methods to be used, (2) the number of occurrences and intervals between each recurrence to be used in multivariable analyses, and (3) change in patient characteristics at each new time zero to be used in analyses. Thus, if the modulated renewal assumption can be shown to be valid, it increases the power and utility of the analysis tremendously. For example, Hickey and colleagues demonstrated that each repeated episode of thromboembolism following mitral valve commissurotomy increased the risk (shortened the interval) of the next\(^2\) (Fig. 6-30). Kubo, Naftel, and colleagues demonstrated that rejection after cardiac transplantation behaved as a modulated renewal process, and among other factors, number of previous rejection episodes was a risk factor for subsequent episodes\(^3\) (Fig. 6-31). Blackstone and colleagues exploited the modulated renewal process methodology for reoperations, periprosthetic leakage, and replacement device endocarditis after valve replacement.\(^4\)

From a data handling perspective, the patient’s follow-up record is segmented just as described earlier in this section for the “Repeated Events Approach,” but the starting time

---

Figure 6-28  Repeated morbid events data. Conceptual graph of incomplete data in a group (cohort) of patients followed cross-sectionally after mitral valve replacement (MVR) with a mechanical prosthesis, depicting repeated morbid events. Deaths are depicted by \(D\), and the morbid event (thromboembolism) is depicted by \(E\). Censored patients (alive at follow-up) are indicated by arrows.

**A**  Calendar date is along horizontal axis, and each patient enters on a different date of operation, similar to depictions in Fig. 6-19. Five patients have experienced the morbid event, and two of these have experienced two events; one has experienced three events. However, note that follow-up continues beyond these events.

**B**  Patients are again ordered for analysis by aligning them at time zero.

**C**  From a purely practical point of view, the longitudinal record of each patient is broken into segments, each with a starting and ending time.

**D**  In a modulated renewal process analysis, all segments are moved back to time zero (and for analysis, they would also be reordered from shortest to longest interval, which is not depicted here).
Figure 6-29  Illustration of repeated events data. Repeated bloodstream infections after left ventricular assist device (LVAD) insertion are shown. A, Cumulative number of bloodstream infections, expressed on vertical axis as number per patient (repeating events analysis). Each circle represents an infection, vertical bars represent asymmetric 68% confidence limits (CL), and numbers in parentheses are number of patients remaining at risk. Solid line enclosed by dashed 68% CLs is the parametric estimate of bloodstream infections from which hazard for event was derived. B, Hazard function for bloodstream infections expressed on vertical axis as percent per month (solid line enclosed by 68% CLs). C, Cumulative number of bloodstream infections according to type of LVAD. Open circles represent events experienced by patients receiving implantable pneumatic HeartMate devices (IP); solid circles, vented electric HeartMate devices (VE); and open squares, Novacor devices. (From Navia and colleagues.\textsuperscript{N4})

Figure 6-30  Freedom (risk-adjusted) from a postcommissurotomy thromboembolic event, illustrating analyses of repeated morbid events as a modulated renewal process. Top curve represents freedom from first thromboembolic event, and time zero is time of operation. Middle curve represents freedom from a second thromboembolic event among 33 patients who had a first thromboembolic event after commissurotomy, and time zero for this depiction is time of first thromboembolic event. Lowest curve represents freedom from a third thromboembolic event among patients who already had experienced two, and time zero is time of second episode. (From Hickey and colleagues.\textsuperscript{H20})
of each segment is set to zero and the ending time to duration of the segment.\textsuperscript{31}

**Weighted Events**

When a machine is repaired, there is a cost associated with the repair. Thus, in industrial settings it is important not just to estimate the risk (hazard) of repair but also to weight those risks by the cost of repair.\textsuperscript{37,38} (Fig. 6-32). Mathematically, cost is taken into account by what is termed “weighting” of the hazard estimate. This simply means the hazard is multiplied by the cost.

Medically, there are a number of cost scales that can be used to quantify, or at least grade, severity of an event. The UAB group, for example, used a simple 5-point scale for residual neurologic consequences of a thromboembolic episode, with 0 being no consequences and 4 being death.\textsuperscript{327}

Nonparametric estimation is in the cumulative cost domain, and Nelson’s method is used.\textsuperscript{37,38} The Blackstone-Naftel-Turner parametric hazard function method also accommodates weighted events and complete multivariable analysis.\textsuperscript{844}

**Competing Risks**

Competing risks analysis is a method of time-related data analysis in which multiple mutually exclusive events are considered simultaneously.\textsuperscript{34,317} It is the simplest form of continuous-time Markov process models of transition among states.\textsuperscript{46} In this simplest case, patients make a transition from an initial state (called *event-free survival*) to at most one other state that is considered to be terminating (Fig. 6-33). Thus, there is a single set of intervals from time zero to the earliest occurring of each event for a given patient. Rates of transition from the initial state to one of the events (called an *end state*) are individual independent functions. One way to think about this is that the initial state is represented by a bucket of water (Fig. 6-34). The transition rates are holes in the bucket of varying size. If all but one hole is blocked, the amount of water filling a container beneath the hole is identical to an ordinary survival function turned upside down. In a competing risks analysis, one is interested in discovering the amount of water in each of several containers when all the holes are unblocked simultaneously.

**Motivation**

Analysis of a single time-related event is performed in isolation of any other event. This is ideal for understanding that specific phenomenon. In contrast, competing risks analysis considers multiple outcomes in the context of one another. It is thus an integrative analysis.

Fig. 6-35 shows three events following CABG: death before reintervention, reintervention by percutaneous methods, and operative reintervention. At time zero, all patients are alive and without reintervention. They then migrate at different rates into the above various end states (Fig. 6-35, A). The consequence of these migrations is that the initial state is gradually emptied, and the reintervention states and death state fill (Fig. 6-35, B).

The nature of migration into each of these end states is itself an important phenomenon. Results from the Cardiac Transplant Research Database\textsuperscript{356} and the UAB group\textsuperscript{416} show the provocative difference in the various competing hazard functions for modes of death after transplantation, just as the UAB group had shown for modes of death after valve replacement.\textsuperscript{540}

---

**Figure 6-31** Freedom from transplant rejection after 1 year or any rejection episode later than 1 year, stratified according to number of rejection episodes during first year after transplantation. Data illustrate a repeated event analyzed as a modulated renewal process. Vertical bars represent 70% confidence limits. Key: CTRD, Cardiac Transplant Research Database. (Redrawn from Kubo and colleagues.\textsuperscript{5,35})

**Figure 6-32** Weighted repeated events. This compartmental analog shows patients experiencing an initial episode such as a cardiac valve replacement, at time zero. A repeating morbid event is then shown (e.g., thromboembolism). Rate at which these occur is depicted by \( \lambda \)s (which may differ after each event). In addition, medical cost of each episode is depicted by a severity weight (\( W \)). From each compartment (after each event), the patient may die, an eventuality governed by another set of hazard rates not depicted.
Figure 6-33  Competing risks data. Conceptual graph of incomplete data in a group (cohort) of patients followed after coronary artery bypass grafting (CABG) for death (D), redo CABG, or percutaneous coronary intervention (PCI). Depiction is similar to Fig. 6-13. A, Calendar date is along horizontal axis, and patients are operated upon on various dates. They are systematically followed and their status ascertained as of a common closing date, shown by vertical line. Notice that one patient died a while after redo CABG and another after PCI. Four patients experienced no events and are censored. B, Patients are aligned at time zero and rank ordered from shortest to longest follow-up time. First occurring event is shown. Thus, the two patients who died after redo CABG or PCI are depicted only to their intervention (other analyses of events following redo CABG and PCI should also be performed). In this way, each patient falls into exactly one of four mutually exclusive categories: PCI, redo CABG, death before either of these interventions, and event-free survival. Notice that each patient has in this depiction, unlike A, a single follow-up interval. This common follow-up interval to all events is characteristic of this simplest form of competing risks analysis.

Figure 6-34  Competing risks cartoon using a bucket and water analogy. In each case, large bucket is initially filled with water at time zero and represents event-free survival. Each spigot represents a route of exit of water from main bucket to smaller, initially empty, containers. Rate of flow is governed by position of tap. A, In ordinary analysis of single time-related events, there is only one tap. In competing risks analysis, this is analogous to closing all but one tap to permit estimation of its properties (called the hazard function). B, In the simplest competing risks analysis, two taps are opened simultaneously, and each water molecule (representing patients) must flow into only one container through one of the spigots. Level of water across time as each container fills (and main bucket empties) is quantified by the cumulative incidence function. C, A more complex competing risks case with three taps opened. Reintervention is broken down into the two mutually exclusive components of percutaneous coronary intervention (PCI) and repeat coronary artery bypass grafting (CABG).
In the early 18th century, some progress was made in the war against smallpox by inoculating people with small doses of the virus to establish immunity to the full-blown disease. The technique was 10% fatal in otherwise healthy individuals! The search for reliable low-risk protection became intense. Because governments at that time were supported in part by annuities, it was of considerable economic importance to know the consequences a cure of smallpox might bring upon the government’s purse. Daniel Bernoulli tackled this question by classifying deaths into mutually exclusive categories, one of which was death from smallpox. For simplicity, he assumed that modes of death were independent of one another. He then developed kinetic equations for the rate of migration from the state of being alive to any one of several categories of being dead, including from smallpox. It was like hanging a bucket of water with multiple different sizes of holes in the bottom (see Fig. 6-34) and assuming no interactions between the holes. He could then compute how stopping up one large hole, smallpox, would influence both the number of people still alive and the redistribution of deaths into the other categories.

The triumph of the “war on smallpox” came in 1796, just 36 years after his publication.

**What’s in a Name?**

Competing risks analysis has many names, which makes communication among disciplines, as well as assembly of a common body of methodological knowledge, difficult. In vital statistics, competing risks are often called *disease-specific event rates*. In actuarial statistics, they may be called *multiple decrement analyses*. In statistics, they are usually called competing risks, but also *cumulative incidence functions* or *marginal or conditional survival analyses*. In demographics, they may be called *crude vs. net vs. partial crude survival functions*. In medicine, and heart valve procedures specifically, the terms *cumulative events*, *multiple decrement*, *competing risks*, *mode-specific survival*, and *actuarial analysis* (competing risks are called *actual and single-event analyses actuarial*). These methods are contrasted as if they were competing methods, or indeed, as if one were right and the other wrong. We must emphasize that each answers different questions, and assuming independence, the hazard functions are the same. Had one of them not yet been invented, the other surely would have because of the different questions answered. Individual event analyses (actuarial) using the entire patient cohort answer the question, “What is the probability of this event among patients still exposed to risk of the event, and what are its risk factors?” It is an unconditional probability. It is relevant to the investigation of a phenomenon. Such an investigation has to be conducted (as best as possible) free from confounding by occurrence of other outcomes. In contrast, competing risks analyses address the question, “How many patients are expected to experience a certain event before they experience another (specified) event?” Thus, individual event analyses indicate the probability of operative CABG as a function of age; competing risks analyses may indicate that few elderly patients will survive to experience such a reoperation.

We caution against direct display of actual and actuarial estimates on the same graph. In fact, each has a different scale (probability scale for individual events; cumulative incidence

---

**Figure 6-35** Illustration of competing risks. Figure depicts time-related competing events after coronary artery bypass grafting. **A**, Risk-unadjusted migration rates (hazard functions) into each of three mutually exclusive event categories: death before reintervention, reoperation by reoperation, and reintervention by percutaneous coronary intervention (PCI). **B**, Competing risks depiction of consequences of the three migration rates shown in **A**. Units along vertical axis are cumulative incidence. Rates shown in **A** deplete proportion (%) of patients “alive, without reintervention” and increase proportion dying before reintervention or experiencing reintervention by reoperation or PCI. At all points in time, percentage of patients in all categories sums to 100%, as shown in percentages at 12 years in right margin of figure. (From Blackstone and Lytle.)

---

Because many possible paths of migration exist, it is important for understanding each phenomenon to isolate it from all others, much as one would perform a controlled experiment with all other factors held constant. If one assumes that the rates of migration (hazard functions) are independent of one another, factors influencing those rates (incremental risk factors) can be discovered and their influence explored. So long as it is reasonable to assume independence of events, such analyses are valuable to estimate matters like how often death would occur in the absence of reintervention.

However, individual analyses do not address the question of how often an event might occur in the presence of competing risks of other events. For example, it is valuable to know the influence of age and extent of grafting on reintervention or death. “How often will elderly patients need reoperation given the risk of mortality from old age itself?”
scale for competing risks). Two aspects of scale are noted by Grunkemeier and colleagues.\textsuperscript{328} First, actuarial estimates of multiple different events do not sum to 100%. They should not; this is not a defect but a property of unconditional independent events. Competing risks are conditional, which implies \textit{multiplication} rather than \textit{addition}. Indeed, it is easy to show that multiplication of independent survivorship functions yields event-free survival. Second, they note that the complement of the cumulative incidence function of competing risks is usually a higher number than actuarial estimates. Again, this is guaranteed because competing risks must all sum to 100%, and this number is “adjusted” for occurrence of several competing risks. The more events considered to be competing, the higher the number will be. This “instability” is not a defect of competing risks analysis but rather a fundamental property. In the water bucket analogy, if more holes are punched in the bucket, there are more routes of exit, and each container under each hole will be filled less than when there were fewer holes. Because Grunkemeier and colleagues turn cumulative incidence curves upside down, “less filling” is equivalent to their “higher number.”

Ideally, because competing risks estimates are of the number of patients (or percentage of all patients) in each end state, they should be plotted on the scale of cumulative incidence. In such a plot, the initial state empties (decreases) and all other states fill (increase) (see Fig. 6-35, B).

Limitations and Assumptions

An important assumption of time-related analyses is \textit{noninformative censoring}.\textsuperscript{335} Either systematic anniversary or cross-sectional follow-up methods help with this assumption. However, in analysis of morbid events, death is a censoring mechanism, and it may not be independent of morbidity. In competing risks analysis, all events cause censoring of one another, and the possibility of informative censoring multiplies.

The number of hazard phases resolved in parametric hazard estimation depends on length of follow-up. Therefore, their ability to extrapolate beyond the length of follow-up is limited.

The number of events limits the number of risk factors that can be identified in either Cox proportional hazards analysis or hazard function multivariable analysis (see Box 6-5). If the latter is performed, this limitation is true within each hazard phase.

LONGITUDINAL OUTCOMES

In analysis of time-related events, the event is assumed to be a point process; that is, it is assumed to occur at some specific point in time, and the analysis focuses on the distribution of times until that event occurs. Many phenomena of equal importance to the cardiac surgeon are not point processes but outcomes that evolve across time: longitudinal data. Longitudinal data may be continuous, ordinal, or polytomous (unordered list of possible outcomes).

Specific examples include time-related change in NYHA functional class after a Dor procedure, degree of return of valvar regurgitation and its progression after mitral valve repair, change in ventricular volume after MI, sensitization after left ventricular assist device insertion, pulmonary function after single or double lung transplantation, and atrial fibrillation episodes after a maze procedure. For all these phenomena, information generally is obtained from patients periodically, usually at irregular intervals that differ from patient to patient. These are \textit{longitudinal outcomes}.\textsuperscript{318}

Assessment of longitudinal outcome may be interrupted (censored) permanently by death, temporarily at active cross-sectional follow-up, or by other events that remove patients from risk, just as in time-related events studies (see “\textit{Fundamentals}” under Time-Related Events earlier in this section). One would like to use the data up to the time of censoring. Furthermore, the clinical investigator is interested in factors that affect longitudinal evolution of these phenomena.

Historical Note

Severe technologic barriers to comprehensive analysis of longitudinal data existed before the late 1980s.\textsuperscript{332} Repeated-measures analysis of variance for \textit{continuous} variables had restrictive requirements, including fixed time intervals of assessment and no censored data. \textit{Ordinal} logistic regression for assessment of functional status was useful for assessments made at cross-sectional follow-up,\textsuperscript{11,320} but not for repeated assessment at irregular time intervals with censoring.

In the late 1980s, Zeger and his students and colleagues at Johns Hopkins University incrementally but rapidly evolved the scope, generality, and availability of what they termed “longitudinal data analysis.”\textsuperscript{331} Their methodology accounts for correlation among repeated measurements in individual patients and variables that relate to both the ensemble and the nature of the variability. Because average response and variability are analyzed simultaneously, the technology has been called “mixed modeling.” The technique has been extended to continuous, dichotomous, ordinal, and polytomous outcomes using both linear and nonlinear modeling.

Because of its importance in many fields of investigation, the methodology acquired different names. In 1982, Laird and Ware published a \textit{random effects model} for longitudinal data from a frequentist school of thought.\textsuperscript{14} In 1983, Morris presented his idea on \textit{empirical Bayes} from a Bayesian school of thought.\textsuperscript{325} In the late 1980s, members of Zeger’s department at Johns Hopkins University developed the \textit{generalized estimating equation} (GEE) approach.\textsuperscript{318}

Goldstein’s addition to the Kendall series in 1995 emphasized the hierarchical structure of these models.\textsuperscript{317} His is a particularly apt description. The general idea is that such analyses must account for covariables that are measured or recorded at different hierarchical levels of aggregation. In the simplest cases, time is one level of aggregation, and individual patients with multiple measurements is another. These levels have their corresponding parameters that are estimated, and each may require different assumptions about variability (random vs. fixed-effects distributions).

Except under exceptional circumstances, these techniques have replaced former restrictive varieties of repeated-measures analysis, which we now consider of historical interest except for controlled experiments designed to exactly meet their assumptions.

Concept

One way to think about the concepts underlying longitudinal data analysis is to consider it as a method that summarizes the results of individual regression analyses for each
Individual data points cannot be treated as independent observations. Instead, trends and variability must be analyzed at each successive level of aggregation.

**Implications**

Cardiac surgeons have often collected information on longitudinal outcomes only at the time of last follow-up, such as most recent NYHA functional class, most recent echocardiographic assessment of valve regurgitation after repair, or most recent degree of sensitization at transplant after implanting a permanent left ventricular assist device. Such a strategy cripples establishing time trends, because each patient contributes only one data point, preventing trends from being identified at the individual patient level. Therefore, it is imperative that every observation of longitudinal outcome be gathered and included in the analysis as part of the follow-up process.

A further cautionary note is that one-time survey of patients at follow-up (e.g., a quality-of-life questionnaire) also represents a single observation per patient. Yet often, inferences are desired of a longitudinal nature. It is a huge

---

**Figure 6-36** Hypothetical illustration of longitudinal data. Pressure gradient, determined by echocardiography, is shown on vertical axis, and years after operation on horizontal axis. Measurements were obtained at two cross-sectional follow-up studies about 6 months apart in 14 patients. **A**, Scattergram of all measurements. **B**, One hypothetical set of measurements in individual patients, with their two measurements connected by solid lines. In most cases, gradient increased between successive measurements. **C**, Another hypothetical set of measurements in individual patients, connected by solid lines. In most cases, gradient decreased between successive measurements. In both **B** and **C**, data points are identical to those shown in **A**.

---

*Note: The diagrams in Figure 6-36 show scattergrams and trends for hypothetical data.*
assumption that ensemble averages based on one point per patient will reflect what multiple longitudinal measurements per patient would tell you (although repeated testing bias must also be considered).

**Assumptions**

Assumptions underlying longitudinal models are important to understand. At one time, mixed models demanded repeated values to be measured at identical times for all subjects. As mathematical and statistical developments progressed, flexibility increased. Thus, today, longitudinal data analyses can be employed for data:

- Observed at haphazard intervals
- With a differing number of observations (including one) per patient
- Encompassing an observation period of variable length
- Containing missing observations in a sequence of observations
- Having sequences interrupted by a censoring mechanism such as death

This flexibility comes at a price. The most important price is the assumption that censoring for any reason is noninformative with respect to the outcome being assessed. Although this assumption is similar to that for time-related events, some aspects of longitudinal data make them even more susceptible to informative bias. If, first, it is not hard to imagine settings in which various factors “deplete” availability of longitudinal outcomes in a systematic fashion. For example, if the outcome is NYHA functional status, death interrupts assessment, and it is likely that the sickest patients with highest NYHA class die; the remaining patients may be more robust, leading to the possible inference that results are improving with time. Immunologic sensitization during permanent left ventricular assist device operation may be interrupted by availability of a donor heart sooner than if patients are doing well, or it may postpone transplant longer than usual; thus, degree of sensitization in remaining patients may skew the ensuing estimates up or down. If patients are being followed longitudinally for rhythm after a maze operation, those with return of atrial fibrillation may be assessed more often than those in sinus rhythm; prevalence of atrial fibrillation may, therefore, appear higher than it actually is. Patients assessed by coronary angiography for recurrent angina often become the basis for assessing longitudinal patency of coronary artery bypass conduits; these patients may not be representative of all patients (estimates are likely to be overly pessimistic). It is questionable whether patients remaining after these mechanisms of censoring are representative of the original group. Biased inferences could result from this informative censoring.

Just as Berkson and Gage in the early 1950s found that one should ignore follow-up intervals beyond the point at which about 10% of the original group was followed, we believe a similar truncation of longitudinal data should be considered. But this does not address an important bias of ascertainment. For example, patients being monitored longitudinally for a disease or because of a recurrent event (e.g., return of atrial fibrillation after ablation, recurrent angina after CABG) may be observed more frequently than patients deemed to be disease or symptom free.

**Modulators**

Factors modulate longitudinal outcomes just as they do any other type of outcome, so multivariable analysis within the longitudinal analysis domain is necessary. Currently the facility for such analyses is limited in available statistical software. However, this may provide an opportunity to use newer algorithmic techniques for risk factor identification, such as random forests. To temporarily overcome these limitations, at present we perform preliminary analyses under the assumption of independence of observations using available multivariable analysis tools. We then construct the longitudinal models “by hand.”

It would also not be surprising if, just as in analysis of time-related events after cardiac surgery, different factors modulate different time frames of longitudinal evolution. However, in most implementations of longitudinal analyses, time is treated no differently from any other variable, so there is little opportunity for variables to meaningfully modulate temporal rates of change. The Cleveland Clinic group is developing a set of novel methods for analysis of longitudinal data that treat time in a special way. One of these is **temporal decomposition**.

**Temporal Decomposition of Longitudinal Data**

Using the same strategy and mathematical formulation that Blackstone, Naftel, and Turner did for time-related events, the temporal occurrence of a binary event, such as presence or absence of atrial fibrillation, is conceived as the addition of a number of temporal components or phases. Each phase is modulated simultaneously by log-linear additive function of risk factors.

For example, Fig. 6-36 illustrates temporal decomposition for return of atrial fibrillation after a surgical ablation procedure in patients with mitral valve disease. Fig. 6-37, A shows decomposition into two phases, early and late. These generate the overall atrial fibrillation pattern of Fig. 6-37, B. Risk factors are identified for both these phases and overall. These are illustrated for extent of lesion set used for ablation (Fig. 6-37, C) and left atrial volume (Fig. 6-37, D).

As of yet, we have not written either robust software for this or a robust method for risk factor identification. However, the method has been extended to ordinal outcomes, such as return of atrophicventricular valve regurgitation after repair, and continuous outcomes, such as regression of left ventricular mass after aortic valve replacement for stenosis and for spirometry values after lung transplantation.

---

**Section V Use of Knowledge**

**TRANSFORMING STATISTICAL INFERENCES INTO CLINICAL INFERENCES**

Statistical inferences focus on interpreting magnitude and variability of parameter estimates, reliability of numeric results, summary statistics, behavior of CLs, P values, and many other numeric results. The data truly speak through these results, often revealing what is important and what is not. However, numeric information often does not lead to the kind of mental picture or overview of the data that is needed to generate new knowledge. There must be a view of
analysis on linearizing transformations of scale that may be needed to faithfully depict the relationship (see “Multivariable Analysis” in Section IV). Our experience indicates that most relations of continuous variables with outcome are smooth. They do not show sharp cut-offs (see “Continuity versus Discontinuity in Nature” in Section I), although they may well show evident differences (see Appendix 6B).

Use of Incremental Risk Factors

Multivariable analysis identifies incremental risk factors for outcomes, and this provides one form of new knowledge. The risk factors identified are sometimes proclaimed by cardiac surgeons and others to be “truly independent,” suggesting that such a risk factor is independent of the action of any other risk factor in exerting its influence. Such is not the case, and this idea is not the origin of the adjective “independent.” An independent variable is simply one that may be associated with the dependent (outcome) variable (see Box 6-18). Draper and Smith state, “The words ‘independent variables’ must not be too literally interpreted. In a particular body of data, two or more independent variables may vary together in some definite way.”

In addition to generating specific new knowledge by identifying risk factors for an outcome, multivariable analysis (see Box 6-18) can be used for patient-specific predictions. The wood, not just the trees. Something further is therefore needed to translate statistical inferences into clinical inferences and new knowledge.

One of the most powerful tools to accomplish this is graphics. An important reason for our using and even developing completely parametric models was that they so easily allow graphics to be generated in the form of nomograms, as advocated by the Framingham investigators. For example, if an analysis indicates an association of survival with age, we want to know what the shape of that relationship is. Is it relatively flat for a broad range of age and then rapidly increasing at either extreme of age? Or does risk increase rather linearly with age? Although the answers to these questions are contained within the numbers on computer printouts, these numbers are not easily assimilated by the mind. However, they can be used to demonstrate graphically the shape of the age relation with all other factors held constant (see “Risk Adjustment” in Section VI).

Because graphics are so powerful in the process of generating new knowledge, an important responsibility is placed on the statistician to be sure that relations among variables are correct. Often, variables are examined and statistical inferences made simply to determine whether a continuous variable is a risk factor, without paying particular attention to what the data convey regarding the shape of the relationship to outcome. Instead, the statistician needs to focus during

Figure 6-37 Temporal pattern of atrial fibrillation after surgical ablation. A, Decomposition of pattern into early and late components (phases), each of which will be modulated by risk factors. B, Overall temporal prevalence of atrial fibrillation. C, Effect of lesion set on pattern of atrial fibrillation after ablation. D, Effect of left atrial volume on 1-year prevalence.
Risk-adjusted comparisons can be made of the results of different surgeons, different interventional cardiologists, different methods, and different institutions. Multivariable analysis for these purposes is usually best performed in a parsimonious manner.

Multivariable analysis of clinical experiences can also be used to investigate the nature of cardiac surgery for a specific situation, such as transposition of the great arteries or the post–cardiopulmonary bypass state. For such purposes a series of sequential analyses are often useful, rather than a single analysis performed in a parsimonious manner. In sequential analysis, often the patient-specific potential risk factors are first examined and the multivariable equation for the outcome event generated. Then the procedural variables may be entered, and their effect on the certainty and strength of the patient-specific variables studied. New ideas then generate reanalyses, reevaluation of the correlations between risk factors, and additional new analyses.

Multivariable analysis can also be used to examine and interpret the way one risk factor modulates influence on outcome of another. One such use is to determine if a risk factor, such as age, is neutralized with experience. Another is to determine if treatments modulate some risk factor differently from another (interaction terms). All of this emphasizes the care with which all multivariable analyses must be made. Good, reliable, and valid analyses are not made by computers alone, but by people using computers expertly as just one tool of analysis and synthesis.

**SCIENTIFIC PAPER**

A scientific paper is a formal communication of new knowledge generated by a scientific study. It can be argued that science must be communicated to exist. The importance of communicating clinical research is that evidence-based medicine is literature-based medicine. Thus, medical research can have life-and-death implications, although Day comments, “Good scientific writing is not a matter of life or death... it’s much more serious than that.”

Unlike most other forms of communication, it has all the following elements:

- It is in the public domain and not proprietary.
- It is objective.
- It presents sufficient information to allow verification elsewhere.
- It builds on what has been previously discovered.
- It predicts what should subsequently transpire in an orderly universe.
- It is not written with just authority as its basis, but rather with information, data, and analyses at its core.
- It does not intuit or pass along traditions, but draws inferences and relates these to the context of past investigations.
- It is a formally structured communication.

The structure of a scientific paper is said to have been formalized by Louis Pasteur, who established the “IMRD” format for reporting scientific information: Introduction, Methods, Results, Discussion. This format has been codified into requirements of all scientific journals. It provides a valuable structure for thinking about and clearly expressing the findings of one’s research. However, a scientific paper is not literature to be read from beginning to end. Rather, it is for selective strategic reading.
structure) linear. That is, the paper, written on the basis of what has been discovered from the investigation, likely cannot simply reflect the original study proposal. The best way then to begin writing a scientific paper is to study intently the descriptive statistics, results of the various analyses, tabular results, and graphical depictions from the analyses, allowing “the data to speak for themselves.”

Goals for the paper are then set that establish its message and those purposes of the study that relate directly to supporting this message. These purposes will comprise the last sentences of the introduction. Methods and results likely should follow, then completing the initial portion of the introduction and discussion. We recommend writing the abstract last because it condenses all the text from the introduction through discussion. In the following text, each element of a manuscript is defined and described.

### Title

The title introduces the work. It may be the only thing read and so must entice intended readers. A good title is short but specific, truly represents the content of the paper, is indexable, and avoids jargon, qualifiers, abbreviations, and “filler.”

### Ultra-Mini Abstract (the “Message”)

The ultra-mini abstract is the truest two or three sentences (50 words maximum) that capture the essence of the findings—the message of the paper. It is not a brief summary of results. Rather, it is the inferences that will be supported by the results. It is often identical to the conclusion of an abstract.

Only if one can simply and succinctly understand the findings of the study and articulate what they mean will one be able to convey them clearly to the reader. By experimentation, we found that if the essence can be stated adequately in fewer than 25 words, the paper may have low information content and should be conveyed as a brief communication or letter to the editor. If it cannot be stated in 25 to 50 words, there may be information overload, and the study should be split into more than one manuscript, each focused on a different aspect of the results.

Once the essence is written, the entire manuscript—tables, figures, and text—should be sharply focused on those results that are supportive of the paper’s message. Other information should be either relegated to appendices (for the aficionado—usually electronic only) or eliminated altogether.

### Introduction

An introduction answers four important questions:

- What is the problem addressed?
- Why is it important?
- What is the context?
- What is the specific purpose of the study?

Start by writing a clear statement of the purpose of the study. Although this has been the most important aspect of the original research proposal, it now must be refined and either limited or expanded to include the one, two, or three aspects of the study that led to the essence of the findings.

For example, your original research purpose may have been to discover any possible adverse effect of reoperation for bleeding on hospital outcomes. However, to investigate this properly, you likely would have determined the prevalence of postoperative bleeding and incremental risk factors associated with bleeding, perhaps then using these to develop a propensity score so that apples-to-apples comparison could be made of outcomes in patients who did and did not require reoperation. Thus, for the manuscript, the stated purpose may be to (1) determine the prevalence of postoperative bleeding, (2) identify incremental risk factors for postoperative bleeding, and (3) compare the prevalence of hospital complications between those who experienced bleeding and those who did not. These purposes lay a complete roadmap for every subsequent section of the paper.

These purposes constitute the last part of the introduction, preceded by a paragraph simply setting the problem being addressed, its importance, the context of the study, or the controversy. (A mistake many writers make is to confuse the function of an introduction with that of a discussion or an exhaustive review of the literature.) For a specialty journal, there is no need for the introduction to start with a review of the literature. Rather, within the first two sentences, state the questions your research addresses (the gap in knowledge) and why it is important to answer it.

Given a clear message for the paper (the 50-word essence) and a clear statement of purpose or purposes that will support that essential message, it becomes rather easy to organize subsequent sections of the paper (Patients and Methods, Results, and Discussion) to exactly follow the organization suggested by the purposes (using identical words each time). In this way, the manuscript stays focused, supporting material is highlighted, and triage of extraneous information is facilitated.

### Patients and Methods

This section tells how the study was done. It is rarely read in its entirety, in part because readers assume that the peer-reviewed process has vetted the methods. There are some important elements for a clinical paper that have to be provided about the patients: what was done and where, inclusive dates (time frame), number of patients, inclusion and exclusion criteria, and patient characteristics. End points (outcomes) should be defined and details of follow-up (active and passive) summarized. Data analysis should be organized according to each purpose of the study. Finally, details of the presentation should be provided.

### Results

This section answers the simple question, “For each purpose, what was found?” This is the core—the lasting value—of the paper. Of necessity, it is rarely all the raw data. Rather, it is a selected well-digested summary that relates directly to purposes of the paper. It does not interpret the results of the study; it uses tables and figures to summarize and illustrate the results. It is an unfortunate fact that reviewers of manuscripts suggest elimination of tables and figures as a first priority to shorten a paper. Instead, it is text that should be shortened (including placing detailed methods in electronic appendices).
Discussion

The discussion tells the reader how the authors have interpreted the results. A suggested outline for a discussion is:

- Brief summary of results (controversial)
- Principal findings, organized by purpose that puts results into context of work by others
- Limitations
- Conclusions (inferences, clinical recommendations)

The discussion should be concise and focused. Interpretation should be reasonable (e.g., avoiding causal statements when only associations are established), and quotation of work by others should be accurate. Inferences should be supported by the data and speculations beyond that so identified. There should be no new results introduced. Promissory notes should be avoided.

Submission

Coupled with initial manuscript writing, decision should be made regarding the appropriate audience, and therefore journal, for the paper. As general rules, manuscripts of interest to a broad spectrum of medicine should be targeted to general medical journals; those that should be read by both cardiologists and cardiac surgeons should be targeted to general cardiology journals; those that should be read by cardiac surgeons should be targeted to cardiac surgical journals.

When the manuscript has been completed, one may be tempted to send it immediately to the targeted journal, but the quality of the manuscript can be improved considerably by allowing it to sit on the shelf for a time. After a few weeks, review the manuscript afresh from beginning to end, along with comments that may have been solicited from coauthors. By this time, three things have happened. First, you have distanced yourself just a bit from the manuscript and can see more clearly its possible deficiencies. Second, the passage of time has allowed your unconscious mind to work on the material, and by the time the manuscript is revisited, this process has provided further insights and clarity. Third, you have had the opportunity to present the material intramurally and have received valuable feedback. In other words, the work has matured. (In addition, the manuscript shelf provides the best possible resource for abstracts for upcoming scientific meetings.)

Responding to Reviewers

The next important step is to respond to peer review of the manuscript. Some authors become despondent and never revise and return their paper. Others decide to send the original manuscript to another journal, ignoring the peer review, which is wasteful of reviewers’ time and expertise. Others respond defensively, making little change in the manuscript. Instead, this important phase of generating new knowledge should be viewed as an essential exercise to improve the manuscript. Sometimes it will require performing new analyses or gathering new information. If some point is confusing to a reviewer, and particularly if it is confusing to more than one, or if the reviewers have completely missed the point, simplification and clarity are needed. Rethink the

purposes, structure the paper anew, move overly detailed material from the text to appendices, construct new tables and simplify others, prepare more intuitive graphics, or state things more clearly and logically. The peer review process may delay publication for some days to weeks, but as a whole, it functions superbly to improve the quality of papers.

SCIENTIFIC PRESENTATIONS

Meeting Abstract

The best possible preparation for writing and submitting a meeting abstract and for subsequently presenting the findings is to have completed a well-crafted manuscript. There is no substitute for this. If it is not possible to complete all analyses and to prepare a manuscript, at least enough of this must be done so the essence of the findings is known, the purpose of the study is clear, and the conclusions are supported.

It is common practice to use meeting abstract deadlines either to drive the research process or serve as a triage function for bouncing half-formulated and partially analyzed data off reviewers; if the paper is not accepted, the research is not pursued. This is not serious clinical research. It also represents a lack of understanding of the process whereby papers are accepted for presentations at meetings. For example, if there are two excellent abstracts submitted by two groups on the same subject, one may be taken and the other not; it would be a mistake for the submitter of the rejected abstract to conclude that the work is unworthy! A poor abstract may be the only abstract submitted on a subject that is deemed to be needed for a well-rounded meeting, so it is accepted. An entire category of abstracts may be jettisoned because there is no room for them on the program. Other abstracts, because of the appealing way they are crafted, are accepted, but the work is of less than stellar quality when presented.

A meeting abstract does not serve the same function as the abstract for a scientific paper. Its purpose is to get the work onto a program. Thus, crafting a meeting abstract is an art. The title must be eye-catching. Such a title may not be appropriate for a manuscript, but it is the first thing the graders will see. Second, the purposes and conclusions of the abstract must be clear and must match one to one. The purposes and conclusions may be all that is read before the abstract is discarded! If there is a gripping title, clear and interesting purposes, and new conclusions, the abstract graders will read the methods and results sections. There is no sense in including detailed methods that are well known; instead, focus on those that (1) succinctly define the patient sample, (2) address each purpose, and (3) make the study novel or more valid than other work in the field. Results are usually less detailed than for a manuscript abstract, highlighting just those numeric findings that relate to the purposes. A well-crafted table, or especially a seminal figure, often speaks louder than words and may constitute nearly the entire results section. Importantly, the presentation can be almost entirely crafted from this abstract.

Presentation

Preparation

For a short 5- to 10-minute presentation, you must know the intended audience. Is it a general audience for whom medical jargon and abbreviations will not be understood, or
is it a group of experts in your field who will be distracted by summary of well-known introductory material?

Text
Before writing the text (which we recommend), clearly articulate the message you wish to convey to your audience. For a short talk, this will be two or three main points. Your talk should focus on these points and nothing more. Ideally, it will be divided with clear signposts (orally or visually) for each point.

What is generally not taught to presenters is that the audience will listen serially. No one in the audience can go back to review the material; there is no second chance to determine whether your progression of thought is logical or to study a table or figure in detail. The classic IMRD format for a scientific paper is not conducive to serial aural disclosure!

Elements of a good presentation are more akin to telling a good story than writing a good scientific paper.⁹ At the outset, you must capture the attention of the audience. This can be accomplished, for example, by illustrating the nature of the problem that is the object of the presentation. This may be a clinical example, an echocardiogram, a picture of a pathologic specimen, or a statement of controversy. The purposes of the research can then be presented, followed by a simple depiction of the characteristics of the patients being studied. The temptation will now be to present methods, followed by results and discussion. This should be resisted. Instead, as you present evidence (“let the data speak for themselves”), weave in methodology for obtaining the data and results of analysis if essential. Generally, however, very little presentation of methodology is necessary for clinical studies, and the time restrictions preclude lengthy description. Results should be presented extraordinarily simply with “just in time” listening; that is, introduce nothing before it is needed. Typically, slides (generally computer-generated presentation frames) should contain only one idea each and as few words as possible.

Your presentation delivery should be semi-conversational, with a balance between formal and casual styles. Above all, plainly emphasize the message you want to deliver by connecting with the audience through attitude, energy, and motions. Ways to engage the audience include introducing ideas in threes (I came, I saw, I conquered; the good, the bad, the ugly), contrasting pairs, introducing anticipation, and using occasional pauses and repetition. Although it may seem awkward, you connect best with an audience if your eyes are “up” at the beginning and ending of sentences, and “down” on your text in the middle of sentences.

At the end of the presentation, it is common for speakers to simply summarize the results. But if the presentation has been logical and has focused primarily on results, there is little need for recapitulation. It is better to spend the last portion of the presentation on the clinical inference you have drawn from the study. Leave the audience with the essence of your findings (“the message”) and what it should mean to them and to their patients. End the talk with a simple “thank you” so that the audience knows you are finished.

Finally, never plan to give a presentation without writing the manuscript, preferably prior to submission of the abstract. Presentations are soon forgotten, or are remembered but not retrievable because the presenter has never pushed the study through to publication.

Visuals (“Slides”)
The purpose of visuals accompanying a presentation is to emphasize and illustrate your ideas. They are not for entertainment or to provide supplemental material. They are not the talk.

Although visuals are a matter of taste, a few comments may be helpful for those who have never been taught the art of creating presentation slides, but rather follow the formats and styles generally seen in medical meetings.

Keep the slides plain with no distracting or extraneous material. Avoid textured backgrounds that distract listeners from your talk. Eliminate “cute” transitions from slide to slide. Simple graphs and figures are more effective than complex ones. Package one thought per slide. Avoid complete sentences and paragraphs on slides; references in tiny print cannot be seen.

Use as few “word slides” as possible. Those that are used are most effective if they have single-line titles, three or fewer major heads, and only one subhead level. It is best to set a word slide format and stick to it rather than showing a haphazard mix of left-justified and centered text starting at different spots on the slide. A consistent format reduces the work of the listener so that he or she can listen to you.

Visual order when first seeing a slide is top down, left to right, and clockwise. Thus, text and visuals should follow this order.

We recommend avoiding tables. Generally, only specific pieces of information on a table are useful. There are usually ways to present them as bar graphs or pie charts that are more readily digested.

From a practical standpoint, use a sans serif font of no less than 32-point size so that slides are visible from the back of the auditorium.

Question and Answer Period
The question and answer period is part of your presentation, and you should be prepared for it. Your attitude should be that this is a final opportunity to get your message across. Anticipate what questions the audience should have for you. You don’t have to respond directly to the questions actually asked if they lead you away from your message; rather, rephrase the question to bring it back to your message.

Finally, in many meetings there may be no questions. A well-prepared moderator should have a question for you, but if not, you have been given an opportunity to drive home your message. So if there is silence, you might say, “You may be wondering…” or “A question I have been thinking about….” This in turn may stimulate someone in the audience to ask a question along these lines.

DECISION SUPPORT
Publication is a static medium. However, most analyses generate mathematical models that, at least in theory, can be solved for the characteristics of a specific patient (patient-specific predictions), complete with CLs. Fig. 6-26 illustrates how these equations can be used to predict survival for a specific patient, were they to be initially managed medically, surgically, or by percutaneous intervention. Used in this way, static presentation of “risk factors” becomes a basis for dynamic decision support for individual patients.
The most important impediment to using equations resulting from clinical research data analysis is lack of the CPR (see “Computer-Based Patient Record” in Section II). If such systems were in place to provide values for variables in the course of working up a patient, they could be automatically inserted into appropriate equations, the equations solved, and the solutions displayed. These results could then be used by physicians for making recommendations about the most appropriate course of treatment, and also by patients as a personalized basis for informed consent.

It will be argued that medical and surgical treatment are changing so rapidly that no data from the past are relevant for today’s decision support; at best, general guidelines and judgment are all that is available. However, this gives more credit to new therapy than medical and surgical innovations deserve. Furthermore, a decision must be made, and making it on the basis of past data is likely to be less faulty than using no data at all.

In most places in the world today, the resources available for cardiac operations are insufficient to treat every patient potentially amenable to this kind of intervention. Thus, a process of triage (the sorting process used by military surgeons during combat) is consciously or unconsciously used to allocate resources among the patients most likely to benefit.112 Again, such decisions are best made when potential benefits can be described factually and with knowledge of the degree of uncertainty attached to the conclusions. The special circumstances of each patient and the need for continued probing into the possibility and methods of extending and improving the results of cardiac surgery must also form part of each patient care decision.

To improve surgical outcome, errors (both active and latent) must be reduced and scientific progress made. Errors can be reduced by various mechanisms of decision support, particularly obvious pharmaceutical errors. Error reduction in the operating room may be reduced by the vigilance suggested in “Human Error” in Section I.

Some surgical failures are related to inadequacies in the decision-making process for an individual patient, either as a result of human error or lack of scientific progress. For example, deciding not to operate on a patient whose risks without operation are known to be significantly greater than those with operation is a human error. Deciding to operate on a patient whose risk of an early fatal outcome is probable with considerable certainty is also an error.

Analysis of clinical information, either by use of risk-adjusted information from applying benchmarks (see “Risk Stratification” in Section VI) or by formal analysis of surgical experience, yields risk factors that may be amenable to neutralization (see Appendix 6C).

Decision Making for Individual Patients

When cardiac operation is advised, it is in anticipation of cure or palliation. In either case, operation should be recommended only when life expectancy and functional capacity are predicted to be better with than without operation. Thus, each patient care decision involves a comparison, and the comparison should be made with full knowledge of the degree of uncertainty imposed by the available data and their analysis.836 In fact, one goal of research is providing this information for decision making in as many areas of cardiac surgery as possible and with as high a degree of certainty as possible.

When patients fall into defined categories for which reliable information is available, individual patient care decisions can be made largely on the basis of prior appropriate comparisons of the options. That is, the option can be chosen that has been shown to result in the lowest hospital mortality, the highest long-term survival, and the least incidence of reoperation in similar patients. One of the goals of this book is to present data in sufficient detail to be useful for most individual patient care decisions. However, decision making is not always easy. Indeed, some decisions that may appear easy in fact are not. This is when solution of equations using a patient’s specific characteristics becomes valuable.

When reliable information is unavailable or the options being considered are different from those that have been studied, the same principles can be used, but only anecdotal information, judgments, and general knowledge of the area are available as a basis for the decision. Obviously, the degree of uncertainty is considerably greater. In such situations, a proper clinical study of some type is needed to generate the knowledge desired.

---

**Section VI  Special Methods and Controversies**

**RISK STRATIFICATION**

The goal of risk stratification is to account broadly for differences in patient characteristics that affect outcomes of interest. These include cost of healthcare services and outcomes that have been selected to reflect institutional quality822,823 (clinical report cards815,816). Risk stratification can be used for profiling practices or to develop guidelines and indications for procedures.

There are two general approaches to risk stratification: risk scores and risk equations.

Risk Scores

Primarily in the older literature, risk scores were reported that were based partly on data and partly on expert opinion.821,822 These have a common feature: addition of risks. Those that understand probability theory will immediately notice that the logistic equation, by virtue of the exponential function, is a multiplicative function of risk factors (see Fig. 6-1, A and Box 6-5).811 Even today, investigators attempt to develop “modern” additive risk scores, claiming that busy physicians can add but not multiply.811

Unless a score is specifically calibrated to outcome, it is useful merely for risk stratification, not for calculation of absolute risk.

Initial use of risk scores was to broadly classify patient mix according to outcome, usually into a small number of groups with increasing risk (see “Classification Methods” later in this section). Subsequently, however, they have been used as a basis for reimbursement, quality assessment, and institutional comparisons rather than generation of new knowledge. Therefore, they have been simultaneously welcomed and
distrusted. What is likely true is that they perform well for risk-stratifying typical patients, but poorly for patients at the extremes of low and high risk.

Risk Equations

Multivariable analysis is used to develop risk equations, usually by logistic regression. The equation is used to calculate absolute risk of events in a group of patients (e.g., those from an institutional experience), or the calculation may be left in terms of logit units as a type of quantitative score. Patients can then be sorted according to increasing probability score for risk stratification.

Use of multivariable analysis for risk stratification was anticipated by Gordon and Kannel in the Framingham study when they wrote, “In the multivariate case it is possible to make statements for one variable which are invariant whatever the values assumed by the other variables. This makes it possible to estimate the net effect of one variable taking into account the effect of other related variables.”

If equations are used, the distinction between risk stratification (grouping) and risk adjustment (placing patients on a level playing field) becomes blurred.

**RISK ADJUSTMENT**

Risk adjustment has been used in two senses. In both, a formal statistical multivariable model has been generated and then used in a predictive fashion. In the first, predictions are made in which a single variable is explored in relation to outcome while all other variables are held constant. This technique is an essential part of clinical research, and we have termed such depictions *nomograms*.

The second use is part of a process whereby two or more protocols, procedures, surgeons, physicians, or institutions with patient populations that are to some extent heterogeneous are compared with regard to outcome. A multivariable risk factor equation is used to generate hypothetical patient populations that are identical except for the variables being compared (leveling the playing field).

To generate the risk factor equation, a large group of patients representing all the subgroups being compared (e.g., institutions) are pooled, and a multivariable analysis of the pooled data is performed in which the subgroups themselves may or may not be variables. From a statistical point of view, it would seem ideal to assess subgroups as institutions within the context of the analysis. This could include exploration of specific interaction of subgroups with other variables, and other investigations that might yield important insight into institutional variance. This has been done, for example, in the context of the Congenital Heart Surgeons Society.

More commonly, subgroups are ignored completely when generating a generic overall equation that will be applied to them subsequently. This is the strategy behind the EuroSCORE.

In contrast, the Society of Thoracic Surgeons Database adjusts for within-institution variance. 

**Technique of Risk Adjustment**

After the risk factor equation is generated, it is typically used as follows. Characteristics of each patient in a subgroup (institution, country) are inserted into the regression equation, and the equation is solved to yield the absolute predicted risk of the outcome of interest for each patient. These individual probabilities are added to yield expected outcome. Expected outcome is then compared to actual outcome.

The theory behind this technique is this: When estimates of the weights (the βs, coefficients, or parameter estimates; see Box 6-5) are generated by maximum likelihood estimation, events are conserved. Conservation of events is, in statistics, analogous to conservation of mass in biochemistry. Specifically, if for the patients used to generate the equation, the probability of the event is calculated for each patient, the sum of these probabilities is guaranteed to equal the total number of events that actually occurred. If for some subgroup of patients this sum deviates from actual, either unaccounted-for factors have not been included in the risk factor equation, or the subgroup is behaving differently from the average.

**Comparison Statistic**

One statistic that may be used to compare observed (O) and expected (E) number of events in a subgroup of n patients is the chi-square goodness-of-fit test. A value for chi-square (χ²) is obtained from the formula:

$$\chi^2 = \frac{n(O - E)^2}{E(n - E)}$$  \hspace{1cm} (6-21)

A P value is obtained from a chi-square table or computer program equivalent.

DeLong and colleagues have studied eight methods for comparing observed and expected outcomes, focusing particularly on fairness in judging a subgroup to be an “outlier.”

Treasure and colleagues have developed a highly sophisticated method of using risk-adjusted CUSUM charts to continuously monitor deviation of individual institution programs from the norm.

**Illustrations of Risk Assessment**

Risk adjustment by multivariable analysis can be illustrated as follows. Hospital A experienced 18 (8.3%) hospital deaths among 205 patients undergoing mitral valve replacement, while hospital B experienced 16 (2.6%) hospital deaths among 612 patients undergoing the same operation. The *P value* for the difference is <.0001, so the difference is unlikely to be due to chance alone.

Hospital A believes the difference is attributable to a more severe case mix, while hospital B believes it reflects a difference in expertise. Using a risk-adjustment equation that accounts for NYHA functional class, age, left ventricular size, and other factors, a probability of death is computed for each patient by solving the logistic equation, using the patient’s specific values for each of the risk factors. The 205 probabilities for hospital A are summed and found to total 11.07, the number of expected deaths (if divided by 205, this yields 5.4%). The difference between expected deaths (11.07) and observed deaths (18) is unlikely to be due to chance alone, *P = .03*.

This is equivalent to saying that if the patients in hospital A had been operated on in hospital B, their mortality would have been 5.4%, not 8.3%. We could ask for the hospital mortality had B’s patients been operated on at hospital A. We already know that hospital A had a higher actual than expected...
mortality, and that actual divided by expected mortality equals 1.6. This ratio quantifies the difference in what could be called the expertise of the two institutions. This means that had hospital B’s patients been operated on at hospital A, there would have been more deaths, specifically, 1.6 times 16 or 26 deaths; 26 deaths among 612 patients is a mortality of 4.3%. This is what the state of New York has termed risk-adjusted mortality (the state as a whole is analogous to hospital B), an index it uses to rank hospitals.199

Controversies

Naturally, different risk adjustment equations yield different estimates of expected events.565,566 In addition, the variables used in developing the risk equation—administrative, laboratory, or clinical—make a difference.11 Even more important is the number of risk factors in the risk equation (richness, depth).59,74 Probabilities for patients with a large number or unusual combination of risk factors—the very patients for whom we want risk adjustment—are systematically underestimated.59

Residual Risk

A valuable adjunct to risk adjustment methodology is analysis of residual risk. In analysis of residual risk, the risk score for each patient is calculated. For logistic regression, this is the logit of the probability of the event; for Cox proportional hazards modeling, it is the sum of the weighted risk factors; for hazard function regression, it is the sum of the weighted factors in each hazard phase (see Box 6-5). These are forced into the model, and a search is made for risk factors not accounted for by the risk score or for factors in the risk score that are either underweighted or overweighted.59

For example, Sergeant and colleagues studied 3720 patients prospectively, applying a previously published time-related equation to generate a survival curve for each.52,59 The patients were subsequently followed up and comparison made of actual and expected survival (see Fig. 6-2, A). Estimated survival was too optimistic, so an analysis of residual risk was performed. Five residual risk factors were found, falling into three categories:

- Two factors had been suspected in the original analysis, but they occurred so infrequently that reliable parameter estimates could not be computed.
- Two variables were related to preoperative atrial and ventricular rhythm disturbances. These data had been available for the original analysis, but the investigator ignored them because he thought they were unimportant.
- The fifth variable identified a patient subset that had not been represented at all (extended indication) in the original data set.

These residual risk factors accounted for only a small fraction of the new patient group, but a group whose risk was vastly underestimated (see Fig. 6-2, B and Table 6-2).

This experience has driven us to the opinion that clinically rich models, rather than simple ones, are required for accurate risk adjustment. The factors liable to lead to risk underestimation are (1) rare factors, (2) factors that are important but not included in models, and (3) factors related to subgroups for whom indication for operation has been extended beyond that of patients included in developing the models.

META-ANALYSIS

Definition

Meta-analysis combines or integrates the results of multiple independently conducted clinical trials, observational clinical studies, or sets of individual patient data that are deemed combinable with respect to a common research question, then analyzes them statistically.115 Other terms for meta-analysis are quantitative overview, pooling studies, systematic review, and quantitative synthesis. The root of the prefix meta—means “later in time.”

Historical Note

There is a nearly 300-year history of using statistical methods to draw inferences broader than any individual study from a combined analysis of results. In 1722, Cotes used weighted averages to combine measurements of different astronomical observers.226 In 1805, Legendre introduced the now familiar method of least squares, used in linear regression (see Box 6-5), for similar synthesis. In 1904, Pearson averaged five different estimates of correlation because “many of the groups… are far too small to allow any definite opinion being formed.”177 In 1931, Trippett combined P values.15 In 1937 and 1938, Cochran and Yates combined results of agricultural experiments.51,72

Beecher is credited as having performed the first medical meta-analysis in 1955, but the appropriate methodology developed primarily in educational research.810 In 1976, Glass coined the term meta-analysis to mean “the analysis of analyses.”148 Most statistical procedures used today were introduced at that time in the social sciences.

In 1993, clinicians, epidemiologists, statisticians, and other professionals joined together to prepare, maintain, and discriminate comprehensive and systematic reviews of health-related questions. This was called the Cochrane Collaboration, named after epidemiologist Archie Cochrane.821,C6 In 1994, an international group developed the Quality of Reporting of Meta-analyses (QUOROM) guideline document for meta-analysis of randomized clinical trials.823 Subsequently these were updated to checklists and diagrams called Preferred Reporting Items for Systematic Reviews and Meta-analyses (PRISMA).824 A parallel effort was mounted to develop a guidance document for meta-analysis of observational studies, MOOSE.556

Motivation

Motivations for meta-analysis are to:

- Increase sample size and thereby better protect against either (1) misplaced enthusiasm for positive results (type I error) or (2) failure to find a beneficial effect (type II error)
- Detect small effects (or exclude small effects more definitively)
- Detect bias of reporting multiple, possibly underpowered, trials (positive results of trials tend to be reported more frequently than negative ones)
Make better use of studies performed independently by synthesizing the results
Suggest the most promising avenue for future research on a subject and the sample size likely needed to study the question definitively
Formalize the review process of past studies, including independent assessment of study quality by individuals not associated with the original studies
Determine whether “enough is enough” and no further corroborative studies are needed to establish a relation
Corroborate, refute, or modify evidence-based medical guidelines that emanate from expert opinion and literature review rather than from statistical analysis of data

Types
Meta-analyses may be categorized according to (1) type of studies assembled and (2) type of data gathered. The types of analyses assembled may be only randomized clinical trials, only observational clinical studies, or a combination. Just as any clinical study, there is a presumed hierarchy of quality; generally, preference is given to randomized clinical trials.

Type of data used in a meta-analysis may be (1) summary (aggregated) statistics or (2) raw individual patient data from each trial or study, the highest level of quality. The latter is considered to be the most time-consuming and politically most difficult to perform, because investigators are often wary (and rightly so) of relinquishing raw data to a third party.

Conduct
Because the design of a meta-analysis is that of an observational study of accumulated evidence from prior investigations, a rigorous plan for conducting the study must be put into place. Elements of conduct include:

- Formulating the question to be addressed, without which comparability of studies cannot be assessed
- Establishing criteria for studies to be included and excluded
- Identifying all relevant studies
- Assessing the quality of each study
- Establishing a rigorous protocol for data extraction, including calculations necessary for putting all data into a standard format on a uniform scale
- Extracting and verifying data
- Diagnosing bias and sensitivity to inclusion and exclusion criteria to be sure the analysis should proceed further
- Diagnosing heterogeneity among studies that may call into question poolability
- Analyzing the analyses, generally using mixed (hierarchical) models that account for fixed and random effects at various levels of aggregation (see “Longitudinal Outcomes” in Section IV)

In calculating an overall effect from multiple studies, the simple arithmetic average gives misleading results. Specifically, small studies have more scatter by chance alone and should be weighted less than large studies. Proper analyses can be broadly grouped into two approaches that differ only in the way variability among studies is managed: (1) fixed effects models that assume variability is simply random variation and (2) random effects models that assume a different mechanism of variation for each study. Tests of heterogeneity of variation may be used to assess which model may be more applicable. Ideally, features of each study, such as gender ratio, publication date, patient status, and age, are incorporated into the analysis. Such a model has both fixed and random effects. Details of these and other considerations are found in the now abundant literature on the topic.

We enumerate these points of study conduct to emphasize that meta-analysis is a disciplined, rigorous, and often statistically challenging type of observational study. In the cardiac surgical literature, including some publications cited in this book, less rigorous methods have been used to synthesize multiple independent, but related, analyses. Attention to meta-analytic techniques is necessary to raise the quality of such syntheses.

Limitations
Shortly after its introduction, Eysenck declared meta-analysis “mega-silliness.” Similar skepticism or outright disdain has been voiced in medicine. These attitudes are based on such findings as two separate meta-analyses of the same subject coming to diametrically opposite conclusions and the contradiction of meta-analysis results by large randomized trials.

Not often appreciated is that limitations of meta-analyses are similar to those of observational clinical studies. First, they require an extremely focused question, without which it is not possible to assess combinability of studies. It may be found that in fact there are no truly combinable studies for some topics of interest, or that there are too few studies to achieve sufficient statistical power to determine from diagnostic testing whether the studies are combinable (heterogeneity).

Second, it may be difficult to assemble the entire literature on a well-framed question. Medical libraries are generally more successful in doing this than physicians using search engines. References in identified articles must be found. In the process, it is common to uncover either wholly duplicate publications or some overlap that may be challenging to pull apart. Even a thorough search will not correct for confounding from publication bias that favors large studies, positive results, and mainstream topics.

Third, different meta-analyses may produce conflicting results, depending on thoroughness of the search and evaluation of applicability and combinability. These represent forms of selection bias over and above publication bias.

Fourth, there are limitations of data. One would like to adjust the analysis for multiple variables, but often the number of variables in common across studies is small. This is why combining individual data with many variables in common leads to the most robust estimates.

Finally, there are limitations in methodology, variance in professional skill and experience in using the methodology, and potential problems in both data presentation and interpretation.

CLASSIFICATION METHODS
Classification methods encompass a group of machine learning methods that will become of increasing importance in
analysis of clinical experiences. The techniques may be purely logic based, high-order logic and ontology-based (artificial intelligence), or algorithmically based. Classification methods can be used in a number of ways for the following:

- Classification (e.g., stages of disease, associations with outcomes)
- Identification, including nonlinear effects and complex interactions
- Prediction

Classifying Disease

Classification and regression tree (CART) and recursive partitioning analyses have been particularly useful in devising simple classification trees for cancer. Thus, they would seem ideal for risk stratification, not just disease classification. However, single trees grown in this way are unstable. Instability is a consequence of high prediction error that involves a trade-off between bias and variance. Growing a shallow tree (few branches) reduces variance and improves interpretation but introduces bias and inflates prediction error. Growing a richer tree (more branches) reduces bias but can inflate variance. To reduce prediction error, bias, and variance simultaneously, a whole forest of trees is needed. To do this, bootstrap samples are drawn from the original data (drawn randomly with replacement; about a third of observations are not chosen and a third duplicated). Simple trees are grown from each sample, followed by aggregating the results (so-called bagging). Prediction error is assessed by using the observations not selected for a given bootstrap sample (called “out-of-bootstrap” samples). Using a variety of random forest methods, we have constructed a new staging system, for example, for esophageal cancer.

Identifying Risk Factors

Risk factor identification is surely a classification problem: a variable is a risk factor or it is not. Enormous strides have been made in machine learning (see “Multivariable Analysis” in Section IV) for this and other classification problems. Prominent among current researchers in this area are Jerome Friedman and colleagues at Stanford University and the late Leo Brieman at the University of California, Berkeley. Their work addresses the instability of a single multivariable analysis of a single set of data, using resampling and other adaptive methods to arrive at a believable set of variables that can be claimed as risk factors. We have extended this work to survival data.

Two features of analyses are important to emphasize. First, there is no assumption of additivity, a hallmark of most regression models. This permits possible complex nonlinearities to be identified. Second, complex interactions are an intrinsic aspect of the analyses, a property that was of particular importance in developing a cancer staging system. However, because a forest of trees can become a “black forest,” identifying the variables of greatest importance for scientific insight and prediction can be challenging.

Two types of approaches we have explored are (1) a calculation of variable importance, quantified as increase in prediction error when “noise” is substituted for a variable; and (2) tree depth, variables that tend to be initially split near the root of the tree (see Fig. 6-16).

In identifying risk factors using these machine learning methods, we have been exploring criteria other than $P$ values for variable selection. $P$ values are highly dependent on $n$. An alternative is to approach variable selection as a signal-to-noise problem. One can ascertain for each variable its “noise” threshold by “noising-up” the variable (random permutation to generate noise) and examining whether the effect of the variable is outside the noise (signal) or within it. This approach is less dependent on $n$ than are $P$ values.

An important finding of our work with variable importance is that incorporating some variables in random forest analyses actually increases prediction error. It has formerly been thought that the more variables included, the better the prediction. This makes us believe that there may be a quantitative theorem of parsimony hidden in these analyses.

Finally, any machine learning algorithm can be tuned and variably supervised by humans. At present, optimum speed of learning (fast learning, slow learning) is uncertain. Because classification methods are computationally simple and therefore fast, we are exploring the possibility of combining forest-based variable selection with regression modeling, and even with aspects of artificial intelligence–based machine learning.

Predicting Outcome

One motivation for using classification methods to predict outcome is to answer the question, “Who will experience the event (and when)?” Conventional methodology is focused on probabilities, not “who” and “when.” Nevertheless, any method that more accurately identifies patients at risk is valuable. The methods include neural networks, which have largely been replaced by a host of machine learning techniques, multivariable optimal discriminant analysis, and more recent additions to the arsenal, such as logistic analysis of data (LAD), which is a purely mathematical technique. However, to date it is not clear that these methods outperform the standard regression approaches outlined in this chapter.

An interesting hypothesis is that deterministic, logic-based, artificial-intelligence machine learning technology can be coupled with more “black box” technologies, such as random forests, to discover why a particular prediction is being made for a given patient. This may be particularly valuable in genomic analyses of cancers, for example, to identify genes that machine learning technologies have identified that affect rate of cancer recurrence.

Limitations

A limitation of many machine learning techniques is that they either require data in dichotomous format, or split continuous variables into optimal classes rather than treating them as a continuum. This at times produces results that defy continuity in nature and represent local properties of a specific data set and not generalizable information. One advantage of techniques such as random forests is that in aggregating trees over a large forest (e.g., 10,000 trees), the results become essentially continuous.

The most important limitation of the methods at this writing is that they are still young and developing rapidly. Software is beginning to be available, but the user community is still narrow.
Chapter 6 Generating Knowledge from Information, Data, and Analyses

6A Knowledge-Generating Team

Serious clinical research in cardiac surgery can be accomplished, no doubt, by the cardiac surgeon alone. Individual cases can be reported (case reports) with keen insight. Data can be entered and tallied with both simple calculators and user-friendly statistical software such as SPSS (http://www.spss.com).

More commonly, though, a surgeon or full-time clinical investigator will be either the leader of, or the medical expert for, a small to medium-sized research team. With the growing sophistication of data management and analytic tools, it becomes necessary to assemble a research group with varied roles and expertise, all focused on the goals of clinical investigation.

Structure

Regardless of whether the same individuals are involved, clinical research generally includes two fundamentally different activities: (1) continuous registry and database activity (see Box 6-1) and (2) individual clinical studies activity. The registry activity involves gathering and entering data for a prescribed set of core data elements for every case. Until the advent of effective computer-based patient record (CPR) systems in the form of values for variables (rather than narrative) that contain the life history of a patient, at least some portions of a registry or database will have to be abstracted manually from medical records (see “Computer-Based Patient Record” in Section II). Individual clinical studies activity can be categorized roughly into two classes that require different skill sets: (1) clinical trials (either intramurally funded or extramurally sponsored by government or industry) and (2) studies of clinical experience (cohort studies).

Roles

Surgeon-Investigator

The surgeon (clinical) investigator, with collaboration of key individuals in data management, statistics, and study coordination, must develop the clinical question (aims, objectives), define the study group of interest, identify variables and endpoints (outcomes) of interest, review the literature, and develop all elements of a study protocol (see “Technique for Successful Clinical Research” in Section I). He or she must adjudicate data quality, often gather values for variables in addition to the core data elements, help interpret the analyses performed, putting them into clinical context, present the findings to colleagues, and write manuscripts.

Data Manager

There is no more key support person than the data manager. He or she is at the interface between data gathering and data analysis. Assembly of data for meaningful analysis is often complex, requiring information to be retrieved from a variety of electronic sources. Data managers usually need formal training in computer science and specifically in database construction and management. They must master an effective data query language.

Their most valuable skill, however, perhaps inborn rather than developed, is attention to the smallest detail of the data. Surgeons are usually not of the temperament for this kind of work, and statisticians by training are “big-picture” oriented; if surgeons see the forest, data managers must see the trees. Thus, data management is not simply skill in formulating databases, writing and executing query logic, and documenting these in detail (although these are important); rather, it is skill in examining the actual data, finding errors in them, finding inconsistencies and deviation from the norm that should be verified, verifying what appear as outliers, and assessing quality of data for every variable.

The surgeon and data manager then together organize the variables in a way that is meaningful for analysis. If time-related or longitudinal outcomes are being assessed, we recommend that the data manager become expert in forming intervals and assessing time-related data (time zero, events, intervals), two of the most demanding and essential tasks for such analyses.

For larger clinical quality and research organizations, a member of the data management team is the statistical programmer, who must convert data from database format into analysis data sets that make sense to the statistician (see “Data Conversion for Analysis” under Technique for Successful Clinical Research in Section I).

Data Gatherers

Persons skilled in data gathering for data entry fall into a hierarchy of individuals. For gathering some variables, expert medical domain knowledge as possessed by the surgeon or a knowledgeable research nurse is essential. Other data elements can be extracted by individuals with little formal training other than medical terminology. Essential ingredients are accuracy and integrity. Accuracy may be inborn and is indispensable; it can be assessed prospectively by testing and maintained by quality management and education.

Education/Quality

If large quantities of data are maintained, one or more individuals must assess the quality of the data and from these findings educate the data gatherers. Such individuals must have expert medical domain knowledge; for example, the surgeon or a research and education nurse. In large organizations, this role includes maintaining clinical documentation of the database, keeping current with new surgical trends, and pruning variables that no longer are of value or are of questionable quality.

Statistician

Most serious clinical research efforts require equally serious collaboration with one or more statisticians. The applied
Nonoverlapping Confidence Limits

To find the point at which the effect of a variable is evident using nonoverlapping CLs, consider a simple linear relationship between effect $x$ and outcome $z$:

$$z = \beta_0 + \beta_1 x_1$$  \hspace{1cm} (6B-1)

where coefficients $\beta_0$, the intercept, and $\beta_1$, the slope, are determined from a regression analysis (see Box 6-5). The first requisite is to select a reference value of $x_1$ call it $x_1$. The object is to find a different $x_2$, call it $x_2$, at and beyond which the effect is evident—that is, different from that at $x_1$.

The CLs for $z$ at $x_1$, calculated from the variance of $z$, $\text{Var}[z(x_1)]$, and a confidence coefficient transformed to an appropriate $t$ (e.g., $t = 1$ for 68.3% CL), are calculated as follows:

$$\text{Var}[z(x_1)] = V_0 + V_1 x_1^2 + 2\text{Cov}_{0,1}x_1$$  \hspace{1cm} (6B-2)

and

$$\text{CL}[z(x_1)] = z(x_1) \pm t \sqrt{\text{Var}[z(x_1)]}$$  \hspace{1cm} (6B-3)

where $V_0$ and $V_1$ are the variances of $\beta_0$ and $\beta_1$ (variance being the square of the standard deviation, SD) and $\text{Cov}_{0,1}$ is the covariance term between $\beta_0$ and $\beta_1$ ($\text{Cov}_{0,1}$ is related to the correlation $r$ between $\beta_0$ and $\beta_1$ by the expression $SD_{\beta_0}SD_{\beta_1}r$). The CLs of the unknown $x_2$ are given by Appendix Equations 6B-2 and 6B-3, with $x_2$ substituted for $x_1$.

Because CLs of $z(x_2)$ must exactly equal either the upper or lower CLs of $z(x_1)$, we can write, using Equations 6B-2 and 6B-3:

$$\text{CL}[z(x_1)] = \text{CL}[z(x_2)] = z(x_2) \pm t \sqrt{\text{Var}[z(x_2)]}$$  \hspace{1cm} (6B-4)

or

$$\text{CL}[z(x_1)] = \beta_0 + \beta_1 x_2 \pm t \sqrt{V_0 + V_1 x_2^2 + 2\text{Cov}_{0,1}x_2}$$  \hspace{1cm} (6B-5)

The only unknown in Equation 6B-5 is $x_2$, which, in this case, can be found using the general solution for roots of a quadratic equation. For uncomplicated situations that reduce to Equation 6B-5, the four roots (two each for the ± expression) can be calculated using a handheld calculator program. Two of the roots will simply yield $x_1$. Which of the other two roots is the desired $x_2$ is easily selected by inspection. For more complex multivariable cases, the equation must be solved for explicit values of all variables except $x_2$; thus, even a complex set of coefficients often can be reduced to the form of Equation 6B-5. However, if higher-order terms in $x$ (higher powers) are involved, it is probably easier to solve the

6B

Equations for Calculating Evident Differences

**Nonoverlapping Confidence Limits**

To find the point at which the effect of a variable is evident using nonoverlapping CLs, consider a simple linear relationship between effect $x$ and outcome $z$:

$$z = \beta_0 + \beta_1 x_1$$  \hspace{1cm} (6B-1)

where coefficients $\beta_0$, the intercept, and $\beta_1$, the slope, are determined from a regression analysis (see Box 6-5). The first requisite is to select a reference value of $x_1$ call it $x_1$. The object is to find a different $x_2$, call it $x_2$, at and beyond which the effect is evident—that is, different from that at $x_1$.

The CLs for $z$ at $x_1$, calculated from the variance of $z$, $\text{Var}[z(x_1)]$, and a confidence coefficient transformed to an appropriate $t$ (e.g., $t = 1$ for 68.3% CL), are calculated as follows:

$$\text{Var}[z(x_1)] = V_0 + V_1 x_1^2 + 2\text{Cov}_{0,1}x_1$$  \hspace{1cm} (6B-2)

and

$$\text{CL}[z(x_1)] = z(x_1) \pm t \sqrt{\text{Var}[z(x_1)]}$$  \hspace{1cm} (6B-3)

where $V_0$ and $V_1$ are the variances of $\beta_0$ and $\beta_1$ (variance being the square of the standard deviation, SD) and $\text{Cov}_{0,1}$ is the covariance term between $\beta_0$ and $\beta_1$ ($\text{Cov}_{0,1}$ is related to the correlation $r$ between $\beta_0$ and $\beta_1$ by the expression $SD_{\beta_0}SD_{\beta_1}r$). The CLs of the unknown $x_2$ are given by Appendix Equations 6B-2 and 6B-3, with $x_2$ substituted for $x_1$.

Because CLs of $z(x_2)$ must exactly equal either the upper or lower CLs of $z(x_1)$, we can write, using Equations 6B-2 and 6B-3:

$$\text{CL}[z(x_1)] = \text{CL}[z(x_2)] = z(x_2) \pm t \sqrt{\text{Var}[z(x_2)]}$$  \hspace{1cm} (6B-4)

or

$$\text{CL}[z(x_1)] = \beta_0 + \beta_1 x_2 \pm t \sqrt{V_0 + V_1 x_2^2 + 2\text{Cov}_{0,1}x_2}$$  \hspace{1cm} (6B-5)

The only unknown in Equation 6B-5 is $x_2$, which, in this case, can be found using the general solution for roots of a quadratic equation. For uncomplicated situations that reduce to Equation 6B-5, the four roots (two each for the ± expression) can be calculated using a handheld calculator program. Two of the roots will simply yield $x_1$. Which of the other two roots is the desired $x_2$ is easily selected by inspection. For more complex multivariable cases, the equation must be solved for explicit values of all variables except $x_2$; thus, even a complex set of coefficients often can be reduced to the form of Equation 6B-5. However, if higher-order terms in $x$ (higher powers) are involved, it is probably easier to solve the
equation using an iterative method for solving nonlinear equations.

\[ P \text{ Values} \]

If, instead of (or in addition to) determining an evident difference using nonoverlapping CLs, one wishes to detect an evident difference at some level of significance (\( P \text{ value} \)), then Equations 6B-1 and 6B-2 are used to define \( z(x_1), z(x_2), \) \( \text{Var}[z(x_1)],\) and \( \text{Var}[z(x_2)] \). Then the general equation for a test of significance is used:

\[
t = \frac{z(x_1) - z(x_2)}{\sqrt{\text{Var}[z(x_1)] + \text{Var}[z(x_2)]}} \quad (6B-6)
\]

where \( t \) is the number of standard deviations represented by the selected significance level (\( P \text{ value} \)). Expanding Equation 6B-6:

\[
t = \frac{z(x_1) - (\beta_0 + \beta_1 x_1)}{\sqrt{\text{Var}[z(x_1)] + \text{Var}[z(x_2)]}}
\]

\[
\text{Equation 6B-7}\]

yields an equation with only one unknown, \( x_2 \). In the simplest cases, Equation 6B-7 can be solved using a solution for roots of a quadratic equation. Higher-order terms of \( x \) require use of iterative methods.

Note that if Equation 6B-2 represents a logistic equation, solving for evident differences is performed in the logit domain, not the probability domain. Similarly, if time-related evident differences are desired, calculations are performed in the domain in which estimation of the parameters is performed.

**REFERENCES**

Multivariable analysis (see Box 6-18) can be used to discover if an incremental risk factor has been neutralized with experience (see “Incremental Risk Factor Concept” in Section IV). Date of operation (expressed on a “continuous” scale from, for example, the beginning of a program or beginning of a calendar year) is multiplied by the risk factor to form a new variable, called an interaction term, and the risk factor, date of operation (both called main effects), and interaction term are forced into the multivariable model. If a risk factor has been completely neutralized, the magnitude of the interaction term should have a sign opposite that of the main effect and be of equal magnitude.

Besides complete neutralization of a risk factor, risk factors may be partially neutralized. This may be documented by observing over time, for example, a decreasing strength of a risk factor. Risk factors may also be neutralized effectively by an overall change in risk, recognized by a decrease in the intercept without change in magnitude of risk factors.

**Interaction**

A note on interaction terms and their interpretation in general is in order. Interaction can be found between factors \( x_1 \) and \( x_2 \) in the following ways, particularly if one (say \( x_2 \)) is dichotomous:

- \( x_1, x_2, x_1 \cdot x_2 \)
- \( x_1, x_1 \cdot x_2, x_1 \cdot (1 - x_2) \)
- \( x_1, 1 - x_2, x_1 \cdot (1 - x_2) \)

Note that the interaction term is the one that multiplies one \( x \) by another. Depending on the signs and magnitude of these factors, they provide equivalent model fit but different insights. Specifically, they may identify possible neutralization of an effect. In another setting, they examine the relation when a factor is present, and the same relation when it is not. Finally, the increment of risk from interaction can be quantified. Thus, simply multiplying two factors should not be done blindly but in several ways to explore each aspect of interaction.

Results
Stenotic atherosclerotic coronary artery disease (CAD) is narrowing of the coronary arteries caused by thickening and loss of elasticity of their walls (atherosclerosis) that, when sufficiently severe, limits blood flow to the myocardium. Initially, the disease limits only coronary flow reserve (increase in flow that normally accompanies increased myocardial oxygen demands), but when sufficiently advanced, CAD reduces blood flow through the affected artery even at rest. In its most severe form, atherosclerotic CAD occludes the coronary artery.

HISTORICAL NOTE

Development of coronary cineangiography by Sones and Shirey at the Cleveland Clinic during the early 1960s made possible direct identification of stenotic and occlusive atherosclerotic lesions in the coronary arteries during life and laid the foundation for coronary artery surgery. Sporadic surgical attempts to improve coronary blood flow had previously been made, but these efforts were ineffective because of lack of precise anatomic diagnosis. In 1951 in Montreal, Vineberg attempted to improve coronary blood flow had previously been made, but these efforts were ineffective because of lack of precise anatomic diagnosis. In 1951 in Montreal, Vineberg and Miller reported direct implantation of an internal thoracic artery (ITA), also known as the internal mammary artery (IMA), into the myocardium. More than a decade later, the Cleveland Clinic group demonstrated that this procedure brought new blood to the left ventricular (LV) myocardium, but the new blood flow was too limited in quantity and distribution to be effective. In 1954, Murray and colleagues were considering a direct surgical approach to CAD and reported experimental studies of anastomosing the ITA to a coronary artery. Shortly thereafter, Longmire and colleagues at the University of California in Los Angeles reported a series of patients in whom direct-vision coronary endarterectomy was performed without cardiopulmonary bypass (CPB). Subsequently, CPB was used to facilitate the operation, and Senning reported patch grafting of a stenotic coronary artery in 1961. At about this time, Effler and colleagues at the Cleveland Clinic began their pioneering efforts to achieve myocardial revascularization by a direct surgical attack on stenotic coronary lesions, as demonstrated by Sones using coronary angiography.

DEFINITION

Largely overlooked is the first operation for CAD by Kolesov in Leningrad in 1964, in which the ITA was anastomosed to the left anterior descending coronary artery (LAD), probably without knowledge of this contribution, in May 1967, Favaloro and Effler at the Cleveland Clinic began performing reversed saphenous vein bypass grafting, and by January 1971, this group had performed 741 such operations. Even earlier, Garrett, at that time working with DeBakey in Houston, successfully performed a reversed saphenous vein coronary artery bypass graft to the LAD in...
an unplanned way, at restudy 7 years later, the vein graft was patent.

Progress was rapid after this early era. In 1968 in New York, Green and colleagues re-reported anastomosing the distal end of the left ITA to the LAD using a dissecting microscope, and Edwards and colleagues began using this procedure at UAB in 1969. In Milwaukee in 1971, Flemma, Johnson, and Lepley described the technique and advantages of sequential grafting, in which one vein was used for several distal anastomoses. Advantages of this technique were further amplified by the reports of Bartley, Bigelow, and Page in 1972 and Sewell in 1974. Bilateral ITA grafting was performed at least by 1972 and probably as early as 1968. Thus, within a very short time, the foundations were laid for rapid worldwide adoption of coronary artery bypass grafting (CABG).

MORPHOLOGY

Development of Coronary Artery Stenosis

Atherosclerosis, the most common form of arteriosclerosis, is a process that occurs in coronary arteries, as in other blood vessels, consists of focal intimal accumulations of lipids, complex carbohydrates, blood and blood products, fibrous tissue, and calcium deposits, as well as associated changes in the media. Lipoid foci are associated with or converted into plaques of fibrous or hyaline connective tissue, although at least some atherosclerotic plaques may result from organization of thrombi.

Fibrolipoid plaques may become thick enough to encroach on the lumen of the artery, producing a stenotic lesion. Probably episodically and at times over a period of years, new material is deposited on the luminal side of the plaque, resulting in further narrowing and sometimes complete coronary occlusion. Small blood vessels form around and within the plaque. Gradual regression of plaque enlargement, seen clinically as regression of stenoses in a few patients, and development of collateral coronary blood flow can result in at least partial spontaneous restoration of antegrade regional myocardial blood flow.

Hemorrhage may occur suddenly within a plaque (see “Atherosclerotic Plaque Rupture and Thrombosis” later in chapter); occasionally this may suddenly increase the degree of coronary stenosis and precipitate acute myocardial infarction (MI) or unstable angina pectoris. Thrombosis occasionally complicates the coronary atherosclerotic process, generally when there is luminal narrowing. Sudden complete obstruction may result, and it is generally agreed that acute thrombotic occlusion is the genesis of acute MI in most patients. Rapid recanalization frequently follows this process. Platelet aggregation within the lumen of an already narrowed coronary artery may induce thrombosis or suddenly narrow the lumen and provoke an acute MI or unstable angina, and it may play a role in development of the atherosclerotic plaque itself. Platelet aggregation releases thromboxane A2, an extremely potent vasoconstrictor. Thus, interrelationships among atherosclerotic narrowing, platelet aggregation, and coronary spasm are important.

The atherosclerotic process usually affects multiple coronary arteries. In 1975, Gensini reported that 40% of patients with CAD sufficient to lead to cineangiographic study had important stenoses in all three major coronary arteries, and in 30% two vessels were involved. Ninety-five percent of patients with complete occlusion of one artery had important stenoses in at least one of the other two arteries.

Atherosclerotic CAD usually involves the proximal portion of the larger coronary arteries, particularly at or just beyond sites of branching. Thus, stenoses in the main trunks of the LAD, circumflex (Cx) coronary artery, and right coronary artery (RCA) often involve the first of the secondary branches (first diagonal branch of LAD, obtuse marginal branch of Cx artery, and posterior descending branch of RCA). When CAD is more extensive in the main trunks, origins and first portions of secondary branches may be involved. Diffuse distal disease severe enough to render the patient unsuitable for CABG is uncommon. In 10% to 20% of patients with atherosclerotic CAD, the left main coronary artery is importantly stenotic.

Occasionally, a major coronary artery may lie beneath a muscle bridge. This is most common in the middle third of the LAD, but sometimes one or all of the obtuse marginal branches of the Cx artery are buried in muscle throughout their course. These portions of artery are typically free of severe atherosclerotic changes.

Myocardial Infarction and Morphologic Sequelae

When myocardial blood flow is sufficiently impaired in relation to myocardial oxygen demands, myocardial necrosis occurs. The resultant infarction may be subendocardial—that is, not involving the entire thickness of the ventricular wall, but only the inner third. In its most extreme form, subendocardial infarction may be diffuse and result from multiple-system disease. More often, however, subendocardial infarcts are regional and result primarily from a stenotic lesion in one or two systems. These infarcts are generally less extensive than so-called transmural infarcts, but still have serious implications. A transmural MI involves the entire thickness of the ventricular wall. Transmural infarction usually results from a sudden increase in luminal narrowing or complete obstruction of the artery supplying that area, or a sudden generalized increase in myocardial oxygen demand in the presence of a severely stenotic coronary artery. Although categorization of acute infarctions as subendocardial or transmural is convenient, most transmural MIs are not homogeneous but contain islands of viable muscle of varying number and size.

The process of infarction is complex. Animal studies indicate that some myocardial cells die after 20 minutes of complete coronary artery occlusion, and that extensive myocardial cell death occurs after 60 minutes. Although these time frames may vary, some reperfusion generally occurs within the ischemic area of myocardium within minutes of onset of acute ischemia, particularly in the zone between ischemic and nonischemic myocardium (border zone). If this spontaneous reperfusion occurs within 3 to 4 hours, the amount of necrosis is limited, at times substantially, and mortality is decreased. The process is complex because, in addition to these beneficial effects, spontaneous reperfusion can result in hemorrhage, edema, and ventricular electrical instability.

Healing of the acute MI leaves a scarred area of myocardium. In most cases, this area is a mixture of fibrous tissue and viable myocardial cells in varying proportions. Such scarring is evident from (1) intraoperative inspection of areas of
previous infarction at the time of CABG and (2) change from akinia or dyskinesia to hypokinesia or normal wall motion in some LV wall segments when patients go from a symptomatic to an asymptomatic state after percutaneous coronary intervention (PCI) or CABG. When the scar is almost all fibrous tissue, it is usually large, and the LV wall may become akinetic or aneurysmal (see Chapter 8).

These morphologic changes may be self-aggravating because of their effect on circulation to the subendocardial layer. Repeated infarctions may occur and add still more scarring. In the aggregate, myocardial scarring leads to LV systolic and diastolic dysfunction and, ultimately, if the patient survives long enough, to the syndrome of chronic heart failure with elevated right atrial and jugular venous pressure, hepatomegaly, and fluid retention. More often, however, patients with severe ischemic LV dysfunction die of another infarction or ventricular fibrillation.

Atherosclerotic Plaque Rupture and Thrombosis

Several studies have emphasized the dynamic nature of coronary atherosclerotic plaque as a fundamental feature of CAD.\textsuperscript{106,128} Rupturing, or rupture, of atherosclerotic plaques is probably the genesis of the acute coronary syndromes termed unstable angina and acute MI. When this occurs, mural or occlusive coronary thrombosis often coexist and contribute further to development of the unstable states.\textsuperscript{220}

Coronary stenoses that produce less than 50% reduction in lumen diameter are often the site of the atherosclerotic plaque rupture that precipitates unstable angina or acute MI.\textsuperscript{11,17,128} More severe stenoses also undergo plaque rupture, and total vessel occlusion may occur. However, an acute ischemic episode does not always develop, possibly because severely stenotic lesions are long-standing and have stimulated development of a protective collateral circulation.

Certain atherosclerotic plaques appear to have a higher risk of rupture than others. These plaques are characterized by relative softness, a high concentration of cholesterol and cholesterol esters, and a lipid pool that tends to be situated eccentrically.\textsuperscript{128} Rupture is through the cap of the plaque, and areas in which the cap lacks underlying collagen support seem particularly vulnerable.\textsuperscript{11,111}

**Clinical Features and Diagnostic Criteria**

**Routine Methods**

CAD is usually first suspected with development of the symptom complex of angina pectoris or an acute MI, occasionally because of electrocardiographic (ECG) evidence of a silent acute MI, a positive ECG response to a graded exercise test, or sudden death with resuscitation. Occasionally, CAD is first suspected because of cardiomegaly and symptoms of chronic heart failure without any other obvious cause.

The precise nature, location, duration, and severity of any chest pain are determined by carefully questioning the patient. Precipitating causes and maneuvers that relieve the pain are noted, as are any recent changes in pain pattern. Findings on physical examination are usually nonspecific.

Many noninvasive tests, beginning with a chest radiograph and ECG at rest and during exercise and then proceeding to more complex studies, are currently used to identify and quantify CAD and its sequelae. However, such tests cannot yet define extent or distribution of anatomic coronary disease with great accuracy. From a surgical standpoint, therefore, properly performed coronary angiography remains the definitive diagnostic procedure (see “Coronary Angiography” in text that follows). Contrast-enhanced computed tomographic coronary angiography (CTCA) is emerging as a promising technique for detecting coronary artery disease (see “Computed Tomographic Angiography” later in this section) and may, with increased spatial and temporal resolution, be suitable as an accurate and noninvasive method to select candidates for CABG.\textsuperscript{115,11,10,111,546,153} Methods of evaluating LV function are also necessary. These may be based in part on historical data, physical findings, and chest radiography. Noninvasive and invasive special study methods may be used. Even when complex study methods are employed, results must be interpreted with knowledge of the simple but reliable clinical data. An ejection fraction (EF) of 35% has a different implication when accompanied by minimal LV enlargement seen on a chest radiograph than when enlargement is marked. An EF of 30% is much more ominous when accompanied by important elevation of jugular and right atrial pressure with hepatomegaly and fluid retention than when these pressures are normal. Exercise capacity may be variable in patients with similar EFs, and the variations are prognostically important. It should be emphasized, however, that heart size can be deceptive because it can remain normal in the presence of severe LV dysfunction.

Important associated conditions such as hyperlipidemia, arterial hypertension, and diabetes, and a history of MI, smoking, or a particularly stressful occupation or lifestyle should be noted. Because arteriosclerosis is the cause of CAD, its presence elsewhere in the circulatory system should be sought. A history suggesting transient cerebral ischemic attacks or stroke, particularly when carotid bruits are present, must be carefully pursued. A history of intermittent claudication and presence of diminished femoral, popliteal, or pedal pulses are indicative of peripheral arterial occlusive disease. The thoracic and abdominal aorta are examined for possible aneurysm or occlusive disease. Renal and pulmonary function should also be evaluated.

**Coronary Angiography**

Coronary angiograms provide important information. Their quality must be sufficient to permit detailed assessment from several angles of both coronary ostia and all major and minor branches of the left and right coronary arterial systems. However, angiography remains an imperfect method. Severity of a visualized stenotic lesion may be underestimated, and diameter of vessels distal to a stenosis is often underestimated.

Assessment of coronary arteries at operation by external palpation or probing of the open vessel cannot substitute for coronary angiography. When the arteries cannot be adequately filled by contrast media, however, or the available study is incomplete and cannot be repeated (this should be uncommon), intraoperative observations can be used to supplement angiographic findings. The surgeon should assess all coronary arterial branches carefully at the time of operation, rather than assume the coronary angiogram is a totally accurate diagnostic tool.
Recording and Reporting Data

Whatever the techniques used for coronary angiography, methods of recording and analyzing the data are crucial. A 75% cross-sectional area loss (50% diameter) is considered an important but moderate stenosis, and a 90% cross-sectional area loss (67% diameter) is considered severe (Fig. 7-1). Some groups consider only those lesions with 70% or more diameter loss (90% or more cross-sectional area loss) as important; an appropriately documented basis for this has not been established.

Extent of important coronary artery stenoses has conventionally been summarized as “single-vessel,” “double-vessel,” or “triple-vessel” disease, usually with left main coronary artery disease as a separate category. This chapter uses the terms single-system, two-system, and three-system disease, because each coronary system (LAD, Cx, and RCA) consists of several vessels. Use of the term system is therefore more accurate than vessel.

These classifications have been criticized because they give no indication of the amount of LV myocardium rendered ischemic by the lesions. For example, a stenosis in the LAD system has a different significance when it lies at the origin of a large first diagonal artery than when it involves the middle third of the LAD beyond its major septal and diagonal branches, or only the first portion of a large first diagonal branch. A single stenosis in the proximal portion of the Cx artery varies in significance depending on whether this artery is dominant. Single-system disease involving the proximal RCA has a different implication from that involving only the posterior descending branch of the RCA. Many other examples can be given of the inadequacies of these classifications.

A few classification systems have been described to circumvent these limitations. These include Gensini’s old and rather complex scheme that takes into account severity of the stenoses, the various segments of the coronary artery tree involved, and the area of myocardium usually perfused by them; a simple scheme from Massachusetts General Hospital; and the method of the Coronary Artery Surgery Study (CASS) of the U.S. National Heart, Lung, and Blood Institute (NHLBI), dividing the coronary arteries into a total of 27 specified segments. Some myocardial jeopardy scores have attempted to provide similar information but are limited by the assumption that akinetic areas cannot be revascularized.

Whatever the recording and reporting methods, they are not a substitute for the surgeon critically reviewing cineangiograms before deciding for or against operation, and again immediately before operation.

Computed Tomographic Angiography

Although conventional coronary angiography remains the gold standard to determine extent and severity of CAD and indications for CABG, CTCA using 64-slice multidetector CT scanners (MDCT) has been evaluated as an alternative method to select patients for CABG (Fig. 7-2).

Initial studies suggest that this technique is a suitable alternative to conventional coronary angiography in selected patients. However, concerns regarding exposure to excessive radiation and the small but defined increased risk of cancer in later life associated with exposure to radiation may limit its widespread application.

Coronary Intravascular Ultrasound

Intravascular ultrasound (IVUS) uses a high-frequency miniaturized ultrasound transducer positioned on the tip of a coronary artery catheter to provide detailed cross-sectional images of the coronary vessel wall (Fig. 7-3, A). Unlike coronary angiography, which details only luminal encroachment, IVUS provides images of the atherosclerotic plaque, characterizes its composition, and assesses severity of stenosis (Fig. 7-3, B). When compared with formalin-fixed and fresh histologic specimens of coronary arteries, it correlates significantly ($P < .0001$) with coronary artery cross-sectional area ($r = 0.94$), residual lumen cross-sectional area ($r = 0.85$), and percent cross-sectional area ($r = 0.84$). It is useful in determining the need for CABG in situations when the severity of coronary artery stenosis cannot be precisely determined by angiography, particularly for left main and LAD disease (Fig. 7-3, C).

Coronary Artery Pressure and Fractional Flow Reserve

Fractional flow reserve (FFR) is a simple, reliable, and reproducible physiologic index of lesion severity in patients with intermediate stenosis, and is another method to determine the need for CABG and PCI in equivocal situations, particularly stenosis of the left main coronary artery. The concept of FFR is illustrated in Fig. 7-4. Pressure measured distal to the stenotic coronary lesion during maximum hyperemia (Pd) divided by mean aortic pressure (Pa) correlates with maximum myocardial blood flow in the presence of a stenosis $Q^f$ divided by the normal maximum myocardial blood flow $Q^m$. FFR 0.75 to 0.80 or less is generally an indication for intervention.

Left Ventricular Function Testing

Resting and Exercise Tests

Because resting LV function is presumed to depend on the amount of myocardium that is free of scar, severity of LV dysfunction may be a surrogate for amount of myocardial scar. This may not be entirely accurate in patients with ischemic heart disease, because ischemia may result in myocardial stunning or hibernation and reversible depression of at least systolic LV function (see “Myocardial Cell stunning” in Chapter 3). CABG and PCI do not favorably affect myocardial scarring.

Figure 7-1 Diagrammatic representation of relationship between two methods of estimating severity of coronary artery stenosis. (From Brandt and colleagues.)

Resting and Exercise Tests

Because resting LV function is presumed to depend on the amount of myocardium that is free of scar, severity of LV dysfunction may be a surrogate for amount of myocardial scar. This may not be entirely accurate in patients with ischemic heart disease, because ischemia may result in myocardial stunning or hibernation and reversible depression of at least systolic LV function (see “Myocardial Cell stunning” in Chapter 3). CABG and PCI do not favorably affect myocardial scarring.
Figure 7-2  A-C. Multidetector computed tomographic volume rendering images show significant stenoses of major coronary arteries (arrows), suggestive of three-system disease. These coronary lesions (arrows) were confirmed on conventional coronary arteriography (D-E), and patient underwent coronary artery bypass grafting. Key: LAD, Left anterior descending coronary artery; LCx, left circumflex coronary artery; RCA, right coronary artery. (From Lee and colleagues.26)
Global and Segmental Function

Exercise LV function in patients with ischemic heart disease is characteristically depressed; this reflects loss of coronary flow reserve imposed by the distribution and severity of CAD. Amount of decrease in EF or other measures of the heart’s response to stress is a surrogate for the distribution and severity of coronary arterial stenoses.

Systolic and Diastolic Function

LV function can be expressed as systolic or diastolic function. Systolic function is determined by contractility of the ventricle (see “Cardiac Output and Its Determinants” in Section I of Chapter 5). Diastolic function describes compliance, or extensibility, of the ventricle, which is related to preload.

Global LV function is usually described by an index of overall ventricular systolic function, most often EF. EF is not independent of preload or afterload and therefore is not an ideal index, but it is the one most frequently used and is reasonably satisfactory. EF is obtained commonly and least accurately by visual estimation from a cineangiographically recorded left ventriculogram, more accurately (and originally) by quantitative angiography, and also by noninvasive methods such as radioisotopic imaging and echocardiography.

The CASS score was developed by CASS investigators as a measure of global LV function and actually is a summation of five segmental wall scores based on wall motion observed in the right anterior oblique (RAO) projection of the
Atherosclerotic Plaque Rupture and Thrombosis

B21,H15,J5,R9

is a risk factor because plaque rupture is frequently the inciting incident leading to progression in severity of coronary artery stenosis. Eccentric positioning of the lipid pool within the plaque appears to predispose to rupture and thus progression in severity of stenosis. 

Stenotic Coronary Artery Disease

The natural history of patients with a given severity and distribution of CAD depends in part on the rate of progression of both. As an added complexity, regression of some lesions also occurs. In general, however, both severity and distribution of CAD tend to increase with time, although the rate of increase is highly variable and difficult to predict. In general, over a 2-year period in patients with already important stenoses, 20% of the stenoses increase in severity, and about half of patients develop important new lesions. The mechanism of increase in severity is variable, but atherosclerotic plaque rupture and thrombosis play important roles in some cases (see “Atherosclerotic Plaque Rupture and Thrombosis” earlier in this chapter).

Of the usually accepted risk factors for presence of stenotic CAD, not all have been helpful in predicting its rate of progression. Aggressiveness of the atherosclerotic process seems to be a risk factor for progression; surrogates for it include young age at presentation with symptomatic CAD, peripheral arterial disease, diabetes, and hyperlipidemia. Nature of the atherosclerotic plaque is a risk factor because plaque rupture is frequently the inciting incident leading to progression in severity of coronary artery stenosis. Eccentric positioning of the lipid pool within the plaque appears to predispose to rupture and thus progression in severity of stenosis. Rheologic factors play a role; the more severe the stenosis, the more rapid the progression toward total occlusion.

cineangiogram. Table 7-1 shows the relationship between EF and CASS scores. Other scoring systems have also been developed.

Segmental wall function refers to function, usually systolic, of segments of the LV wall. Methods usually depend on observation of wall motion or wall thickening throughout the cardiac cycle. Analysis of segmental wall motion is particularly informative in patients who have previously sustained MIs.

Load-Independent Function

High LV afterload tends to depress LV systolic function and therefore cardiac output, and high LV preload generally increases cardiac output (see “Cardiac Output and Its Determinants” in Section I of Chapter 5). Methods previously discussed generally do not reflect load-independent LV function and are therefore suboptimal.

NATURAL HISTORY

Gaps exist in knowledge of the natural history of atherosclerotic CAD. Many of these gaps will be permanent because withholding treatment is no longer justifiable. The closest approach to natural history comes from data gathered in patients seen and treated medically before about 1970. Unfortunately, many studies from that era have the disadvantage that patients were not categorized according to anatomic extent of their disease and LV function.

A further complexity is that in nearly all studies since 1970, patients initially undergoing no treatment or medical treatment have properly been allowed thereafter to cross over to interventional treatment (PCI or CABG). This has made it even more difficult to generate accurate information about the natural history of CAD.

Stenotic Coronary Artery Disease

The natural history of patients with a given severity and distribution of CAD depends in part on the rate of progression of both. As an added complexity, regression of some lesions also occurs. In general, however, both severity and distribution of CAD tend to increase with time, although the rate of increase is highly variable and difficult to predict. In general, over a 2-year period in patients with already important stenoses, 20% of the stenoses increase in severity, and about half of patients develop important new lesions. The mechanism of increase in severity is variable, but atherosclerotic plaque rupture and thrombosis play important roles in some cases (see “Atherosclerotic Plaque Rupture and Thrombosis” earlier in this chapter).

Of the usually accepted risk factors for presence of stenotic CAD, not all have been helpful in predicting its rate of progression. Aggressiveness of the atherosclerotic process seems to be a risk factor for progression; surrogates for it include young age at presentation with symptomatic CAD, peripheral arterial disease, diabetes, and hyperlipidemia. Nature of the atherosclerotic plaque is a risk factor because plaque rupture is frequently the inciting incident leading to progression in severity of coronary artery stenosis. Eccentric positioning of the lipid pool within the plaque appears to predispose to rupture and thus progression in severity of stenosis. Rheologic factors play a role; the more severe the stenosis, the more rapid the progression toward total occlusion.

Left Ventricular Dysfunction

Stress-Induced Dysfunction

First indications of LV dysfunction in patients with ischemic heart disease are localized abnormalities of regional wall motion (LV systolic function) during exercise or other forms of stress. These abnormalities are the result of transient myocardial ischemia, which can be demonstrated as myocardial perfusion defects during exercise. Global LV systolic function improves during exercise in normal persons, except in old age. By contrast, when initially localized areas of myocardial ischemia become sufficiently extensive, global LV systolic function declines during exercise. Exercise-induced ECG changes also reflect these reversible myocardial perfusion abnormalities, which may be so severe as to cause hypotension during exercise testing. Related to this exercise-induced decrease in function in some patients, LV end-diastolic volume responds abnormally to exercise by increasing, often to more than 50% above resting value. These reversible abnormalities of regional myocardial perfusion and wall motion occasionally occur at rest, most often in patients with unstable angina.
Abnormalities of LV diastolic function during stress can be demonstrated in most patients with extensive CAD. These abnormalities take the form of reduced peak LV filling rate and increased time to peak filling rate. These phenomena are the clinical reflection of the laboratory demonstration that ischemia impairs rate of diastolic relaxation of papillary muscle, related to the fact that myocardial relaxation during early diastole is an active, energy-dependent process. Abnormalities of diastolic function in patients with coronary artery stenoses may also reflect lack of an increase in early diastolic coronary blood flow.

In the aggregate, these purely ischemic abnormalities of LV systolic and diastolic function may be severe enough during stress to result in a considerable increase in LV end-diastolic pressure. This may produce dyspnea and even transient paroxysmal nocturnal dyspnea and pulmonary edema, as well as angina, during severe ischemic episodes. Further evidence that these abnormalities of LV systolic and diastolic function can result from myocardial ischemia alone is provided by their reversal after successful PCI or CABG.

**Dysfunction at Rest**
LV dysfunction with the patient at rest and under no stress has been considered the result of myocardial scar. Therefore, it can be expected that it will not improve after neutralization of the coronary arterial stenoses by CABG or PCI. However, there is evidence that myocardial stunning or hibernation, or both, may be responsible at times for considerable LV dysfunction, and that this element of resting LV dysfunction can be relieved by revascularization.

Myocardial scars from previous MIs also result in abnormalities of LV diastolic function. Both clinical and experimental studies indicate that increase in LV end-diastolic volume, which results from both diastolic and systolic abnormalities of function, is directly related to the amount of scar in the ventricle.

Patients whose LV function is depressed from myocardial scarring exhibit morphologic, physiologic, and functional variability. Some have moderately increased LV end-diastolic pressure at rest and a considerably reduced exercise capacity but only a mildly increased cardiac size on chest radiography. These patients have moderate scarring and marked ischemic dysfunction in scarred or non-scarred parts of the ventricles that can often be improved by revascularization. Some have chronic symptoms of pulmonary venous hypertension and may still be helped by revascularization. A few have moderate or severe cardiomegaly, reduced cardiac output, importantly elevated right atrial and jugular venous pressure, hepatomegaly, and fluid retention. Patients in the latter group have advanced LV dysfunction from extensive myocardial scarring, and it generally cannot be improved by operation unless the scar is discrete, is full thickness (aneurysmal or akinetic), and can be resected (see Chapter 8).

**Unfavorable Outcome Events**

**Stable Angina**
Development of chest discomfort or pain on exertion is common in patients with coronary artery stenosis, but chest discomfort is not an inevitable accompaniment of even important CAD. Severity of angina is typically categorized by the Canadian class system, which differs from the New York Heart Association (NYHA) classification for heart failure. 

- **Class I:** angina occurring only with strenuous or prolonged exertion at work or recreation and not with ordinary physical activity (thus, Class 0 means no angina under any circumstance).
- **Class II:** angina occurring with walking rapidly on level ground or a grade and with rapidly walking up stairs. Ordinary walking for fewer than two blocks on level ground or climbing one flight of stairs does not cause angina except during the first few hours after awakening, after meals, under emotional stress, in the wind, or in cold weather. This implies slight limitation of ordinary activity.
- **Class III:** angina occurring when walking fewer than two blocks on level ground at a normal pace, under normal conditions, or when climbing one flight of stairs. This implies marked limitation of ordinary physical activity.
- **Class IV:** angina occurring with even mild activity. It may occur at rest but must be brief (<15 minutes) in duration. (If the angina is of longer duration, it is called *unstable angina*.) This implies inability to carry out even mild physical activity.

Angina generally results from reduction in coronary flow reserve in a portion of the myocardium; the more severe the reduction, the greater the severity of angina. However, severity of angina also depends on amount of stress or exercise, which increases myocardial oxygen demand in proportion to the intensity of the activity. Standardization of demand gives graded exercise testing its advantage in quantifying to some extent the amount of “reversible ischemia” (more properly, the amount of reduction of coronary flow reserve). Absence of angina does not eliminate the possibility that the patient has “reversible ischemia.” Although angina tends to become more severe as time passes, a number of patients do not experience this trend.

**Unstable Angina**
Unstable angina undoubtedly signifies a prognostically important change in the coronary circulation, but the syndrome takes so many different forms that its precise definition has been difficult. Not surprisingly, different practitioners and even different randomized trials have used different definitions. In 1989, Braunwald devised a classification system to ensure uniformity of categorization and provide diagnostic and prognostic information.

Although “unstable angina” implies several syndromes, no differences in outcome have been identified among its subgroups. The term applies to patients with severe and persisting angina on presentation to the physician or hospital, with ECG evidence of ischemia and only minor enzymatic evidence (available only later) of MI. The syndrome is considered more ominous if it occurs in the absence of stimuli that increase total body oxygen consumption or catecholamine release (e.g., unusual emotional stress, fever, infection, hypotension or uncontrolled hypertension, tachyarrhythmia, hypoxemia). Unstable angina also applies to patients who have onset of severe angina (Canadian class IV) within 2 months of presentation or who have recurring or prolonged (>15 minutes) severe angina within 10 days of presentation, whether or not it is of new onset. The term is also appropriate for patients who develop (or continue to have) severe angina in the first 2 weeks after an acute MI. All subsets usually demonstrate ECG evidence of myocardial ischemia during...
severe pain, and no enzymatic evidence of more than minimal myocardial necrosis.

The cause of unstable angina is now considered to be an acute change in coronary circulation with or without changes in related neurohumoral responses. Unstable arteriosclerotic plaque, which may fissure and rupture, is the genesis of unstable angina in many patients (see “Arteriosclerotic Plaque Rupture and Thrombosis” earlier in this chapter).\textsuperscript{225} However, superimposed thrombosis and platelet aggregation complicate local situations,\textsuperscript{225,226} and the clinical state largely depends on activity of the patient’s thrombolytic state and mechanisms for reversing platelet aggregation. The process is reversible but tends to recur either as another episode of unstable angina or as an acute MI.

**Acute Myocardial Infarction**

Prevalence of acute MIs in patients with coronary artery stenoses is not known precisely, but it is surely affected by prevalence of risk factors. For example, patients with severe proximal LAD lesions have a particular tendency to develop acute and often fatal MI.\textsuperscript{215} Among patients who are sufficiently symptomatic and undergo coronary angiography, at least 10% have an acute MI within 1 year, 30% within 5 years, 40% within 10 years, and 50% within 15 years, as determined from patients assigned to initial medical treatment in the Veterans Administration (VA) randomized trial of stable angina.\textsuperscript{229}

Acute MI is usually caused by acute subtotal or total occlusion of the vessel supplying the infarcted region, and the vessel usually does not have well-formed collateral arteries. This fact has been suspected for many years and gave rise to the early phrase “coronary thrombosis.” However, thrombosis was first convincingly demonstrated by DeWood and colleagues in Spokane, Washington, in a series of patients undergoing emergency CABG for acute infarction.\textsuperscript{214} Often the acutely occluded vessel has not previously had a severe stenosis, which is consistent with the concept that the myocardium supplied by the diseased vessel is usually devoid of important collateral vessels. Current information suggests that rupture of an unstable arteriosclerotic plaque is the genesis of the acute reduction in luminal diameter, often accompanied by thrombosis and platelet aggregation (see “Arteriosclerotic Plaque Rupture and Thrombosis” earlier in this chapter).\textsuperscript{225,213}

The greater the number of MIs, the greater the likelihood the patient will have another one, which may indicate that some people generate more unstable plaques than others. Also, the more coronary artery systems (LAD, Cx, RCA) that contain important stenoses, the greater the probability of an acute MI.\textsuperscript{229} This may simply be due to the increased number of coronary arteriosclerotic plaques available to rupture.

Early (3-month) mortality after acute MI is difficult to define for the current era. Hospital mortality is usually described, but the early phase of the hazard function continues for about 3 months. In the past, hospital mortality in a heterogeneous group of patients admitted with acute MI was 10% to 50%, depending on prevalence of risk factors. Death was usually in acute or subacute cardiac failure, or suddenly with ventricular fibrillation.\textsuperscript{242} Size of the infarct was an important risk factor; hospital mortality was 5% for patients with small infarcts vs. 50% for those with large infarcts (involving 40% or more of LV mass).\textsuperscript{226,21} Reserve in the adjacent “nonischemic” myocardium appeared also to relate to probability of surviving an acute MI, indicating the importance of metabolically supporting this area and revascularizing it even if the stenoses are not severe.\textsuperscript{224} Overall probability of death was higher after the second infarction and still higher after the third, related to scarring imposed by previous infarctions. Development of pulmonary edema soon after acute MI increased risk of death, but 1-year mortality was as low as 10% when other risk factors were favorable.\textsuperscript{221}

Currently, therapy is directed toward use of inhibitors of platelet aggregation, thrombolytic agents, heparin, and PCI as soon as possible after onset of infarction. Although the optimal protocol may be arguable, effectiveness of this therapy is not. Hospital mortality has been reduced to about 7% to 10% by these measures. When cardiogenic shock develops, emergency PCI or CABG with maximal measures for myocardial management can salvage many patients (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3).\textsuperscript{A13,A15,G17,H19,H20,L5}

**Death**

Approximately 70% to 80% of a heterogeneous group of patients with CAD of sufficient severity to cause them to seek medical advice ultimately die a cardiae death. The remaining 20% to 30% die of unrelated causes. Overall survival for a heterogeneous group of patients with clinically evident CAD is 75% at 5 years after initiation of medical treatment, 60% at 10 years, and 45% at 15 years.\textsuperscript{229} However, time-related probability of death in a group of CAD patients is so related to prevalence of risk factors that overall estimates are of little value.

Most often, death occurs with acute or subacute cardiac failure, often within a few months of an acute MI and sometimes precipitated by a ventricular arrhythmia.\textsuperscript{229} Infrequently, death is attributable to chronic heart failure, either late after one or more infarctions or without any identifiable earlier episode of infarction. This mode of death is generally characterized by a slow downhill course, eventually leading to hepatomegaly, ascites, and ultimately death. Death in this mode is usually the direct result of myocardial scarring.

About 20% of patients with important CAD who have had no interventional therapy die suddenly.\textsuperscript{229} Acute MI is not the only cause of sudden death. Presumably, sudden cardiac death in patients with ischemic heart disease can result from acute, severe myocardial ischemia, resulting in ventricular fibrillation, asystole, or acute severe depression of ventricular function.\textsuperscript{B18}

**Incremental Risk Factors for Unfavorable Outcome Events**

Understanding the benefit of interventional therapy, whether CABG or PCI, demands a knowledge of the incremental risk factors for unfavorable outcome events in patients treated medically for CAD.

Multivariable analysis is used to generate incremental risk factors for various unfavorable events after CABG, PCI, or medical treatment. However, those identified are often surrogates for more basic risk factors, and at times several surrogates for the same basic risk factors appear. Box 7-1 presents the basic risk factors as currently perceived. In the future, these factors themselves may become more clearly identifiable.

Factors/events listed are not the result of a formal multivariable analysis, but rather a composite of many such analyses. These categories constitute reversible ischemia.

Reduced Regional Coronary Flow Reserve
Reduced regional flow reserve results from severity of the coronary arterial stenoses and number of coronary arterial systems with important stenoses. The left main coronary artery is an additional “system.”

Time-related survival for a heterogeneous group of patients with single-system stenosis is high, approximately 90% to 95% at 5 years (Fig. 7-5, A). At 15 years, survival is about 50%. Additional risk factors relating to reduction in regional coronary flow reserve include (1) specific vessel(s) diseased, (2) location of stenosis within the vessel, and (3) severity of stenosis. Because time-related mortality from single-system disease is relatively low, the differences attributable to further refinements in this category will be small and therefore difficult to identify. Also, inferences from the analyses are only as good as reliability of the cineangiogram.

In any event, single-system disease with stenosis in the RCA appears to confer better survival than can be expected with LAD disease, at least for 5 years (RCA 96%, LAD 92%). When single-system stenosis is in the LAD, a very proximal location (proximal to the large septal branch) imposes less favorable survival than more distal lesions (proximal 90% at 5 years, distal 98%). Although not conclusively demonstrated, more severe stenoses (>90%), especially those proximal in the artery, probably impose higher time-related mortality than less severe stenoses.

Patients with two-system disease as a heterogeneous group have lower survival than those with single-system stenoses, with 5-year survival of about 88% (Fig. 7-5, B). At 15 years, survival is about 56%. When the LAD is one of the two systems, the same effects of location and severity as mentioned for single-system disease pertain. Differences in outcome between single- and two-system disease are not as great as those between two- and three-system disease.

As a heterogeneous group, patients with three-system disease have a 5-year survival without interventional treatment of about 70% (Fig. 7-5, C) and a 10- and 15-year survival of about 60% and 40%, respectively. Factors affecting survival in patients with important single-system disease involving the LAD also affect survival in patients with three-system disease. Also, the greater the number of systems with important proximal stenoses, the lower the time-related survival: at 5 years, survival with no, one, two, and three systems with proximal stenoses is 71%, 64%, 51%, and 45%, respectively. Important left main coronary artery disease imposes an even lower survival: 40% to 60% at 5 years (Fig. 7-5, D). Survival falls to about 10% to 26% by 15 years (Fig. 7-6).

Severity of angina is a surrogate for the basic risk factor of severity of reduction in coronary blood flow reserve (Fig. 7-7). Also, graded exercise testing (GXT) is a surrogate for the basic risk factor of severity of reduced coronary blood flow reserve and is related to outcome events in CAD patients. For example, in the heterogeneous group of patients randomly assigned to initial medical treatment in the European Coronary Surgery Study Group randomized trial, 1-, 5-, and
Figure 7-5  Survival of medically treated men with coronary artery disease, stable angina of at least 6 months’ duration, and less than severe left ventricular dysfunction enrolled in the U.S. Veterans Administration (VA) Cooperative Study (solid squares). 83 For comparison, survival is shown of a population matched for age and gender from the 1976 U.S. life tables (solid line). Data for other groups of medically treated patients published earlier by Burggraf, 86 Oberman, 87 and Webster and their colleagues are also shown. Lower survival in the last three groups may have been the result of less restrictive selection of patients than for the VA group and better medical treatment in the more recent VA group. Data from the Coronary Artery Surgery Study (CASS), in which important stenosis meant a 70% diameter reduction, are also presented. 88 These data include patients treated medically in the current era with all types of ventricular function. Left main coronary artery data from CASS refer to left main coronary artery plus triple-system disease.

Figure 7-6  Nomograms of specific solutions of multivariable risk factor equations illustrating effect of number of coronary artery systems with important stenoses on time-related freedom from cardiac death in patients randomly assigned to initial medical treatment in Veterans Administration randomized trial of chronic stable angina. For this depiction, patients were censored if they crossed over to coronary artery bypass grafting. Values for each risk factor in the specific solutions of the multivariable equation represented by these nomograms are provided in the American College of Cardiology/American Heart Association Joint Task Force Subcommittee on Coronary Artery Bypass Graft Surgery. 41 A, Patients with normal left ventricular (LV) function. B, Patients with importantly impaired LV function. Key: ACC, American College of Cardiology; AHA, American Heart Association; CABG, coronary artery bypass grafting; LM, left main coronary artery disease; SD, systems diseased.
10-year survival was 94%, 83%, and 71% in patients with a mildly positive GXT but 92%, 77%, and 62% in those with a strongly positive GXT. Similarly, in a study from the CASS Registry, survival at 12 years after medical treatment was substantially lower among patients with a strongly positive GXT (55% for men, 62% for women) than among those with a mildly positive test (75% for men, 82% for women).

Progression of Coronary Arteriosclerosis
Rate of progression of coronary arteriosclerosis, which could also be termed aggressiveness of the arteriosclerotic process, cannot as yet be examined directly in multivariable risk factor analyses. Its surrogates have appeared in a number of such analyses. The surrogates may be a substitute not solely for one basic risk factor but at times for several factors. Among them are young age at presentation, diabetes, hypertension, and hyperlipidemia.

An important advance has been the demonstration that progression of arteriosclerotic CAD can be slowed, and that regression of some lesions in some circumstances can be initiated by intensive lipid-lowering therapy.

Coronary Arteriosclerotic Plaques
Number of previous episodes of acute MI may be a surrogate for coronary arteriosclerotic plaques as well as for total area (or number) of arteriosclerotic plaques within the coronary arterial tree. Presence of unstable angina and number of recent episodes may likewise be surrogates. In this regard, however, status of the patient’s fibrinolytic and disaggregating systems also plays a role. During very active periods, these systems may neutralize the effects of plaque rupture and minimize severity and frequency of unstable angina and acute MI.

Myocardial Scar
To the extent that resting LV dysfunction in patients with CAD is related directly to amount of scar in the myocardium, surrogates for presence and extent of this basic risk factor include number of prior episodes of acute MI, resting LV systolic and diastolic dysfunction (presence and severity) determined by any of several methods, and a history of chronic heart failure.

Reversible ischemia is capable of producing resting LV dysfunction. Myocardial stunning may persist after reversible ischemia has disappeared and result in LV dysfunction. Unfortunately, methods for distinguishing between scar and reversible ischemia, although useful, are neither entirely accurate nor precise. The frequent finding of only a 0.05 to 0.10 increase in preoperatively depressed EF in many patients after CABG suggests that the proportion of LV dysfunction not attributable to myocardial scarring is small.

In CAD patients treated noninterventionally, mild resting LV dysfunction (EF 35%-50%) minimally affects survival, but severe dysfunction (EF < 35%) substantially reduces it. Thus, other factors being equal, 1- and 5-year survival in patients with mild LV dysfunction is about 95% and 80%, respectively, whereas with severe dysfunction it is about 70% and 40%. Good LV function is found more frequently in patients with single-system disease than those with three-system disease (Table 7-2).

Secondary Conditions
Certain conditions develop secondary to ischemic heart disease and are additional incremental risk factors for death and other unfavorable events.

Hemodynamic Instability Grade 1 hemodynamic instability is mild and responds to catecholamine infusion. Grade 2 is more severe and responds only when intraaortic balloon pumping is added. Grade 3 is unresponsive even to addition of intraaortic balloon pumping and requires cardiopulmonary support (cardiopulmonary bypass, extracorporeal membrane oxygenation) or a ventricular assist device (see Section 1 in Chapter 5). Because hemodynamic instability in patients with ischemic heart disease typically reflects acute myocardial ischemia or necrosis and produces secondary deleterious effects throughout the body, it adversely affects outcome.

Ischemic Instability Ischemic instability is a state of unstable angina and implies acute myocardial ischemia. It carries the risk that severe myocardial stunning and necrosis or ischemic ventricular electrical instability can develop acutely.

Ventricular Electrical Instability Either ischemic or secondary to phenomena associated with myocardial scarring,
ventricular electrical instability is a risk factor incremental to that of the basic milieu that gives rise to it.

Coexisting Conditions

Older Age Older age at presentation is a risk factor for death in patients with ischemic heart disease, and probably acts as a coexisting condition rather than directly affecting CAD.

Diabetes Diabetes is a strong risk factor for death in CAD patients because of its effect as a coexisting condition and its accelerating effect on the arteriosclerotic process. Fig. 7-8 illustrates the powerful effect of diabetes in elderly patients who have undergone PCI.

Hypertension The strong effect of hypertension as a risk factor for death in CAD patients is related to kidney damage, intracranial complications, LV hypertrophy, and acceleration of the arteriosclerotic process (Fig. 7-9).

Gender Although overall mortality is lower in women with angina than men, for patients older than 65, relative risks are similar (2.7 vs. 2.4, respectively).

Other Comorbidity Any serious coexisting disease adversely affects survival in patients with CAD. Of particular importance, because of their prevalence in this group of patients, are chronic obstructive pulmonary disease and chronic renal disease. Smoking can be considered an important coexisting condition.

TECHNIQUE OF OPERATION

Most patients undergoing CABG have extensive three-system disease, often with important stenoses in four, five, or six arteries. Many have substantial impairment of LV function. This discussion focuses on operation under these circumstances and tactics for accomplishing optimal revascularization and optimal intraoperative management of the myocardium.

Surgical management of arteriosclerotic CAD has evolved from treatment primarily of patients with stable coronary syndromes undergoing elective operation, to treatment of more heterogeneous groups of patients with various clinical syndromes who are older and have more comorbid conditions, including patients who require urgent or emergency operation. Economic and other external pressures often result in CABG being performed within hours after diagnostic coronary angiography or PCI.
At present, CABG with use of total CPB through a full sternotomy remains the most widely used surgical technique. Because of extensive experience, this approach is the technique to which all others must be compared. Other techniques currently in use include CABG through a full sternotomy but without use of CPB, and operations through smaller sternal, parasternal, or thoracotomy incisions with or without use of CPB (see Fig. 2-23).

Here, the conventional operation with CPB, as well as the off-pump procedure, are presented. Other procedures are discussed under Special Situations and Controversies later in this chapter.

Preoperative Preparation

Many patients come to CABG taking β-adrenergic receptor or calcium channel blocking agents, angiotensin-converting enzyme (ACE) inhibitors, digitalis preparations, antiarrhythmic agents, and platelet antiaggregating drugs. Some are receiving intravenous heparin and nitroglycerin. It is advisable in most circumstances to continue β-adrenergic receptor and calcium channel blockers, as well as ACE inhibitors, up to the time of operation (see “Management of Preoperative Medications” in Section I of Chapter 4). Several studies have shown a tendency toward development of acute MI in patients in whom β-adrenergic receptor agents are discontinued. Boudoulas and colleagues demonstrated an important increase in adrenergic tone in most patients the day before operation that could be reduced by propranolol. Propranolol has also been shown to lessen prevalence of intraoperative ventricular arrhythmias without compromising LV function in low or moderate dosages. Patients receiving preoperative β-adrenergic receptor agents, amiodarone, or sotalol are less likely to develop atrial fibrillation postoperatively. Digitalis preparations can be discontinued preoperatively unless atrial fibrillation is present (see Chapter 4). They can be administered intraoperatively and postoperatively for control of heart rate if atrial fibrillation or other atrial arrhythmias are present.

Platelet antiaggregating drugs such as abciximab, eptifibatide, tirofiban, clopidogrel, prasugrel, and ticagrelor bind to the glycoprotein IIb/IIIa platelet receptors. When feasible, these drugs as well as aspirin should be discontinued at the appropriate time interval before operation (each has a different half-life) if the patient has a stable coronary syndrome, because their use is associated with increased postoperative bleeding and need for transfusion of blood products.

Patients who have received plasminogen-activating (fibrinolytic) agents such as streptokinase, alteplase, and reteplase are less likely to develop atrial fibrillation postoperatively. Digitalis preparations can be discontinued preoperatively unless atrial fibrillation is present (see Chapter 4). They can be administered intraoperatively and postoperatively for control of heart rate if atrial fibrillation or other atrial arrhythmias are present.

They can be administered intraoperatively and postoperatively for control of heart rate if atrial fibrillation or other atrial arrhythmias are present.

Operating Room Preparation

Anesthetic methods for CABG are described in Chapter 4. After inserting an endotracheal tube and appropriate monitoring devices (see Chapter 2), the skin is prepared over the chest, abdomen, groin, one or both arms if indicated, and the complete circumference of both legs, including the feet. Draping includes isolating the feet, genitalia, and pubis and placing sterile waterproof drapes beneath the legs.

Surgical Strategy

The prime objective of CABG is to obtain complete revascularization by bypassing all severe stenoses (at least 50% diameter reduction) in all coronary arterial trunks and branches having a diameter of about 1 mm or more. Because five or more individual conduits cannot be conveniently used in most patients, at least some of the grafts may require sequential (side-to-side) anastomoses. To increase the likelihood that the entire graft will remain patent, the distal end-to-side anastomosis of a sequential graft should be made, whenever possible, to a relatively large artery with a substantial proximal stenosis and good runoff. Although it is not clearly established whether grafts with more than one distal anastomosis have the same, higher, or lower patency rates than those with only a single distal anastomosis, several studies suggest that sequential grafts are associated with higher mean flows and graft patency. As a general principle, conservation of conduit by employing sequential grafting is prudent because of the likelihood of subsequent CAGB or peripheral arterial procedures that may require use of saphenous vein grafts.

A widely used strategy involves routine use of the left ITA to the LAD and segments of saphenous vein to the remaining coronary arteries requiring revascularization. The right ITA, one or both radial arteries, and the right gastroepiploic artery can also be used in combination with the left ITA. Sequential anastomoses with the ITA and radial artery can be performed with satisfactory results. Figs. 7-10 and 7-11 show the most widely used combinations and configurations of bypass grafts. Details of graft placement are often individualized according to location and severity of arteriosclerotic disease, surgeon preference, availability of suitable conduit, and knowledge of the long-term function of various conduits.

The cineangiogram provides key information for planning CABG, but based on either the cineangiogram or observations made at operation, the surgeon may elect to open vessels suspected of having important stenosis. A few errors will inevitably be made regarding which vessels should be grafted. The surgeon must decide which error is more acceptable: opening and grafting an artery that does not need it or failing to open and graft a vessel with an important stenosis. The latter is generally considered a more serious error.

Coronary Artery Bypass Grafting

With Cardiopulmonary Bypass

A median sternotomy is made, and at the same time a segment of greater saphenous vein (or radial artery or other conduit) is removed. Before the pericardium is opened, the left ITA (and the right if indicated) is completely mobilized. Heparin is administered as dissection of the ITA is being completed. The ITA is then divided. A bulldog clamp or clip is placed on the artery near the open end, and the distal segment of the artery on the chest wall is ligated or clipped. The pericardium is opened, and pericardial stay sutures are placed. Purse-string sutures are placed at the sites for cannulation and also in the ascending aorta and right atrial wall for controlled aortic root perfusion and delivery of cardioplegia into the coronary sinus (see Fig. 2.22). Because arteriosclerosis is frequently present in the ascending aorta and proximal aortic arch in patients with CAD, particularly elderly patients, epi-aortic ultrasonographic scanning of the aorta is advisable.
Figure 7-10 Combinations and configurations of saphenous vein bypass grafts. **A**, Vein graft is anastomosed side to side to a diagonal branch of left anterior descending coronary artery (LAD) and end to side to LAD. **B**, In circumflex system, vein graft is anastomosed side to side to one or more proximal marginal branches and end to side to most distal marginal branch. **C**, Sequential grafts to circumflex system (Cx) can be extended to include branches of right coronary artery (RCA). **D**, In RCA system, vein graft can be anastomosed side to side to posterior descending coronary artery and end to side to one or more left ventricular branches of RCA. **E**, Sequential grafts to RCA system can be extended to include branches of Cx artery. Direction of a sequential graft to RCA and Cx artery systems (configuration **C** or **E**) is chosen so that the largest coronary artery branch is placed at end of sequence.
before aortic cannulation to obtain information that can lead
to safe positioning of cannulae and aortic clamps (see “Epi-
aortic Ultrasonography” in Chapter 26).510,542,523,67,92

CPB is established using a single venous cannula. Cata-
ters for administering cardioplegic solution are placed into
the ascending aorta and coronary sinus through the previ-
ously placed purse-string sutures and secured with tourni-
quets. The aorta is clamped and cardioplegic solution infused
(see “Cold Cardioplegia, Controlled Aortic Root Reperfu-
sion, and [When Needed] Warm Cardioplegic Induction” in
Chapter 3). The heart can be covered with cold saline during
administration of cold cardioplegia to facilitate cooling.

With the heart retracted out of the pericardial cavity and
toward the head of the patient by an assistant standing to the
surgeon’s left or by traction sutures placed on the acute
margin of the heart, the first anastomosis of the conduit that
has been selected is made to the distal RCA or to the poste-
rior descending artery (PDA) (see Fig. 7-10, D). (See “Distal
Anastomosis” later in this chapter.) Sequential anastomoses
of the conduit can be performed to more distal branches of
the RCA or to the marginal branches of the Cx coronary
artery (see Fig. 7-10, E). The graft is then distended gently
with cardioplegic solution, positioned along the right atrium
up to the right side of the ascending aorta, and transected at
the point that will permit a smooth course of the conduit
without kinking or tension. The free end of the graft is
spatulated.

The heart is then retracted to the right by the assistant. A
separate conduit is anastomosed to one or more of the mar-
ginal branches of the Cx artery (see Fig. 7-10, B). The graft
is properly oriented to avoid twisting, and the heart is repo-
sitioned in the pericardial cavity. The graft is disended gently
Right gastroepiploic artery or splenic artery may be used to bypass branches of right and circumflex coronary arteries in combination with ITA or other grafts to LAD circulation.

Figure 7-11, cont’d  

**E**, Right ITA can be brought across midline and used to bypass LAD, and if indicated, left ITA can be anastomosed to one or more marginal branches of left circumflex coronary artery. **F**, When extensive revascularization of posterior wall of left ventricle (LV) is required, a posteriorly positioned sequential vein graft (or radial artery) in combination with a left ITA graft to the LAD is typically used. **G**, Radial artery graft may be used as a sequential graft to bypass arteries on lateral and posterior surfaces of LV. Radial artery can be anastomosed proximally to left ITA, which is used to bypass the LAD. Alternatively, radial artery can be anastomosed directly to ascending aorta. **H**, Right gastroepiploic artery or splenic artery may be used to bypass branches of right and circumflex coronary arteries in combination with ITA or other grafts to LAD circulation.

with cardioplegic solution, cut to the appropriate length, and spatulated. This graft can be positioned anterior to the pulmonary artery or passed through the transverse sinus for anastomosis to the right side of the aorta. A third segment of conduit can be anastomosed to one or more diagonal branches of the LAD. This segment can be brought anterior to the pulmonary artery or through the transverse sinus.

The ITA is cut to the appropriate length, and a bulldog clamp is placed on the proximal portion. If the operation has been performed using hypothermia, rewarming is begun at this time. The pericardium is incised widely to permit proper alignment of the ITA with the LAD and its diagonal branches, taking care to avoid injury to the left phrenic nerve. A pad is placed beneath the LV, and the LAD is isolated and incised. The distal end of the ITA is spatulated and sutured to the LAD and sequentially to a diagonal branch of the LAD if indicated (see Fig. 7-11, A and B).

The aortic clamp is removed, a partially occluding clamp is placed on the ascending aorta, and two or three openings are made with a punch in the isolated aortic segment. The grafts are sutured to the aorta so that they are free of kinking or tension. If grafts have been passed through the transverse sinus, they are anastomosed to openings made on the right lateral surface of the ascending aorta. Because of increasing evidence implicating the arteriosclerotic ascending aorta as an important source of emboli to the brain and other organs, it
may be preferable to avoid placing the partially occluding clamp on it and to perform the proximal anastomoses during a single period of aortic clamping with the heart arrested. A25

The partially occluding clamp (or the aortic clamp if a partially occluding clamp has not been used) is then removed. Air is evacuated from the ascending aorta, and controlled aortic reperfusion, if indicated, is begun. Once rewarming has been completed and the heart is beating well, CPB is discontinued and cannulae are removed. Temporary atrial and ventricular pacing wires and chest drainage tubes are placed. Remainder of operation is completed in the standard manner (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2).

Without Cardiopulmonary Bypass

Perfection of techniques and equipment for stabilizing the beating heart has resulted in an increased number of CAGB procedures performed without use of CPB (OPCAB). Procedures involving placement of grafts to more than one of the three major coronary arteries are generally performed through a median sternotomy. With development of stabilization devices that permit adequate and safe exposure of all surfaces of the LV, OPCAB can be safely performed in patients with three-system disease and with left main coronary artery disease. C43,K36,P20,Y1

In contrast to CAGB performed with CPB, methodology for OPCAB continues to evolve, and many issues relating to preoperative selection and preparation of patients, their anesthetic management, and conduct of the operation remain incompletely defined and unresolved. The following discussion presents a generalized representation of OPCAB, with schematic illustrations of the techniques and equipment for exposing and stabilizing surfaces of the LV.

Anesthetic management of patients undergoing CAGB without CPB is discussed in Section I of Chapter 4. Close communication between the surgeon and anesthesiologist is essential during OPCAB. The surgeon must inform the anesthesiologist when and how the heart is being displaced, when a coronary artery is occluded, and when a shunt or other perfusion device is used. The anesthesiologist must keep the surgeon informed of ischemic changes detected by the ECG, occurrence of arrhythmias, and the patient’s overall hemodynamic status. When the heart is displaced, amplitude of the ECG signal may be greatly decreased, and thus severity of ST-segment changes indicative of ischemia may be underestimated. Transesophageal echocardiography is used to monitor regional wall motion and right and left ventricular volumes.

A median sternotomy is made, and at the same time a segment of the greater saphenous vein (or a radial artery or other conduit) is removed (see “Vein Graft” in text that follows). Before the pericardium is opened, the left ITA and right ITA (if indicated) are completely mobilized (see “Internal Thoracic Artery” later in this chapter). Heparin is administered as dissection of the ITA is being completed. The ITA is then divided. A bulldog clamp is placed on the artery near the open end, and the distal segment of the artery on the chest wall is ligated or clipped. The pericardium is opened and pericardial stay sutures placed. Epiaortic ultrasonographic scanning of the ascending aorta to detect severe atherosclerosis that may affect the conduct of the operation is advisable in older patients (see Chapter 26). R10,C42,F23,G7,W2

Heparin dose, optimal activated clotting time (ACT), and protocol for administering protamine vary from institution to institution. Heparin dose varies from a minimum of 5000 units to full heparization (3 mg · kg⁻¹). Protocols to reverse heparin activity with protamine range from no administration to partial or full doses.

Hypothermia should be avoided. Normothermia can be maintained by use of warm intravenous and irrigating fluids or a heated mattress or blanket, by humidification of the airway, and by maintaining a warm temperature in the operating room.

Hemodynamic stability during manipulation of the heart can be preserved by several maneuvers. These include placing the patient in the head-down (Trendelenburg) position, which increases preload by redistributing blood volume; rotating the operating table; and opening the right pleural space by incising the pericardium vertically. The latter two maneuvers minimize the manipulation required to create optimal exposure of the lateral wall of the LV. Placing and using temporary ventricular pacing wires will prevent prolonged periods of bradycardia. Preoperative insertion of an intraaortic balloon pump in high-risk patients may increase tolerance of the heart to manipulation.

Exposure of the LV surfaces containing the arteries to be bypassed is achieved by different combinations of elevation (apex of heart toward ceiling) and lateral displacement (apex of heart to right or left). To facilitate these maneuvers, a heavy suture (size 0 silk or polyester) is placed in the posterior pericardium opposite the oblique sinus and midway between the right and left inferior pulmonary veins (Fig. 7-12, A), the most dependent portion of the pericardial cavity. R10 This should be done quickly to avoid prolonged hypotension. The suture should not be placed too deeply because this may result in injury to the descending aorta or esophagus. The suture is passed through a wide strip of cloth tape (Fig. 7-12, B), and a snare is placed over both ends of the suture and tightened (Fig. 7-12, C). By adjusting orientation of the snare and tape sling and the traction placed on them, adequate exposure of the coronary arteries requiring bypass grafting can be accomplished in nearly all patients. R10 Circumferential pressure on the heart should be avoided.

Next, the artery to be grafted is stabilized with a device that depresses the myocardium to expose the segment to be grafted (Fig. 7-13, A). Alternatively, a device that elevates the myocardium on both sides of the segment of artery to be grafted (typically a suction device) can be used (Fig. 7-13, B).

Exposure of the posterior descending branch of the RCA is achieved by marked elevation of the apex of the heart with minimal lateral displacement. This is facilitated by applying traction on the ends of the cloth tape upward toward the head and to the left (avoiding compression of the heart) and using downward traction on the snare (Fig. 7-14, A). A stabilizing device is then applied.

Exposure of the distal RCA is obtained by leftward traction on the ends of the cloth tape, downward traction on the snare, rotation of the table to the left, and use of Trendelenburg position.

The LAD is exposed by traction on the ends of the cloth tape to the left and upward toward the head and gentle downward traction on the snare. A stabilizing device is then applied (Fig. 7-14, B). These maneuvers are applied more
Figure 7-12 Maneuvers to facilitate exposure of surfaces of left ventricle. A, Heavy suture (size 0 silk or polyester) is placed in posterior pericardium opposite oblique sinus and midway between right and left inferior pulmonary veins. B, Suture is placed through a wide strip of cloth tape. C, Snare is placed over both ends of suture and tightened.

Figure 7-13 Stabilization devices to facilitate exposure of segment of artery to be grafted. A, Generic device that depresses myocardium on both sides of artery. B, Generic device that elevates myocardium on both sides of artery, using suction.
After exposing the appropriate wall of the LV, the artery to be grafted is encircled proximal to the site of the arteriotomy with a fine suture, an elastic vessel loop, or a tourniquet. Encircling the artery distal to the arteriotomy site is not always necessary and should be avoided when possible. After the stabilization device is applied, the artery is incised, and anastomosis to the appropriate conduit is performed using techniques described later in this chapter (see “Distal Anastomoses”). Performing the anastomosis can be facilitated by use of a blowing device that disperses humidified carbon dioxide over the anastomotic site to remove blood. This device should be directed at the anastomotic site only during actual placement of sutures to minimize injury to the endothelium of the coronary artery. An intracoronary shunt may also facilitate performing the anastomosis, although it also may result in injury to the endothelium (Fig. 7-15). When the anastomosis is performed on a distal RCA that is not critically narrowed or occluded proximally, a shunt may be particularly valuable because bradycardia and hypotension may occur when the artery is temporarily occluded. A shunt may also provide sufficient distal flow to an arterial segment that may be an important source of collateral blood flow to other segments of the LV that have not been bypassed, thus preventing hypotension and cardiac decompensation.

Proximal anastomoses of vein grafts, radial arteries, or free ITA grafts to the ascending aorta are performed after placing a partially occluding clamp on the aorta (see “Proximal Anastomoses” later in this chapter). These can be performed before or after the distal anastomoses. Temporary atrial and ventricular pacing wires (if not already in place) and chest drainage tubes are placed. Remainder of the operation is completed in the standard manner (see Chapter 2).

When OPCAB is used in patients with multisystem disease, sequence of performing the distal anastomoses becomes important. As a general rule, it is advisable to first graft the artery or arteries that have evidence for collateral blood supply to the distal arterial bed. If an ITA graft is used, the clamp on the ITA pedicle is released as soon as the distal anastomosis to the coronary artery is completed. If a vein graft or another conduit is used, the proximal anastomosis of this conduit to the aorta is performed before the distal anastomosis. Flow is thus established to the distal arterial bed as soon as the distal anastomosis is completed. Vessels without demonstrable collateral blood supply are then grafted. With this approach, important collateral flow is not interrupted before flow through the grafts is established.

The common practice of performing the left ITA to LAD anastomosis first is based on the principle of restoring flow to the anterior wall and septum of the LV before substantial manipulation of the heart is performed to expose the Cx arterial branches. This approach may be valid in many patients, but it is not advised if the LAD provides substantial collateral flow to the remainder of the LV.

Vein Graft

After preoperative examination of both legs with the patient erect, and with ultrasonic imaging when indicated, the right or left greater saphenous vein is chosen for removal. Presence of superficial varicosities does not indicate an unusable saphenous vein. However, wound healing may be poor in such extremities. If possible, a leg without varicosities is chosen; multiple large varicosities in the saphenous vein render it

Figure 7-14  Exposure of posterior and anterior descending coronary arteries. A, Posterior descending coronary artery. Heart is elevated with minimal lateral displacement by upward traction toward the head on ends of tape and downward traction on the snare. Stabilizing device is then applied. B, Anterior descending coronary artery. Ends of tape are pulled upward and slightly to patient’s left, and downward traction in opposite direction is exerted on snare. Stabilization device is then applied.
unsuitable. If vein from one leg is too short or too abnormal for use, an additional segment of appropriate length is removed from the other leg. Occasionally, particularly during reoperations, suitable segments of greater saphenous vein cannot be found, and the lesser saphenous vein can be used if it is of adequate diameter. If suitable segments of vein cannot be found in the legs by any method, use of alternative conduits becomes necessary. These include the right ITA, one or both radial arteries, right gastroepiploic artery, inferior epigastric artery, and, in rare circumstances, the splenic or ulnar artery. The cephalic vein can be taken from wrist to shoulder, but its walls are usually thinner than those of leg veins, and its late patency is less. In critical situations in which sufficient autologous conduit is not available, suitable prepared allograft veins may be used, recognizing their reduced long-term patency.

For removal of the greater saphenous vein, the leg is abducted and the knee flexed about 45 degrees and supported (Fig. 7-16, A). If the vein from the lower leg is to be used, the initial skin incision is made just anterior to the medial malleolus. If the upper portion of the vein will be used, the initial skin incision is made in the groin. The desired plane is accessed by blunt dissection with scissors down to the level of the vein. Skin and subcutaneous fat are undermined with the scissors, staying just superficial to the saphenous vein and spreading the tips of the scissors over the vein. A continuous incision or multiple small incisions over the length of the vein may be used (Fig. 7-16, B and C). Creation of flaps is avoided. Care is taken to preserve the saphenous nerve. The vein may divide just above the knee, becoming confluent again just below the knee. Either of the two branches may be the larger vessel, which is preserved. The saphenous vein usually becomes too large and unsuitable for bypass purposes just before it penetrates the fascia lata and joins the femoral vein. Therefore, dissection is usually not performed in this area.

Whenever possible, a single long segment (usually 50-65 cm) of the greater saphenous vein is removed. About 12 to 15 cm may be needed for diagonal branches of the LAD, about 20 to 24 cm for marginal Cx branches, and about 18 to 22 cm for the RCA and its branches. So long as the external diameter of the vein is greater than about 3.0 to 3.5 mm, vein width is probably not an important consideration. Large veins generally reduce in size with time after insertion, and thus adaptation to function can occur. Veins of overall poor quality should be avoided whenever possible; experience in peripheral vascular surgery indicates they are prone to failure.

When the usable vein has been exposed and its length measured, the proximal (femoral) end is isolated and divided between ligatures. A vascular clamp is placed on the vein to mark what will become the distal end of the graft. The vein is then removed, retracting it upward so that just enough tension exists to expose but not tear the branches. Branches may be ligated with fine sutures and divided, or divided between hemostatic clips (Fig. 7-17, A). The saphenous vein must not be narrowed by ligating or clipping the branches too close to it (Fig. 7-17, A [upper inset]). Branches should be ligated or clipped flush with the saphenous vein to avoid creating diverticula, which can be the nidus for thrombus formation (Fig. 7-17, A [lower inset]). After division of all branches and removal from its bed, the vein is divided between ligatures at its peripheral end (proximal end of the graft) and removed.

Alternatively, the greater saphenous vein can be removed endoscopically. Using small transverse or vertical incisions, a lighted dissector is introduced into the wounds (Fig. 7-18, A). A plane of dissection anterior to the vein is established with a balloon-tipped dilator or other device (Fig. 7-18, B) and the dissector used to isolate the vein and its branches (Fig. 7-18, C). The branches are clipped and divided with a cautery, and after ligating its proximal and distal ends, the vein is removed. Time required to remove veins with this technique is somewhat longer than with the conventional method, but a lower prevalence of leg wound complications and leg discomfort have been observed.

If the lesser saphenous vein is to be used, it can be removed with the patient in the prone or supine position with the leg...
Figure 7-16  Removing greater saphenous vein. A, Location of greater saphenous vein and line of incision. B, Continuous incision over entire length of saphenous vein. C, Multiple small incisions over saphenous vein.

Figure 7-17  Division of side branches of saphenous vein using fine ligatures or hemostatic clips. A, Venous branches should be secured just flush with saphenous vein to avoid narrowing (upper inset) or creating diverticula (lower inset), which can be a nidus for thrombus formation. B, Avulsed branches are secured with a double-loop 7-0 polypropylene suture.

- Vasodilating drugs (nitroprusside, papaverine) can be added to reduce vasospasm. The vein is gently
  been added. Vasodilating drugs (nitroprusside, papaverine)
  to which a small amount of heparinized blood (30 mL) has
  temperature, heparinized, balanced salt solution (500 mL)
  end of the graft is removed. The vein is flushed with a room-
  with a ligature. The previously placed clamp on the central
  adaptor is inserted into the open peripheral end and secured
  administered.

- It is generally agreed that details of removing and storing saphenous veins until their insertion are important in mini-
  minimizing damage, which may include intimal disruption, depo-
  sition of platelets and leukocytes on the intimal surface,
  damage to smooth muscle, and disruption of the extracellular
  matrix. Despite this general agreement, opinions differ as to which maneuvers or interventions result
  in the least injury. Overdistention of the vein \[ \text{H}^{3} \] and venous spasm \[ \text{H}^{18} \] are surely disadvantageous. No consensus exists as
  to the optimal temperature to maintain the graft or the optimal solution to flush and distend the graft before
  its insertion.

### Arterial Grafts

#### Internal Thoracic Artery

The ITA is usually mobilized immediately after dividing the sternum, and before incising the pericardium and administ-
ering heparin. A standard sternal retractor can be used to widely
separate the divided sternal edges, tilting the retractor to
elevate the left half of the sternum and expose the ITA.
Alternatively, an externally positioned retractor, such as that
developed by Favaloro, can be used. With either type of
retractor, the operating table is elevated and rotated to opti-
lessly expose the undersurface of the left sternal segment and
left ITA. The ITA can be skeletonized or removed as a pedicle
with the internal thoracic veins, fat, muscle, and pleura. Skel-
etonization better preserves blood supply of the sternum and
may be preferable in situations in which risk of sternal infec-
tion may be increased (e.g., obese patients, diabetic patients,
use of both ITAs).

Fig. 7-19 shows the technique for removing the ITA with
a pedicle. An incision using the electrocautery at low power
is made in the parietal pleura and muscle on the medial side
of the ITA, several millimeters from the accompanying inter-
nal thoracic vein (Fig. 7-17, A). The incision is extended
along most of the length of the vessel down to the sixth intercostal space. A parallel incision lateral to the ITA and the
accompanying lateral internal thoracic vein (if present) is
made. Dissection is begun in the sixth intercostal space,
where there are usually no branches. Using the tip of the
electrocautery blade without current, the pedicle is freed
from the sixth costal cartilage. With the pedicle gently
retracted downward and with gentle blunt dissection, the
intercostal arteries are identified and either occluded with
small metal clips and divided, or simply divided with the
electrocautery (Fig. 7-19, B). The ITA should not be grasped
with instruments.

The pedicle is dissected up to the level of the second or
first rib (Fig. 7-19, C), and the left phrenic nerve is identified
and protected. If there is sufficient length, the internal tho-
racic vein is preserved at its junction with the brachiocephalic
vein; if not, the vein is ligated or clipped and divided. It is
not necessary to routinely divide the proximal branches of
the ITA, although it is recognized that such branches, if not

either straightened (prone position) and elevated or flexed at
the knee and rotated medially (supine position). If the prone
position is used, the patient is subsequently repositioned and
redraped in the supine position. Initial skin incision is made
posterior to the lateral malleolus and extended superiorly
toward the popliteal fossa. The vein is divided at the level
where it penetrates the deep fascia to join the greater saphe-
nous vein. The sural nerve lies parallel to the vein and is
preserved. Branches of the vein are secured and divided as
described for the greater saphenous vein.

Leg incisions are closed with continuous absorbable suture
in the subcutaneous layers. A small drainage catheter is placed
beneath these layers in the thigh, and the skin is closed with
a continuous subcuticular suture or with metal clips. This can
be done immediately after the vein is removed or deferred
until after CPB has been discontinued and protamine
administered.

The vein is removed to a preparation table, and a small
adaptor is inserted into the open peripheral end and secured
with a ligature. The previously placed clamp on the central
end of the graft is removed. The vein is flushed with a room-
temperature, heparinized, balanced salt solution (500 mL)
to which a small amount of heparinized blood (30 mL) has
been added. Vasodilating drugs (nitroprusside, papaverine)
can be added to reduce vasospasm. The vein is gently

distended (<150 mmHg) with the solution. Any remaining
unsecured branches are ligated or clipped and any constrict-
ing adventitial bands removed. Branches that have been
avulsed are secured with 7-0 polypropylene sutures (see Fig.
7-17, B). The vein is then gently distended and clamped at
the end, and a thin straight line is drawn along its length
with an indelible surgical pencil. The vein is placed in the
heparinized solution at room temperature until used.

Figure 7-19  Preparation of internal thoracic artery (ITA) pedicle. A, Using electrocautery, pleura and muscle are incised on either side of ITA and its accompanying veins. B, Branches of ITA and accompanying veins are divided between clips or with electrocautery. C, Dissection is continued to level of second or first rib. D, ITA pedicle is divided at level of sixth or seventh intercostal space. E, End of ITA is freed from adherent fascia, muscle, and veins.

divided, can result in “steal” of blood from the LAD in some situations.510

After proximal dissection is completed, heparin is administered and the ITA divided in the sixth or seventh intercostal space (Fig. 7-19, D). The proximal end is controlled with a small bulldog clamp or clip and the distal end ligated or clipped. The ITA is wrapped in a sponge saturated either with a balanced salt solution containing papaverine (20 mg) dissolved in 20 mL of saline solution, or with 500 mL of lactated Ringer solution to which 50 mg of sodium nitroprusside and 30 mL of heparinized blood have been added. If the ITA bleeds freely, even though not briskly, the graft is generally considered satisfactory for use. The ITA is not probed or injected with fluid unless there is no flow; probing or
PART II Ischemic Heart Disease

Figure 7-19, cont’d  F, ITA is incised to appropriate length. G, For a side-to-side anastomosis using the ITA, pleura is incised over artery at site of anastomosis. H, Anastomosis is completed using a continuous 7-0 or 8-0 polypropylene suture.

injecting may produce endothelial damage and dysfunction.\textsuperscript{16} If the right ITA is to be used, it is prepared in the same manner. The internal thoracic vein leaves the chest wall to enter the brachiocephalic vein at a lower level on the right than on the left, and it is usually divided. Care is taken to avoid injuring the phrenic nerve.

The left ITA pedicle is brought into the surgical field after the LAD has been opened, usually through a wide incision in the pericardium. The ITA is cut obliquely at the site for anastomosis and freed from adjacent tissue for a short distance (Fig. 7-19, E). It is then incised at the bottom of the bevel for the appropriate distance to correspond to the size of the opening in the artery (Fig. 7-19, F). It is anastomosed to the artery with a continuous 7-0 or 8-0 polypropylene suture. The ITA is not dilated or otherwise manipulated, and only the adventitia is grasped with forceps. After anastomosis is completed, the pedicle is tacked to the epicardium with a fine suture on both sides of the artery.

If the ITA is to be anastomosed to a diagonal branch of the LAD as well as to the LAD itself, anastomosis to the diagonal artery is performed first. The pleura is incised over the ITA at the site of the anastomosis (Fig. 7-19, G). The anastomosis is completed with a 7-0 or 8-0 polypropylene suture (Fig. 7-19, H). Anastomosis to the LAD is then performed.

When the left ITA does not reach the LAD but is patent, it can be used as a free graft. The proximal end of the ITA can be anastomosed directly to the aorta, to the right ITA, or to a segment of vein that has been used to bypass other coronary arteries. Patency of free ITA grafts is almost as good as that of in situ ITA grafts.\textsuperscript{12} If the ITA has been used as a pedicle graft and is under tension after CPB is discontinued,
it can be lengthened by completely dividing the tissues of the pedicle at several sites.

**Radial Artery**

Before operation, an Allen test is performed on the nondominant hand. The radial and ulnar arteries are compressed at the wrist while the patient opens and closes the fist vigorously (5-10 times) to produce blanching of the skin on the palm of the hand. Pressure on the ulnar artery is then released while the radial artery remains compressed. Skin of the palm of the hand should immediately become flushed as flow is restored to the palmar arch from the ulnar artery. If the test is equivocal, ultrasonic imaging may be necessary to establish the safety of removing the radial artery.

The arm is positioned on an arm board at the side of the patient. An incision is made in the forearm beginning over the radial pulse at the wrist (Fig. 7-20, A). It is then extended proximally over the belly of the brachioradialis muscle. The lateral antebrachial cutaneous nerve is located lateral to the incision and retracted. The deep fascia is opened at the wrist, exposing the radial vascular pedicle. Incision in the fascia is extended proximally, exposing the muscles of the forearm (Fig. 7-20, B). The superficial radial nerve is also lateral to the incision and should be preserved.

The vascular pedicle containing the radial artery and accompanying veins is mobilized in the middle of the forearm, then encircled in this area with an elastic vessel loop for retraction (Fig. 7-20, C). Dissection proceeds proximally up to the origin of the recurrent radial artery and distally to the tendons at the wrist. Branches of the artery and accompanying veins are controlled with small hemostatic clips or with cautery and are divided lateral to the accompanying veins. Proximal and distal ends of the artery are ligated, and the artery is removed. Alternatively, the artery can be removed using an endoscopic technique.

After removal, a small olive-tipped catheter is inserted into the distal end of the artery. The artery is gently irrigated and dilated with heparinized whole blood or a solution of lactated Ringer solution (500 mL) to which 50 mg of sodium nitroprusside and 30 mL of heparinized blood have been added. The graft is then immersed in this solution until it is used. The incision in the arm is closed with two continuous absorbable sutures in the subcutaneous and subcuticular layers. A compression dressing is applied, and the arm is repositioned for proper orientation.

**Right Gastroepiploic Artery**

To expose the right gastroepiploic artery, the midline incision over the sternum is extended over the upper abdomen, and the linea alba is divided halfway from the tip of the xiphoid to the umbilicus (Fig. 7-21, A [inset]). With the sternum divided, excellent exposure of the upper abdomen can be obtained. The triangular ligament of the liver is divided, and the liver is retracted superiorly and to the right. Branches of the right gastroepiploic artery to the stomach and omentum are ligated or clipped and divided, creating a pedicle (Fig. 7-21, A). Dissection extends from the pylorus along the greater curvature of the stomach until sufficient length is achieved. After the distal end is divided, the arterial pedicle is wrapped in a sponge saturated with a solution containing 50 mg of sodium nitroprusside and 30 mL of heparinized blood dissolved in 500 mL of lactated Ringer solution.

The prepared pedicle can be positioned either anterior or posterior to the duodenum and stomach, depending on anatomic conditions (Fig. 7-21, B). The pedicle should be positioned where there is the least amount of tension and distortion. A circular opening is made in the diaphragm medial to the inferior vena cava, and the pedicle is passed through this opening into the pericardial cavity.

The right gastroepiploic artery can be used to bypass most coronary arteries, but it is usually anastomosed to the distal RCA or PDA (see Fig. 7-11, H) because these arteries are closer to the proximal portion of the gastroepiploic artery than other vessels. This approach allows creation of an anastomosis with a relatively large diameter. Anastomoses can be performed to the LAD or its diagonal branches by bringing the pedicle anteriorly over the acute margin of the heart. The pedicle can also be positioned adjacent to the atrioventricular groove posteriorly and anastomosed to a marginal branch of the Cx coronary artery (see Fig. 7-11, H).

**Inferior Epigastric Artery**

The inferior epigastric artery (IEA) originates from the medial side of the external iliac artery posterior to the inguinal ligament. The IEA pursues a course along the medial edge of the deep inguinal ring, encircling the vas deferens in men and the round ligament in women. It then ascends obliquely toward the umbilicus. In an angiographic study of 100 right IEAs by Schroeder and colleagues, 96 were considered suitable as conduits for CABG. The mean length in situ from the origin to the distal bifurcation was 13 ± 1.3 cm, and the mean diameter measured 5 cm from its origin was 2.4 ± 0.40 mm.

The IEA is removed through a paramedian incision beginning at the umbilicus. Incision follows the external edge of the rectus muscle and ends 2 to 3 cm above the inguinal ligament. The anterior sheath of the rectus muscle is divided and the muscle retracted medially. The artery is mobilized with accompanying veins, and branches of the IEA and accompanying veins are clipped and divided. The pedicle containing the artery is divided at or near its origin and at the level of the first major bifurcation. The IEA is removed and wrapped in a gauze sponge soaked with a solution containing papaverine or sodium nitroprusside and immersed in this solution until it is used (see “Radial Artery” earlier in this chapter). The abdominal wound is packed with a gauze sponge and closed in two layers with absorbable suture after discontinuing CPB.

**Splenic Artery**

When no other conduit is available, the splenic artery can be used. It is exposed through a midline extension of the median sternotomy. The lesser peritoneal sac is opened to gain access to the splenic artery, which courses along the superior margin of the pancreas. Branches of the artery to the pancreas are ligated or clipped and divided, and the artery is then mobilized in the hilum of the spleen, where it is ligated and divided. It is not necessary to remove the spleen because it is also supplied with blood from short gastric branches of the
Figure 7-20  Removing radial artery.  **A**, Location of radial artery and line of incision.  **B**, Deep fascia is divided over vascular pedicle, which contains radial artery and accompanying veins.  **C**, Elastic vessel loop is passed around pedicle and branches of radial artery and accompanying veins are doubly clipped and divided.
The epicardium is incised over the area of the coronary artery that has been selected for anastomosis using a scalpel blade with a rounded end or small scissors. The anterior surface of the artery can be cleared by gentle brushing with the scalpel blade. Even when crystalloid cardioplegic solution has been infused, careful inspection of the artery usually reveals a thin central line that is red or translucent, indicating location of the lumen. The anterior wall of the artery is opened longitudinally in this area with a pointed scalpel blade to avoid injury to the posterior wall (Fig. 7-22, A). The blade must enter the artery obliquely to avoid this injury. The incision is enlarged with fine angled scissors to a length of 4 to 6 mm (Fig. 7-22, B and C). The incision in the epicardium must extend beyond each end of the arteriotomy to facilitate the anastomosis. The artery is sized by passing calibrated probes into it, and patency of the proximal and distal segments is assessed.

When the end of the vein (or other conduit) is being prepared for the most distal anastomosis, it is beveled so that the circumference of the opening is slightly larger than the opening of the artery. The incision is made about 10% to 20% longer than that in the artery, and sutures in the vein are placed slightly farther apart than those in the artery to create the desired “cobra head” configuration. If the vein is small, a larger vertical incision provides a larger hood over the distal anastomosis.

The technique of anastomosis uses one double-armed 6-0 or 7-0 polypropylene suture placed as a continuous stitch (Fig. 7-23, A). Stitches in the coronary artery generally are placed from intima to adventitia (inside to outside). The stitch pierces the intima near the vessel edge, but often emerges through periarterial tissue several millimeters away from the edge. Stitches in the vein are passed from outside to inside. The stitches are generally placed separately through the artery and the vein unless it is convenient to place them with one pass of the needle holder. Even then, the vein and artery should be held apart so that the needle can be visualized after it has pierced the vein and before it pierces the artery (Fig. 7-23, A). This maneuver ensures that the stitch is placed accurately and no extraneous tissue has been incorporated.

The sequence of stitching varies from one location on the heart to another and may vary in the same location because of special conditions of exposure or arterial pathology. For anastomoses to the left coronary system, the suture is passed first through the vein (outside to inside) near the midpoint of the arterial wall opposite the surgeon for the LAD system (see Fig. 7-23, A) and to the surgeon’s right for branches of the Cx system. The suture is then passed through the artery (inside to outside) and continued to the heel of the anastomosis. The vein is approximated to the artery by tension on the suture, and the stitch is placed accurately and no extraneous tissue has been incorporated.

The sequence of stitching varies from one location on the heart to another and may vary in the same location because of special conditions of exposure or arterial pathology. For anastomoses to the left coronary system, the suture is passed first through the vein (outside to inside) near the midpoint of the arterial wall opposite the surgeon for the LAD system (see Fig. 7-23, A) and to the surgeon’s right for branches of the Cx system. The suture is then passed through the artery (inside to outside) and continued to the heel of the anastomosis. The vein is approximated to the artery by tension on both ends of the suture (Fig. 7-23, B). The suture line is then continued around the toe of the anastomosis, and the two ends of the suture are tied (Fig. 7-23, C).

For anastomoses to the right coronary system, the suture is passed first through the vein (outside to inside) near the midpoint of the wall of the artery opposite the surgeon (Fig. 7-24, A). It is then passed through the artery (inside to outside) and continued to the toe of the anastomosis. The vein is approximated to the artery, and the suture line is completed around the heel of the anastomosis and remaining far wall of the artery (Fig. 7-24, B). The two ends of the suture are then tied (Fig. 7-24, C).

Distal Anastomoses

The technique for anastomosing the ITA to the LAD and its diagonal branches is described earlier (see Fig. 7-19, E to H). Here, techniques for anastomosis of a segment of vein are described. Although the description is explicitly for vein grafts, the techniques are applicable to anastomosis of ITA, radial artery, and other conduits to a coronary artery.
Figure 7-22  Distal anastomosis in coronary artery bypass grafting.  
A, Anterior wall of coronary artery is opened with a scalpel.  
B and C, Incision is enlarged to the appropriate length with angled scissors.

B, Vein is approximated to artery.  
C, Suture line is continued around toe of anastomosis and ends of suture tied.
Figure 7-24  Technique of anastomosis for right coronary system grafts. A, Suture line begins near midpoint of arterial wall and is continued to toe of anastomosis. Inset, Direction of suture placement. B, Vein is approximated to artery, and suture line is continued around heel of anastomosis. C, Suture ends are tied.

For sequential anastomoses in which the vein or other conduit will lie perpendicular to the arterial branches, the conduit can be opened perpendicular to its long axis for the side-to-side anastomosis if it is of sufficient diameter (Fig. 7-25, A). The incision should not exceed one third of the circumference of the conduit. The anastomosis is begun at the midpoint of the arteriotomy on the right side. The suture is passed inside to outside on the artery and then through the vein at the midpoint of the incision on its right side (Fig. 7-25, B). The suture is continued across the heel of the anastomosis, along the left side, across the toe of the anastomosis, and completed at the midpoint on the right side. If the vein is small or if the radial artery or ITA is used, the conduit is incised parallel to its long axis (Fig. 7-25, C), the diamond anastomosis. The anastomosis is begun close to the midpoint of the arteriotomy on the right side, and the suture is passed through the graft close to the right end of the longitudinal incision (Fig. 7-25, D). The suture line is continued leftward across the heel of the anastomosis and completed as already described.

For terminal end-to-side anastomosis, the conduit is beveled and the suture line begun at the midpoint of the arteriotomy on the left side (Fig. 7-25, E). The suture line is continued to the right across the proximal end of the arteriotomy and along the right side of the artery to its midportion. Using the other end of the suture, the anastomosis is completed by continuing the suture line across the distal end of the arteriotomy and completing it at the midpoint on the right side.

If the conduit and artery are parallel rather than perpendicular, a side-to-side anastomosis is performed as shown in Fig. 7-25, F and G. The technique is identical to that for side-to-side anastomosis of the ITA to the LAD (see Fig. 7-19, G-H). After each sequential anastomosis is completed, the conduit is gently distended by injection of cardioplegic solution or a balanced salt solution to avoid excessive length or tension between sequential anastomoses.

Coronary Artery Endarterectomy

Endarterectomy is most often performed on the distal RCA and its major branches and only infrequently on branches of the Cx artery and LAD. If the distal RCA and its branches are diffusely diseased or occluded, endarterectomy is an alternative to bypass of the branches.

A common procedure involves incising the distal RCA just proximal to the origin of the PDA (Fig. 7-26, A). An endarterectomy plane in the outer third of the medial layer of the artery is developed with a dissector (Fig. 7-26, B). A small curved clamp is placed beneath the isolated atheromatous core, which is divided (Fig. 7-26, C). Using the dissector, the core is freed distally from the arterial wall (Fig. 7-26, D). The core is then teased from the PDA and distal RCA using a clamp and exerting pressure on the core in the opposite direction from the clamp (Fig. 7-26, E). The core usually separates cleanly from the distal vessels and is then removed from the proximal RCA using the same technique (Fig. 7-26,
Figure 7-25  Technique of sequential grafting. **A**, Vein graft is opened perpendicular to its long axis. **B**, Anastomosis is begun at midpoint of arteriotomy on its right side. **C**, Alternatively, vein is incised parallel to its long axis. **D**, In alternative approach (diamond anastomosis with longitudinal incision in graft), suture is passed through graft close to right end of incision and continued across heel of anastomosis. **E**, End-to-side anastomosis. *Inset*, Direction of suture placement for side-to-side and end-to-side anastomoses. **F** and **G**, Side-to-side anastomosis. Technique is identical to that in Fig. 7-16, **G** and **H**. Key: **A**, Coronary artery; **G**, graft.

A saphenous vein or other conduit is then sewn to the edges of the artery with 6-0 or 7-0 polypropylene suture (Fig. 7-26, **G**).

Proximal Anastomoses

After completing the last distal anastomosis, and when the procedure is being performed with CPB, the proximal anastomoses are performed. The aortic clamp can be removed, and a partially occluding, side-biting clamp placed on the ascending aorta. This permits reperfusion of the heart and resumption of cardiac contractions as rewarming is completed. However, the side-biting clamp is not necessary, and is not used when there is important arteriosclerosis of the ascending aorta (see “Surgical Strategy” earlier in this chapter) or if it is of insufficient length. In these situations, the aortic clamp is left in place and the heart remains arrested.

Using a punch, openings are made in the ascending aorta. Vein grafts or other conduits are positioned so that they will be free of kinking or tension when the heart is filled with blood. They are aligned properly using the mark previously placed on the conduit to avoid twisting. The vein is cut obliquely and incised to create a circumference that is 10% to 20% larger than that of the circular opening in the aorta, resulting in a “cobra head.” A double-armed 5-0 or 6-0 polypropylene suture line is begun in the middle of the right
Endarterectomy of right coronary artery (RCA). A, RCA is incised just proximal to origin of posterior descending coronary artery (PDA). B, Endarterectomy plane is developed with a dissector. C, Atheromatous core is divided over a clamp. D, Core is freed distally from arterial wall. E, Core is teased from posterior descending coronary artery and distal RCA. F, Core is removed from proximal RCA. G, Vein graft is sewn to edges of artery (see Fig. 7-24).

Edge of the vein graft, passing the suture from outside to inside on the vein and then inside to outside on the aorta (Fig. 7-27, A). This suture line is continued leftward across the heel of the anastomosis. The vein is approximated to the aorta by exerting tension on both ends of the suture. The suture line is continued across the toe of the anastomosis (Fig. 7-27, B), and the ends of the suture are tied on the right side of the anastomosis (Fig. 7-27, C).

When CPB is not used, these proximal anastomoses are generally performed before the distal anastomoses using a partially occlusive, side-biting clamp (see “Without Cardiopulmonary Bypass” under Coronary Artery Bypass Grafting earlier in this chapter). When CPB is used, proximal anastomoses can be performed before or after CPB is established, but before the aorta is occluded and cardioplegic solution is administered. Use of CPB facilitates performing proximal anastomoses because of lower pressure in the ascending aorta.

Several devices are available to attach vein grafts to the aorta without use of sutures. Other devices permit suture of grafts to the aorta without need for aortic clamping.

Emergency Operation for Cardiogenic Shock

If the patient is hemodynamically unstable at the time of operation, an intraaortic balloon pump is inserted if one is not already in place. Appropriate monitoring devices are inserted, the sternum quickly opened, and CPB expeditiously established. The left ITA can be mobilized after CPB is established, with the heart decompressed but still beating. Saphenous vein is removed from one or both legs as needed.
Reoperation

**Secondary Median Sternotomy**

The technique of most (but not all) CABG reoperations is similar to that of the original operation, with a few important differences. Sternotomy is most often made with an oscillating saw (see Section III of Chapter 2 for technique). Vein grafts are obtained from the leg, and one or both ITAs can be mobilized if they were not used at the initial operation. The radial artery can also be used. If difficulties are anticipated with mobilizing the heart, ascending aorta, or previously inserted vein grafts (i.e., they are adherent to the undersurface of the sternum), provisions are made for peripheral cannulation, such as through the femoral or axillary artery and femoral vein (see “Cardiopulmonary Bypass Established by Peripheral Cannulation” in Section III of Chapter 2). CPB can be established before dividing the sternum, then temporarily discontinued until the heart has been mobilized, or it can be established and maintained until the operation is completed.

After the sternum is divided, and if peripheral cannulation is not used, the right atrium and ascending aorta are mobilized to permit placing cannulae and clamps. Mobilization of the ventricles (the left in particular) is begun only after CPB is initiated. The heart is completely mobilized. If the left or right ITA was used at the initial operation and is patent, the pedicle is sufficiently mobilized to permit placing a small clamp across it. Manipulation of previously placed vein grafts is minimized to avoid dislodging atheromatous debris into the distal coronary circulation.

The heart is completely mobilized. If the left or right ITA was used at the initial operation and is patent, the pedicle is sufficiently mobilized to permit placing a small clamp across it. Manipulation of previously placed vein grafts is minimized to avoid dislodging atheromatous debris into the distal coronary circulation.

After CPB is established and cardioplegic solution is administered into the aortic root. Subsequent infusions are given into the aortic root or retrogradely into the coronary sinus (see “Technique of Retrograde Infusion” in Chapter 3). Severely narrowed or diffusely atherosclerotic vein grafts are divided and ligated immediately after the first dose of antegrade cardioplegia. If there is concern about possible dislodgement of atheromatous debris into the distal coronary circulation as a result of manipulating a diseased graft, it is divided and ligated proximally, and retrograde cardioplegia is then administered. This may permit washout of debris from the opened graft. The distal end of the divided graft is then ligated.

Managing vein grafts that have no or minimal evidence of atherosclerosis (as determined by angiography) and that are soft and relatively normal in appearance is controversial. Some centers favor complete removal of grafts that have been in place for more than 5 or 6 years; other centers leave such grafts in place. If a diseased graft is to be removed and there is no important obstruction in the coronary artery distal to the site of attachment, it is possible in some circumstances to leave a small cuff of this graft adjacent to the artery, which can then be anastomosed to the new graft. If there is important occlusive disease in the coronary artery distal to the site of the previous anastomosis, a new vein graft should be anastomosed directly to the artery beyond the obstruction. If an ITA is to be attached to the LAD previously bypassed by a vein graft that is not occluded or critically stenotic, the vein graft should not be ligated, because the ITA may not initially provide sufficient flow to prevent serious myocardial ischemia.

A diligent search should be made for all graftable vessels. After completing the distal anastomoses, proximal anastomoses to the ascending aorta are completed. In general,
it is preferable to perform these anastomoses with the aortic clamp in place, thus avoiding need for placing a partially occluding clamp on the aorta. After completing the proximal anastomoses, the aortic clamp is removed and the operation completed as previously described.

Reoperations can be performed without use of CPB, employing the OPCAB technique described previously in this chapter.\textsuperscript{S16,S55}

**Left Thoracotomy**

An alternative approach through a left thoracotomy is a convenient and safe method for reoperation\textsuperscript{K20,S71,S81,K1,1} and is frequently chosen when branches of the Cx artery and diagonal branches of the LAD are to be revascularized. Occasionally, branches of the posterolateral segment of the RCA are accessible through this approach. It is particularly useful in the presence of a patent and functioning ITA graft to the LAD. It may also have value when the ascending aorta is heavily calcified and therefore hazardous to manipulate.

It is sometimes necessary to remove the needed segment of saphenous vein with the patient supine. After rotating the patient to a near right lateral decubitus position, a left thoracotomy is made through the bed of the resected or nonresected fifth rib. The left femoral artery and vein are simultaneously exposed through a vertical or oblique groin incision after rotating the patient’s hips back toward the surgeon. The femoral artery and vein are cannulated, making certain the 28F, 30F, or 32F long venous cannula passes over the promontory of the sacrum and into the inferior vena cava (see “Cardiopulmonary Bypass Established by Peripheral Cannulation” in Section III of Chapter 2). CPB is established in the usual manner, and the patient’s body temperature is reduced to about 22°C with perfusate. If an additional route of venous return is necessary, the pulmonary artery is cannulated with an angled cannula (28F, 30F, or 32F) positioned across the pulmonary valve into the right ventricle. Usually the heart spontaneously fibrillates, but if not, it is electrically fibrillated. Once the patient’s nasopharyngeal temperature is below about 25°C, CPB flow can be reduced to about 1.0 to 1.5 L · min\(^{-1}\) · m\(^{-2}\). A left-sided heart vent may be needed and can be inserted into the left atrial appendage or through the left inferior pulmonary vein. Distal anastomoses are made as usual, using fine sutures or elastic tourniquets around the coronary artery.

When these maneuvers have been completed, rewarming is begun, and the heart usually spontaneously defibrillates. Proximal anastomoses, performed with a side-biting clamp, are made to the proximal descending thoracic aorta, curving the bypass graft superiorly over the hilum of the lung or inferiorly around the hilum, attaching the vein to the lower descending thoracic aorta. The left subclavian artery can also be used as a site for attaching grafts. Remainder of operation is completed in the usual manner.

Reoperations using the left thoracotomy approach can also be performed without CPB.\textsuperscript{K71,S54}

**SPECIAL FEATURES OF POSTOPERATIVE CARE**

**Early Postoperative Care**

Most patients are extubated either in the operating room or a few hours postoperatively and discharged from the intensive care unit the following day. Discharge from the hospital to outpatient supervision may occur on the third or fourth postoperative day. Thus, postoperative care is simple in most patients (see Chapter 5).

Occasionally, 8 to 12 hours after operation, arterial blood pressure falls to levels 10% to 20% below normal, whereas pedal pulses remain full and cardiac index is greater than 2.0. No treatment or a low-dose (2.5 μg · kg\(^{-1}\) · min\(^{-1}\)) infusion of dopamine is indicated.

Oral β-adrenergic receptor blocking agents may be given beginning 4 to 6 hours postoperatively. This regimen is continued until discharge as prophylaxis against supraventricular tachyarrhythmias.\textsuperscript{K23,W16} Alternatively, no prophylactic medication is given, although a case can be made for prophylaxis in elderly patients, who are more susceptible to postoperative atrial fibrillation.\textsuperscript{K22,H11} Digitalis is not routinely used prophylactically because it may produce atrial and ventricular arrhythmias and is less effective than other drugs.\textsuperscript{K52} Other drugs or combinations of drugs are recommended by some authors.\textsuperscript{K21,K3,K12,K4,K82} Biatrial pacing may reduce the prevalence of postoperative atrial fibrillation.\textsuperscript{S53,S4,S27,S14}

Warfarin is not routinely administered. A modification of the aspirin-dipyridamole protocol evolved by Chesebro and colleagues is used to enhance graft patency because of its antiplatelet effect.\textsuperscript{S27,S28} In this modified protocol, aspirin (325 mg) is administered through a nasogastric tube 1 hour after operation. Another 325 mg is given by nasogastric tube 7 hours postoperatively and is continued by mouth once daily thereafter.\textsuperscript{G19,G20} Although perioperative bleeding may be increased with this protocol, major complications are not encountered. The patient is advised to continue this protocol for at least 1 year.\textsuperscript{F14} Aspirin in a dose of 80 mg daily may be sufficient for maintenance, except in large patients. In patients with a history of aspirin intolerance, clopidogrel, ticlopidine, or prasugrel may be substituted. Heparin (5000-7500 units every 8 to 12 hours) can be administered subcutaneously as prophylaxis against deep venous thrombosis and pulmonary embolism in the first 48 to 72 hours postoperatively.

Occasionally, intraaortic balloon pumping is required for a few hours to a few days after operation (see Chapter 5). The indication is usually low cardiac output with high left atrial pressure or occasionally occurrence of intractable ventricular arrhythmias intraoperatively or early postoperatively. If this is not effective, placing temporary left and right ventricular assist devices may be necessary (see “Temporary Ventricular Assistance” in Section I of Chapter 5).

**Late Postoperative Care**

In contrast to many surgical procedures, CABG is simply one facet of treatment of patients with arteriosclerotic CAD. Late postoperative care relative to the basic disease—arteriosclerosis—is as important as late postoperative care relative to the bypassing conduits. This has been discussed in considerable detail in reports by the American College of Cardiology/American Heart Association (ACC/AHA) Joint Task Force Subcommittee on Coronary Artery Bypass Graft Surgery.\textsuperscript{A5,E2}

**Facilitation of Complete Recovery**

Facilitation of Complete Recovery

During the first 6 to 8 weeks of convalescence from CABG, patients often have a poor appetite, insomnia, emotional depression, loss of sexual ability, lack of desire to return to
work, and visual, memory, or intellectual deficits and other potentially disabling manifestations of the postoperative state. Studies have documented the transient nature of most of these phenomena. The responsible physician and staff should reassure the patient in this regard and help him or her return to usual activities as rapidly as possible. During this period, excessive medications may predispose the patient to symptoms, and their minimization is frequently beneficial.

A program of daily exercise should be started as soon as the patient leaves the hospital, with emphasis on regular walking for progressively longer periods. This program should be individualized, based primarily on knowledge of completeness of the operation and LV function, and on preoperative physical status of the patient. Formal programs of rehabilitation can be helpful in guiding some patients through the resumption of physical activity. Ultimately, and unless specifically contraindicated, patients should be encouraged to obtain some form of regular physical activity daily and to increase this over the months after operation. Patients who were active and gainfully employed before surgery are urged to return to full activity and employment as soon as possible and, except in unusual circumstances, no later than 2 to 3 months postoperatively.

Promotion of Graft Patency

Aspirin (325 mg · day⁻¹) should be administered immediately after operation and continued for at least 1 year postoperatively. Efficacy of this regimen has been well established, particularly when anastomoses have been made to smaller coronary arteries (Table 7-3). However, more recent studies indicate that a lower dose of 80 to 100 mg daily appears to be as effective as 325 mg. Ticlopidine, clopidogrel, or prasugrel can be used in patients who are allergic to or intolerant of aspirin.

Control of Risk factors for arteriosclerosis probably retards, and may even reverse to some extent, development of atherosclerosis in vein grafts. This is an added reason for recommendations in the text that follows.

Control of Risk Factors for Arteriosclerosis

A well-developed body of knowledge exists concerning risk factors for arteriosclerosis. The general consensus is that this knowledge should be focused on patients who have established CAD and who undergo CABG. Smoking must be stopped, and cessation must be emphasized to the patient even before operation. An appropriate body weight should be maintained, even if special dieting is required. Hypertension and saturated fats in the diet must be controlled, and serum lipids should be kept within proper levels through dietary measures and administration of specific medication if required.

RESULTS

Because CABG is probably the most completely studied operation in history, an enormous amount of information is available about outcomes. There is minimal value in presenting outcome simply as “survival” or “freedom from some unfavorable event” of a heterogeneous group of patients. Only risk-adjusted depictions are truly informative, as emphasized early by DeRouen, Detre, Green, Kouchoukos, and their colleagues.

This section makes no comparisons of outcomes after medical treatment or PCI. Instead, this information is presented later in this chapter under Indications for Operation, because such comparisons are the basis for these indications. Where appropriate, comparisons between CABG performed with and without CPB are presented.

Early (Hospital) Death

Risk of early (hospital) death has been extensively studied. Risk stratification models have been created to provide accurate prediction of operative risk for groups of patients

undergoing CABG (see “Risk Stratification” in Section VI of Chapter 6). Large databases have been established in single institutions and in multicenter studies, and analyses of these data have established the predictive power of certain preoperative variables. In an analysis of seven large datasets representing more than 172,000 patients, Jones and colleagues identified seven variables most predictive of early mortality:

- Older age (Fig. 7-28)
- Female gender
- Previous CABG
- Urgency of operation
- Increasing LV dysfunction
- Left main disease
- Increasing extent of coronary artery disease

The relative mortality risks of these variables are shown in Table 7-4 for six of the data sets.

Older age has consistently predicted operative risk after CABG (see Fig. 7-28). Female gender is also independently associated with increased operative risk. Previous CABG and emergency operation are associated with substantial increases in relative risk (2.0 or greater). Other variables associated with increased early mortality are recent (<30 days) Q-wave myocardial infarction and comorbidities (e.g., diabetes, metabolic syndrome, end-stage renal disease, valvular heart disease, chronic obstructive pulmonary disease, severe peripheral arterial disease, anemia, atrial fibrillation), and perhaps lack of use of the ITA.

In randomized clinical trials comparing on-pump and off-pump procedures, no difference in early mortality was observed, although Tarakji and colleagues have raised the possibility of decreased intermediate-term survival in their meta-analysis of randomized trials.

### Time-Related Survival

In general, after isolated CABG, approximately 98% of heterogeneous groups of patients survive at least 1 month, and 97%, 92%, 81%, and 66% survive 1, 5, 10, and 15 years or more, respectively (Fig. 7-29, A).

The hazard function for death has an early and rapidly declining phase that merges with a constant hazard phase at about 6 months, and this gives way to a gradually rising phase of hazard at about 1 year (Fig. 7-29, B). This rising phase probably results from closure of grafts, progression of native arterial disease, but mostly from comorbidities. This phase of hazard is particularly favorably affected by use of ITA grafts.

### Morbidity

Common postoperative complications that result in substantial morbidity and their management are discussed in Chapter 5. Several of these morbidities deserve special emphasis.

### Adverse Cerebral Outcomes

Postoperative neurologic deficits are an important cause of postoperative morbidity and mortality after CABG. Important neurologic injury occurs in up to 5% to 6% of patients who undergo CABG with CPB. In several randomized trials, a lower prevalence of neurologic injury was not observed among patients undergoing OPCAB procedures.

A multicenter study by Roach and colleagues of 2108 patients undergoing CABG with CPB documented adverse cerebral outcomes in 129 patients (6.1%). Type 1 deficits (major focal deficits, stupor, and coma) occurred in 3.1%, and type 2 deficits (deterioration in intellectual function or memory) in 3.0% of the patients. In addition to increased early mortality in these groups (21% for type 1 and 10% for type 2 deficits), hospital length of stay and likelihood of discharge to a nursing home were substantially increased compared with the remaining patients. Predictors of type 1 deficits included presence of proximal aortic arteriosclerosis, history of prior neurologic disease, use of intraaortic balloon pump, diabetes, hypertension, unstable angina, and older age.

Tarakji and colleagues differentiated intraoperative strokes from those occurring after awakening, finding that either operative or off-pump techniques that avoided manipulation of the arteriosclerotic aorta were associated with fewer intraoperative strokes.

### Mediastinitis

Deep sternal wound infection occurs in 1% to 4% of patients after CABG with CPB and is associated with increased mortality. Obesity is a risk factor for mediastinitis. Other factors associated with an increased prevalence of deep wound infection include diabetes, previous CABG, use of both ITAs, and duration of operation. Randomized trials have shown that off-pump CABG is not associated with a lower prevalence of sternal wound infection.

### Renal Dysfunction

In a multicenter study of renal dysfunction after CABG with CPB in 2222 patients, “dysfunction” was defined as a postoperative serum creatinine level of 2.0 mg · dL−1 or greater, or an increase of 0.7 mg · dL−1 or more from preoperative level. Renal dysfunction occurred in 171 (7.7%) patients.

and 30 (1.4%) required dialysis. Early mortality was 0.9% among patients who did not develop renal dysfunction, 19% in those with renal dysfunction who did not require dialysis, and 65% among those who required dialysis. Preoperative risk factors for renal dysfunction included advanced age, moderate to severe cardiac failure, previous CABG, diabetes, and preexisting renal disease.55 In two randomized trials, prevalence of postoperative renal failure was similar in on-pump and off-pump groups.66,52

**Modes of Death**

Most deaths early and late after CABG are from cardiac failure, which could be termed cardiac death (Table 7-5). A smaller proportion of deaths (about 15%) are sudden, considerably less than in the natural history of patients with CAD. Although it is difficult to be certain, about 25% of all deaths early and late after CABG are unrelated to the ischemic heart disease or the operation.

**Incremental Risk Factors for Premature Death**

Many patient-specific risk factors for death in patients with arteriosclerotic heart disease pertain to patients who have undergone CABG (see Box 7-1). In addition, procedural and institutional incremental risk factors affect outcome (Table 7-6).
Figure 7-29  Survival after coronary artery bypass grafting (CABG). A, Time-related survival in a heterogeneous group of patients. *Circles,* individual deaths, positioned along horizontal axis at time of death and along vertical axis according to Kaplan-Meier estimator; *vertical bars,* 70% confidence limits; *parentheses,* number of patients still being traced; *solid line* (not visible in some areas because of density of circles), nomogram of separately determined parametric survival; *dashed lines* enclose 70% confidence limits; *dot-dash-dot line,* survival of age-gender-ethnicity–matched general population. B, Hazard function for death in same group of patients. Note (1) early, rapidly declining phase; (2) constant phase, which elevates entire hazard function above baseline; and (3) slowly rising third phase. (Modified from Sergeant and colleagues. 124)

Data from Sergeant and colleagues.229

*Cardiac failure, which could be termed cardiac death, is considered acute when it occurs within 3 days of an operation or a new myocardial infarction; subacute when it occurs between 3 days and 6 weeks of such events; and chronic when it occurs more than 6 weeks after an event that appears responsible for it, or when death is in the syndrome of chronic heart failure but is not preceded by an identified proximal previous event.

Institution where procedure is performed may also be a risk factor.

The Califf-Harrell nomogram and its conceptual bases are fundamental to understanding risk factors and outcome after interventional therapy21 (Fig. 7-30). Only patient risk factors summarized as “reversible ischemia” (see Box 7-1) can be neutralized by CABG (or PCI), and when neutralized, outcome is determined in large part by other risk factors. “Vessel stenoses neutralized” (see Fig. 7-30) depicts potential for improvement (“comparative benefit”) by interventional therapy because this possibility is determined by number of systems (vessels) stenosed. Actual improvement, or “comparative benefit,” is determined by the actual number of systems with important stenoses that are in fact neutralized by interventional therapy.

The depiction emphasizes that the greater the number and severity of patient-specific risk factors, the greater the comparative benefit (in terms of survival) of interventional therapy. At the same time, 5- or 10-year survival is less when patient risk factors are numerous. It also illustrates that the favorable effect of interventional therapy is difficult to demonstrate, even though present on conceptual grounds, in most patients with good LV function and few unfavorable risk factors.

A classic parsimoniously derived multivariable risk factor equation for death after CABG has been derived by
Use of CABG for primary reperfusion during Q-wave MI has a minimally unfavorable effect on time-related outcome (Fig. 7-31, D). In particular, events at some time after medical treatment (PCI) over medical treatment. Comparative benefit is difference in percent freedom from cardiovascular deaths after two treatments at some time. Patient’s position on horizontal axis conceptually is determined by sum of all patient risk factors, such that the higher the percent freedom from cardiovascular death, the fewer the risk factors in the particular patient. Comparative benefit, along vertical axis, is determined by interrelationship between patient’s position along horizontal axis and number of coronary arteries with stenoses completely neutralized by interventional therapy (isobars). Values of isobars are in fact hazard ratios that represent effect on comparative benefit of number of arteries with important stenosis in patients undergoing CABG, assuming all stenoses are neutralized by interventional therapy. Nomogram pertains when time (t) is 2 to 7 years (time of approximately proportional hazards) after CABG (or PCI) and when early risks of intervention (CABG or PCI) are negligible. Abstract equation is as follows:

\[
\text{Comparative benefit} = S_{\text{CABG}}(t) - S_{\text{m}}(t)
\]

where:

- \(S_{\text{CABG}}(t)\) is survival after CABG
- \(S_{\text{m}}(t)\) is survival with medical treatment
- \(t\) is time

Key: \(CABG\), Coronary artery bypass grafting; \(h\), hazard ratio; \(LM\), left main coronary artery; \(S_{\text{CABG}}\) survival after CABG; \(SD\), vessels diseased (stenosis > 50%); \(S_{\text{m}}\) survival with medical treatment; \(t\) time. (Modified from Califf and colleagues,\textsuperscript{41} and from Califf RM, Harrell FE Jr: personal communication; 1990.)

Figure 7-30  Nomogram of an equation describing comparative benefit of coronary artery bypass grafting (CABG) or percutaneous coronary intervention (PCI) over medical treatment. Comparative benefit is difference in percent freedom from cardiovascular deaths after two treatments at some time. Patient’s position on horizontal axis conceptually is determined by sum of all patient risk factors, such that the higher the percent freedom from cardiovascular death, the fewer the risk factors in the particular patient. Comparative benefit, along vertical axis, is determined by interrelationship between patient’s position along horizontal axis and number of coronary arteries with stenoses completely neutralized by interventional therapy (isobars). Values of isobars are in fact hazard ratios that represent effect on comparative benefit of number of arteries with important stenosis in patients undergoing CABG, assuming all stenoses are neutralized by interventional therapy. Nomogram pertains when time (t) is 2 to 7 years (time of approximately proportional hazards) after CABG (or PCI) and when early risks of intervention (CABG or PCI) are negligible. Abstract equation is as follows:

\[
\text{Comparative benefit} = S_{\text{CABG}}(t) - S_{\text{m}}(t)
\]

where:

- \(S_{\text{CABG}}(t)\) is survival after CABG
- \(S_{\text{m}}(t)\) is survival with medical treatment
- \(t\) is time

Key: \(CABG\), Coronary artery bypass grafting; \(h\), hazard ratio; \(LM\), left main coronary artery; \(S_{\text{CABG}}\) survival after CABG; \(SD\), vessels diseased (stenosis > 50%); \(S_{\text{m}}\) survival with medical treatment; \(t\) time. (Modified from Califf and colleagues,\textsuperscript{41} and from Califf RM, Harrell FE Jr: personal communication; 1990.)

Blackstone, working with Sergeant and colleagues\textsuperscript{16,24,28} (Table 7-7). Actual risk factors are similar to those derived from other experiences.

Strength and shape (time of maximal effect) of risk factors are best determined by nomograms that also have the advantage of presenting risk-adjusted depictions (see Chapter 6). Number of systems with important stenoses is a weak risk factor for death after CABG in the first 5 years (Fig. 7-31, A) when revascularization is complete and the ITA is used for the LAD graft. Also, number of diseased vessels and even left main coronary artery stenosis, as well as number of distal anastomoses, are not risk factors for hospital death when an adequate operation has been performed.

Pre-CABG LV function, expressed as ejection fraction, has a powerful effect on time-related outcome (Fig. 7-31, B-C), particularly when it is low.\textsuperscript{8,34} Surprisingly, some patients with low EF have none of the symptoms of chronic heart failure. Presence of this syndrome, often associated with secondary mitral regurgitation (see Chapter 10), increases the risk above that for low EF alone.\textsuperscript{11,18,66}

Unstable angina has a minimally unfavorable effect on survival (Fig. 7-31, D).

Some patients undergo CABG soon after an acute MI. Use of CABG for primary reperfusion during Q-wave MI has been largely superseded by thrombolysis and PCI. Early risks of CABG are increased only when operation is performed for acute hemodynamic deterioration after an acute (usually Q-wave) MI or for any reason within about 8 days of a Q-wave infarction.\textsuperscript{50,6,16} Early mortality in patients operated on for cardiogenic shock after an acute MI also depends on other risk factors and largely on methods of treatment. When intense resuscitative measures such as intraaortic balloon pumping stabilize the hemodynamic state before operation, early mortality may be as low as 5%.\textsuperscript{644} When cardiogenic shock is present until operation or until establishment of CPB, mortality is higher.\textsuperscript{24} However, using best available methods of myocardial management intraoperatively (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3) and with intensive postoperative care, including ventricular assist devices when needed (see “Treatment of Low Cardiac Output” in Section I of Chapter 5), at least 50% of patients survive the early postoperative period.\textsuperscript{8,14,15,15,15} Late survival depends on prevalence of other risk factors.

Nonuse of the ITA as a bypass graft to the LAD is a strong procedural risk factor and the basis for its near-routine use (Fig. 7-32) (see “Internal Thoracic Arteries” under Graft Patency later in this chapter). Older age at operation docs

Data from Sergeant and colleagues24; KU Leuven, 1971-1992; n = 9600.
Key: LAD, Left anterior descending coronary artery.

Figure 7-31 Nomograms of specific solutions of KU Leuven multivariable risk factor equation for death after coronary artery bypass grafting (CABG), illustrating strength and shape of certain risk factors for death (see Table 7-7).24 In all figures, dashed lines represent 70% confidence limits. A, Risk-adjusted effect on survival after CABG of number of stenosed systems. B, Risk-adjusted effect of moderate and severe left ventricular dysfunction. C, Risk-adjusted effect of left ventricular ejection fraction (EF), continuously represented along horizontal axis, on survival to 5, 10, and 20 years after operation. D, Risk-adjusted effect of pre-CABG unstable angina, both after “cooling” and when refractory to treatment, compared with moderately severe but stable angina.
The hazard function for return of angina, although also having a constant phase, is dominated by an early phase that peaks at about 3 months after operation and by a late, steadily rising phase that becomes evident about 3 years postoperatively (Fig. 7-33, B). The early-peaking phase is probably most often due to incomplete revascularization, as well as early graft closure. Therefore, return of angina early after CABG is an indication for restudy of the coronary circulation.

The late-rising phase of hazard for return of angina is due to progression of native-vessel disease and narrowing or closure of one or more grafts.

The most interesting aspect of risk factors for return of angina is that nonuse of the ITA has only a mild effect, at least in the KU Leuven (Katholieke Universiteit, Leuven, Belgium) experience but some studies suggest that it does. Risk of sternal wound complication is increased by the double-ITA procedure in obese or diabetic patients. Older age as a risk factor for death is receiving increasing attention as the population ages. Although hospital stay is longer and early complications more frequent in elderly patients, highly favorable results can be obtained with CABG, even in those over age 75. This situation has been well summarized in the reports by the ACC/AHA Joint Task Force Subcommittee on Coronary Artery Bypass Graft Surgery.

Return of Angina

Evidence from evaluation of symptoms and from graded exercise testing shows that CABG usually relieves angina. However, return of angina is the most common post-CABG ischemic event. In a heterogeneous group of patients, only about 60% were free of angina 10 years after CABG (Fig. 7-33, A).

Data from Sergeant and colleagues.\textsuperscript{276} KU Leuven, 1971-1992; \( n = 9600 \).

Key: LAD, Left anterior descending coronary artery.

Figure 7-34  Effect of use of internal thoracic artery (ITA) on return of angina after coronary artery bypass grafting, illustrated in nomograms of specific solutions of multivariable risk factor equations represented by Table 7-8.  A, Time-related, risk-adjusted freedom from return of angina.  B, Hazard function for return of angina. (From Sergeant and colleagues.\textsuperscript{276})
Patient incremental risk factors for return of angina are not powerful compared with those for death. This implies that return of angina is inherent in stenotic arteriosclerotic CAD. Procedural risk factors for return of angina are likewise not very powerful, as seen in the case of the ITA. The inference again may be that the process leading to return of angina is inherent in arteriosclerotic CAD.

Myocardial Infarction

Perioperative MI, usually defined by appearance of new Q waves in the ECG or elevation of serum levels of myocardial biomarkers, is most often related to inappropriate myocardial management, but can also result from technical problems or incomplete revascularization. Prevalence of MI is highly variable and depends on the criteria used, but it is approximately 2.5% to 5%.\(^{19,21,17,33}\) Perioperative infarction, when quantitatively more than trivial, is a risk factor for later death.\(^{8,3,39}\)

Including perioperative cases, MI is relatively uncommon after CABG, with 94% of patients in the KU Leuven experience free of infarction for at least 5 years, and 73% for at least 15 years (Fig. 7-36). However, the hazard function for MI begins to increase at about 4 years postoperatively. Risk factors for the first post-CABG infarction (excluding those that occur perioperatively) are relatively few (Table 7-9).

Survival appears to be considerably adversely affected by occurrence of post-CABG MI\(^{14,13,35}\) (Fig. 7-37). Furthermore, time-related freedom from subsequent post-CABG MI declines with each MI episode (Fig. 7-38).

Sudden Death

Time-related prevalence of sudden death is low after CABG; this may be an important factor in the survival benefit derived from CABG.\(^{18}\) In the KU Leuven experience, 97% of patients were free of sudden death 10 years after CABG (Fig. 7-39, A). The late phase of the hazard function rises more slowly than in other post-CABG ischemic events\(^{29}\) (Fig. 7-39, B). Not unexpectedly, poor LV function before CABG is statistically the most significant risk factor for sudden death.

(Table 7-10). A patient with a preoperative EF of 65% has only a small probability of dying suddenly within 15 years, whereas a patient with EF of 25% before CABG has a 15% probability of sudden death within that period. 429 (Fig. 7-40).

Failure to Work

Time-related freedom from failure to work has been less well documented than for other outcome events. Its time course is probably similar to that of freedom from angina. Patients who are free of angina after CABG are more likely to be working than those with angina. 449

A common belief is that CABG does not improve prevalence of gainful employment among patients with ischemic heart disease, 47,113,114,570 but this has not been a universal finding. 123,445 Failure to take into account the differing prevalences of risk factors for failure to work after CABG explains many of the discrepancies in results. 444 Patients working before CABG have the highest probability of continued employment after operation. 47,549 Under “favorable circumstances” (as defined by risk factors listed in Table 7-11), more than 80% of patients not working at the time of CABG are working 1 year later; 20% or fewer are working after CABG when the risk factors are “unfavorable.” 420

Failure to Work

Unsatisfactory Quality of Life

Even though unsatisfactory quality of life after CABG is one of the most important unfavorable outcome events, quantifying it is difficult because it is a composite of at least three factors: (1) freedom from limiting angina or heart failure; (2) reasonable freedom from need for medication, rehospitalization, and reintervention; and (3) preservation of a reasonable exercise capacity. Most surviving patients have a satisfactory quality of life early after CABG, but the probability of retaining this gradually begins to decline after about 5 years. 440 Rate of decline is probably similar to that of freedom from angina.
Neurobehavioral and Neurologic Outcomes

Unrelated to cardiac aspects of CABG, the damaging effects of CPB usually required for operation are postulated to result in neurobehavioral disturbances and decline in cognitive function in some patients (see “Neuropsychological Subsystem” in Section I of Chapter 5). These disturbances are sufficiently mild that they might not be apparent unless patients are tested specifically for them. Their prevalence has been reduced by incorporating appropriate filters into the arterial tubing from the pump-oxygenator to the patient. As many as 75% of patients may exhibit these subtle defects when tested 8 days after CABG, but by 3 to 6 months postoperatively that proportion drops to only about 10% to 30%. Prevalence is unfavorable affected by preoperative and postoperative anxiety and depression and by older age. Only rarely are patients aware of or handicapped by these defects. Of interest, decline in cognitive function occurs in up to 45% of patients who undergo major noncardiac operations and also in patients with CAD who do not undergo CABG.

Gross neurologic defects, usually in the form of transient or permanent sequelae of strokes, are more serious but

Data from Boulay and colleagues and Varnauskas.
Improvement in segmental wall motion 12 months after CABG has been observed even in areas of scarring from previous MI. Brundage and colleagues showed that 19 of 29 LV wall segments with asynergy at rest preoperatively had improved function, and some even had normal function late postoperatively. This finding supports the concept that viable muscle cells, which may be hibernating, are scattered through hypokinetic and, at times, akinetic and dyskinetic segments, and that wall motion in such segments can be improved by CABG. When segmental wall contraction does not occur after CABG, incomplete revascularization is the cause in some patients.

When preoperative global LV dysfunction is severe (EF < 30%), myocardial scarring is usually greater and usually limits recovery of LV function. In some patients, however, improvement in regional and global LV function occurs with CABG in this setting, and symptoms of pulmonary venous hypertension may regress. Several studies confirm that preoperatively depressed resting global LV systolic function (estimated by EF or dP/dt) is less depressed as early as 2 weeks after CABG. When this improvement fails to occur, incomplete revascularization is usually found. Hellman and colleagues have demonstrated, in a slightly different setting, that 16 of 19 post-CABG patients with preoperative resting EFs of less than 40% showed similar or increased EFs with exercise early postoperatively (±2 weeks) and no deterioration of regional wall motion. This finding supports the concept that postoperative exercise improves scarred myocardium. When segmental wall contraction does not occur after CABG, incomplete revascularization is the cause in some patients.

Use of Medication

Almost all studies report a decrease in use of vasodilators and β-blocking agents after CABG. The cooperative randomized study by the European Coronary Surgery Study Group, for example, found about 70% of patients randomized to medical treatment taking β-blockers during the first 3 years of follow-up in contrast to 25% of surgical patients. In the CASS trial, also randomized, surgically treated patients used fewer antianginal medications at 5 years than patients treated medically. By 10 years, however, the difference was likely due to chance.

Functional Capacity

Maximal exercise capacity of patients is improved by CABG, and ECG abnormalities during exercise are usually importantly reduced. Degree of recovery and ultimate exercise capacity reached depend on preoperative LV function, graft patency, and completeness of revascularization. Increase in functional capacity, as evidenced by an increase in cardiac output with exercise postoperatively, is greater in patients with complete revascularization (26% vs. 6%; P = .0001). Maximal exercise capacity generally is improved more by CABG than by medical treatment, at least for 3 to 10 years. The mechanisms of improvement in functional capacity after CABG are complex. Improvements in resting and stress LV function greatly contribute to the improved functional capacity (see next subheading). However, Serruys and colleagues found that an increase in maximal heart rate, presumably secondary to increased myocardial blood flow, is also an important determinant of increased functional capacity.

Left Ventricular Function

Resting Perfusion

Resting regional perfusion defects (at least in patients with unstable angina) are improved after CABG in at least 65% of patients, indicating that preoperative resting perfusion defects were caused at least in part by ischemia; that is, scarred areas (if present) contained considerable amounts of viable muscle. Most patients who show no improvement commonly have occluded grafts to the area. Wainwright and colleagues demonstrated that resting regional myocardial perfusion defects usually persist in areas supplied by ungrafted vessels (incomplete revascularization).

Left ventricular wall segments that are hypokinetic, akinetic, or even dyskinetic at rest preoperatively often have improved systolic function after CABG. This is associated with increased regional myocardial perfusion. Improvement in segmental wall motion 12 months after CABG.
**Ventricular Arrhythmias**

Successful CABG with relief of myocardial ischemia and its symptoms generally does not decrease frequency or severity of exercise-induced or resting ventricular arrhythmias, including ventricular tachycardia and fibrillation, although reports to the contrary exist. This lack of favorable effect occurs because areas of ventricular scarring, rather than areas of myocardial ischemia, appear to be essential to arrhythmia development.

Failure of simple CABG to abolish serious ventricular electrical instability in most patients is particularly unfortunate because exercise-induced ventricular tachycardia or ventricular fibrillation carries a poor prognosis in patients with CAD. Sudden death is one mode of death late postoperatively. Therefore, when operation is contemplated in patients with important intractable ventricular tachyarrhythmias, consideration should be given to implantation of a cardioverter-defibrillator (ICD) or procedures directed specifically at the ventricular arrhythmia, even in the absence of LV aneurysm (see Chapter 16).

Exceptions to these general statements are the few patients without ventricular scars or aneurysm in whom life-threatenning ventricular arrhythmias occur purely from reversible LV myocardial ischemia. CABG can relieve the arrhythmic tendency in these patients.

A study of 900 patients with depressed LV function (EF < 36%) and abnormalities on resting signal-averaged ECGs suggested increased risk for postoperative ventricular arrhythmias. In the Coronary Artery Bypass Graft Patch Trial, 454 patients were randomized to CABG and 446 to CABG plus ICD. During an average follow-up of 32 months, there was no evidence of improved survival among the patients in whom an ICD was implanted.

**Coronary Flow Reserve**

CABG is usually successful in improving coronary flow reserve (ability to increase flow in response to increased myocardial oxygen demand or pharmacologic vasodilatation). Surprisingly, coronary flow reserve returns to normal levels in many patients. This subject has been reviewed in detail by Wilson and colleagues. Flow reserve has been obtained from measurements made in the operating room after CABG and has been confirmed in postoperative patients. Ability to increase coronary flow is absent when there is a stenotic coronary lesion beyond the graft.

In general, a patent anastomosis between a graft and a coronary artery perfuses only that segment of myocardium to which the native artery has supplied blood. However, about 25% of grafts distribute blood well beyond the segment of myocardium that would have been expected to be supplied by the native vessel. Often the area unexpectedly perfused by the graft is in the distribution of an occluded native vessel to which there is an obstructed graft. Importantly, segmental contractility is often improved postoperatively in the unexpectedly perfused area. This phenomenon probably explains the finding of a functionally excellent result despite presence of one or two occluded grafts.

Not unexpectedly, in the few studies done late postoperatively, flow is greatest in vein grafts to the LAD system. Using a radiographic densitometric method, Hamby and colleagues found at 2 weeks after operation a mean flow of 79 mL·min⁻¹ in grafts to the LAD (range, 39-179) and 65 and

![Figure 7-41 Relationship between change in saphenous vein bypass graft flow and change in diameter between early (2 weeks) and late (average 1.5 years) postoperative study by radiographic methods. In general, decrease in diameter correlates with decrease in flow. Key: CIRC, Circumflex coronary artery; LAD, left anterior descending coronary artery; RCA, right coronary artery. (From Weisz and colleagues.)](image)

68 mL·min⁻¹ in those to the RCA and Cx artery, respectively. Flow through patent grafts during the early postoperative period is not directly related to graft size measured by cineangiographic techniques, and is presumably determined primarily by size of the arterial bed distal to the anastomosis.

An average of 2.5 years later, about 35% of vein grafts showed an important (average 45%) reduction in flow compared with early postoperatively. Thirty-five percent showed only a mild decrease during this period, and 30% showed no change. Such reductions of flow probably result largely from morphologic changes in the graft; thus, Weisz and colleagues found that change in graft flow was associated with a similar directional change in graft caliber (Fig. 7-41).

Although concern has been expressed about flow capabilities of the ITA as a bypass graft, the bulk of evidence supports the ability of this vessel to supply a normal coronary flow reserve to a LAD with distal branches that are free of disease. This evidence has been well summarized by Hodgson and colleagues, who have also shown that adequate coronary flow reserve is provided when the ITA is used for sequential grafting.

Separate ITA grafts can provide adequate flow to the entire left coronary system.

**Graft Patency**

*Internal Thoracic Arteries*

The ITA has proved an excellent conduit for use in CABG. About 90% to 95% of left ITAs whose distal end has been anastomosed end-to-side to the LAD are patent 10 to 20 years after operation (Fig. 7-42), and closure after that time is uncommon. However, up to 10% of patent grafts have stenoses late postoperatively. Accumulated information strongly suggests that most of the stenoses do not progress to occlusion. Use of the
ITA as a free graft from aorta to LAD provides patency almost as high as with an in situ graft. Favorable performance of the ITA when anastomosed to the LAD is partly related to continued function of its endothelial cells. Endothelium-derived relaxing factor and prostacyclin are produced by human ITAs, which may be an important factor in the high patency of ITAs and their excellent function as bypassing conduits. In addition, the ITA, when used for CABG as well as in its native position, has been shown to resist development of arteriosclerosis. Intimal hyperplasia develops in the ITA graft, however, and may be a cause of stenosis. Other factors contributing to occlusion or stenosis (including the “string sign”) of ITA conduits include mild target stenosis, competitive flow, and sequential grafting.

Another factor favorable to ITA patency is its grafting to the LAD, which has large runoff through the diagonal and septal branches. In support of this, ITA grafts to vessels other than the LAD have lower patency that may not be substantially different from that of vein grafts.

Use of bilateral ITA grafts has been favored by some groups, and evidence exists that use of both ITAs enhances survival of some subgroups of patients. Of interest, an analysis of the Society of Thoracic Surgeons database of 540,000 patients undergoing CABG between 2002 and 2005 indicated that bilateral ITA grafts were used in only 4.0%. Wound complications are more prevalent when bilateral ITA grafting is performed, particularly in obese and diabetic patients. Extensive surgical procedures may be required to treat them. Decreased sternal perfusion has been demonstrated after ITA harvesting using the pedicle technique. Skeletonization of the ITA results in greater sternal perfusion than the pedicle technique and may be associated with fewer sternal wound complications. A particularly beneficial effect has been observed in diabetic patients.

**Other Arterial Grafts**

The radial artery, right gastroepiploic artery, and inferior epigastric artery are used by a number of surgeons in combination with one or both ITA grafts or vein grafts and when an ITA graft is not available. Early (<13 months) patency of radial artery grafts exceeds 90% and does not differ from ITA patency. A native coronary stenosis of less than 70% is associated with lower patency of a radial artery graft than if the stenosis is 70% or greater. In a study of long-term patency of 1108 radial artery grafts, reported patency of 89% at a mean follow-up interval of 48 months. Of 318 grafts in place for more than 5 years, 294 (92%) were patent. Of 107 in place for more than 7 years, 99 (92%) were patent. Patency was highest for grafts placed to the LAD (96%) and lowest for grafts to the RCA (83%). Mechanisms of failure did not involve arteriosclerosis. For many surgical groups, the radial artery is currently the conduit of second choice behind the ITA.

In a study by Suma and colleagues of gastroepiploic artery grafts in 685 patients who underwent postoperative angiography in 122 patients early (11 ± 5 days) and in 72 patients late (11 ± 6 months) after operation. Early patency was 98%, and late patency was 93%. Of 14 grafts that were occluded or threadlike at the late study, 8 were anastomosed to arteries with a stenosis of 60% or less.

**Saphenous Vein Grafts**

Saphenous veins used as free aortocoronary grafts develop a unique remodeling and disease complex. The condition begins with diffuse intimal thickening, so-called intimal hyperplasia, which is a universal finding in vein grafts that have been in place for more than 1 month. This process is not progressive. Thickness of the intimal hyperplasia seems to be inversely related to flow in the graft, and the process appears to result in a matching of vein lumen size to that of the coronary arteries supplied by the graft. Intimal hyperplasia is thus best considered as a remodeling process.

As a result of these changes, most grafts show an angiographically detectable diffuse reduction in diameter. By 1 year afterimplantation, the diameter tends to approximate that of the recipient coronary artery; this diffuse smooth narrowing is not related to graft occlusion. Indeed, by increasing velocity of flow, remodeling may be beneficial, particularly when the vein is large initially.

Of greater importance is development of lesions in the vein graft that are indistinguishable morphologically from the fibrous plaques of arteriosclerosis. These atherosclerotic lesions are rarely found in saphenous vein grafts that have been in place for less than 3.5 years. By 10 years after CABG, however, most saphenous vein grafts have undergone at least some atherosclerotic changes that are sometimes severe. Whether this acceleration is related solely to morphologic damage to the graft caused by its removal and insertion into the arterial system, or whether it is caused by the patient’s tendency to develop arteriosclerosis, or whether
both occur, is uncertain. Both factors probably play a role, because hyperlipidemia is a risk factor for extensive vein graft atherosclerosis.\textsuperscript{C3,P3,S51,S57,S58} Also, aggressive efforts at controlling cholesterol levels retard progression of vein graft atherosclerosis.\textsuperscript{B30,C7}

About 20\% of vein grafts have proximal suture line stenosis within 1 year; about one fourth of these are found to be occluded 5 years later.\textsuperscript{G43} Almost 50\% of patients have some narrowing of the distal anastomosis within 1 year, but most have not progressed by 5 years after CABG.\textsuperscript{G43} Unfortunately, minimal information is available on the relationship of type of anastomosis (e.g., end-to-side, side-to-side) to frequency and severity of anastomotic strictures. Anastomotic strictures may result from a localized separate process or may be a local manifestation of atherosclerosis.

Thrombosis, another process that can reduce graft patency, may develop early postoperatively. Endothelial cell loss and exposure of the basement membrane and collagen to blood tend to appear early after inserting the vein graft, predisposing it to early accumulation of platelets, fibrin, and thrombus on its luminal surface.\textsuperscript{B2,S65,P3,S51,S57,S58} More often, thrombosis develops later in heavily atherosclerotic areas.

Related to all these processes, about 10\% of vein grafts close within the first few postoperative weeks, at least when antiplatelet therapy is not used. One- to 2-year patency in recently reported trials ranges from 75\% to 85\%.\textsuperscript{B17,G16,M2,Z3} Late patency is highly variable, but only 50\% to 80\% of grafts are patent in heterogeneous groups of patients.\textsuperscript{B47,G43,H1,K28} However, patency has been about 80\% when the greater saphenous vein has been used to bypass the LAD, which has a large runoff.\textsuperscript{L26,C14,K16,S3,S27} Clopidogrel, when combined with aspirin, has not been shown to increase graft patency or to reduce the frequency of adverse cardiovascular events at 1 year.\textsuperscript{G5,K38}

Other Vein Grafts

Patency of lesser saphenous vein grafts appears to approach that for the greater saphenous vein.\textsuperscript{C22} Patency is lower when the bypass graft is to a particularly small coronary artery or one that supplies a heavily scarred area, perhaps because in both circumstances there is low graft flow. Upper extremity veins have even lower patency.\textsuperscript{W14} Cryopreserved allograft veins may be used when no other suitable autologous graft is available; late patency is substantially less than that of ITA and saphenous vein grafts.\textsuperscript{L26}

Postoperative Progression of Native Coronary Artery Disease

Most important native-vessel coronary artery stenoses proximal to a bypass graft become more severe or totally obstructive within 5 years of CABG.\textsuperscript{B48,G43,H32,A4} Rates of progression of lesser stenoses proximal to a bypass graft remain uncertain. Important stenoses distal to the anastomosis also have a strong tendency to obstruct within 5 years.\textsuperscript{G43,N9} Lesser stenoses distal to a functioning bypass graft tend to remain unchanged.\textsuperscript{G43,N1} However, one study reported considerable progression of lesser distal arterial stenoses when the bypass graft to the artery was nonfunctioning.\textsuperscript{N9}

Lesser stenoses in ungrafted arteries progress in severity with less frequency than important stenoses, but 25\% to 50\% of such lesions progress within 5 years.\textsuperscript{G43,A4} In a group of patients undergoing CABG, Laks and colleagues found progression of proximal stenosis in 16 (27\%; CL 20\%-34\%) of 60 nonbypassed RCAs with less than 50\% narrowings at a mean follow-up of 20 months.\textsuperscript{A4} Two (3\%; CL 1\%-8\%) of the 60 had progressed to complete obstruction.

Important stenoses in ungrafted vessels progress after operation, presumably at about the same rate as in the natural history of CAD (see “Stenotic Coronary Artery Disease” earlier in this chapter). Controversy continues as to whether important stenoses progress less rapidly in ungrafted than in grafted vessels.\textsuperscript{E16,N9} Some information suggests that the rate is the same in both.\textsuperscript{B48,G43,P2}

New stenoses appear in apparently nonstenotic arteries that were not grafted.\textsuperscript{G48,H3} In following patients randomized to surgical vs. medical treatment, Palac and colleagues found new lesions within 5 years in about 15\% of both groups.\textsuperscript{P2} These figures may be different in patients and populations in whom risk factors for arteriosclerosis are altered.

Subsequent Reintervention

Prevalence of reintervention (repeat CABG or PCI), as with other outcome events, varies according to the patient’s characteristics before the first CABG, details of the first CABG itself, and to a lesser extent, management of the patient after the first operation. In a heterogeneous group of patients, freedom from reintervention is about 97\% 5 years after the initial operation, 89\% at 10 years, and about 72\% at 15 years.\textsuperscript{S27} (Fig. 7-43, A). Instantaneous rate of reoperation begins to rise appreciably after about 5 years (Fig. 7-43, B).

Vein graft atherosclerosis is the most common cause of reintervention, with progression of native- vessel disease the second most common.\textsuperscript{A14,L27} Thus, more frequent use of the ITA to the LAD has reduced the frequency of reoperation and lengthened the interval between first and second coronary operation.\textsuperscript{L3,L6,L27,S3} Use of both ITAs may further reduce prevalence of reintervention.\textsuperscript{B17,L31}

Results of a formal risk factor analysis for reintervention in the KU Leuven experience showed that younger age at first CABG increased risk of reoperation (Table 7-12 and Fig. 7-44, A). Young age as a risk factor is also evident in other studies.\textsuperscript{F14,K16,L3,S27} and is a surrogate for “aggressiveness of the atherosclerotic process.” In contrast to most other experiences, at KU Leuven, use of the ITA did not reduce reoperations appreciably (Fig. 7-44, B).

Operative risk of a second CABG is about twice that of the first.\textsuperscript{F14,L21,L27,Q3} Higher prevalence of risk factors in patients undergoing repeat CABG, rather than the procedure itself, is the more important reason for this increased early risk. Including hospital deaths, 10-year survival in a heterogeneous group of patients is about 65\%.\textsuperscript{L27} Considering deaths both early and late after repeat CABG, important left main coronary artery disease, three-system involvement, and severity of LV dysfunction are the most important risk factors.\textsuperscript{L27}

Symptomatic improvement is usual in surviving patients, particularly when symptoms are severe before reoperation. Thus, in the Cleveland Clinic experience, 89\% of those with severe angina before reoperation experienced either no angina or only mild angina postoperatively.\textsuperscript{L27}

Transmyocardial revascularization using a laser to create transmural channels has been applied to patients with severe angina after CABG (see Special Situations and Controversies later in this chapter).\textsuperscript{P17} It can be used as sole therapy or in combination with repeat CABG.
PCI is being used with increasing frequency in symptomatic patients after CABG. Compared with balloon angioplasty, stenting of vein graft stenoses results in higher procedural effectiveness (92% vs. 69%) and greater increase in luminal diameter early after the procedure. Freedom from death, MI, repeat CABG, or revascularization of the targeted vessel is substantially better in the stent group (73% vs. 58%).

INDICATIONS FOR OPERATION

The bases of the indications for CABG involve comparative benefits of operation relative to those of no treatment (natural history), medical treatment, or treatment by PCI. A complexity of these apparently simple propositions is that comparative benefit of CABG may be greater in one circumstance (e.g., severe vs. mild LV dysfunction) compared with another, yet the actual time-related survival after CABG is less21 (Fig. 7-45). The manner by which addition of the risk factors appears to amplify the contribution of another is explained under Multivariable Analysis in Chapter 6.)

Operation and other interventional therapies should increase regional coronary flow reserve. Small reductions in flow reserve are minimally life threatening; large reductions are life threatening. Use of techniques to quantify these reductions, such as thallium-201 single-photon emission CT and dobutamine stress echocardiography, permits predictions and comparisons of outcomes that are more accurate and precise.31

Traditionally, physicians and surgeons have talked with patients about “your chances” of “being alive” or “without pain” 1 year from now, or 5 or 15 years from now. A phrase such as “you have 95 chances out of a 100 of being alive for at least 10 more years” is frequently used, but such estimates have often been made on a qualitative basis. However, in an era when several different treatments are available, these types of predictions and comparisons for an individual patient with ischemic heart disease are often difficult to make. Fortunately, an enormous amount of information has been developed about effects of various risk factors on outcomes after different treatments for ischemic heart disease. Contrary to the belief of some, almost all this information is harmonious rather than internally conflicting. The remaining problem is efficient use of the data for (1) predicting and comparing for individual patients and (2) retrospectively evaluating quality of care and appropriateness of intervention (comparative effectiveness).23,29

For most patients with congenital heart disease and for some with other diseases, the condition that requires surgical treatment is similar from patient to patient and is the dominant risk factor. This fact makes predicting and comparing for individual patients straightforward. In contrast, stenotic arteriosclerotic CAD varies enormously from patient to patient, and the variations themselves are powerful risk factors. Therefore, recommendations to patients on the basis of predictions and comparisons of outcomes in heterogeneous groups of patients are of little value. Patient-specific predictions and comparisons are required. General indications for CABG are discussed in the text that follows.

Stable Angina

Stable angina is usually well relieved by CABG, even though not permanently so; it can also be favorably influenced by modern medical treatment, and under many circumstances by PCI.32,115,23,58,111,218 Furthermore, it is well established that CABG can accomplish considerably more than simple relief of angina. Thus, presence of chronic stable angina unrelied by medical treatment is no longer an automatic indication for CABG. Rather, duration of relief of angina and effect on time-related probability of survival must be the major considerations. These factors depend not only on presence of angina but also on all the patient-specific risk factors for unfavorable outcome events in patients with ischemic heart disease (see Box 7-1) and on procedural risk factors for the various interventions.

Patients with mild chronic stable angina (Canadian class I or II) can be considered to have mild reversible ischemia, which if confirmed by noninvasive testing, is not per se an indication for CABG or other forms of interventional therapy. However, severity and number of coronary stenoses, ischemic burden assessed by noninvasive testing, and severity of LV dysfunction may combine to give these patients better survival and relief of angina with intervention224 (see Fig. 7-6). When a clear comparative benefit of CABG over PCI or medical treatment can be predicted for an individual patient with mild reversible ischemia, such as when important stenoses in all three systems and LV dysfunction are present, operation is usually indicated.224

Data from Sergeant and colleagues\textsuperscript{127}; KU Leuven, 1971-1992; \( n = 9600 \).

\textsuperscript{1}Includes only variables present before first CABG and procedural variables at first CABG.

Key: LAD, Left anterior descending coronary artery.

When chronic stable angina is \textit{moderate or severe} (Canadian class III or IV) despite optimal medical treatment, interventional therapy is usually advisable. When important stenoses are present in only one system, PCI often suffices.\textsuperscript{125} Although no benefit on mortality has been demonstrated with PCI compared with medical therapy in this setting, more patients treated with PCI are free from angina at 1 and 5 years.\textsuperscript{24} In patients with two-system disease without proximal LAD disease and no or minimal LV dysfunction, randomized trials and meta-analyses indicate that there is no or only a modest survival benefit with CABG compared with PCI, but up to a fivefold reduction in need for reintervention.\textsuperscript{24} For patients with high-grade stenosis of the proximal LAD in the setting of two-system disease (particularly with demonstrable ischemia on noninvasive testing and depressed LV function), CABG is preferred over PCI.\textsuperscript{24} When important stenoses are present in all three systems, or if left main coronary stenosis is present, CABG is indicated.
Figure 7-44  Nomograms illustrating strength and shape of risk factors for reintervention after coronary artery bypass grafting (CABG) in KU Leuven experience. A, Effect of age at initial CABG, depicted along horizontal axis. Predicted percent freedom is along vertical axis. Isobars represent interval between time of first CABG and time of estimation of prevalence of reintervention. B, Effect of using internal thoracic artery (ITA) as a conduit to left anterior descending coronary artery (LAD) at first CABG. (From Sergeant and colleagues; KU Leuven, 1971-1992; n = 9600.)

Figure 7-45  Comparison of survival after nonrandomly assigned coronary artery bypass grafting (CABG [Surgical]) with initial medical treatment in patients with three-system disease and severe angina, according to severity of left ventricular (LV) dysfunction. Symbols represent published nonparametric estimates. Solid line enclosed within dashed CLs are parametric estimates. For survival estimates, CLs are 70%; for survival differences, CLs are 90%. A, Survival in patients with mild LV dysfunction. B, Comparative benefit, indicating that surgical benefit is unlikely to be caused by chance alone. C, Depiction similar to A, but in patients with severe LV dysfunction. Survival 1 month and 5 years after CABG is less than when LV dysfunction is severe. D, Depiction similar to B, but in patients with severe LV dysfunction. This emphasizes that surgical benefit is greater when LV dysfunction is severe than when it is mild, even though 1-month and 5-year survival after CABG are lower than when dysfunction is mild. Key: CASS, Coronary Artery Surgery Study. (From ACC/AHA Guidelines and Indications for Coronary Artery Bypass Graft Surgery.)
and preferred because it provides a survival advantage and a marked reduction in need for repeat intervention compared with PCI.\textsuperscript{24,70}

Number of Systems with Important Stenoses

**Left Main Stenosis**

In general, stenosis of at least 50% in the left main coronary artery, either alone or in combination with stenoses in other coronary arteries, confers a sufficiently poor survival prognosis with medical treatment, and CABG is generally indicated.\textsuperscript{20,25} This is true even when the angina is well controlled by medical treatment or the patient is asymptomatic.\textsuperscript{75} The more severe the left main stenosis, the more urgent the need for CABG. There is emerging evidence that PCI in lower-risk subsets of patients with left main stenosis provides equivalent outcomes to CABG at least for the first 3 years after intervention.\textsuperscript{76} However, there is a fourfold increase in repeat revascularization with longer follow-up.\textsuperscript{24,77}

**Three-System Disease**

In general, patients with good LV function and mild or moderate reversible ischemia have a sufficiently good outlook with noninterventional therapy that CABG or PCI need not be advised as initial therapy, even with threesystem disease.\textsuperscript{B32,M34} (Fig. 7-46, A). Periodic reevaluation is clearly indicated, however, because change in any one of a number of variables may make CABG advisable. If patients in this category have impaired LV function, their long-term prognosis with medical treatment is sufficiently poor and the prognosis after CABG sufficiently good that CABG is indicated, even though survival is similar at 5 years (Fig. 7-46, B).

When one or more important proximal stenoses are part of the three-system disease, particularly when one is in the LAD, in general the prognosis with noninterventional therapy becomes less favorable, whereas that after CABG is not adversely affected.\textsuperscript{M34,V6} Thus, even with mild angina and good LV function, CABG is indicated and preferred over PCI when one or more important proximal stenoses coexist with three-system disease.\textsuperscript{E2,K24,P9}

**Two-System Disease**

In general, PCI appears to be effective interventional therapy for many patients with important (at least 50% stenoses) two-system CAD.\textsuperscript{K9,K24} Also, prognosis with medical treatment is considerably better in patients with two-system disease than in those with three-system disease.\textsuperscript{K9} Thus, CABG is not indicated in the majority of patients with mild angina and two-system disease. However, when such patients have left main equivalent disease, a severe proximal stenosis in the LAD, or impaired LV function, CABG is indicated.\textsuperscript{E2,K24,P9}

Indications for CABG are stronger when angina is more severe (Canadian class III or IV). These indications are in addition to those described for patients with two-system disease without proximal LAD stenosis, but with a large area of viable myocardium and high-risk criteria on noninvasive testing.\textsuperscript{E2,K24,P7}

**Single-System Disease**

CABG is infrequently indicated for patients with single-system disease. Results of CABG in this setting are excellent,\textsuperscript{L36} but results of medical treatment and of PCI are also good, although probably not as long lasting.\textsuperscript{F19} Bypass of the LAD with the ITA is an appropriate option in asymptomatic and symptomatic patients with proximal LAD stenosis and evidence of extensive ischemia on noninvasive testing or depressed EF (<50%).\textsuperscript{B49,R2} Results of metaanalyses comparing CABG and PCI in this setting demonstrate no significant difference in mortality or stroke, but a threefold increase in recurrent angina and a fivefold increase in repeat target-vessel revascularization with PCI at 5 years.\textsuperscript{K28,K22}

**Left Ventricular Function**

Patients with good LV function have a good prognosis with medical treatment, even in the presence of important three-system disease, but in many patients, survival is not improved by immediate CABG (see Fig. 7-46, A). Depressed LV function adversely affects outcome after CABG, even though in general the comparative benefit of CABG (vis-à-vis medical treatment) is greater the more depressed the LV function, and indications for operation are more compelling\textsuperscript{75} (Fig. 7-47). However, risks and benefits of CABG become more uncertain when resting LVEF is less than 30%, and
CABG. Exercise or resting thallium-201 scintigraphy, especially using the technique of enhancement by reinjection of thallium, may be particularly helpful in distinguishing between scar (which would contraindicate interventional therapy) and ischemia. Dobutamine stress echocardiography, positron emission tomographic (PET) scanning, and cardiac magnetic resonance imaging can also distinguish ischemic or hibernating myocardium from scar.

Performing CABG “prophylactically” in asymptomatic patients who have preserved LV function without noninvasive evidence for ischemia is undesirable from several standpoints. Medical treatment, including specific measures against unfavorable lipid profiles, may considerably or even indefinitely delay need for interventional therapy. Duration of the favorable effect of CABG appears to be finite, and for this reason alone, CABG should be delayed as long as is safe for the patient. Ideally, methods for prediction of the imminence of acute MI (the sequela of which are the usual causes of depressed LV function) should be perfected so that CABG can be performed at the most appropriate time.

Unstable Angina

Unstable angina is usually best managed initially by intense medical treatment; surgical intervention in the presence of ongoing ischemic instability is rarely required. In this discussion the description of “unstable angina” in the ACC/AHA Joint Task Force Subcommittee report is used.

Once the unstable state is controlled and the patient has been evaluated with noninvasive and invasive studies, the usual indications for CABG pertain. In some situations, however, indications for interventional therapy of some type become stronger than in patients with stable angina. Indications are particularly strong in patients with left main or left main equivalent disease, three-system disease, LV dysfunction, ongoing ischemia, or angina at rest. Indications are less strong in the subset of patients with unstable angina who have “new-onset angina.”

Uncomplicated Non–Q-Wave Myocardial Infarction or Non–ST-Segment Elevation Acute Coronary Syndrome

In general, patients with non–Q-wave MI or non–ST-segment elevation acute coronary syndrome have the same indications for CABG (and for the same reasons) as patients with unstable angina.

Uncomplicated Q-Wave or ST-Segment Elevation Myocardial Infarction

In an era of increasing success with thrombolytic therapy for acute MI, and more recently with PCI, CABG is infrequently indicated to treat patients with uncomplicated MI. However, contrary opinions to this approach exist.

When important angina persists early after an episode of acute MI, indications for operation are identical to those for unstable angina, and results are almost as good. Because early risks of undertaking CABG after acute MI are less the longer the interval since onset of the episode, delaying the procedure for a minimum of 48 hours is often advisable.
Myocardial Infarction with Hemodynamic Deterioration

Acute hemodynamic deterioration is a serious and often fatal complication of ongoing MI, and delay in interventional therapy is probably disadvantageous. There is little doubt that more than 50% of patients with this complication can be salvaged by emergency CABG. However, PCI is also effective in this setting.

When CABG is used for patients with acute hemodynamic deterioration during ongoing MI, an effective regimen of myocardial management is essential (see “Cold Cardioplegic, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3). Even then, recovery of some patients may not be possible, because patients in whom cardiogenic shock develops during an episode of acute MI are often elderly, have a low EF on admission, a history of previous infarctions and coronary artery interventions, and a particularly large area of acute infarction. These are all important risk factors for death in this setting.

Acute Complications during Percutaneous Coronary Intervention

Emergency CABG is indicated after unsuccessful PCI when hemodynamic compromise occurs or when there is evidence of ongoing ischemia or threatened occlusion of a major coronary artery with substantial myocardium at risk. Removal of a fractured guidewire or an underdeployed stent may occasionally be required. If the hemodynamic state is severely compromised, CPB can be initiated in the catheterization laboratory (see “Cardiopulmonary Bypass Established by Peripheral Cannulation” in Section III of Chapter 2). When CABG is performed under these conditions, myocardial management should be that described under “Myocardial Infarction with Hemodynamic Deterioration” earlier in this chapter.

Emergency CABG under the circumstances just described is associated with higher mortality and occurrence of perioperative infarction than elective CABG. Factors that affect outcome include presence of cardiogenic shock, older age, LV dysfunction, previous infarction, and previous CABG. With increasing use of intracoronary stents, frequency of emergency CABG after PCI has declined.

Recurring Myocardial Ischemia

Evidence of return of important myocardial ischemia and symptoms may require consideration of repeat CABG. When these symptoms develop and cineangiographic study shows evidence of ongoing ischemia or threatened occlusion of a major coronary artery with substantial myocardium at risk, PCI is indicated. PCI to the native-vessel disease for which bypass grafting was originally performed is occasionally possible, but in many cases these vessels have occluded by the time reintervention is under consideration.

When the cause of the recurring myocardial ischemia is graft disease, PCI is less effective and risks distal embolization of debris. Stenting of vein grafts is more effective in this setting than balloon angioplasty.

If PCI is not feasible, CABG is indicated in patients with moderate or severe angina despite optimal medical treatment if bypassable vessels are present in at least one system with noninvasive evidence for myocardium at risk (but preferably two or more systems). CABG may be the sole therapy or combined with transmyocardial laser revascularization.

SPECIAL SITUATIONS AND CONTROVERSIES

Coronary Artery Bypass Surgery versus Percutaneous Coronary Intervention

PCI is now an established method of management for many patients with arteriosclerotic CAD. Although initially used for treating single-system disease, PCI is currently being applied to patients with multisystem disease, including left main coronary artery stenosis. In addition to being less invasive, the advantages of PCI over CABG include shorter period of initial hospitalization and shorter recovery time. Disadvantages of PCI as the initial intervention include restenosis of the treated arteries and a higher prevalence of target-vessel revascularization. In general, a lesser degree of revascularization is achieved with PCI than with CABG in comparable patients.

During the 1990s, results of nine randomized clinical trials comparing PCI and CABG were published. Outcomes with respect to the major end points examined were summarized in a document jointly published by the American College of Cardiology and American Heart Association (Table 7-13). Several inferences can be drawn from these studies. Early mortality was comparable for the two interventions. Prevalence of early Q-wave MI was generally higher among the CABG patients, but this was unlikely due to chance in only two of the trials. Using a weighted average, prevalence was 4.1% among the CABG patients and 2.3% among the PCI patients. Initial costs and length of stay were lower for PCI than for CABG. Patients with PCI were able to exercise more at 1 month and return to work sooner.

In the Balloon Angioplasty Revascularization Investigation (BARI) and the Emory Angioplasty versus Surgery Trial (EAST), extent of revascularization achieved with CABG was higher than with PCI.

When late results were examined, there was no statistically significant difference in survival in any of the nine trials at follow-up periods ranging from 1 to 5 years (see Table 7-13). In the subset of patients with diabetes, however, all-cause mortality and cardiac mortality were higher in those treated with PCI in BARI (35% vs. 19% and 11% vs. 5.8%, respectively). A similar finding in diabetic patients was observed in the Coronary Angioplasty versus Bypass Revascularisation Investigation (CABRI), but not in EAST. No difference in prevalence of Q-wave MI or the combined end point of death and MI was demonstrated in any of the trials (see Table 7-13) or in subsequent meta-analyses. Most of the trials found that CABG resulted in greater freedom from angina.

The most striking difference between CABG and PCI was need for subsequent procedures. Prevalence was 4 to 10 times higher for PCI in every trial (see Table 7-13).

In several studies that examined quality of life and cost, physical activity and employment were similar for both procedures after 3 years, and functional status was equivalent at 5 years in BARI. Employment and emotional health were also similar. The early cost benefit of PCI decreased during follow-up because of more frequent need for repeat procedures and hospitalization.

<sup>d</sup>Planned 5-year follow-up (interim results).
After excising arteriosclerotic debris, patch-graft enlargement of the artery is extended a variable distance onto the left main artery. An incision in the aorta just anterior to the left main coronary artery is exposed. The pulmonary trunk is dissected away from the ascending aorta, and the left main coronary artery is exposed. The surgical angioplasty for the left main coronary artery and to a lesser extent for ostial lesions of the RCA \textsuperscript{51-1,19,15,52} has been reported. Yeh and colleagues reported that anginal relief of 64% to 92% was noted when endarterectomy was done to the graft, compared with 29% when endarterectomy was not done. \textsuperscript{53} However, many studies suggest that the patency and flow in grafts to endarterectomized arteries is comparable to that of nonendarterectomized arteries. Whether perioperative MI is more likely to occur when endarterectomy is employed is controversial, \textsuperscript{52} as is the relative completeness of revascularization that can be achieved with the two techniques.

**Endarterectomy**

Although some surgeons frequently use endarterectomy, particularly in the distal RCA, most prefer to use the more distal branches of this artery for anastomosis to a bypass graft rather than endarterectomize the parent trunk and graft to it. Some surgeons continue to employ long endarterectomies, even in the LAD, and report good results. \textsuperscript{53,58,62}

Lower patency of grafts to endarterectomized arteries has been reported. Yeh and colleagues reported that graft patency of 64% when endarterectomy was done to the graft, compared with 92% when endarterectomy was not done. \textsuperscript{53} However, many studies suggest that patency and flow in grafts to endarterectomized arteries are comparable to those to nonendarterectomized arteries. Whether perioperative MI is more likely to occur when endarterectomy is employed is controversial, \textsuperscript{52} as is the relative completeness of revascularization that can be achieved with the two techniques.

**Surgical Angioplasty**

Surgical angioplasty of major coronary artery branches has limited value. However, some surgeons have successfully used angioplasty for the left main coronary artery and to a lesser extent for ostial lesions of the RCA \textsuperscript{51-1,19,15,52} has been reported. Yeh and colleagues reported that anginal relief of 64% to 92% was noted when endarterectomy was done to the graft, compared with 29% when endarterectomy was not done. \textsuperscript{53} However, many studies suggest that the patency and flow in grafts to endarterectomized arteries is comparable to that of nonendarterectomized arteries. Whether perioperative MI is more likely to occur when endarterectomy is employed is controversial, \textsuperscript{52} as is the relative completeness of revascularization that can be achieved with the two techniques.

**Small Distal Vessels**

Small distal vessel size does not represent a contraindication to operation. Levin and colleagues found that bypass grafts could be successfully placed in 73% of vessels considered inadequate because of severe distal narrowing or absence of filling on the angiogram. \textsuperscript{1,13}

**Transmyocardial Laser Revascularization**

In the 1950s, Goldman and colleagues\textsuperscript{518} and Massimo and Boffi\textsuperscript{519} proposed that conduits could be created in the subendocardium through the LV cavity to direct blood through the coronary sinusoids and into ischemic areas of the myocardium. Subsequently, Sen and colleagues used direct needle acupuncture to create communicating channels in ischemic myocardium. \textsuperscript{52} Mihoseini and Cayton\textsuperscript{528} and Okada and colleagues\textsuperscript{529} used a laser to create transmyocardial channels. Initial observational studies in patients with severe angina who underwent transmyocardial laser revascularization (TMLR) suggested that the procedure improved symptoms. \textsuperscript{522,523}

Currently, TMLR is performed with a carbon dioxide or holmium laser. In a typical procedure, 10 to 50 channels are created in areas of ischemic myocardium. If TMLR is the sole therapy, a left anterior thoracotomy is made, and the procedure is performed without use of CPB. TMLR can also be performed in conjunction with primary or repeat CABG using CPB or with OPCAB. Laser channels are created in ischemic areas that are not amenable to bypass grafting.

Four randomized clinical trials compared TMLR with medical therapy in patients with severe angina refractory to medical treatment, reversible ischemia of the LV wall, and CAD not amenable to CABG or PCI. Findings indicated that TMLR results in substantial improvement in symptoms. \textsuperscript{A1,A19,F17,S12} In three of the three trials, sustained relief of angina at 5 years was greater in the TMLR patients. \textsuperscript{A2,A17,H22} Exercise tolerance was not improved in the two studies that evaluated it. \textsuperscript{A1,S12} In two of the three trials in which myocardial perfusion was assessed at rest and during stress, TMLR did not improve it. \textsuperscript{A19,S12} In the third study, magnitude of improvement in symptoms was disproportionate to improvement in perfusion. \textsuperscript{F17} TMLR was not associated with improved LV systolic function or survival 1 year after enrollment.

Mechanisms of action for TMLR remain unclear. These include placebo effect, creating channels that provide increased blood flow to the ischemic myocardium, proliferation of new blood vessels (angiogenesis), denervation of ischemic myocardium, and infarction of ischemic myocardium.

TMLR can be performed with hospital mortality not exceeding 5% to 10% in properly selected patients. \textsuperscript{A18,A19,B68,F17,H23,S12} It can be performed as adjunctive therapy in patients undergoing CABG who would be incompletely revascularized by CABG alone. Superior relief of angina at 5 years has been demonstrated in a randomized trial. \textsuperscript{A28} Guidelines for TMLR as sole therapy or in combination with CABG have been published by the Society of Thoracic Surgeons. \textsuperscript{B31}

**Gene Therapy**

Enhanced understanding of the molecular biology of vascular cell activation and proliferation has resulted in development
of interventions at the level of gene expression to enhance the microcirculation of ischemic muscle and alter the course of vein graft atherosclerosis. Vascular endothelial growth factor (VEGF) has been administered to patients with ischemic myocardium as sole therapy by direct injection using a mini-thoracotomy or as an adjunct to CABG. Human fibroblast growth factor (FGF) has been used for a similar purpose. These studies have demonstrated evidence for improved myocardial perfusion in treated areas of the LV and improvement in symptoms early after treatment.

Ehsan and colleagues have demonstrated experimentally that a single intraoperative transfection of vein grafts with a decoy oligonucleotide that blocks cell-cycle gene transactivation, provides long-term resistance to neointimal hyperplasia and atherosclerosis. This has resulted in a reduction in primary graft failure unlikely to be due to chance when used in high-risk patients having CABG or peripheral arterial occlusions. However, a large randomized trial of more than 3000 patients whose vein grafts were treated with oligonucleotide or placebo failed to demonstrate higher patency of the treated grafts at 12 to 18 months.

Combined Carotid and Coronary Artery Disease

Carotid artery disease is an important risk factor for stroke after CABG. Hemodynamically significant carotid artery stenoses are associated with as many as 30% of strokes occurring after CABG. Prevalence of hemodynamically significant carotid artery disease among patients undergoing CABG increases with increasing age. In a nonconsecutive series of 1087 patients 65 years of age and older undergoing cardiac surgical procedures (91% with CAD) who had preoperative carotid duplex ultrasonography, prevalence of a 50% or greater stenosis of one or both carotid arteries was 17%; for an 80% or greater stenosis, it was 5.9%. Prevalence of a 50% or greater stenosis was 8% in patients between ages 65 and 69, increasing to 17% for patients age 80 and older. Incremental risk factors for presence of an 80% or greater stenosis were a previous history of transient ischemic attack or stroke, female gender, left main coronary artery disease, peripheral arterial disease, and history of smoking.

Presence or absence of a cervical bruit is poorly predictive of high-grade stenosis even in the setting of known symptomatic carotid artery disease (sensitivity 63%, specificity 61%). Carotid duplex ultrasonography is currently the most widely used preoperative screening technique to detect important carotid artery disease in patients undergoing CABG. It is used selectively in some centers and routinely in others to detect disease in older patients. If the preoperative carotid duplex study demonstrates high-grade (>75% to 80%) stenosis, and the patient's hemodynamic state is stable with no critically stenotic coronary arteries, carotid angiography is usually performed. Carotid and CABG procedures are staged, performing the carotid endarterectomy first. If the patient is hemodynamically unstable, or if there is high-grade left main coronary artery or proximal LAD disease, the carotid angiogram is often omitted, and a combined carotid and CABG procedure is performed.

This approach is justified because prophylactic carotid endarterectomy has been shown to be superior to conservative therapy for preventing stroke in symptomatic or asymptomatic patients with high-grade stenosis, and carotid artery disease is an important risk factor for stroke in patients with CAD.

When a combined procedure is performed, carotid endarterectomy may be done before CPB is established. Alternatively, endarterectomy can be performed during hypothermic CPB, which may provide additional brain protection during occlusion of the carotid artery. In patients with severe stenosis of one carotid artery and severe stenosis or occlusion of the contralateral carotid artery, deep hypothermia with or without a brief interval of circulatory arrest may be advantageous.

Superiority of the combined vs. staged approach has not been established by prospective trials. An individualized, patient-specific approach, with the decision based on symptoms and relative severity of the carotid and coronary artery disease, appears prudent and is used in many institutions. In experienced centers, staged or concomitant carotid endarterectomy and CABG can be accomplished with an early mortality that does not exceed 4%, stroke occurrence of less than 4%, and 10-year freedom from stroke of 88% to 96%.

Coronary Artery Aneurysm and Dissection

Coronary artery aneurysm is a localized dilatation that is saccular or fusiform in shape and exceeds the diameter of normal adjacent segments or the diameter of the patient’s largest coronary artery by 1.5 times. In patients undergoing coronary angiography, prevalence ranges from 0.4% to 4.9%. The majority of coronary aneurysms are arteriosclerotic in origin. These aneurysms may also be congenital, result from Kawasaki disease, or develop after PCI. Aneurysms occur most often in the RCA; the left main coronary artery is involved infrequently.

No clinical features distinguish coronary aneurysms, and the natural history is largely unknown. Diagnosis is usually made by coronary angiography. Rupture was reported in 12% of a series of 53 autopsied cases reported by Daoud and colleagues in 1963. In CASS, however, which included more than 20,000 patients who underwent coronary angiography, no case of rupture was observed among 978 patients in whom coronary artery aneurysms were detected. Thrombus develops in these aneurysms and may be a source for distal embolization. Bypass grafting of an artery containing an aneurysm, with or without ligation of the artery distal to the aneurysm, may be indicated in patients who have important occlusive disease in the artery or evidence of distal embolization in the absence of occlusive disease.

Coronary artery dissection is a rare cause of ischemic heart disease and sudden death. Coronary dissection can occur spontaneously or result from aortic dissection, blunt chest trauma, cardiac catheterization, coronary angioplasty, or CABG. Dissection has been observed after intense physical exercise and cocaine abuse. Predisposing factors include arteriosclerotic CAD, pregnancy, and Marfan and Ehlers-Danlos syndromes. Sudden death is the most frequent clinical presentation. In patients who survive the initial event, medical therapy is appropriate for those without ongoing ischemia. Stenting or CABG is advisable for symptomatic patients. Patients with dissection of the left main coronary artery should undergo CABG.

**Definition**

A postinfarction left ventricular (LV) aneurysm is a well-delineated transmural fibrous scar, virtually devoid of muscle, in which the characteristic fine trabecular pattern of the inner surface of the wall has been replaced by smooth fibrous tissue. In such areas, the wall is usually thin, and both inner and outer surfaces bulge outward. During systole, the involved wall segments are akinetic (without movement) or dyskinetic (paradoxical movement).

Scars and infarcts are not considered aneurysms. Unlike aneurysms, they are not discrete, the LV wall is not thin, and the scar is interspersed with muscle. The definition of aneurysm and the criteria for separating an aneurysm from other types of LV scars are controversial, and some clinicians have adopted a broader, non-morphologic definition rather than the one given earlier. Johnson and colleagues defined aneurysm as “a large single area of infarction (scar) that causes the LV ejection fraction to be profoundly depressed (to approximately 0.35 or lower).” Although realistically the definition of LV aneurysm is less important to the surgeon than are criteria for and results of surgical excision of LV scars, lack of uniformity of definition complicates almost all discussions of this entity. For example, many reports indicate that most patients with LV aneurysms have single-system left anterior descending coronary artery (LAD) disease, whereas others find that nearly all patients have multiple-system disease. Many patients with multiple-system disease have scars rather than true aneurysms.

**Historical Note**

Although John Hunter and others recognized that LV aneurysms occurred, it was not until the 1880s that the relationships among stenotic coronary artery disease, myocardial infarction (MI), myocardial fibrosis, and LV aneurysm were recognized. Until about 1950, few cases were diagnosed during life, but thereafter the ability to diagnose LV aneurysms improved. In 1967, Gorlin and colleagues reported that a strong suspicion of aneurysm could be obtained in 75% of patients with this complication of MI based on history, physical examination, and apex cardio, electrocardiographic, and radiologic studies. Many clinicians believe the prevalence of LV aneurysms has been decreasing since about 1980. Surgical treatment of postinfarction LV aneurysm probably began in 1944 when Beck reinforced such a lesion with fascia lata in an effort to reduce...
expansile pulsation and prevent rupture. A closed ventriculoplasty, done with a special side-biting LV clamp, was reported in 1955 by Likoff and Bailey. A few years later, Bailey reported five survivors among six patients treated by this method. In 1959, Cooley and colleagues in Houston reported the first successful open excision of an LV aneurysm using cardiopulmonary bypass (CPB).^13^

**MORPHOLOGY**

**Gross Pathology**

The wall of a mature aneurysm is a white fibrous scar, visible externally on the cut surface as well as endocardially. Characteristically, the aneurysmal portion of the LV wall is thin, the endocardial surface is smooth and nontrabeculated, and the area is clearly demarcated. In more than half of patients, varying amounts of mural thrombi are attached to the endocardial surface. The mural thrombus may calcify, as may the overlying pericardium, which is often densely adherent to aneurysm’s epicardial surface.^39,54^ Such classic LV aneurysms are at one end of the spectrum of postinfarction LV scars. At the other end the diffuse, scattered, and at times sparse punctate scars, frequently visible at operation in areas of previous MI. These scars are usually not transmural, and the LV wall is not thinned or only minimally so. The endocardium beneath retains its trabeculations, and the area of scarring is not clearly demarcated from the rest of the wall. Mural thrombi are not commonly present, and the pericardium is not commonly adherent to the area. Between these extremes is a continuous spectrum of postinfarction LV scarring, because in an area of MI, myocardial necrosis is rarely homogeneous (see “Myocardial Infarction and Morphologic Sequelae” in Chapter 7).

**Microscopic Pathology**

A mature aneurysm consists almost entirely of hyalinized fibrous tissue. However, a small number of viable muscle cells are usually present. Fibrous tissue of the type present in aneurysms takes at least 1 month to form, although collagen is present within 10 days of infarction. Thus, when an aneurysm is said to be present (based on wall thinning and dilatation) within 1 week or so of a first infarction, the wall is composed largely of necrotic muscle and is not therefore by definition a true (mature) aneurysm.

**Location**

About 85% of LV aneurysms are located anterolaterally near the apex of the heart. Few are confined to the lateral (obtuse marginal) area, and only 5% to 10% are posterior, near the base of the heart. Posterior, or inferior, aneurysms (i.e., those occurring in the diaphragmatic portion of the LV) are in some ways different from apical and anterolateral aneurysms. Nearly half of posterior aneurysms are false aneurysms (see “False Left Ventricular Aneurysm” under Special Situations and Controversies), whereas nearly all anterolateral and apical aneurysms are true aneurysms.^15^ Virtually all lateral aneurysms are false aneurysms. True posterior wall postinfarction aneurysms are associated with a high prevalence of postinfarction mitral regurgitation secondary to ischemia or necrosis of the papillary muscle.^15,51^ (see Chapter 10).

**Coronary Arteries**

Somewhat less than half of patients undergoing resection of classic LV aneurysms or scars have stenotic coronary artery disease confined to the left anterior descending coronary artery (LAD).^5,18,14,2,12,5,7,19,3,5,1,1,13,1,16,18,1,19,3,4,9^ More often, multiple-system disease is present. The discrepancy between the reported prevalence of single- and multiple-vessel disease may be related to differences in the definition of LV aneurysm, to different sources of the material (clinical, surgical, or postmortem), and in the case of surgical material, to case selection. A patient with single-system disease is more apt to survive an acute infarction and appear in a surgical series than is a patient with multiple-system disease.

**Left Ventricle**

Postmortem studies indicate that most patients with classic LV aneurysms have increased cardiac volume and weight.^39,4,4^ The increase in volume is in part the result of simple thinning and bulging of the aneurysmal portion of the LV wall. However, nonaneurysmal portions of the LV also increase in volume and thickness secondary to hemodynamic stress placed on them by akinesia of the aneurysmal segment (remodeling) and by the Laplace law. Inactivation (by akinesia or dyskinesis) of at least 20% of the LV wall area is required for LV enlargement to occur.^2,4^ The larger the akinetic or dyskinetic area, the greater the enlargement of the rest of the ventricle. The time course of these events has not been clearly defined.

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

Morphologic diagnosis of postinfarction LV aneurysm can be made with assurance only at operation or autopsy. This is because the akinetic or dyskinetic segmental wall motion of an LV aneurysm can be mimicked by nontransmural scars or early infarcts that are not morphologic aneurysms. Thus, Froehlich and colleagues found no aneurysm at operation in 3 of 18 patients (17%; CL 7%-31%) with a preoperative diagnosis of aneurysm and only a questionable aneurysm, which was plicated, in an additional 4 patients (22%, CL 12%-37%).^17^ Small and moderate-sized aneurysms are often associated with no specific symptoms, although the patient may experience angina because of stenoses in other portions of the coronary arterial tree. Patients with large LV aneurysms, however, usually present with dyspnea that often has persisted from the time of infarction. Heart failure requiring medication for control may have appeared by the time of presentation to the physician.^25,3^ (Table 8-1). Symptoms related to ventricular tachycardia occur in 15% to 30% of patients and may become intractable to medical treatment and cause death.^23,6^ Although about half of aneurysms contain thrombus, thromboembolism occurs in only a small proportion of patients. On physical examination, palpation over the heart often demonstrates a diffuse, sustained apical systolic thrust and a double impulse. On auscultation, usually a third heart sound and often a fourth (atrial) sound are present. There may be an apical pansystolic murmur if mitral regurgitation is present. Chest radiography and fluoroscopy may show an external bulge or convexity when the aneurysm is large enough and profiled. Methods of LV imaging—namely, left ventriculography, two-dimensional and transesophageal...

echocardiography, radionuclide cardiac blood pool imaging, computed tomography (CT), and magnetic resonance imaging (MRI)—are all useful diagnostic techniques (Fig. 8-1).13,16,16 However, an incorrect preoperative or preoperative diagnosis of aneurysm is still sometimes made. Ventriculography is a sensitive imaging method. When there is akinesia or dyskinesia of the wall segment during systole, a permanent outward bulging or convexity, thinning of the wall and lack of inner wall trabeculation, and clear demarcation of the area from the remaining ventricle, the diagnosis is probably correct. Wall thinning and even bulging of the contrast-medium–lined LV cavity may not be detected when there is extensive smooth mural thrombus, and it is often difficult to define the margins of an area with akinesia. Identification of significant mural thrombus adds to the probability of aneurysm, as does presence of calcification in the wall. Right heart catheterization is useful because it enables measurement of pulmonary artery pressure and calculation of cardiac output. From the left heart study, LV end-diastolic pressure, ejection fraction, and end-diastolic volume are measured or calculated. Coronary angiography is always performed.

Figure 8-1  Cine (ultrafast) computed tomographic images at four adjacent anatomic levels (upper left, cranial, to lower right, caudal) demonstrate an anterior left ventricular (LV) aneurysm. There is severe thinning of the anteroseptal and anterior walls and bulging of the LV anteriorly. (From Higgins.15)
Development of Left Ventricular Aneurysm

Historically, about 10% to 30% of patients who survived a major MI developed an LV aneurysm.\textsuperscript{A3, N1} Today, the prevalence appears to have lessened thanks to improved treatment of patients with acute MI. The most important development may be widespread use of thrombolytic therapy and percutaneous coronary interventions, which have reduced the prevalence of permanently occluded LADs. Other improvements include better management of hypertension and avoidance of corticosteroids, both of which are risk factors for development of aneurysms.\textsuperscript{B16, M12} The mechanisms by which LV aneurysms form are not completely elucidated. Occurrence of a large transmural infarction is a prerequisite. It has been suggested that patients who develop LV aneurysms have few intercoronary collateral arteries.\textsuperscript{B14, C6, J15} It is postulated that a rich collateral blood supply to an area of MI tends to increase the number and size of the islands of viable myocardial cells in the area and decrease the probability that the necrosis is extensive enough to result in a thin-walled transmural scar. This hypothesis is supported by Forman and colleagues, who studied 79 patients undergoing cardiac catheterization 6 months after a first MI.\textsuperscript{J9} They found total occlusion of the LAD and poorly developed collateral flow to be the determinants of LV aneurysm formation. Apparently, normal or supranormal systolic function in adjacent ventricular segments is necessary for generating sufficiently high intraventricular pressure and wall tension in the infarcted area to result in aneurysm formation.\textsuperscript{A3}

Pathophysiologic Progression of Aneurysm

Whether large LV aneurysms are large from inception or gradually enlarge once formed is uncertain. The mechanism for increasing symptomatology that characterizes the life history of many patients with large LV aneurysms has not been clearly established.\textsuperscript{C2, C14, J6} It may be due to a gradual increase in the size of the area of akinesia or dyskinesia and to a consequent gradual reduction in stroke volume and global ejection fraction.\textsuperscript{A7, J6} The nonaneurysmal portion of the LV wall is subjected to increased systolic wall stress as ventricular size increases (as described by the Laplace law) and may ultimately lose its systolic reserve and contribute to LV enlargement and failure.\textsuperscript{J6} This process is aggravated by any myocardial ischemia that develops in the nonaneurysmal portion of the ventricular wall.

Left Ventricular Function

An aneurysm changes the curvature and thickness of the LV wall, and because these are determinants of LV afterload (wall stress), global LV performance is altered.\textsuperscript{D10, N2} Also, a large LV aneurysm leads to global cardiac remodeling with generalized dilatation.\textsuperscript{N2} Variations in intrinsic properties of scar, muscle, and border-zone tissue can affect both systolic and diastolic function.\textsuperscript{K5} Finally, paradoxical movement in the aneurysmal portion of the wall reduces efficiency of the ventricle because systolic work is wasted on expansion of the aneurysm.\textsuperscript{J15}

Function in uninvolved segments of the LV per se (segmental ejection fraction) has been difficult to study because of the complexities of assessing ventricular function in this setting. However, when echocardiographically determined wall thickening is used as a measure of regional systolic function, it appears that systolic function is maintained in the remote nonaneurysmal portions of the ventricle.\textsuperscript{N2} Early in systole, the aneurysm and border zones bulge outward (paradoxical movement) as systolic intraventricular pressure rises to a maximum. Later in systole, after the aortic valve has opened and wall stress is falling, some wall thickening occurs in the border zones, contributing to ejection.\textsuperscript{N2}

Right Ventricular Function

Right ventricular (RV) function may be impaired in patients with LV aneurysm. This may result from akinesia or dyskinesia of the ventricular septum, impaired RV wall motion near the apex, increased pulmonary artery pressure, occlusive disease of the right coronary artery, and increased volume of the LV within the pericardial cavity.\textsuperscript{B13, C1, G6}

Survival

The complexities of ischemic heart disease in general and the difficulties in identifying true LV aneurysms have mitigated against achieving a clear understanding of survival and risk factors for death of patients with LV aneurysms. Patients with an LV akinetic area (not all of which are true aneurysms) are reported to have a 5-year survival without operation of 69%,\textsuperscript{B12} perhaps only a little less than that dictated by their coexisting coronary artery disease. Patients with a dyskinetic area of LV wall (many of which are probably aneurysms) have a 54% 5-year survival, which is reduced to 36% when myocardial function in the remainder of the ventricle is reduced.\textsuperscript{N12} Size of the aneurysm is a risk factor for premature death in surgically untreated patients. In patients with small aneurysms (usually without symptoms of heart failure), the probability of surviving is dictated primarily by severity and extent of the coronary arterial stenoses and is greater in asymptomatic than in symptomatic patients (Fig. 8-2).\textsuperscript{G3} Prognosis is adversely affected by dyskinesia rather than akinesia in the aneurysm; the former is usually associated with a low global LV ejection fraction.\textsuperscript{F3} The functional characteristics of the remainder of the ventricle are also major determinants of survival. In addition, all the usual risk factors for premature death in patients with ischemic heart disease (see Table 7-2 in Chapter 7) pertain to patients with LV aneurysm.\textsuperscript{F2}

---

**Figure 8-2** Five-year survival with left ventricular aneurysm but without operation for 20 patients with few or no symptoms and for 20 symptomatic patients. (Modified from Grondin and colleagues.\textsuperscript{G1})
TECHNIQUE OF OPERATION

Most patients who undergo resection of postinfarction LV aneurysms or other scars also require coronary artery bypass grafting (CABG). The following discussion augments the description of CABG in Chapter 7.

Preoperative and operating room preparations, removal or preparation of grafts, and median sternotomy are accomplished as described in Chapters 2 and 7. The pericardial adhesions over the LV are not lysed at this point. If CABG is to be performed, and if the proximal anastomoses are to be placed first, this is done now. If the LAD is to be revascularized, the left internal thoracic artery is prepared. Moderately hypothermic CPB is established using double venous cannulation and caval taping or a single venous cannula. A left atrial or LV vent is not inserted. Dissection of adhesions between the LV and pericardium is deferred until the aorta is clamped, to avoid dislodging and embolizing mural thrombus.

Because patients with large LV aneurysms usually have heart failure and the operation may be prolonged, warm induction of cardioplegia after aortic occlusion and controlled reperfusion with initially hyperkalemic, modified, and enriched blood may be used (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3). Retrograde cardioplegia (see “Technique of Retrograde Infusion” under Methods of Myocardial Management during Cardiac Surgery in Chapter 3) and a “no-touch” technique may be particularly useful.57 Adhesions, if thin, can be mobilized over the entire aneurysm. If the classic method of repair is anticipated and the aneurysm is densely adherent to the pericardium, the LV can be separated from the aneurysm without disturbing these adhesions. The aneurysm is incised at some convenient point, and loose thrombus is sought and removed. When the aneurysm contains considerable thrombus and debris, a sponge is placed deep inside the ventricle over the aortic and mitral valves to prevent debris from entering the aorta and left atrium. This sponge is removed after the dissection is completed. A small sump sucker is placed through the incision into the ventricle and is positioned so as to maintain a pool of blood within the open ventricle below the level of the ventriculotomy. This prevents air from entering the aorta, coronary ostia, and left atrium. The incision is extended around the entire aneurysm, leaving a thin rim of scar tissue to facilitate closure.

A true aneurysm has a smooth endocardial surface. Additional endocardial tissue may be removed and other procedures done if the patient has a history of life-threatening ventricular arrhythmias (see Section V, “Ventricular Tachycardia and Ventricular Fibrillation in Ischemic Heart Disease,” in Chapter 16). When large amounts of thrombus are present, the ventricular cavity is carefully inspected and thoroughly irrigated to remove all debris. If the aneurysm wall is left adherent to the pericardium, thrombotic material is removed from it (this can be done later during rewarming, after the ventricle is closed), and the avascular fibrous tissue is left attached to the pericardium.

Reconstruction of the Left Ventricle

Anterior Aneurysm

When reconstruction is performed with the classic technique (linear closure), a line of closure is selected that will least distort the LV. After opening the ventricle and excising the scar (Fig. 8-3, A), a stay suture is placed at each end of the line of closure (Fig. 8-3, B). If the aneurysm is small, closure of the LV can be accomplished with two rows of a simple continuous suture using No. 0 or 1 polypropylene on a large curved needle. More often, closure is performed with heavy double-armed sutures (No. 1 or 2 silk or polyester) that are placed horizontally immediately adjacent to one another, incorporating strips of polytetrafluoroethylene (PTFE) felt (see Fig. 8-3, B). These sutures are placed deep into the ventricular septum (see Fig. 8-3, B [inset]) to exclude as much septal scar as possible.314 As these sutures are tied, beginning at the basal portion of the ventricle, volume from the pump-oxygenator is infused, and the lungs are gently inflated to evacuate air from the pulmonary veins and left atrium. Saline can also be infused into the open LV. When this suture line is completed, it is reinforced with two continuous No. 0 or 1 polypropylene sutures that are positioned at each end of the incision, placed through the felt and through the edges of the myocardium superficial to the mattress sutures, and tied to each other (Fig. 8-3, C). Incorporation of the distal portion of the LAD into the suture lines should be avoided.

An alternative procedure is patch closure of the defect in the LV (Fig. 8-4).11,64 This technique has been termed “endoaneurysmorrhaphy” by Cooley11 and “endoventricular circular patch plasty repair” by Dor.65 The rationale for this technique is based in part on the fact that, coexisting with anterior LV aneurysm, scar tissue and akinesis or dyskinesis are present in the anterior portion of the LV septum. When a patch is used for closure, the area of septal scarring can be excluded from the reconstructed LV. This may result in improved LV function.11,6,52 Furthermore, curvature of the left anterior wall may be maintained.18 Based on echocardiographic measurements in normal hearts, Fontan determined that the patch should be oval and should have a long diameter of 2 to 2.5 cm in situ. Thus, it should be made 2.5 to 3 cm in length to compensate for the space taken up by the suture line.14 A patch that is too large may result in too large an end-diastolic LV volume and thus a reduced global ejection fraction. A patch that is too small may reduce LV volume and compliance.52 A preshaped balloon of known volume (50 to 60 mL) can be inserted into the opened LV cavity to facilitate creating a chamber of appropriate size and shape.53 After opening the LV, the line of demarcation between scar and contractile LV myocardium is identified (Fig. 8-4, A [inset]). This may be facilitated by palpation if cardioplegia is not used during this portion of the operation.52 A purse-string suture of No. 2-0 polypropylene is placed at the junction of scar and contractile septal and free wall myocardium (Fig. 8-4, B). The longitudinal and transverse dimensions of the resulting defect are measured. A patch of gelatin or collagen-impregnated polyester (that can be lined with autologous pericardium) with slightly larger (0.5 cm) dimensions is fashioned and then sutured into place with slightly larger (0.5 cm) dimensions is fashioned and then sutured into place with a continuous No. 3-0 polypropylene suture (Fig. 8-4, C). Before completing the suture line, air is evacuated from the LV by infusing volume from the pump-oxygenator, gently inflating the lungs, and injecting saline into the ventricle. This suture line must be watertight to avoid formation of a false aneurysm. The remnant of the aneurysm is trimmed, if necessary, and is closed securely over the patch with a continuous No. 2-0 polypropylene suture (Fig. 8-4, D).

A second alternative procedure in patients without a calcified aneurysm, and the rare patient with a small LV cavity, is
Figure 8-3  Technique for repair of anterior left ventricular aneurysm by linear closure. A, After the aorta is clamped and cardioplegic solution has been infused, an incision is made in the thinnest portion of the aneurysm parallel to the interventricular groove. If pericardial adhesions are dense, the aneurysm can be left attached to the pericardium. The scar is excised (inset). B, After all the scar has been excised, traction sutures are placed at each end of the anticipated line of closure. The defect is closed with No. 1 or 2 double-armed silk or polyester sutures placed horizontally and immediately adjacent to one another. These sutures are placed deep into the ventricular septum to exclude as much septal scar as possible (inset). C, Suture line is reinforced with two continuous No. 0 or 1 polypropylene sutures positioned at each end of the incision, placed in scar tissue superficially to the mattress sutures, and tied to each other. Key: LV, Left ventricle; RV, right ventricle.

direct LV reconstruction using multiple concentric purse-string sutures without a patch.\textsuperscript{C4,K8}

**Posterior Aneurysm**

The techniques described for repairing anterior LV aneurysms are also applicable to posterior aneurysms. However, the defects remaining after excision of the scar or after circular reduction with a suture are generally smaller. Injury to the posterior papillary muscle at the lateral edge of the defect and to the posterior descending coronary artery on the medial edge of the defect must be avoided.

**Associated Mitral Regurgitation**

Mitral regurgitation of variable degree is often present in patients with LV aneurysm. If repair of the valve is possible, it may be accomplished with standard techniques through a left atrial approach (see Technique of Operation in Chapter 11). Alternatively, the “edge-to-edge” repair technique proposed by Alfieri and colleagues can be performed through the ventriculotomy.\textsuperscript{M1}

If valve replacement is indicated, it can be performed through the opened LV for posterior as well as anterior aneurysms (Fig. 8-5). The ventricle is opened through the aneurysm as previously described, and the mitral valve is examined (Fig. 8-5, A). If replacement is indicated, the mitral valve leaflets are excised, and all chordae tendineae are transected. A small remnant of anterior leaflet is left adjacent to the aortic valve cusps (Fig. 8-5, B). The valve holder apparatus is removed from the appropriately sized mechanical or bioprosthetic valve, and the valve is inverted and suspended by two hemostats. Interrupted pledgeted mattress sutures of No. 2-0 polyester are placed through the mitral anulus, with the pledgets positioned on the atrial side (Fig. 8-5, C). These sutures are placed through the sewing ring of the prosthesis on the undersurface of the flanged portion (see Fig. 8-5, C). The valve is then lowered into the anulus and the sutures tied (Fig. 8-5, D). A soft rubber catheter is used to keep the prosthesis leaflets in the open position until air is evacuated from the pulmonary veins and left atrium. The LV is then reconstructed using one of the techniques previously described.

**SPECIAL FEATURES OF POSTOPERATIVE CARE**

Postoperative care is the same as that for other patients after intracardiac operations (see Chapter 5) and particularly after CABG. The detailed late-postoperative care required for patients undergoing CABG (see Special Features of Postoperative Care in Chapter 49) should also be applied to patients whose operation has included resection of a postinfarction LV aneurysm.

**RESULTS**

Survival

**Early (Hospital) Death**

Hospital mortality after LV aneurysm repair, with or without concomitant CABG, is about 5% to 7%\textsuperscript{C3,E2,F4,J2,J4,J5,K4,K7,M9,S6,V5,Z1} down from 10% to 20% in the earlier era (1958-1978) of cardiac surgery.\textsuperscript{B5,B18,C12,C14,M13,R3,R8}

Reduced mortality is related to improved surgical techniques, better myocardial management, greater efforts to perform concomitant CABG, better protection against embolization during operation, and use of adjunctive measures in patients with associated intractable ventricular tachycardia. No consistent difference in early mortality has been demonstrated between the classic (linear closure) and endoaneurysmorraphy (circular or patch closure) techniques.\textsuperscript{J2,K4,K7,M9,R3,S6,V5,Z1}

**Time-Related Survival**

Overall time-related survival of heterogeneous groups of patients undergoing resection of LV aneurysms has varied, but in general, 30-day and 1-, 3-, and 5-year survival has been about 90%, 85%, 75%, and 65%, respectively.\textsuperscript{B5,B18,C13,E2,F6,K7,S6} Several studies\textsuperscript{M9,V5} report higher 5-year survival (80% to 88%). In the Surgical Treatment for Ischemic Heart Failure (STICH) trial, the only randomized trial to compare CABG with CABG plus surgical ventricular reconstruction in patients with an ejection fraction of 35% or less and dominant anterior LV dysfunction (akinesia or dyskinesia), 5-year survival among the 501 patients randomized to CABG plus surgical ventricular reconstruction was 67%.\textsuperscript{K6} It did not differ significantly from survival of 499 patients randomized to CABG alone (Fig. 8-6). Not unexpectedly, differences in outcome after surgical and nonsurgical treatment are particularly evident in patients with coexisting three-system disease.\textsuperscript{F1}

**Modes of Death**

The most common mode of death early after operation is acute cardiac failure.\textsuperscript{S6,V3,V5} Late postoperatively, the mode of death is progressive chronic heart failure in about one third of patients and acute heart failure after another MI in another third. Intractable ventricular tachycardia and sudden death have been the mode in about 15% of patients in the past, but the prevalence may be lower now as a result of more effective intraoperative management and medical and surgical treatment.

**Incremental Risk Factors for Premature Death**

In patients undergoing LV aneurysmectomy, risk factors for premature death and other unfavorable outcomes are generally the same as those in other patients with ischemic heart disease. The lower probability of time-related survival of patients undergoing LV aneurysmectomy (with or without concomitant CABG) is explained for the most part by their greater likelihood of having risk factors relating to myocardial scarring.\textsuperscript{C8}

**Severity and Extent of Coronary Arterial Stenoses**

When complete revascularization is not accomplished in operations for ischemic heart disease, severity and extent of residual coronary arterial stenoses may appear as risk factors for most unfavorable outcome events. In surgical series in which the severity and extent of coronary artery disease have not been identified as risk factors for death early or late after operation,\textsuperscript{B10,C13,F3,K7,R3,W1} the presumption is that complete revascularization was accomplished. In other studies, preoperative severity and extent of coronary arterial stenoses have been risk factors.\textsuperscript{B5} Presumably, they represent groups of patients in whom revascularization was necessarily incomplete.
surrogates identified as risk factors include preoperatively reduced cardiac output, elevated LV end-diastolic pressure, impaired septal systolic function, higher New York Heart Association (NYHA) functional class (Fig. 8-8), poor segmental wall motion, and ventricular tachycardia. Also related to the extent and location of myocardial scarring is the complication of life-threatening ventricular tachycardia. This is clearly a risk factor for death, both early and late

Extent and Location of Myocardial Scar

By definition, patients with LV aneurysm have considerable myocardial scarring, and the scar often is neither completely removed nor exteriorized by the operation. New scar formation occurs at the suture lines. Nonaneurysmal muscle may be scarred as well. Risk factors for death both early and late after resection of LV aneurysms that are surrogates for myocardial scar include preoperative resting LV dysfunction and chronic heart failure (Fig. 8-7). Other

Figure 8-5 Replacement of mitral valve through left ventricle (LV). A, An incision is made in the thinnest portion of the aneurysm parallel to the interventricular groove, and the mitral valve is examined. Chordae tendineae are divided at the tips of the papillary muscles. B, Mitral valve leaflets are excised. A small rim of anterior leaflet is left adjacent to aortic valve cusps. C, Valve holder apparatus is removed from mechanical valve or bioprosthesis, and valve is inverted and suspended by two hemostats. Interrupted, pledgeted mattress sutures of No. 2-0 polyester are placed through the mitral anulus, with pledgets on atrial side of anulus. These sutures are then placed through the sewing ring of the prosthesis on the underside of the flanged portion. D, The valve is lowered into the anulus and the sutures tied. The LV is reconstructed using one of the techniques described in Figs. 8-3 and 8-4.
or observational study has demonstrated a favorable effect of this procedure on late survival when compared with linear closure or other techniques.\textsuperscript{2,4,6,9}

**Other Risk Factors**

Other risk factors for death and other unfavorable outcome events after CABG (see Tables 7-2, 7-7, and 7-8 in Chapter 7) also pertain to patients undergoing LV aneurysmectomy. For example, older age at operation is clearly a risk factor for death, both early and late after aneurysmectomy.\textsuperscript{7,6,9}

**Symptomatic Results**

Most long-term survivors have substantial improvement in symptoms. The majority are in NYHA functional class I or II.\textsuperscript{6,8,16,33,37,38,39,54} Improvement has also been demonstrated with exercise testing.\textsuperscript{32} Several\textsuperscript{30,33,35} but not all\textsuperscript{54} comparative studies have demonstrated greater symptomatic improvement among patients undergoing patch closure than among those who had linear closure of the ventriculotomy.

**Late Postoperative Left Ventricular Function**

Determining LV function late after resection of LV aneurysms presents the same problems and complexities as it does in the case of the aneurysmal LV before operation (see “Left Ventricular Function” under Natural History earlier in this chapter). However, a reasonable amount of information is available. The relationship between improvement in LV
performance and symptomatic improvement is not entirely clear. Some patients with symptomatic improvement are without demonstrable improvement in LV function.\textsuperscript{14,17} It is possible that current techniques of studying LV function do not identify the small increases in LV function that allow symptomatic improvement. Although improvement is often noted in indices of LV function after aneurysmectomy without or with CABG,\textsuperscript{13,17} it does not always occur. Possible mechanisms for failure to improve include:

- incomplete aneurysm resection (e.g., Froehlich et al. found in most of their patients that only 50\% of the noncontractile area visualized by left ventriculography was resected\textsuperscript{17});
- small size of the aneurysm, leading to small changes in function after resection; and
- intraoperative damage to nonaneurysmal portions of the ventricle.

Also, despite improved resting LV function, some patients show no improvement in exercise ejection fraction or stroke volume.\textsuperscript{31,18} Often, however, the improvement in global and regional ejection fraction during exercise is striking.\textsuperscript{32,33} Paradoxical movement in the segments in the border zone during isovolumic contraction is usually eliminated by aneurysmectomy.\textsuperscript{34} This effect may be the result of more favorable geometry in these segments, a reduction in wall stress related to decreased chamber size, or better coronary perfusion produced by CABG. Wall thickening increases in some but not all uninvolved (remote) segments; in some improved segments, operation fails to increase blood supply.\textsuperscript{35} Improvements in LV function are most evident in patients with heart failure preoperatively.\textsuperscript{32}

A reduction in end-diastolic pressure is well correlated with clinical improvement in some patients.\textsuperscript{87} In 1969 in three patients with single-system LAD disease and classic aneurysm, Harman and colleagues demonstrated that simple resection without CABG increased LV ejection fraction, stroke volume and stroke work, and cardiac index and reduced LV end-diastolic pressure and volume.\textsuperscript{34} Two of the three patients were also relieved of angina pectoris. The data suggest that the resection and resultant decrease in LV volume decreased wall force according to the Laplace law. The decreased tension (afterload) during systole probably increased the rate of fiber shortening, thereby increasing stroke volume, and decreased myocardial oxygen consumption, thereby decreasing angina pectoris (see “Ventricular Afterload” under Cardiac Output and Its Determinants in Section I of Chapter 5).

INDICATIONS FOR OPERATION

A large LV aneurysm in a symptomatic patient, particularly one with angina pectoris but also in one with heart failure, is an indication for operation. Appropriate CABG is indicated at the time of aneurysmectomy, as described in Chapter 7. Currently, the patch closure technique for remodeling ventriculoplasty is the most widely used for repair of anterolateral aneurysms or areas of akinesis. In view of the high risk of operation in patients with advanced chronic heart failure, operation may not be indicated when the known risk factors are highly unfavorable to survival. It is apparent (see Fig. 8-8) that a patient with an LV aneurysm, NYHA class V, a myocardial score of 8 (two-system disease) or more, and severe heart failure has an 80\% probability of hospital death (CL 55%-90\%); if the myocardial score is 11 or greater, the risk approaches 100\%. In these circumstances, operation may be contraindicated, although current methods of myocardial management may allow some such patients to survive operation and be clinically improved. The risk is lower when heart failure is less severe; under such circumstances, operation is clearly advisable. In borderline cases, coexisting akinesia or dyskinesia of the posterior-basal segment of the LV is recognized as an additional risk factor.

When the LV aneurysm is small or moderate in size, its presence is not an indication for operation per se. This conclusion is based in part on the fact that many preoperatively diagnosed aneurysms are not found to be aneurysms at operation or autopsy. Patients in such situations are advised about operation based on their coronary artery disease and LV function (see Chapter 7) rather than on their aneurysm. In this regard, it is noteworthy that an aneurysm that remains small 1 year after MI is unlikely to enlarge progressively thereafter, and embolization from it is unlikely. When indications for resection of an LV aneurysm or akinetic area are present, operation need not be deferred to permit maturation of the aneurysm. Walker and colleagues reported one hospital death among 20 patients (5\%; CL 0.6%-16\%) undergoing operation within 8 weeks of acute infarction.\textsuperscript{89} Six of the patients underwent early operation because of recurrent ventricular tachycardia. The long-term results were excellent, with 92\% survival at 5 years. Similar results (low operative mortality, satisfactory 3- to 5-year survival) have been reported by Di Donato and colleagues\textsuperscript{85} and Battaloglu and colleagues.\textsuperscript{86}

LV scars encountered in the operating room during surgery for coronary artery disease may require excision if they clearly contain little muscle and are of important size. Di Donato, Dor, and colleagues have demonstrated comparable improvement in resting ejection fraction in patients with akinetic scars and those with dyskinetic scars (aneurysms) following endoventricular circular patch plasty repair.\textsuperscript{14,84} They and others\textsuperscript{56,81} have postulated that patients with heart failure, previous anterior MI, and LV dilatation or akinesia may benefit from this type of repair as well. Results from a multicenter registry of 1198 patients undergoing endoventricular patch plasty repair indicate a 30-day mortality of 5.3\% (CL 4.6%-6.0\%) and 5-year survival of 69\%.\textsuperscript{84} Among a cohort of the surviving patients, mean LV ejection fraction increased from 30\% ± 11\% to 40\% ± 12\% (P < .001), and mean LV end-systolic volume index decreased from 80 ± 51 mL · m⁻² to 56 ± 34 mL · m⁻². The STICH trial demonstrated comparably low 30-day mortality (6\% in 501 patients having the combined procedure, CL 4.9%-7.3\%) and comparable 5-year survival (67\%).\textsuperscript{85} Mean LV end-systolic volume index decreased from 83 mL · m⁻² to 67 mL · m⁻² (P < .001).

SPECIAL SITUATIONS AND CONTROVERSIES

Intractable Ventricular Tachyarrhythmias

Although intractable ventricular tachyarrhythmias occur in patients with ischemic heart disease in the absence of areas of LV scarring, they are more common in patients with LV aneurysms or extensive fibrosis. However, only a small proportion with LV aneurysms develop intractable ventricular tachycardia.\textsuperscript{89} Most patients in whom such an arrhythmia
develops have poor global LV function, and it has been suggested that ventricular tachyarrhythmias are particularly likely to occur when the ventricular septum has been involved in the infarction. As a corollary, poor LV function and nonresponsiveness to drug therapy for ventricular tachycardia have been identified as risk factors for sudden cardiac death. Management of patients with the combination of LV aneurysm and intractable ventricular tachyarrhythmias is discussed in detail in Section V, “Ventricular Tachycardia and Ventricular Fibrillation in Ischemic Heart Disease,” in Chapter 16.

False Left Ventricular Aneurysm

The aneurysms discussed in this chapter, so-called true aneurysms, are formed by scarring, thinning, and stretching of an infarcted area of LV wall. This process generally produces a wide-mouthed aneurysm. By contrast, a false aneurysm may develop after acute rupture of an infarcted area of LV. Such ruptures are usually fatal, but when the pericardium is sufficiently adherent to the epicardium, rupture may result only in a localized hemopericardium. Persistent communication of the hemopericardium with the LV cavity results in gradual expansion of the hemo-pericardium into a false aneurysm whose wall is composed of pericardium and adhesions and occasionally of myocardium, and whose mouth is usually narrow. These aneurysms have a strong tendency to rupture in contrast to true aneurysms. False aneurysms are much more likely than true aneurysms to occur posteriorly (on the diaphragmatic surface of the LV) or laterally.

Differentiation between true and false aneurysms can be difficult because the imaging characteristics of the two entities are often similar. However, Doppler color flow imaging and transesophageal echocardiography are useful techniques for demonstrating the presence of a false aneurysm.

Resection of an LV false aneurysm is clearly advisable. The resection may pose formidable problems when the aneurysm sac extends anteriorly beneath the sternum. It is then necessary to begin CPB via cannulae introduced into the femoral artery and vein. If the false aneurysm is very large, the patient is cooled to 20°C before the sternum is opened. As soon as possible, the aorta is clamped, cardioplegia induced (see Chapter 3), and the operation begun. The false sac is entered, and blood from this sac is returned to the circuit using cardiotomy suckers. The aneurysmal wall is resected or left alone, and the LV is reconstructed using techniques described earlier in this chapter (see Technique of Operation). When indicated, CABG is also performed.

Postinfarction Left Ventricular Free Wall Rupture

Acute rupture of the free wall of the LV is an infrequent but serious complication of acute MI, occurring in 2% to 4% of patients. Among 1048 patients with acute infarction and cardiogenic shock evaluated in the SHOCK (SHould we emergently revascularize Occluded Coronaries in cardiogenic shock?) trial and registry, free wall rupture or tamponade was present in 28 (2.7%). It is the second most common cause of death following acute infarction (behind acute cardiac failure), accounting for up to 20% of early deaths. Occasionally the rupture is massive, and death quickly results from exsanguination. Cardiac rupture is more often a gradual process, beginning with small areas of endocardial necrosis. These permit formation of hematomas, which gradually dissect through the necrotic myocardium into the pericardium, resulting in tamponade and cardiogenic shock. If rupture is massive (the so-called blowout phenomenon), death occurs suddenly. If it is not, tamponade develops more slowly, allowing time for diagnosis and surgical treatment. Rupture occurs most commonly on the lateral or anteroapical wall of the LV and generally in the middle of the ventricle along the axis from base to apex. Myocardial free wall rupture should be suspected in patients with recent MI who have recurrent or persistent chest pain, hemodynamic instability, syncope, signs of pericardial tamponade, or transient electromechanical dissociation. Diagnosis can be made most expeditiously with echocardiography, which demonstrates a pericardial effusion or pericardial thrombus (Fig. 8-9). Operation is indicated unless the patient is moribund. If the patient is hemodynamically unstable with evidence of tamponade, rapid infusion of fluids and pericardiocentesis may permit stabilization. An intraaortic balloon should be inserted. If the hemodynamic state does not improve, CPB should be established by peripheral cannulation (see

Figure 8-9 Echocardiographic apical two-chamber view of left ventricular (LV) free wall rupture. A, Apical LV expansion with mild pericardial effusion. B, Fifteen hours later, echocardiogram shows apical expansion with an apical fibrotic cap (arrow), and larger pericardial effusion with signs of cardiac tamponade. (From Haddadin and colleagues.)

Chapter 8 Left Ventricular Aneurysm 441
“Cardiopulmonary Bypass Established by Peripheral Cannulation” under Special Situations and Controversies in Section III of Chapter 2). Preoperative coronary angiography is not advisable unless the hemodynamic state is stable. Several techniques have been used for surgical treatment. The traditional approach has involved use of CPB, infarctectomy, and closure of the defect directly with pledged sutures or a polyester patch. More recently, sutureless techniques have been used. Patches of PTFE felt, polyester, or pericardium (autologous or bovine) have been placed over the site of rupture and secured with various glues (gelatin-resorcin-formaldehyde-glutaraldehyde [GRF], fibrin, cyanoacrylate) with or without suturing the patch to the adjacent noninfarcted myocardium. A number of these procedures have been performed without CPB. This technique appears to be particularly valuable when there is no obvious rupture or “blowout” site. CABG can be added to all these procedures when appropriate.

Operative mortality is substantial and is related principally to hemodynamic status at time of operation. Among a group of 66 patients surgically treated by Loiance and colleagues and followed up to 16 years postoperatively, actuarial survival was 44% at 5 years and 26% at 10 years.1,3

Congenital Left Ventricular Aneurysm

Congenital LV aneurysm is a rare malformation characterized by thinning of the myocardium, with layers of myocardial cells intermingled with various amounts of fibrous tissue.3,6 It is usually located at the apex of the LV and has a broad neck.6 This entity differs from a congenital diverticulum of the LV, which is a noncontractile bulging of the LV into the epigastrum.12 The latter is characterized by an elongated shape and a narrow connection with the LV cavity.6 It is also associated with midline thoracic and anterior abdominal defects. Both conditions are rare and have been treated surgically with good results.3,15,58

Traumatic Left Ventricular Aneurysm

Rarely, violent nonpenetrating chest trauma produces such a severe contusion of the heart that a localized aneurysm forms.2,10 Vascular injury and intramyocardial dissection resulting from blunt trauma may also lead to aneurysm formation.5,55 The aneurysm, which is usually well localized and often thin walled, may be detected early after the trauma or several years later.8,17,51 Because of the thin wall and propensity for rupture, a posttraumatic LV aneurysm should be resected whenever possible.

Postinfarction ventricular septal defect (VSD) is an opening in the ventricular septum resulting from rupture of acutely infarcted myocardium.

**HISTORICAL NOTE**

In 1847, Latham first described a postinfarction VSD at autopsy, but it was not until 1923 that Brunn made the diagnosis clinically. In 1957, Cooley and colleagues first reported surgical repair of a postinfarction VSD 11 weeks after myocardial infarction (MI). The patient died 6 weeks later. The first long-term survivor of such repair was reported by the Mayo Clinic in 1963. Approach through the left ventricle (LV) was described in 1969 by Kay and Dubost and subsequently by Kitamura and colleagues, Javid and colleagues, and others. The double-patch method was described by Iben and colleagues and subsequently modified by Gonzalez-Lavin and Zajtchuk and by Daggett and colleagues. Repair of the ruptured septum through a right atrial approach was reported by Filgueira and colleagues in 1986. In 1987, David and colleagues introduced the concept of endocardial patch repair with infarct exclusion using autologous pericardium.

**MORPHOLOGY**

Postinfarction VSD is usually located in the anterior or apical portion of the ventricular septum (=60% of cases) as a result of a transmural anterior MI. About 20% to 40% of patients have a VSD in the posterior portion of the ventricular septum as a result of an inferior MI. Ventricular septal rupture usually occurs as a complication of a first acute MI. Also, a well-developed collateral coronary circulation is uncommon in hearts with a postinfarction VSD. The defect is generally associated with complete occlusion (rather than severe stenosis) of a coronary artery, usually the left anterior descending coronary artery. Important stenoses often coexist in the right coronary artery system. VSDs may be multiple, and rather than occurring simultaneously, they may develop separately several days apart. The importance of concomitant right ventricular (RV) infarction in patients with postinfarction VSD is now evident. For many years, evidence of RV dysfunction was thought simply to represent poor “adaptation” of the RV to the sudden increase in pulmonary blood flow imposed by the postinfarction VSD. Accumulated information indicates that actual infarction of the inferior RV wall, or at least severe ischemia of that area, is responsible for the dysfunction. A posterior VSD, in particular, may be accompanied by mitral valve regurgitation secondary to papillary muscle infarction or ischemia (see Chapter 10). In about 40% of patients who survive the early period after ventricular septal rupture, the remainder of the infarcted septum and adjacent ventricular wall may become aneurysmal.

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

The first sign of ventricular septal rupture in a patient who has recently sustained an MI is development of a pansystolic murmur, usually at the left lower sternal border, with or without radiation to the axilla, and of varying intensity. If the murmur is overlooked or its importance ignored, most patients with ventricular septal rupture die undiagnosed. The chest radiograph provides evidence of pulmonary venous hypertension and increased pulmonary blood flow. A systolic murmur can result from acute mitral regurgitation secondary to MI as well as from postinfarction VSD, and the two conditions may coexist. Thus, after detection of the murmur, an
examination with two-dimensional echocardiography (either transthoracic or transesophageal) with Doppler color flow imaging is performed to define the site of the VSD, quantify the magnitude of left-to-right shunt, and ascertain presence or absence of mitral regurgitation. Echocardiography is highly sensitive and specific and provides safe and rapid diagnosis. It also permits preoperative analysis of wall motion abnormalities in a high percentage of patients.

Magnitude of left-to-right shunt can also be quantified by the Fick principle (see “Whole Body Oxygen Consumption” under Cardiovascular Subsystem in Chapter 5). A pulmonary artery (Swan-Ganz) catheter is introduced at the bedside. Blood samples are obtained from the right atrium, the pulmonary artery, and a peripheral artery. The left-to-right shunt is usually large, with a pulmonary-to-systemic blood flow ratio \((Q_p/Q_s)\) of 2.0 or greater. Both pulmonary artery wedge pressure, reflecting left atrial and LV end-diastolic pressures, and pulmonary artery pressure are usually elevated. Once the presence of a left-to-right shunt is demonstrated and initial management implemented (see “Preoperative Preparation” under Technique of Operation), coronary angiography should be performed if the patient is hemodynamically stable.

Although some patients with postinfarction VSD will do well without addition of invasive studies, there is accumulating evidence that bypass grafting of stenotic coronary arteries supplying the noninfarcted areas of myocardium is associated with improved early and late survival. Multiple-system coronary artery disease is present in more than 50% of patients. If echocardiographic studies have adequately identified the VSD, presence or absence of mitral regurgitation and LV wall motion abnormalities, intracardiac pressure measurements, and left ventriculography are unnecessary.

**NATURAL HISTORY**

Before the advent of thrombolytic therapy and acute percutaneous coronary artery interventions, postinfarction VSD developed in approximately 1% to 3% of patients. Following introduction of these therapeutic interventions, the frequency has been substantially reduced to less than 0.5% of patients. Ventricular septal rupture generally occurs during the first week after acute MI. There is a high incidence in the first day (94% in the GUSTO-I trial); median time for presentation in the SHOCK trial was 16 hours. Without surgical treatment, early death is common; less than 30% of patients survive 2 weeks, and only 10% to 20% survive more than 4 weeks. Risk of death is greatest immediately after myocardial rupture and then gradually declines. Women and the elderly may be more susceptible.

**TECHNIQUE OF OPERATION**

**Preoperative Preparation**

Because most patients with postinfarction VSD are seriously ill and require operation early after septal rupture, their management before operation is of critical importance. Once the diagnosis of acute postinfarction VSD has been confirmed by echocardiography and a pulmonary artery catheter has been inserted, additional diagnostic studies must be considered before proceeding with operation. (The only exception to this is the occasional patient with essentially no systemic hemodynamic disturbance, as described in “Indications for Operation.”) An intraaortic balloon catheter (IABP) should be inserted urgently, because these patients can deteriorate rapidly. If the patient remains hemodynamically unstable, cardiopulmonary bypass (CPB) can be established by peripheral cannulation (see “Cardiopulmonary Bypass Established by Peripheral Cannulation” under Special Situations and Controversies in Section III of Chapter 2). If indicated, the patient is taken immediately to the cardiac catheterization laboratory for special studies (see “Clinical Features and Diagnostic Criteria” earlier in this chapter), with the IABP or CPB in place and functioning. When the studies have been completed, or if they are not performed, operation is undertaken immediately, because permanent improvement is generally not achieved with support devices alone.

**Initial Steps**

After the usual initial preparations in the operating room (see “General Comments and Strategy” in Section III of Chapter 2), a median sternotomy incision is made. The heart
is disturbed as little as possible before CPB is established. While performing the median sternotomy, removal and preparation of saphenous vein is accomplished in the usual manner (see Chapter 7). Because of the length and complexity of the operation, the surgical plan must be efficient so that aortic-clamp and CPB times are kept to a minimum. CPB is promptly established using two venous canulae and caval tapes. If CPB is established percutaneously before or immediately after the patient is brought to the operating room, central cannulation should be performed and CPB established using a pump-oxygenator designed for operating room use. The femoral lines are clamped and removed, and the femoral artery and vein are repaired at the end of the procedure. The aorta is clamped. Myocardial management may include warm induction of cardioplegia and controlled aortic root reperfusion (see “Cold Cardioplegia, Controlled Aortic Root Perfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3). Because an acute coronary occlusion is typically present, the coronary sinus route of administration should be employed for at least part of the cardioplegic infusion (see “Technique of Retrograde Infusion” under Cold Cardioplegia [Multidose] in Chapter 3). The caval tapes are secured. A left atrial venting catheter may be inserted, but usually is not necessary.

Repair of Defect

The VSD is usually approached through the LV. When located anteriorly, it is approached through the anterolateral infarction (or aneurysm) that is generally present (Fig. 9-2, A). The defect in the septum is typically found immediately beneath this area (Fig. 9-2, B). It is repaired using a collagen- or gelatin-impregnated polyester patch or a patch of autologous or bovine pericardium. The patch is made sufficiently large to cover the adjacent intact but infarcted portion of the septum as well as the VSD. No part of the ventricular septum is resected. The patch is sewn into place on the LV side of the septum, with pledgeted mattress sutures placed away from the edge of the defect into noninfarcted myocardium. The sutures are placed close together and the pledgets placed on the RV side of the defect (Fig. 9-2, C). Alternatively, the patch can be sutured into place with a continuous No. 3-0 or 4-0 polypropylene suture, securing the patch to noninfarcted myocardium on the ventricular septum (Fig. 9-2, D). Infarcted or aneurysmal myocardium on the anterolateral wall of the LV is excised, avoiding the anterolateral papillary muscle. If more than a small amount of tissue is removed from the anterolateral wall, it may be necessary to close the defect in the LV wall with a polyester or pericardial patch. If this is not necessary, the incision in the LV is closed with interrupted heavy (No. 0 or 2-0) silk or polyester sutures placed through strips of polytetrafluoroethylene (PTFE) felt and through the patch that has closed the VSD (Fig. 9-2, E). This suture line is reinforced with a continuous suture of No. 0 or 2-0 polypropylene, which is passed through both strips of PTFE felt, both edges of the myocardium, and the ventricular septal patch (Fig. 9-2, F).

An alternative technique involves suturing a pericardial patch to the LV endocardium adjacent to the area of the infarction. The LV is opened through an incision in the infarcted anterolateral wall. An oval patch (approximately 4 × 6 cm) of bovine pericardium is sutured to the endocardium of the inferior portion of the noninfarcted endocardium of the ventricular septum with a continuous No. 3-0 polypropylene suture (Fig. 9-3, A). The suture line is continued into the noninfarcted endocardium of the anterolateral ventricular wall (Fig. 9-3, B). When placing the continuous suture through the transition zones (superiorly and inferiorly) between the septum and the free wall of the LV, care must be taken to anchor the patch securely to the myocardium to prevent residual communications between the LV and RV. Separate interrupted sutures may be required. Once the patch is completely secured to the LV endocardium, the LV cavity is essentially excluded from the infarcted myocardium (Fig. 9-3, C). The ventriculotomy is closed using two strips of bovine pericardium or PTFE felt (Fig. 9-3, D).

When the VSD is in the apical portion of the septum and is associated with an apical MI, the operation consists of amputating the apex of the ventricle, including the involved portion of the ventricular septum (Fig. 9-4, A). The LV is opened through the infarcted myocardium and the septum examined. If the VSD is immediately adjacent to the area of apical infarction, the apex of the heart is excised, including the involved portion of the septum and adjacent RV (Fig. 9-4, B). Using strips of PTFE felt on each side of the septum and on the edges of the right and left ventricular myocardium, heavy mattress sutures of silk or polyester are placed through these four layers of felt as well as through the right and left ventricular myocardium and the ventricular septum (Fig. 9-4, C). These sutures are tied, thus excluding the interventricular communication and the openings into both ventricles. The resulting suture line is reinforced with a continuous No. 0 or 2-0 polypropylene suture (Fig. 9-4, D).

VSDs located in the posterior septum are more difficult to expose and repair. The heart is lifted out of the pericardium with traction on the LV apex. The defect is approached through a vertical incision in the infarcted LV myocardium (Fig. 9-5, A). If the VSD is relatively small, the necrotic tissue can be excised, including the infarcted free wall of both the RV and LV, often with the overlying occluded posterior descending coronary artery (Fig. 9-5, B). The VSD patch (collagen- or gelatin-impregnated polyester or bovine or autologous pericardium) is placed on the LV side of the septum and secured using mattress sutures of No. 2-0 polyester, with pledgets placed on the RV side of the septum (Fig. 9-5, C). If little or no free wall myocardium has been excised, LV and RV edges are approximated, incorporating the septal patch and two strips of PTFE felt. A large defect in the free wall requires a second patch. The free edge of the septal patch is sutured to the free wall of the LV with interrupted mattress sutures of No. 2-0 polyester using pledgets on the patch and a strip of PTFE on the ventricular wall (Fig. 9-5, D). The patch for closure of the RV is attached to the septal patch already in position and to the free wall of the RV. Pledgets of felt are placed on the inner surface of the RV, and a strip of felt is placed on the outer surface (see Fig. 9-5, D).

Muehrcke and colleagues describe an alternative technique for closure of the free wall when there is extensive infarction. No infarcted muscle on the RV or LV free walls is excised. The septal patch is sutured to the RV edge of the incision that was made to expose the septum. This suture line incorporates the infarcted free wall and a patch of polyester placed over the entire infarcted muscle of the free wall (Fig. 9-5, E).
Figure 9-2  Repair of anterior postinfarction ventricular septal defect. A, Incision is made through the anterolateral infarcted myocardium that is usually present or, if some weeks have elapsed, through the scar or aneurysm that has formed. B, Defect is located immediately beneath incision. C, If interrupted sutures are used, the patch is sewn into place on left ventricular (LV) side of septum, with pledged mattress sutures placed away from the edge of the defect into noninfarcted myocardium (dashed line). Sutures are placed close together, and pledgets are placed on the right ventricular side of the defect. Key: APM, Anterior papillary muscle; LV, left ventricle; RV, right ventricle; VSD, ventricular septal defect.
If a continuous suture technique is used, the patch is sutured to noninfarcted myocardium on the ventricular septum adjacent to the area of infarction using a No. 3-0 or 4-0 polypropylene suture. If patch repair of anterolateral wall is not required, the incision in the LV is closed with interrupted heavy silk or polyester sutures placed through strips of polytetrafluoroethylene (PTFE) felt, edges of the myocardium, and patch that has closed the ventricular septal defect. Suture line is reinforced with a continuous suture of No. 0 or 2-0 polypropylene, which is passed through both strips of PTFE felt, both edges of the myocardium, and ventricular septal patch.
Figure 9-3  Infarct exclusion technique with endocardial patch for repair of anterior postinfarction ventricular septal defect. **A,** Left ventricle (LV) is entered through an incision in the infarcted anterolateral wall. An oval patch of bovine pericardium is sutured to the endocardium of the posterior, noninfarcted portion of the ventricular septum with a continuous No. 3-0 polypropylene suture. **B,** Suture line is continued into the noninfarcted endocardium of the anterolateral ventricular wall.

*Continued*  

---

*Continued*  

---
Pledged sutures are placed circumferentially around the area of infarcted muscle and through the polyester patch, then tied over a strip of PTFE felt (Fig. 9-5, F).

The technique developed by David and colleagues involves an incision in the inferior wall of the LV parallel to the posterior descending coronary artery. The traction sutures are placed on the edges of the ventriculotomy to facilitate exposure (Fig. 9-6, A). The VSD is identified, and a triangular patch of bovine pericardium approximately 4 × 7 cm is sutured first to the fibrous anulus of the mitral valve using a continuous No. 3-0 polypropylene suture. The medial margin of the patch is sutured to noninfarcted muscle of the septum adjacent to the defect (Fig. 9-6, B). The lateral edge of the patch is then sutured to the endocardium of the LV free wall adjacent to the posterior papillary muscle (Fig. 9-6, C). This excludes all infarcted muscle from the LV cavity (Fig. 9-6, D). The ventriculotomy is closed with two layers of sutures buttressed with strips of bovine pericardium or PTFE felt (Fig. 9-6, E).

Associated Procedures

Occasionally, mitral regurgitation may be associated with acute septal rupture, particularly when the infarction is posterior. The mitral valve is replaced (or occasionally repaired) under such circumstances. Replacement is usually best performed through the left ventriculotomy, using interrupted pledged mattress sutures with the pledgets on the atrial side of the anulus. It can also be replaced (or repaired) through a left atrial or biatrial incision (see Chapter 10).

When an LV aneurysm coexists with a postinfarction VSD, it is excised as the initial step in the operation. Then after repair of the VSD, the aneurysm is generally repaired as usual (see Chapter 8). However, improvisation in the repair may be necessary. Rarely, patients with postinfarction VSD are also found to have free wall rupture of the infarct. In surgical

Completion

An essential part of the operation is controlled aortic root reperfusion (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3). During this maneuver, all suture lines are examined. Additional measures are used, if necessary, to establish hemostasis. The remainder of the operation is completed in the usual manner (see “Completing Operation” in Section III of Chapter 2). Particular care is taken to achieve hemostasis. Two right atrial and two RV temporary pacing wires are placed so that atrioventricular sequential pacing can be established, if needed. IABP is resumed during the rewarming phase of CPB and usually is continued into the postoperative period. If CPB cannot be discontinued after about 30 minutes of normothermic partial CPB, temporary ventricular assistance may be required (see “Temporary Ventricular Assistance” in Chapter 5).

SPECIAL FEATURES OF POSTOPERATIVE CARE

Postoperative care is conducted as described in Chapter 5. IABP is continued in a one-to-one mode until cardiac output is adequate; it is then gradually discontinued and the balloon catheter removed. If ventricular assist devices are in place, flow through them is gradually decreased as ventricular function and cardiac output improve (see “Temporary Ventricular Assistance” in Chapter 5). Because patients are often critically
Figure 9-5 Repair of posterior postinfarction ventricular septal defect (VSD). A, Heart is lifted out of pericardial cavity, and VSD is approached through a vertical incision in infarcted left ventricular myocardium. B, Infarcted tissue (right ventricle [RV], left ventricle [LV], and septum) is excised. Dashed lines indicate limits of excision. C, Septal patch is placed on LV side of septum and secured using polyester mattress sutures, with pledgets placed on RV side of septum.

Continued
ill during the early postoperative period, with low cardiac output and often with complicating arrhythmias, a full therapeutic regimen is usually required. This includes optimizing preload with infusion (or removal) of volume, enhancing contractility with inotropic agents, and reducing afterload, if indicated. Attaining a heart rate that results in optimal cardiac output by pacing or pharmacologic agents is also important. Using the technique described earlier under “Clinical Features and Diagnostic Criteria,” measurements are made to detect residual shunt, which can be present because of friability of the septum and relative insecurity of the repair. Transesophageal echocardiography is also useful for this purpose. If the $\frac{Q_p}{Q_s}$ is 1.5 to 2.0 or greater and the hemodynamic state is poor, prompt reoperation should be considered.

Care required late postoperatively by patients undergoing isolated CABG should be applied to those who have undergone repair of a postinfarction VSD (see “Special Features of Postoperative Care” in Chapter 7).

Chapter 9 Postinfarction Ventricular Septal Defect

Time-Related Survival

Time-related survival after repair of postinfarction VSD is less than optimal. In large series of patients with long-term follow-up, 5-year survival ranged from 44% to 57% and 10-year survival from 29% to 36% \(^{(D5,D8,D9,J2,L4,M7)}\) (Fig. 9-7, A). The hazard function for death after repair of postinfarction VSD has not only a high and rapidly declining early phase, but also an appreciable constant phase that is approximately five times greater than that after isolated CABG (Fig. 9-7, B).

RESULTS

Early (Hospital) Death

Hospital mortality after VSD repair is approximately 30% to 40% \(^{(A3,A4,D5,D8,D9,E1,J2,L4,M7,P1,P3)}\). Death may be difficult to prevent because of the extent of myocardial necrosis associated with rupture of the ventricular septum. However, mortality might be reduced by prompt surgical repair, better methods of myocardial management, and more aggressive use of ventricular assistance in the postoperative period.

Figure 9-6, cont’d  

C, Lateral edge of patch is next sutured to endocardium of the LV free wall adjacent to posterior papillary muscle. 

D, This technique excludes all infarcted muscle from LV cavity. 

E, LV is closed with two layers of sutures buttressed with strips of bovine pericardium or polytetrafluoroethylene (PTFE) felt.
Modes of Death

The mode of death in more than half and up to 90% of patients dying early after operation for postinfarction VSD is cardiac failure. This relatively high prevalence is related to extensive MI, complexity of operation, and preoperative organ system dysfunction. Bleeding, sepsis, stroke, gastrointestinal bleeding, and recurrent VSD are other modes of early death. Cardiac failure is also the most common mode of late death. Other modes of late death include sudden death, stroke, sepsis, and MI.

Incremental Risk Factors for Death

Mortality is influenced by several factors that have been identified by a number of multivariable analyses. From these and other studies in the literature, and from knowledge of the risk factors for death and other adverse outcomes in patients with ischemic heart disease (see “Results” in Chapter 7), some inferences can be made. The most important risk factors for death in the early hazard phase are poor hemodynamic state (cardiogenic shock) at operation and acute RV dysfunction (Fig. 9-8). Amount and distribution of myocardial necrosis and scar are responsible for both factors. Poor hemodynamics becomes an even more severe risk factor when present for many hours before surgical intervention. Operation early after rupture of the septum typically carries a higher risk than that undertaken many days or weeks later, principally because of the high prevalence of hemodynamic instability and extensive myocardial necrosis. RV dysfunction results from ischemic injury or frank infarction of the RV and thus is more likely to be present when stenosis or occlusion in the right coronary artery system is located proximally. RV dysfunction may also occur after anterior MI. The higher mortality associated with repair of defects located inferiorly in the septum reported in some series probably relates to the higher prevalence of important right coronary stenosis and RV dysfunction in this group. Mortality may also be related to the greater complexity of posterior repairs and to more frequent involvement of the mitral valve. Severity and distribution of coronary artery disease are also risk factors, but are overshadowed by the patient’s hemodynamic status at operation and amount of damaged myocardium. Comorbidities such as older age at operation, diabetes, and preinfarction hypertension are likely risk factors for death in the early and constant hazard phases. The relatively small number of patients in most reported series has made identification of these and other factors difficult.

Functional Status

The functional status of most patients surviving the period of hospitalization is good. The majority of patients (70% to 95%) are in New York Heart Association (NYHA) functional class I or II.

Residual and Recurrent Defect

A residual VSD has been noted early or late postoperatively in 3% to 40% of patients. Residual VSD may be caused by (1) reopening of a closed defect, (2) presence of an overlooked VSD, or (3) development of a new VSD during the early postoperative period. Reoperation is required for closure of such residual defects when Qp/Qs is greater than 1.
INDICATIONS FOR OPERATION

Postinfarction VSD is almost always an indication for operation, because it produces a large left-to-right shunt and outcome without intervention is extremely poor.

A persisting question is the timing of operation. Repair of postinfarction VSD 2 to 3 weeks or more after septal rupture is relatively safe. By then, edges of the defect have become more fibrotic, and repair is more securely and safely accomplished. Therefore, when the patient presents with satisfactory hemodynamics, repair can be delayed, but there must be a high degree of certainty that the hemodynamics will remain stable. Criteria for deferment include (1) adequate cardiac output, with no evidence of cardiogenic shock; (2) absence of symptoms of pulmonary venous hypertension, or easy control of initial symptoms with appropriate drug therapy; (3) absence of fluid retention, or easy control by diuretics; and (4) adequate renal function, with stable blood urea nitrogen (BUN) and creatinine levels. The natural history of postinfarction VSD suggests that such circumstances are uncommon.

In the vast majority of patients, septal rupture rapidly leads to deteriorating hemodynamics with cardiogenic shock, marked and intractable symptoms of pulmonary venous hypertension, and fluid retention. Immediate study and urgent operation are then indicated. Even if these signs and symptoms are absent and renal function deteriorates, as evidenced by rising BUN and creatinine levels, surgical intervention should be promptly undertaken. The increased risk of early repair is accepted because of the high risk of death without operation.

Delayed detection and referral for surgical treatment of seriously ill patients may make recovery so unlikely that it is appropriate to allow the natural history of the disease to unfold without surgical intervention. For example, the surgeon might see a patient only after profound cardiogenic shock has led to neurologic unresponsiveness, ischemic compromise of a limb or the bowel, or severe impairment of renal function with anuria or greatly elevated BUN and creatinine levels.

SPECIAL SITUATIONS AND CONTROVERSIES

Repair of Defect Through a Right Atrial Approach

Repair of postinfarction VSD can be accomplished through a right atrial or bialtral approach. The potential advantage of this technique is that an incision in the LV myocardium is avoided. Experience with this procedure is limited. Massetti and colleagues have reported one of the larger series (12 patients). There were three early deaths (25%) and one late death. One patient required reoperation for a residual defect 3 months postoperatively, and one had a small residual left-to-right shunt. Of the eight surviving patients who were followed for a mean of 5 years, three were in NYHA functional class I, four in class II, and one in class III.

Percutaneous Closure of Defect

Percutaneous techniques have been used successfully to close congenital VSDs (see “Percutaneous Closure of Ventricular Septal Defects” under Special Situations and Controversies in Section I of Chapter 35). Lock and colleagues achieved successful percutaneous transcatheter closure of postinfarction VSDs in four patients with cardiogenic shock using the Rashkind double-umbrella device. The device emboled to the pulmonary artery in one patient, and the remaining three patients died with evidence of increased shunting across the defect over the ensuing several days. A Rashkind patent ductus arteriosus occluder system has also been used.

Balloon catheters, which are inserted through the LV via the aorta or through the RV and then inflated, and other occluders have been successful in temporarily reducing or eliminating the left-to-right shunt, thereby improving hemodynamic status and permitting a delay in surgical treatment. Percutaneous devices have also been used to close residual septal defects after open repair. Wider use of these or other minimally invasive techniques could substantially improve outcome.

Use of percutaneous closure as the definitive treatment for postinfarction VSD has been reported by Maltais and colleagues using the Amplatzer septal occluder device. Early mortality was 42% among 12 patients. One patient (8%) had a residual septal defect.

Postoperative Mechanical Circulatory Support

Mechanical circulatory support following surgical repair of postinfarction VSD should be considered for patients who cannot be weaned from CPB with maximal inotropic and IABP support (see “Temporary Ventricular Assistance” in Chapter 5).}

10 Mitral Regurgitation from Ischemic Heart Disease

**Definition** 462

Mitral regurgitation due to ischemic heart disease (ischemic mitral regurgitation) is mitral regurgitation caused by ischemic heart disease. This entity must not be confused with mitral regurgitation from other causes that coexist with ischemic heart disease.

**Historical Note** 462

Mitral regurgitation resulting from rupture of a papillary muscle has been long recognized as a rare and frequently catastrophic complication of acute myocardial infarction (MI). A case was identified at autopsy at Johns Hopkins Hospital in 1935, but apparently the diagnosis was first made antemortem in 1948. Mitral regurgitation without papillary muscle rupture, occurring as an acute or chronic complication of ischemic heart disease with or without MI, was described in 1963 by Burch and colleagues. These authors referred to this type of ischemic mitral regurgitation as “papillary muscle dysfunction,” the presence of which was surmised rather than proved. The first successful surgical correction of papillary muscle rupture was reported by Austen and colleagues at Massachusetts General Hospital in 1965. Surgeons at Massachusetts General were also among the first to replace the mitral valve for ischemic mitral regurgitation, beginning in 1970.

DEFINITION

Mitral regurgitation due to ischemic heart disease (ischemic mitral regurgitation) is mitral regurgitation caused by ischemic heart disease. This entity must not be confused with mitral regurgitation from other causes that coexist with ischemic heart disease.

HISTORICAL NOTE

Mitral regurgitation resulting from rupture of a papillary muscle has been long recognized as a rare and frequently catastrophic complication of acute myocardial infarction (MI). A case was identified at autopsy at Johns Hopkins Hospital in 1935, but apparently the diagnosis was first made antemortem in 1948. Mitral regurgitation without papillary muscle rupture, occurring as an acute or chronic complication of ischemic heart disease with or without MI, was described in 1963 by Burch and colleagues. These authors referred to this type of ischemic mitral regurgitation as “papillary muscle dysfunction,” the presence of which was surmised rather than proved. The first successful surgical correction of papillary muscle rupture was reported by Austen and colleagues at Massachusetts General Hospital in 1965. Surgeons at Massachusetts General were also among the first to replace the mitral valve for ischemic mitral regurgitation, beginning in 1970.

MORPHOLOGY

Acute Mitral Regurgitation Complicating Myocardial Infarction

Rupture of Papillary Muscle

Rupture of a papillary muscle occurs as an acute complication of MI, but its prevalence among patients with acute mitral regurgitation in the early stages of infarction is uncertain. About half of these patients have an actual rupture. About one third of patients with rupture may have a complete disruption of the papillary muscle, resulting in flailing of both the anterior and the posterior mitral leaflets. About two thirds of patients have rupture of one or more heads of the papillary muscle rather than a complete rupture of the entire muscle. The posteromedial papillary muscle is ruptured in about 75% of patients and the anterolateral muscle in about 25%. Correspondingly, most patients with acute mitral regurgitation resulting from MI have an inferoposterior left ventricular (LV) infarction. Also, at least in the study of Coma-Canella and colleagues, many have coexisting right ventricular infarction. Regardless, when the LV infarction is located inferoposteriorly rather than anterolaterally, the reason for more frequent rupture of the adjacent papillary muscle is not clear. The difference in collateral circulation to the two areas may play a role. The size and nature of the coexisting acute LV infarction vary, perhaps because of the...
small number of cases in most series. Nishimura and colleagues reported that the infarction is often small, whereas Barbour and colleagues found infarction in more than 20% of the LV wall and septum in the majority of patients. The infarction may be subendocardial or transmural.

Occasionally, papillary muscle rupture is associated with rupture of the ventricular septum as well as with rupture of the free wall of the LV.

Papillary Muscle Necrosis without Rupture

About half the patients who develop severe mitral regurgitation during acute MI do not have papillary muscle rupture, only papillary muscle necrosis. Papillary muscle dysfunction may contribute to resultant mitral regurgitation. However, contiguous MI probably plays a more important role. The distribution of necrotic changes and extent of MI are similar to those described for papillary muscle rupture.

Other Causes

Mitral regurgitation is a frequent complication of acute MI. When Doppler echocardiography is used for diagnosis, mitral regurgitation has been detected in up to 39% of patients early after an infarction. Substantial (moderate or severe) mitral regurgitation is present in 3% to 19% of patients and is an important predictor of mortality. Because papillary muscle rupture or necrosis occurs infrequently after acute infarction, other important causes of mitral regurgitation include (1) changes in configuration of the LV (remodeling), (2) global or segmental LV dysfunction, and (3) changes in function of the mitral valve resulting from leaflet prolapse, abnormal closure, or anular dilatation. Although papillary muscle dysfunction has been implicated as an important cause of ischemic mitral regurgitation, experimental and clinical studies employing two-dimensional (2D) echocardiography have demonstrated that it rarely is causative. LV systolic dysfunction, increased LV chamber sphericity, and regional asynergy of the inferoposterolateral wall overlying the posterior papillary muscle may be important determinants of developing mitral regurgitation. Van Dantzig and colleagues found that changes in the mitral valve anulus and leaflets were of limited importance in the pathogenesis of ischemic mitral regurgitation early after MI. Thus, although there is often no apparent structural abnormality of the mitral valve, changes in configuration and contractile function of the LV after an acute infarction prevent adequate coaptation of the leaflets and result in mitral regurgitation.

Chronic Mitral Regurgitation from Ischemic Heart Disease

Many patients with ischemic heart disease and chronic mitral regurgitation have coexisting mitral regurgitation caused by rheumatic fever, myxomatous degeneration, or other conditions. At operation, distinction between mitral regurgitation coexisting with ischemic heart disease and that caused by ischemic heart disease can be difficult because papillary muscle scarring or fibrosis is not always the result of earlier necrosis or adjacent MI. Chronic regurgitation through the mitral valve apparatus does follow acute MI in some patients. Causes include underlying papillary muscle ischemic dysfunction, papillary muscle scarring and shortening or even lengthening, previous rupture of a portion of the papillary muscle, asynergy of the adjacent LV wall, and LV remodeling, all of which can result from an earlier MI. Chronic regurgitation may also occur through the central part of the valve. This can result from restricted leaflet motion with increased leaflet tethering (Figs. 10-2 and 10-3) and from anular dilatation secondary to ischemic LV dysfunction. Severity and degree of the dysfunction may vary over time according to the degree of remodeling (increased sphericity) that occurs in the individual patient after infarction.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Acute Mitral Regurgitation Complicating Myocardial Infarction

Papillary muscle rupture presents as an acute event within a few hours to 14 days after an MI in 1% to 3% of patients. The onset is usually characterized by pulmonary edema, hypotension, or both, typically 2 to 7 days after acute infarction.

Rupture is signaled by worsening of the patient’s clinical condition. Profound shock indicates gross mitral regurgitation from total rupture; less severe signs suggest less severe mitral regurgitation from partial rupture or LV dysfunction. A new apical systolic murmur can be heard provided cardiac output is adequate and the regurgitation is not severe. The murmur is frequently absent in total rupture and usually present in partial rupture. An apical third heart sound is common, and pulmonary edema is often seen on chest radiography. The heart is usually normal in size or only slightly enlarged, and the left atrium is small.

A pulmonary artery (Swan-Ganz) catheter can provide important information (e.g., excluding the presence of left-to-right shunting) and, when it is in the pulmonary artery wedge position, may demonstrate a prominent v wave on the pressure tracing. Echocardiography (2D or transesophageal) is a valuable diagnostic tool in mitral regurgitation associated with MI. It is used to differentiate between papillary muscle rupture and LV dysfunction. In the latter condition, extensive wall motion abnormalities are usually present. With papillary muscle rupture, the mitral leaflet becomes flail and prolapses into the left atrium during systole. The ruptured portion of the muscle may be directly visualized as a separate mass attached to the chordae.
performed to confirm the diagnosis of mitral regurgitation (or ventricular septal defect or occasionally both) and to define areas of impaired LV contraction or aneurysm formation. In critically ill patients, however, left ventriculography is unnecessary when precatheterization studies have established the diagnosis and only coronary angiography is performed. When the patient is seriously ill, an intraaortic balloon pump (IABP) should be used. If the patient’s hemodynamic state remains unstable, cardiopulmonary bypass (CPB) can be established using a percutaneous technique (see “Cardiopulmonary Bypass Established by Peripheral Cannulation” under Special Situations and Controversies in Section III of Chapter 2). These devices can be left in place until cardiac catheterization is completed and the patient is taken to the operating room.

**Chronic Mitral Regurgitation from Ischemic Heart Disease**

Usually the patient presents with gradually increasing mitral regurgitation. When the murmur dates from an MI, an ischemic etiology is assumed. There may be cardiac enlargement, including left atrial enlargement, hypokinesia, and akinesia at the infarction site. An LV aneurysm may coexist (see Chapter 8). Positron emission tomography (PET) or dobutamine echocardiography may reveal chronically ischemic, hibernating myocardium that may respond to increased blood flow from coronary artery bypass grafting (CABG) alone. Gadolinium contrast-enhanced cardiovascular magnetic resonance reveals myocardial scarring, and if the posterior papillary muscle is extensively scarred (nonviable), mitral annuloplasty may be insufficient to eliminate ischemic mitral regurgitation. Other diagnostic criteria are the same as for other types of chronic mitral regurgitation (see Chapter 11).

**NATURAL HISTORY**

**Acute Mitral Regurgitation Complicating Myocardial Infarction**

Rupture of a papillary muscle is an uncommon complication of acute MI and currently is probably even less common, given the widespread use of thrombolytic and percutaneous interventional therapy for acute infarction. It is, however, a life-threatening complication, with only about 25% of patients treated nonsurgically surviving more than 24 hours after total rupture. Survival after partial papillary rupture is better; more than 70% of patients survive the first 24 hours, and about 50% survive more than 1 month. They are then considered to have chronic mitral regurgitation.
When the papillary muscle remains intact, the natural history of acute mitral regurgitation is less well defined. As previously noted, however, moderate or severe mitral regurgitation in the absence of papillary muscle rupture is present in 3% to 19% of patients early after an acute infarction and is an important predictor of mortality.\(^{1,14,15,15,15}\) Using multivariable analysis, Lehmann and colleagues found that mitral regurgitation of any degree (as detected by left ventriculography) was a predictor of cardiovascular mortality at 1 year (relative risk 7.5; CI 2%-29%; \(P = .0008\)).\(^{1,16}\) In the study of Lamas and colleagues, cardiovascular mortality during 3\(^1/2\) years of follow-up was also higher in patients who developed mitral regurgitation early after acute infarction than in those who did not (29% vs. 12%; \(P < .001\)).\(^{1,17}\) Grigioni and colleagues observed a direct and significant correlation between severity of mitral regurgitation as determined by echocardiography and long-term survival\(^{1,18}\) (see Fig. 10-1). They also observed that mitral regurgitation predicts mortality in excess of that anticipated on the basis of patient characteristics and degree of LV dysfunction.

Chronic Mitral Regurgitation from Ischemic Heart Disease

Mild or moderate mitral regurgitation without papillary muscle rupture is episodic in some patients, presumably a result of changing prevalence and distribution of ischemic myocardium, loading characteristics of the LV, and variations in LV function.\(^{1,14}\) Persistent and severe mitral regurgitation, often associated with moderate or severe LV dysfunction, worsens the prognosis for patients with poor LV function.\(^{1,15}\) Furthermore, increasing severity of mitral regurgitation has an increasingly adverse effect on survival, regardless of type of treatment\(^ {1,18,1,15,1,14,1,12}\) (Fig. 10-4).

TECHNIQUE OF OPERATION

Acute Mitral Regurgitation Complicating Myocardial Infarction

In critically ill patients with this complication of acute MI, IABP is begun as soon as the condition is recognized,\(^{1,13}\) or CPB is established by percutaneous technique if indicated (see “Cardiopulmonary Bypass Established by Peripheral Cannulation” under Special Situations and Controversies in Section III of Chapter 2). In the operating room, the patient is prepared and draped for CABG; the sternotomy, graft preparation, and preparation for CPB are expeditiously accomplished. CPB is established using two venous cannulae. If CPB was established percutaneously before bringing the patient to the operating room, the cannulations just described should be made and CPB established by a pump-oxygenator designed for use in the operating room. The peripheral lines are clamped but left in place. These cannulae are removed in the operating room at the end of the cardiac procedure.

Myocardial management may include warm induction of cardioplegia and controlled aortic root reperfusion (see “Cold Cardioplegia, Controlled Aortic Root Perfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3). Because an acute coronary occlusion is typically present, the coronary sinus route of administration should be employed for part of the cardioplegic infusion (see “Technique of Retrograde Infusion” under Cold Cardioplegia [Multidose] in Chapter 3). The distal anastomoses of the bypass grafts are performed before the mitral valve is repaired or replaced to avoid retracting the heart after a mitral prosthesis (valve or ring) has been inserted and thus prevent possible rupture of an area of infarcted LV.\(^{1,11}\) The proximal anastomoses of the grafts can be performed either immediately after completing the distal anastomoses and before opening the left atrium, or after closing the left atrium. If the left atrium has been closed, these anastomoses can be performed with the aorta still occluded or after removing the aortic clamp and placing a partially occluding clamp on the aorta while rewarming is completed.

The approach to the mitral valve is generally through the left atrium, although an approach through the right atrium may be useful (see “Approach Across the Atrial Septum” under Special Situations and Controversies in Chapter 11). With acute total papillary muscle rupture, the mitral valve is replaced with a mechanical prosthesis or bioprosthesis. Because the mitral annular tissue is usually not thickened and may be more friable than normal, great care must be taken to (1) obtain adequate bites of tissue when placing the annular sutures and (2) avoid excessive traction on these sutures as the valve is lowered into position, to prevent them from pulling through the tissue. Pledged mattress or nonpledgeted simple interrupted sutures are preferred.

When the papillary muscle is not ruptured and the chordal mechanism is intact, or if only one head is ruptured and there is annular dilatation, reparative techniques and anuloplasty with or without use of an anuloplasty ring are preferable to valve replacement\(^ {1,15,1,3}\) (see “Mitral Regurgitation Repair” under Technique of Operation in Chapter 11). If an anuloplasty ring or band is inserted, it is probably preferable to use one that is smaller than the sizer that fits the annulus. After CPB is discontinued and with cannulae still in place, competence of the valve is assessed, preferably by transesophageal echocardiography (TEE). Left atrial pressure should be at least 15 mmHg and systolic arterial pressure above 120 to 130 mmHg during the assessment. If the valve is not competent, CPB is reestablished, cardioplegia is reinfused, and the valve is either repaired again or replaced. The remainder of the operation is completed as usual. An IABP or temporary ventricular assistance may be needed (see “Treatment of Low
Cardiac Output” under Cardiovascular Subsystem in Section I of Chapter 5).

Chronic Mitral Regurgitation from Ischemic Heart Disease

The techniques of repair and replacement of the chronically regurgitant mitral valve are described under “Technique of Operation” in Chapter 11. Difficulties in intraoperative decision making result from (1) time-related variability in the magnitude of regurgitation caused by ischemic heart disease, (2) uncertainty about the precise morphologic basis of the regurgitation, and (3) frequency with which regurgitation is associated with poor LV function. These considerations require careful evaluation of regurgitation and need for mitral repair or replacement preoperatively, in the operating room before CPB is established, after repair while CPB is still in place, and after CPB is discontinued.

Evaluation includes careful assessment of the intraoperative TEE, visual examination of the morphology of the valve, and identification of the location and magnitude of the regurgitation. Identifying the location and assessing the magnitude of regurgitation are accomplished by TEE, recognizing that this technique may overestimate or underestimate the degree of regurgitation (see Fig. 10-2). When the circulation is intact, echocardiographic assessments should be made with left atrial pressure at least 12 to 15 mmHg and systolic pressure above 120 to 130 mmHg.

On direct visualization of the valve, diagnosis of an ischemic etiology for regurgitation is generally made by exclusion. The anulus appears normal or is only slightly dilated. The leaflets are usually normal in appearance, and the chordae tendineae are usually not shortened or elongated. The papillary muscles may be pale, scarred, or normal in appearance. In this setting, repair of the valve with some form of annuloplasty is usually possible (see Chapter 11). When regurgitation is severe both preoperatively and intraoperatively and dominates the clinical picture, mitral repair or replacement is indicated. When severity of regurgitation is variable preoperatively and variable and no more than moderate intraoperatively (particularly when severity lessens after the CABG portion of the operation is completed), and signs and symptoms of myocardial ischemia are dominant, the mitral valve may be left alone. However, this recommendation is controversial. Intermediate situations demand individual intraoperative decision making.

When a repair is performed, the functional status of the mitral valve is evaluated by TEE after discontinuing CPB, with the cannulae still in place and with the systolic arterial pressure above 120 to 130 mmHg. If the hemodynamic situation or the repair is unsatisfactory, CPB can be reestablished and the mitral valve repaired again or replaced. If mitral replacement is necessary, every effort should be made to preserve the chordae tendineae to the posterior leaflet or to both leaflets.

**SPECIAL FEATURES OF POSTOPERATIVE CARE**

The usual management protocols are followed (see Chapter 5). Because patients with mitral regurgitation from ischemic heart disease are apt to have low cardiac output postoperatively, catecholamine support and IABP are required more often than after other procedures.

**RESULTS**

**Early (Hospital) Death**

**Acute Mitral Regurgitation Complicating Myocardial Infarction**

Because of the rarity of the condition, only a few surgical series have been reported. Among those with the largest numbers of patients (between 21 and 55), early mortality ranged from 18% to 22%. For patients without rupture of a papillary muscle who require operation for ischemic mitral regurgitation, hospital mortality is substantial, particularly for patients in cardiogenic shock. With use of appropriate myocardial management (see “Technique of Operation”), early mortality should depend primarily on extent of MI. Chevalier and colleagues and Russo and colleagues reported lower early operative mortality among patients who had concomitant CABG. This supports the earlier observation of Hickey and colleagues that early reperfusion of ischemic myocardium in this setting is beneficial.

**Chronic Mitral Regurgitation from Ischemic Heart Disease**

Recent experience indicates that hospital mortality for patients with chronic ischemic mitral regurgitation who undergo valve repair or replacement, usually in combination with CABG, and who are not in cardiogenic shock, is approximately 3% to 11%. Incremental risk factors for increased hospital mortality include low ejection fraction, extensive coronary artery disease, advanced age, renal disease, lower hematocrit, LV end-diastolic dimension greater than 65 mm, longer CPB time, and need for inotropic support. Among patients who had concomitant CABG, hospital mortality in several large series has not been consistently lower among patients who underwent repair. Concomitant procedures such as LV aneurysmectomy may be associated with increased hospital mortality.

**Time-Related Survival**

When the operation is done acutely for rupture of papillary muscle, late results are favorable. In three of the largest reported series, despite substantial early mortality, 5-year survival was 68%, 65%, and 65%. In the largest reported series (54 patients from Mayo Clinic), 5-year survival was 65 ± 7%, and survival free of heart failure was 52 ± 7% (Fig. 10-5). In this study, 5-year survival of 30-day operative survivors was 79 ± 4%, identical (P = .2) to that of matched controls with MI but without rupture of the papillary muscle. Survival free of heart failure was also similar (10-year survival, 28 ± 8% vs. 36 ± 6%; P = .5).

Overall survival after CABG, including hospital mortality, is distinctly poorer in patients with ischemic mitral regurgitation than in those without it. Also, survival after CABG plus mitral valve replacement or repair is poorer when the regurgitation is ischemic in origin rather than rheumatic or degenerative. These differences probably relate to more LV dysfunction in patients with ischemic mitral regurgitation. Nonetheless, survival of patients with chronic ischemic mitral regurgitation who are treated surgically is better than that of those treated medically.
Risk factors for poor outcomes in patients with ischemic heart disease in general apply to this group as well (see Chapter 7).

Addition of LV aneurysmectomy to the procedure adversely affects long-term survival. Miller and colleagues found poor late results in this group, with only 35% (CL 4%-25%) of hospital survivors alive 3 years later. In a longer experience with valve replacement as an isolated or combined procedure, Karp and colleagues found that preoperative LV aneurysm was a significant incremental risk factor for premature late death.

In the study of Hickey and colleagues, mitral valve repair was associated with better long-term survival than mitral valve replacement. In a more recent nonrandomized study of surgery for ischemic mitral regurgitation, however, Hausmann and colleagues observed similar early and late survival among 197 patients treated by mitral valve replacement and 140 patients treated by mitral valve repair. Seven-year survival was 67% and 62%, respectively, although it was better among patients who had no or minimal mitral regurgitation after the repair (77% at 7 years) than among those who had more extensive regurgitation or mitral valve replacement.

Gillinov and colleagues, using propensity analysis and multivariable hazard function regression, observed that in patients with ischemic mitral regurgitation who were not at high risk (younger age, lower New York Heart Association [NYHA] functional class, fewer wall motion abnormalities, no renal dysfunction), mitral valve repair was associated with higher survival at 5 years (58%) than was valve replacement (36%) (P = .08). There was no survival benefit for mitral valve repair among higher-risk patients. A randomized trial of valve repair vs. valve replacement for patients with severe chronic ischemic mitral regurgitation is ongoing (2010) in the National Heart, Lung, and Blood Institute (NHLBI)-sponsored Cardiothoracic Surgery Network. A concurrent randomized trial of CABG alone vs. CABG plus mitral anuloplasty for moderate chronic ischemic mitral regurgitation is ongoing as well.

INdICATIONS FOR OPERATION

When a patient with an acute MI suddenly develops acute mitral regurgitation, operation is advisable, recognizing that hospital mortality under such circumstances may be substantial. As with acute rupture of the ventricular septum (see Chapter 9), operation should be done before severe hemodynamic deterioration occurs. When the hemodynamic state is stable, one strategy has been to delay operation about 2 weeks to 2 months. However, Nishimura and colleagues reported sudden deterioration followed by death in five patients whose condition had initially stabilized with medical therapy. Therefore, all patients with papillary muscle rupture complicating acute MI should have prompt investigation and operation. Operation should be avoided only when the patient is moribund.

When chronic mitral regurgitation results from ischemic heart disease, indications for operation are less well defined. Infrequently, and particularly when it develops acutely from partial rupture of a papillary muscle after MI, mitral regurgitation dominates the clinical picture and causes the symptoms and disability. Then the decision for operation on the mitral valve is straightforward and based on the usual indications (see Chapter 11). Concomitant CABG is performed if indicated. More often, however, patients with usual symptoms of ischemic heart disease requiring CABG have some signs of...
LV failure and clinical and angiographic evidence of mitral regurgitation. As already mentioned, the degree of regurgitation may fluctuate, but it may be constant and moderate or severe. In the latter circumstance, mitral valve repair or replacement is indicated.

When the severity of regurgitation varies over time, it is more difficult to know when mitral valve surgery should be done at the time of CABG. The effect of CABG alone on this form of mitral regurgitation is not known with certainty. If mitral regurgitation is at least moderate (grade 3 or more on a scale of 1 to 6), however, as determined by intraoperative TEE, and under the appropriate loading conditions, mitral repair or replacement is usually indicated (see “Technique of Operation”). If mitral regurgitation is severe in patients with a low ejection fraction (10%-20%), mitral valve replacement rather than repair may be preferable, because persistent mitral regurgitation after repair is associated with substantial early and late mortality. Patients with severe LV dysfunction and mitral regurgitation who are suitable candidates should be considered for transplantation as an alternative to myocardial revascularization and mitral repair or replacement.183,31

SPECIAL SITUATIONS AND CONTROVERSIES

Controversy persists regarding the role of mitral valve repair or replacement in patients undergoing CABG who have ischemic mitral regurgitation. No randomized trials comparing CABG vs. CABG plus mitral valve repair or replacement in patients with mild or moderate mitral regurgitation, or comparing mitral valve repair vs. mitral valve replacement in patients with severe ischemic mitral regurgitation with or without concomitant CABG, have yet been reported. Until the results of such studies become available, management of patients with these conditions will continue to be individualized, relying on currently available information. Accumulating evidence, however, suggests that in carefully matched patients with severe functional ischemic mitral regurgitation (LV ejection fraction ≤ 45%), long-term survival and functional status are not improved by adding mitral valve anuloplasty to CABG34 (Fig. 10-7). Other observational studies support these findings.

Types of Mitral Anuloplasty Devices

A number of devices have been devised and evaluated for the treatment of ischemic mitral regurgitation. These include posterior anuloplasty bands (flexible or rigid) and complete rings, which can be flexible, semi-rigid, rigid, flat, or shaped. No large trials comparing the relative efficacy of these devices have been performed. An observational study of 169 patients who received either a flexible (n = 117) or rigid (n = 52) ring and who had similar baseline characteristics demonstrated a similar degree of improvement in LV dimensions in the two groups, although systolic function did not improve.34 Fewer patients with rigid rings remained in NYHA class III or IV. Improvement in the degree of mitral regurgitation was better in the rigid-ring group (P = .006). There was also a lower prevalence of recurrent mitral regurgitation in the rigid-ring group.

Restrictive Anuloplasty

Restrictive anuloplasty, a technique for reducing the size of the mitral anulus initially reported by Bolling and colleagues, is widely used for treating ischemic mitral regurgitation.188 Standard sizers are used to determine the size of a ring that conforms to the anterior mitral leaflet and the intertrigonal distance of the mitral valve. A ring two or more sizes smaller than this is selected and used for the repair. Proponents of this technique cite as possible advantages the elimination of mitral leaflet tethering and mitral regurgitation in a sheep model. Division of secondary chords (chordal cutting) has been shown experimentally to decrease mitral regurgitation and reverse remodeling, particularly in patients with LV end-diastolic dimensions of 65 mm or less.34,81,62 Functional mitral stenosis has been reported to occur with this technique.31

Alternatives to Isolated Anuloplasty

for Surgical Treatment

Several alternative strategies have been proposed to address ischemic mitral regurgitation. Division of secondary chords (chordal cutting) has been shown experimentally to decrease leaflet tethering and mitral regurgitation in a sheep model.34 The largest clinical experience with this technique is that of Borger and colleagues.39 Secondary chords to the anterior leaflet, posterior leaflet, and the commissure arising from one or both papillary muscles affected by infarcted myocardium

**Figure 10-7** Survival after coronary artery bypass grafting (CABG) either alone or with concomitant mitral valve (MV) anuloplasty for functional ischemic mitral regurgitation. Symbols represent deaths positioned according to the Kaplan-Meier estimator, vertical bars are 68% CLs, and numbers in parentheses are patients still alive. Solid lines are parametric estimates enclosed within 68% CLs. A, Unadjusted survival, based on 37 deaths after CABG alone and 92 after CABG + MV anuloplasty. B, Propensity-matched survival based on 19 deaths after CABG alone and 19 after CABG + MV anuloplasty. (From Mihaljevic and colleagues,34)
were severed and a posterior undersized anuloplasty band inserted in 43 patients. In comparison with 49 control patients in whom only an anuloplasty band was used, the chordal cutting group had greater mobility of the anterior leaflet ($P = .01$) and less recurrent mitral regurgitation (15% vs. 37%) during the 2-year follow-up interval.

Posterior mitral leaflet extension with pericardium has been evaluated as a method to reduce the severity of ischemic mitral regurgitation. This technique was used by deVarennes and colleagues in 44 patients with severe (4+) ischemic mitral regurgitation, enlarging the posterior half of the posterior leaflet (half of P2 and all of P3) with a 1.0 3.5- to 4.5-cm patch of bovine pericardium. An anuloplasty ring (not downsized) was also used. Actuarial freedom from moderate or severe recurrent mitral regurgitation was 90% 2 years postoperatively, and 92% of the patients were in NYHA class I.

Relocation of the posterior papillary muscle in conjunction with a partially flexible anuloplasty ring (not downsized) has been used in a small number of patients by Kron and colleagues. A 3-0 polypropylene suture is passed twice through the fibrous portion of the tip of the posterior papillary muscle. It is then passed through the adjacent mitral anulus just posterior to the right fibrous trigone. The suture is tightened until leaflet coaptation is achieved. In a series of 18 patients with 2+ to 3+ mitral regurgitation preoperatively, 3 had trace and 15 had no mitral regurgitation 2 months postoperatively.

A papillary muscle sling has been proposed and evaluated by Hvass and Joudinaud to correct ischemic mitral regurgitation. After mobilizing the trabeculations of the posterior papillary muscle through the mitral valve, a 4-mm tube of polytetrafluoroethylene is drawn around the two papillary muscles, forming an intraventricular sling that is secured with sutures so that there is no gap between the muscles. An anuloplasty ring (not or only moderately downsized) is then inserted. Among 37 patients with moderate or severe mitral regurgitation, mean ejection fraction of 30%, and a mean LV end-systolic and end-diastolic dimensions were reduced, ejection fraction increased, and 5-year survival was 80%. Other interventions (edge-to-edge (Alfieri) mitral repair: results in diverse clinical settings. Ann Thorac Surg 2004;77:1598-606.

Mitral Valve Disease with or without Tricuspid Valve Disease
Section I Mitral Valve Disease

DEFINITION
This chapter describes surgical aspects of acquired mitral valve disease, excluding ischemic mitral regurgitation (see Chapter 10). Associated or secondary tricuspid valve disease is also considered (see Section II of this chapter and Chapter 14), as is concomitant coronary artery surgery in patients with nonischemic mitral valve disease (see Section III of this chapter).

HISTORICAL NOTE
Mitral Stenosis
Sir Lauder Brunton was among the first to consider surgical treatment of mitral stenosis in his “preliminary note” in *The Lancet* in 1902. Cutler, then at Western Reserve University Medical School in Cleveland and later the Mosley Professor of Surgery at Harvard Medical School and Peter Bent Brigham Hospital in Boston, did experimental work on surgical approaches to mitral stenosis. In 1923, he and Levine reported an operation via median sternotomy in which a special curved knife was inserted through the left ventricular (LV) apex to cut a stenotic mitral valve.

In 1925, Souttar digitally opened a stenotic mitral valve through the left atrial appendage.

An effective closed surgical approach to mitral stenosis began with Harken and colleagues and Bailey in the United States and Brock and colleagues in London. Harken had been doing animal experiments involving mitral valve surgery at the Boston City Hospital in 1939 before serving with the United States Army in World War II, during which time he became well known for successful removal of missiles and shell fragments from the heart. After the war he continued his work on mitral valve surgery at the Boston City and Peter Bent Brigham Hospitals. Bailey was working primarily at Hahnemann Hospital in Philadelphia. Although their techniques and terminology were somewhat different, their approaches to opening the valve through the left atrial appendage were similar. Technical modifications subsequently
added to closed commissurotomy included Tubb’s transventricular dilator, used with digital control by a finger inserted through the left atrial appendage.\textsuperscript{2}\textsuperscript{2}\textsuperscript{3}

In 1955, surgeons began to think of opening stenosed mitral valves by intracardiac techniques on cardiopulmonary bypass (CPB). However, closed heart operations produced such generally good results that the open heart technique did not come into wide use until after 1970.

Mitral Regurgitation

Although a few ingenious closed methods of surgically improving mitral regurgitation were reported during the 1950s, particularly by Bailey, Davila, Nichols, and their colleagues,\textsuperscript{B1,D11,N9} an effective open approach using CPB was not made until 1957 by Lillehei and colleagues\textsuperscript{4}\textsuperscript{11} and Merendino and Bruce.\textsuperscript{M19} McGoon described an effective repair for mitral regurgitation due to ruptured chordae in 1960.\textsuperscript{M15} In subsequent years, a number of surgeons have contributed technical advances in the repair of mitral regurgitation, particularly Carpentier, Duran, Frater, Reed, and their colleagues.\textsuperscript{C11,D16,L7,R13}

Mitral Valve Replacement

A number of surgeons realized very early the need for replacing at least some diseased mitral valves. However, it was Starr and Edwards from the University of Oregon Medical Center who, in 1961, first reported successful mitral valve replacement using a mechanical prosthesis.\textsuperscript{S32}

Although the Starr-Edwards valve became the “gold standard” in prosthetic valves for most of the next decade, it soon became apparent that aggressive anticoagulation was necessary to control the marked thromboembolic tendency. Valve design focus subsequently was redirected toward lower-profile valves with novel occluder designs. The Bjork-Shiley prosthesis, designed by cardiac surgeon Viking Bjork of Sweden and Earl Shiley in California,\textsuperscript{B20,E44} was the first successful tilting disc valve. It emerged as the leading prosthesis in the 1970s. It was first marketed in 1971 with a carbon-coated disc and both inflow and outflow struts welded to the chromium alloy orifice. The hemodynamics and freedom from hemolysis were superior, but strict anticoagulation was required to prevent valve thrombosis. When a later design change (convexo-concave disc)\textsuperscript{15} was associated with strut fracture,\textsuperscript{11} the valve was eventually taken off the market.\textsuperscript{B27,C34,H16} Enduring bileaflet valves would await the application of pyrolytic carbon technology from the space industry in about 1977. The bileaflet St. Jude Medical valve developed in the late 1970s became the dominant prosthetic valve of the 1980s,\textsuperscript{E10,E11} offering further improvement in hemodynamics, less blood stagnation, greater opening of the leaflets, and a lower risk of thromboembolism.\textsuperscript{C21,C42}

Biological or tissue prosthetic valves had been in development since the 1950s, and in the 1960s formalin fixation was introduced to sterilize and fix heterograft tissue.\textsuperscript{16} When investigators became aware of the tendency of formalin fixation to induce collagen breakdown in valve cusps—with resultant fibrosis, calcification, and degeneration—tissue fixation of porcine valves with glutaraldehyde rapidly became the standard. The first commercially available bioprosthetic valves were developed by Hancock in the United States (1970) and Carpentier in Paris.\textsuperscript{C4,C7,K2}

MORPHOLOGY

Anatomy of the mitral valve is discussed in detail in Chapter 1. Several features are of particular importance in considering valve pathology and reparative techniques. The anterior leaflet is conveniently divided into three sectors: \( A_1 \) laterally, \( A_2 \) centrally, and \( A_3 \) medially. The posterior leaflet is also divided into three sectors: \( P_1 \) laterally, \( P_2 \) centrally, and \( P_3 \) medially\textsuperscript{12} (Fig. 11-1). When the cause of regurgitation is prolapse of the posterior leaflet, sectors \( P_2 \) and \( P_3 \) are usually involved. Additionally, there is usually some degree of annular dilatation.

The right fibrous trigone is adjacent to the posteromedial commissure and is part of the central fibrous body located at the intersection of the membranous septum, mitral and tricuspid anulus, and aortic anulus (Fig. 11-2). The left fibrous trigone is located near the aortic anulus under the left aortic cusp and adjacent to the anterolateral commissure. The posteroanterior and anterolateral papillary muscles give rise to chordae tendineae going to both leaflets. The chords are generally categorized into three groups: first-order chordae originate near tips of the papillary muscles and insert on the free edge of the leaflets. These chordae prevent valve edge prolapse during systole and, when elongated or ruptured, produce mitral regurgitation. Second-order chordae (including two or more longer strut chordae) insert on the ventricular surface of the leaflets at the junction of the rough zone (closer to the free edge) and clear zone, which is demarcated by a ridge that corresponds to the line of leaflet coaptation. Third-order chordae originate from the underlying ventricular wall and insert on the posterior leaflet near the anulus. In addition, distinct commissural chordae exist at the commissures.

Mitral Stenosis

Acquired mitral stenosis usually results from rheumatic heart disease, as does mixed stenosis and regurgitation. It occurs as an isolated valvar condition in 40% of patients with rheumatic heart disease.\textsuperscript{W9}

Commisural fusion and leaflet thickening are the dominant features in clinically important mitral stenosis. The characteristic fusion of the edges of the mitral leaflets in

\[ \text{Figure 11-1} \text{ Segmental leaflet anatomy of mitral valve. Anterior leaflet has three sectors: } A_i, \text{ nearest the anterolateral commissure (labeled by star on left side of diagram); } A_m, \text{ in the mid-leaflet; and } A_s, \text{ nearest the posteromedial commissure (right-side star). Mitral valve and subvalvar apparatus.

Mitral valve prolapse is a billowing of one or both leaflets into the left atrium during ventricular systole, with or without mitral regurgitation. Prolapse of a mitral valve leaflet occurring as an isolated abnormality is a relatively common and complex entity occurring in 1% to 2.5% of the population. Familial mitral valve prolapse is inherited as an autosomal trait. Primary mitral valve prolapse occurs with left atrial hypertension. Organic pulmonary vascular disease may also increase Rp and is often found in young Polynesian and Asian patients, as well as in a small proportion of other patients with long-standing mitral stenosis. Rarely, the vascular disease may progress to obliteration of pulmonary arterioles. Increased Rp produces a rise in pulmonary artery and right ventricular pressure out of proportion to the valve stenosis and left atrial pressure increase, which leads to right ventricular (RV) hypertrophy and secondary tricuspid regurgitation.

Mitrail Stenosis and Regurgitation

Mixed mitral stenosis and regurgitation is primarily rheumatic in origin. Stenosis is produced by varying degrees of commissural fusion and chordal thickening. Regurgitation results from fibrous retraction of the central unfused portion of the leaflets and either chordal shortening or chordal elongation. Shortening restricts leaflet motion and increases the gaping central orifice, whereas elongation permits cusp prolapse. Occasionally, chordae rupture as a result of the rheumatic process.

Endocarditis on a rheumatic stenotic valve adds regurgitation by eroding leaflet or chordal tissue.

Mitrail Regurgitation

Regurgitation may be due to rheumatic valve disease, but has numerous other causes and morphologic patterns.

Rheumatic Mitral Regurgitation

Mitrail regurgitation may occur as a severe lesion (sometimes combined with aortic regurgitation) during the acute rheumatic process in association with extensive myocarditis and sometimes pericarditis and pancarditis. Anular dilatation is the primary cause of regurgitation in this circumstance, with the valve leaflets frequently showing edema only and virtually normal chordae. After remission of the acute process, regurgitation may spontaneously regress, presumably because the myocarditis heals, the heart becomes smaller, and anular dilatation regresses. In most cases, however, there is progressive leaflet thickening, particularly of the posterior leaflet, which becomes retracted and rolled with shortening of chordae. The anterior leaflet is less thickened, and major chordae are frequently elongated, allowing leaflet prolapse. The posterior chordae may also elongate, and occasionally one or more may rupture. Commissural leaflets are obliterated and fused, but the commissures remain more or less open. Calcification is uncommon. Anular dilatation is almost invariably progressive and produces increasing regurgitation.

Mitrail Valve Prolapse

Mitrail valve prolapse is a billowing of one or both leaflets into the left atrium during ventricular systole, with or without mitral regurgitation. Prolapse of a mitral valve leaflet occurring as an isolated abnormality is a relatively common and complex entity occurring in 1% to 2.5% of the population. Familial mitral valve prolapse is inherited as an autosomal trait. Primary mitral valve prolapse occurs with

---

1Variously termed myxomatous mitral valve prolapse, myxomatous mitral valve degeneration, floppy valve, “the symptom complex of midsystolic click and late systolic murmur,” and Barlow syndrome.26
increased frequency in patients with Marfan syndrome and certain other connective tissue disorders.\textsuperscript{1,13}

Our understanding of the anatomic details of prolapsing anterior and posterior leaflet components has been enhanced by the classification of Carpentier\textsuperscript{28,29,425} and others. In a pathologic study, Quill and colleagues identified abnormal (“deviant”) clefts in all valve segments, but most commonly in the P\textsubscript{2} region.\textsuperscript{91} Such abnormal clefts may contribute to mitral regurgitation observed in degenerative mitral valve disease.

Infrequently, in its severe form, mitral prolapse results in important mitral regurgitation (10% of patients).\textsuperscript{425} Nonetheless, in the United States mitral valve prolapse has been reported as the most common cause of surgically treated isolated mitral regurgitation.\textsuperscript{830} The basic pathologic conditions are mitral leaflet redundancy and myxomatous leaflet thickening, resulting at least partly from myxomatous proliferation of the acid mucopolysaccharide within the spongiosa, which replaces collagen in the leaflets. The redundant and elongated leaflets no longer meet properly to support each other during systole, and they begin to overshoot into the left atrium. Not only is the valve thereby rendered regurgitant, but abnormal strain is placed on the chordae as well. The chordae elongate, and ultimately some rupture, producing more regurgitation. These histologic changes and severe valve redundancy are especially pronounced in younger patients with Barlow syndrome. Older patients with degenerative mitral regurgitation are more likely to have fibroelastic deficiency and less redundant valve tissue. These differences have important surgical implications because marked leaflet redundancy with more severe myxomatous changes requires more extensive reconstructive techniques. Calcifications may occur in the mitral anulus, but do not appear to contribute to mitral valve dysfunction.\textsuperscript{347}

	extit{Idiopathic} Chordal Rupture

“Idiopathic” and more or less localized chordal rupture is usually a variant of mitral valve prolapse syndrome,\textsuperscript{13} in which a considerable portion of leaflet tissue is uninvolved by the myxomatous process. In most cases, the posteromedial portion of the posterior leaflet is involved; after chordal rupture, this becomes redundant and flail. More extensive posterior chordal rupture sometimes occurs. Localized chordal rupture may also occur in patients with Marfan syndrome.

Mitral Anular Calcification

Mitral anular calcification may occur in older patients without evident disease of the leaflets or chordae, but it may be more common in patients with myxomatous degeneration and prolapse of the mitral leaflets.\textsuperscript{28,46,57} Anular calcification is probably a degenerative disease, more common in elderly patients and apparently more common in women.\textsuperscript{28} It is also seen in patients with LV hypertrophy, particularly those with hypertrophic obstructive cardiomyopathy (HOCM; see Chapter 19). The process involves the posterior or mural portion of the anulus more often than other portions. Degenerative anular calcification often extends into the adjacent ventricular myocardium, and it may secondarily produce mitral regurgitation or stenosis by displacing or immobilizing the mitral leaflets. Anular calcification considerably complicates mitral repair or replacement.\textsuperscript{1,14}

Ischemic Papillary Muscle Dysfunction or Rupture

Papillary muscle dysfunction or rupture resulting from myocardial infarction or ischemic fibrosis can produce severe mitral regurgitation (see Chapter 10).

Infective Endocarditis

Endocarditis is a relatively uncommon cause of pure mitral regurgitation compared with its etiologic frequency in aortic regurgitation. When the aortic valve is infected and regurgitant, vegetations may drop down onto and infect the central portion of the anterior mitral leaflet, producing perforation and mitral regurgitation. In the absence of aortic valve disease, a normal or abnormal mitral valve may become infected,\textsuperscript{345} with destruction of cusps, chordae, or both (see Chapter 15).

Submitral Left Ventricular Aneurysms

Submitral LV aneurysms frequently result in mitral regurgitation. This unusual type of aneurysm is not ischemic in origin and occurs most often among the southern and western African black population.\textsuperscript{118} It may be multiloculated and have a well-defined neck situated immediately beneath the posterior mitral leaflet. Mitral regurgitation often coexists because of aneurysmal distortion of the posterior leaflet and leaflet prolapse. In rare instances, the aneurysm bulges into the left atrium from behind, partly obstructing the mitral orifice.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Mitral Stenosis

The normal mitral valve orifice area in an adult is 4.0 to 5.0 cm\textsuperscript{2}. Most asymptomatic patients have a mitral valve area less than 2.5 cm\textsuperscript{2}.\textsuperscript{423} The diastolic transmirtal gradient is the fundamental physiologic expression of mitral stenosis. At any given orifice size, the transmirtal gradient is a function of the square of the transvalvar flow rate and diastolic filling time. Thus, for example, doubling the flow rate quadruples the transvalvar gradient. This explains the importance of exertion or other causes of increased cardiac output in development of dyspnea (induced by increased left atrial and pulmonary venous pressure) during the initial stages of mitral stenosis. As heart rate increases, during atrial fibrillation for example, diastolic filling time is greatly reduced, thereby increasing the gradient and left atrial pressure.

Effective atrial contraction during sinus rhythm has a major lessening effect on dyspnea with severe mitral stenosis, because the left atrial pressure is lower than during atrial fibrillation, and the loss of atrial contribution during atrial fibrillation results in about a 20% reduction in cardiac output.

Although the clinical condition of mitral stenosis is a continuum without discrete hemodynamic abnormalities corresponding to functional state, the following hemodynamic guidelines are useful in defining severity of mitral stenosis:\textsuperscript{31}:

- **Mild**: valve area 1.5 to 3.5 cm\textsuperscript{2} and mean diastolic gradient less than 5 mmHg
- **Moderate**: valve area 1.0 to 1.5 cm\textsuperscript{2} and mean diastolic gradient 5 to 10 mmHg

■ Severe: valve area less than 1.0 cm² and mean diastolic gradient greater than 10 mmHg

Patients with moderate mitral stenosis are often asymptomatic at rest or with ordinary activities, particularly until the third or early part of the fourth decade of life. With severe exertion, pulmonary edema may develop suddenly.

Patients with severe mitral stenosis and without important elevation of Rp (“unprotected” mitral stenosis) have easy fatigability and effort dyspnea, orthopnea, and paroxysmal nocturnal dyspnea. As the disease progresses in duration and severity, structural changes (alveolar basement membrane thickening, increased lymphatic drainage, adaptation of neuroreceptors) may allow patients to remain functional for prolonged periods. When Rp rises, the alveolar bed is protected from sudden rises in capillary pressure with exertion, so pulmonary edema does not occur, and orthopnea and paroxysmal nocturnal dyspnea disappear. Hemoptysis is more common in this setting. When the reduction in mitral valve orifice size reaches severe levels, resting cardiac output becomes subnormal, which is usually accompanied by varying degrees of increased Rp (see also Morphology). The patient with advanced mitral stenosis who has low cardiac output and chronic heart failure secondary to high Rp is seldom seen today in developed countries. These patients tend to be women who have marked mitral facies, peripheral coldness, cyanosis, hepatic enlargement and pulsation, high jugular venous pressure with waves of tricuspid regurgitation, and sometimes ascites and peripheral edema.

In most patients, mitral stenosis can be diagnosed clinically based on history, physical examination, chest radiograph, and electrocardiogram (ECG). Auscultatory findings provide good evidence of mitral stenosis when they include a loud first sound, an opening snap, and the characteristic diastolic rumble with a presystolic crescendo when sinus rhythm is present. In severe stenosis the mid-diastolic murmur occupies more than half of diastole, and the opening snap is early.

In surgical candidates with important mitral stenosis, the chest radiograph typically shows some left atrial enlargement, although it is often only about grade 2 (on a scale of 1 to 6, with 6 being most severe). The left atrial appendage may or may not appear prominent along the left upper border of the cardiac silhouette. The LV is normal in size, but the RV and pulmonary trunk are usually somewhat enlarged. When Rp is elevated, the pulmonary trunk, branches, and hilar arteries are more enlarged; once tricuspid regurgitation occurs, there is considerable right atrial and RV enlargement. The lung fields also show varying degrees of pulmonary venous hypertension on the plain chest radiograph (large pulmonary veins in upper lung fields, interstitial pulmonary edema, Kerley B lines, or alveolar pulmonary edema).

The ECG is not diagnostic but often shows P-wave abnormalities characteristic of left atrial enlargement (P mitrale) or atrial fibrillation, and evidence of RV hypertrophy when pulmonary hypertension is present.

Two-dimensional (2D) echocardiography is highly reliable for diagnosing and quantifying severity of mitral stenosis. It demonstrates degree of stenosis, leaflet mobility, thickening and probable calcification, and any subvalvar obstruction. Doppler echocardiography, enhanced by color flow imaging to identify precise flow direction, is valuable for estimating severity of stenosis. Currently these methods suffice for estimating mitral valve area as well as morphology and gradient across the valve. An echocardiographic grading system for mitral stenosis has been endorsed in the American College of Cardiology/American Heart Association (ACC/AHA) guidelines, which is useful for identifying patient suitability for valvotomy (balloon catheter), surgical commissurotomy, or valve replacement (Table 11-1). Greater leaflet mobility, less subvalvar involvement, and less leaflet calcification (grade 1) increases the likelihood of successful valvotomy or commissurotomy.

Cardiac catheterization is usually unnecessary for diagnosing mitral stenosis and estimating its severity. Catheterization is necessary in patients older than about age 35 to study the coronary arteries, however, because about 25% of patients older than 40 with mitral stenosis without angina have important coronary artery disease. When balloon valvotomy is used, prevalvotomy and postvalvotomy measurements are easily made by classic catheterization techniques or by echocardiography. Pulmonary capillary wedge pressure (PCPW) is measured to determine severity of pulmonary venous hypertension. PCPW (which is similar to left atrial pressure) is compared with directly measured LV diastolic pressure to determine transmural gradient; a resting end-diastolic gradient of 10 mmHg or more indicates important mitral stenosis. Mitral valve area is calculated from Gorlin’s modified orifice equation.

From Bonow and colleagues.831
In a patient coming to treatment for mitral stenosis, the possibility of left atrial myxoma must always be considered. Echocardiography can detect a left atrial myxoma\(^ {\text{24}}\) and is the type of screening performed when further information is needed (see Section I, Myxoma, in Chapter 18).

**Mitral Regurgitation**

**Chronic**

Patients with mitral regurgitation are often asymptomatic for many years, during which time LV size may steadily increase and LV contractility decrease. Eventually, effort intolerance develops, and symptoms of pulmonary venous hypertension evolve. Fluid retention and chronic heart failure, occasionally with cardiac cachexia, are characteristic of the late stage of the disease; by then, secondary tricuspid regurgitation is usually evident.

As with mitral stenosis, important mitral regurgitation can usually be diagnosed based on history, physical examination, chest radiograph, and ECG. The classic apical systolic murmur of mitral regurgitation is pansystolic, loudest at the apex, and radiates to the left axilla and left lung base. Classical auscultatory findings in mitral valve regurgitation from prolapse include one or more mid-systolic clicks and a late or holosystolic murmur of mitral regurgitation. When regurgitation is the result primarily of ruptured chordae and prolapse of the posterior leaflet, however, the regurgitant jet is directed toward the roof (superior aspect) of the left atrium and is transmitted to the aortic root. Therefore, the murmur is maximal in the parasternal aortic area and may radiate into the carotid arteries. In contrast to the anterior radiation of posterior leaflet prolapse, the murmur of anterior prolapse radiates posteriorly to the infracostal and posterior cervical area.\(^ {\text{218}}\) As a result of large and rapid mitral valve flow during diastole, an LV filling sound (S\(_3\)) and a diastolic rumble may be present. Two important signs of the severity of regurgitation are an overactive LV impulse at the apex (from LV enlargement) and a precordial lift, the latter the result of systolic pulsation in the enlarged left atrium and right ventricle. There is no correlation between intensity of the murmur and severity of mitral regurgitation, but a true holosystolic murmur is indicative of more severe regurgitation.\(^ {\text{216,88}}\)

In severe chronic mitral regurgitation, the chest radiograph usually is highly characteristic. The left atrium generally is more enlarged than in patients with mitral stenosis, and the left atrial appendage is usually prominent. The LV may be enlarged, and there may be varying degrees of right atrial enlargement, depending on the amount of associated tricuspid regurgitation.

The ECG may remain normal even in the presence of severe mitral regurgitation. However, a pattern of LV hypertrophy is common.

As with mitral stenosis, 2D echocardiography demonstrates the details of leaflet pathology. Both transthoracic (TTE) and transesophageal echocardiography (TEE) are useful. Echocardiographic diagnosis of mitral valve prolapse requires prolapse of 2 mm or more above the anulus in the long-axis parasternal view.\(^ {\text{39}}\) Leaflet thickness of 5 mm or more increases the likelihood of mitral valve prolapse. Prolapse of a specific leaflet can be visualized, and Doppler color flow imaging can identify the location and magnitude of the mitral regurgitant flow. Echocardiography may also be used to estimate both the degree of LV enlargement and, by quantification of shortening fraction, ventricular contractility. Newer echocardiographic methods using 3D techniques offer precise and accurate evaluation of leaflet physiology and specific areas of regurgitation within the valve apparatus. The effective regurgitant area and regurgitant volume can be measured echocardiographically and have been identified as predictors of outcome following mitral valve repair (see Indications for Operation later in this section). The American Society of Echocardiography has recommended grading mitral regurgitation as mild, moderate, and severe (grades 1-3). For refinement of intermediate levels, the terms mild to moderate and moderate to severe can be used.\(^ {\text{22}}\)

Left ventriculography also demonstrates the regurgitant process at the mitral valve and can show leaflet prolapse. Degree of regurgitation can usually be estimated with reasonable accuracy, although if left atrial or LV enlargement is severe, the estimate is less valid. Fairly accurate calculations of regurgitant flow can be made from measurements of LV stroke volume by quantitative left ventriculography, and of forward flow by some measurement of cardiac output.\(^ {\text{33}}\) LV ejection fraction (EF) can also be calculated by quantitative cineangiography or radioisotope techniques. Decisions about treatment of patients with mitral regurgitation may require additional studies from which inferences can be made about LV contractility (see “Mitral Regurgitation” under Natural History later in this section).

**Acute**

Mitral regurgitation may develop acutely as a result of chordal rupture or infective endocarditis or may complicate the course of acute myocardial infarction (see Chapter 10). Symptoms and signs of severe pulmonary venous hypertension suddenly appear. The left atrium and LV are normal in size or only slightly enlarged. The chest radiograph is dominated by signs of pulmonary venous hypertension, and left atrial pressure is high, as is the v wave. A mitral regurgitation murmur is often pansystolic and higher pitched compared with the pansystolic murmur of chronic mitral regurgitation.

**NATURAL HISTORY**

**Mitral Stenosis**

Rheumatic mitral stenosis develops slowly after initial rheumatic involvement of the valve. In the New England area of the United States, the average age of the initial attack of rheumatic fever is 12 years, average age of onset of clinical signs of mitral stenosis 20 years, and age at onset of symptoms 31 years.\(^ {\text{228}}\) Progression of valve fibrosis and calcification is related in part to repeated episodes of rheumatic fever, but mechanical trauma and deposition of platelets and other blood substances resulting from stenosis-induced alterations of flow patterns also play a role.\(^ {\text{54}}\) This progression is a major factor in increasing symptoms, ultimately causing death.

Most patients with mitral stenosis have normal LV wall thickness, volume, and systolic and diastolic function\(^ {\text{510}}\) but do not increase cardiac output under stress, such as when LV afterload is acutely reduced by infusion of sodium nitroprusside.\(^ {\text{339}}\) These findings suggest that the major cause of chronically reduced cardiac output in these patients is obstruction at the mitral valve.\(^ {\text{339,110,212}}\) In some patients with long-standing mitral stenosis, however, minor posterobasal
Mitral Regurgitation

The natural history of mitral regurgitation is difficult to define because (1) etiology is variable, (2) age at onset is variable, (3) mitral regurgitation may be mild and nonprogressive for many years, and (4) LV function, an important determinant of symptoms and survival, deteriorates at different rates.

Patients with mild to moderate mitral regurgitation may remain asymptomatic for many years. Even when mitral regurgitation becomes severe, the effect of changes in global LV function is modified by the fact that total LV load resisting shortening (afterload) is abnormally low in these patients (see “Ventricular Afterload” under Cardiac Output and Its Determinants in Chapter 5). Afterload is low as a result of ejection of part of the LV stroke volume into the low-pressure system.

Regional wall contraction abnormalities develop, perhaps from a rigid mitral valve complex. In a small proportion of patients with apparently isolated mitral stenosis (usually older persons), EF is substantially reduced. Such patients have severe posterobasal segmental wall contraction abnormalities, sometimes anterolateral segmental contraction abnormalities, and occasionally diffuse hypokinesis. Anterolateral segmental contraction abnormalities may be caused by papillary muscle scarring and immobilization. Diffuse hypokinesia may result from scarring and decreased LV compliance secondary to chronic low cardiac output and low coronary blood flow.

Once symptoms develop after the so-called latent period, their progression to a state of total disability (New York Heart Association [NYHA] functional class IV) requires an estimated 7 to 10 years (Fig. 11-3). Average age of death of patients with surgically untreated mitral stenosis is estimated to be 40 to 50 years.

This general pattern of evolution is considerably shorter in some parts of the world and in some races. Polynesians in New Zealand, African Americans in south-central Alabama, Inuits in Alaska, and Asians experience a greatly accelerated evolution of signs, symptoms, and disability. Many reports suggest that in addition to possible genetic factors, economic underdevelopment may play a role.

Other events tend to occur during the lifetime of patients with surgically untreated mitral stenosis, and these in turn may alter the natural history of the disease. Atrial fibrillation usually develops, often occurring first in paroxysmal form. The first paroxysm, usually with tachycardia, may initiate symptoms because patients with mitral stenosis are particularly sensitive to loss of the atrial contribution to ventricular filling and to shortening of ventricular filling. Although originally incited by left atrial hypertension and hypertrophy, atrial fibrillation eventually becomes persistent because of disintegration of the architecture of atrial muscle. Because it reduces cardiac output and elevates left atrial pressure, atrial fibrillation accelerates clinical deterioration of patients with mitral stenosis and indicates a relatively advanced stage of the disease. It is an incremental risk factor for premature death of these patients. Olesen found that in patients with atrial fibrillation, 10- and 20-year survival was 25% and 10%, respectively, whereas in patients in sinus rhythm at initial observation, survival was 46% and 29%, respectively.

Systemic arterial emboli, most of which lodge in cerebral arteries, can suddenly complicate or kill patients with mitral stenosis. Most emboli originate in the left atrial appendage or left atrium, yet often no residual thrombus remains in the heart after embolization. Hoeksema and colleagues found that only 25% of patients with a history of arterial emboli had left atrial thrombi detected at closed commissurotomy. Also, some patients with large left atrial thrombi never have demonstrable embolization. Left atrial thrombosis and embolization are much more common when atrial fibrillation is present than in patients in sinus rhythm. At least 10% of surgically untreated patients develop arterial embolization during their lifetime, and a massive cerebral embolus may suddenly kill a mildly symptomatic patient.

Infectious endocarditis is unusual in patients with mitral stenosis. Massive pulmonary hemorrhage may occasionally develop in patients otherwise mildly symptomatic from mitral stenosis. The association between mitral stenosis and hemorrhage is strongly suggested by its prompt and long-standing remission after surgical treatment of the stenosis.

In fact, the aforementioned features and criteria do not truly represent the “natural” (i.e., untreated) history of mitral stenosis, but rather the spectrum of mitral stenosis in surgically untreated patients receiving medical treatment available in the mid-20th century. The end stage of the disease in many patients is characterized by cardiac cachexia, a state infrequently seen before diuretic therapy became available. The true natural history of mitral stenosis in the first quarter of the 20th century must have been different from that portrayed here, with the interval between onset of symptoms and death much shorter and with different patterns of death.

Likewise, evolution of the rheumatic disease complex is different in patients with mitral stenosis treated surgically vs. medically. The course of the disease varies because the increased lifespan due to surgery now results in development of hemodynamically important rheumatic aortic valve disease and important tricuspid regurgitation in a considerably greater proportion of patients with mitral stenosis (Fig. 11-4).
left atrium; because of this, the LV becomes small, and its wall thickens very early in systole. The resulting favorable relationships in the Laplace law reduce wall stress and afterload. Because of this, LV contractility may gradually deteriorate while LV systolic function (EF) is maintained, the mechanism being reduction in afterload. The EF may even increase during exercise under these circumstances while symptoms remain mild. This compensated period of mitral regurgitation may last for years. Later, as the regurgitation becomes severe and LV contractility decreases, EF may diminish during exercise, even in asymptomatic patients.

These considerations have led to development of techniques for estimating LV function that are independent of preload and afterload. Foremost among these are those that use ventricular end-systolic pressure-volume relations (see “Mitr al Regurgitation” under Indications for Operation, Selection of Technique, and Choice of Device later in this section and “Cardiac Output and Its Determinants” in Section I of Chapter 5).

Patients with mitral regurgitation may develop tricuspid regurgitation, which also affects natural history (see Section II).

Rheumatic Mitral Regurgitation

Patients with rheumatic mitral regurgitation are more likely to have had a previous severe attack of rheumatic fever than those with mitral stenosis. The interval before the appearance of regurgitation also is shorter than for stenosis. Patients with surgically untreated but hemodynamically important rheumatic mitral regurgitation survive similarly to those with mitral stenosis. Furthermore, the curve is different in different environmental and genetic situations, as it is in mitral stenosis. In San Francisco, for example, survival of such patients 5 years after initial evaluation was 80%, with 10-year survival of 60%, whereas in Venezuela, 5-year survival was only 46%. Accelerated forms of rheumatic mitral regurgitation also occur in the same geographic areas where severe mitral stenosis appears in the pediatric population, with important symptoms by age 10 years.

Mitral Valve Prolapse

The natural history of isolated mitral valve prolapse without regurgitation is highly variable, with the majority of patients having age-adjusted survival similar to that of the general population. However, the major predictor of cardiac mortality is moderate to severe mitral regurgitation. Mitral regurgitation associated with mitral valve prolapse has a complex natural history that entails more than leakage at the mitral valve. The mitral leaflets not only prolapse in this condition but are usually thickened as well. Mitral valve regurgitation is not the only event in patients with mitral prolapse. Serious but rarely fatal arrhythmias may occur in patients with only mild regurgitation, and psychiatric disturbances may develop. Symptoms may mimic thyrotoxicosis, hyperadrenergic states, or hypoglycemia.

Patients with the classic form of mitral prolapse, which includes thickening of the leaflets as well as prolapse, have an increased prevalence of infective endocarditis; those with normal leaflets (in the absence of regurgitation) do not. Both groups have a higher prevalence of stroke.

Severe mitral regurgitation requiring valve repair or replacement rarely develops before age 50. Thereafter, the prevalence increases steeply, particularly in men. However, even men with mitral valve prolapse who have reached age 70 years have only about a 5% chance of requiring mitral valve repair or replacement. Once important mitral regurgitation appears, however, it tends to progress just as it does in patients with rheumatic mitral regurgitation. Presumably, as prolapse worsens, support in systole provided by closing of the two leaflets against each other (“stacked rifle effect”) is lost. This puts an abnormally large load on the chordae, which elongate, become thick, and eventually rupture. This process worsens the regurgitation and accelerates the natural history of the disease.

In view of the increasing ability of cardiac surgeons to repair mitral regurgitation, the natural history of severe mitral regurgitation secondary to mitral valve prolapse is of considerable importance. Two Mayo Clinic studies in the mid-1990s called attention to the increased mortality in patients with chronic flail leaflets treated medically.

A 2008 multicenter European study examined the natural history of severe regurgitation caused by one or both flail leaflets (failure of leaflet coaptation with rapid systolic movement of the involved leaflet tip in the left atrium). Involvement was confined to the posterior leaflet in 314 patients (79%), anterior leaflet in 31 (8%), both in 46 (12%), and unspecified in 3 (1%). The long-term outcome with medical treatment included an important likelihood of major adverse events by 8 years, including atrial fibrillation, heart failure, and cardiovascular death. Need for mitral valve surgery (or death from cardiovascular causes) was nearly unavoidable by 8 years after diagnosis. A subgroup analysis of asymptomatic patients with normal ventricular systolic function revealed a 5-year survival of 97% with medical treatment, but the combined occurrence of atrial fibrillation, heart failure, or cardiovascular death was 42% at 8 years. A Mayo Clinic analysis of asymptomatic patients with severe organic mitral regurgitation identified an effective regurgitant orifice (by echocardiography) of at least 40 mm² as a major predictor of late mortality.
Ruptured Chordae Tendineae

Patients with mitral regurgitation and ruptured chordae tendineae may have a slow, insidious development of symptoms. Ruptured chordae of the anterior or posterior leaflet or both are often found at operation, and the mitral valve leaflets have the appearance of myxomatous degeneration. These patients probably represent a subgroup of individuals with mitral valve prolapse. In fact, ruptured chordae may be present in patients with prolapse without important symptoms. Grenadier and colleagues found 11 (8%) of 134 patients with mitral regurgitation due to flail leaflet. (From Grigioni and colleagues."

By contrast, important mitral regurgitation produced acutely by chordal rupture may occur in patients with no previous valve leakage. This happens predominantly in middle-age men. Often it is a complication in the life history of patients with mid-systolic clicks and only trivial murmurs, but without previous evidence of mitral regurgitation. The anterior mitral leaflet and its chordae are frequently entirely normal, with the disease process limited to the medial aspect of the posterior mitral leaflet. In this group of patients with acute and severe symptoms, presumably initiated by sudden chordal rupture, the left atrium and LV are small, left atrial pressure is high, the v wave is greatly accentuated, and there is substantial clinical and radiologic evidence of pulmonary venous hypertension. TTE and TEE are diagnostic. The posteromedial segment of the valve (P2, P3) prolapses, and the ruptured chordae are flail or seen as thickened stubs on the affected portion of the leaflet. If the patient survives the acute event, the LV and left atrium enlarge moderately over time, and symptoms may lessen with appropriate medical management (as has been shown experimentally as well). The patient gradually regains a feeling of well-being. One year later, left atrial and ventricular enlargement may not have progressed, the LV and left atrium seemingly adapting to the volume overload. Years may pass before the self-aggravating tendency of mitral regurgitation results in increased regurgitation volume. After this, the classic natural history of important mitral regurgitation evolves.

In other patients with severe acute manifestations, symptoms improve only mildly with intense medical treatment. Although most patients survive, LV and left atrial enlargement progress steadily in the months after onset. Such patients have a large mitral regurgitant flow. When untreated surgically, they progress through the life history of severe mitral regurgitation more rapidly than most patients; without surgical intervention, they die within 2 to 5 years.

Infective Endocarditis

Infective endocarditis on a previously mildly abnormal mitral valve may produce acute mitral regurgitation. The natural history of that condition is similar to that described for acute chordal rupture, except that early mortality is higher. Infrequently, death is related to uncontrolled infection. Infective endocarditis is discussed in detail in Chapter 15.

TECHNIQUE OF OPERATION

Tricuspid valve regurgitation may be associated with any type of mitral valve disease. Consequently, tricuspid annuloplasty or rarely replacement may have to be performed concomitantly with mitral valve surgery. Techniques for these operations are described in Chapter 14.

Closed Mitral Commissurotomy

After the usual preparations, including placing an arterial catheter in the right radial artery, the patient is positioned in the right lateral decubitus position. The hips are rotated to the patient’s left. The left arm is placed at the patient’s side and hanging slightly over the edge of a well-padded portion of the operating table, with the left hand beneath the hips. This position permits good access to the operative area.

After appropriate skin preparation and patient draping, an anterolateral incision is made over the interspace, through which the impulse of the apex of the LV can be palpated. The incision in the interspace (typically the fifth or sixth) is carried posteriorly, but the latissimus dorsi usually does not require incision. At times, the costal cartilage above or below the incision is transected.

The pericardium is opened anterior to the phrenic nerve. A purse-string suture is placed just off, and usually just lateral and superior to, the LV apex. The purse string is threaded into a Rummel tourniquet or similar device. A similar purse-string suture is placed around the tip of the left atrial appendage. With both the assistant and surgeon grasping their own side of the appendage with a sturdy thumb (tissue) forceps, an incision is made just off its tip. The incision must be of a size to accommodate the surgeon’s right index finger snugly. While bleeding is controlled by opposing the thumb forceps, blood is allowed to escape for two or three brief periods so that small clots may emerge. The surgeon’s right index finger is then insinuated through the appendage into the left atrium and passed directly to the mitral valve. After the valve is evaluated, pressure is applied with the exploring finger against the anterolateral commissure. Occasionally, this maneuver opens a pliable but severely stenotic valve widely and essentially completely, with no further action needed. In most cases, however, a Tubbs dilator is required and is inserted through a small stab wound in the center of the LV apical purse string (Fig. 11-6, A).

An assistant gently secures the Rummel tourniquet that has engaged the apical purse-string suture. Guided by the intraatrial finger and with the setscrew on the dilator...
positioned so that the maximal opening is 2.5 cm, the dilator is passed through the valve. The dilator blades are opened moderately for a few seconds to ensure that each dilating blade is against a leaflet and not a commissure (see Fig. 11-3, B). This and each successive dilatation last only 5 to 6 seconds, and the heart is allowed to recover completely between dilatations. Successive dilatations are then performed, first with the maximum opening set at 2.5 cm and then at about 2.9, 3.3, 3.7, and finally 4.0 cm. In small patients, the maximum dilator setting should be 3.3 to 3.5 cm. If important regurgitation develops after a dilatation, no larger settings should be attempted. Again, after the heart has recovered, the index finger is withdrawn as an assistant places a side-biting clamp across the lips of the incision in the appendage. At times, two Allis-Adair forceps close the incision well, and the clamp is not necessary. The purse string around the entrance of the Tubbs dilator is loosened slightly and then secured as the dilator is removed. No effort is made to tighten the purse string so that all bleeding stops, lest the purse string cut through the ventricular muscle. Digital control suffices for residual bleeding. Several full-thickness interrupted stitches are placed in the stab wound, and the purse-string suture is removed from the tourniquet and tied snugly but not tightly. The incision in the atrial appendage is closed with a few inter-

Figure 11-6 Closed mitral commissurotomy. A, Tubbs dilator (valvulotome). Note setscrew on handle and small size of closed tip. B, Dilator is advanced into mitral valve orifice against right index finger. Blades are opened against leaflets, not against commissures. Key: LV, Left ventricle. (From Ellis.15)
A catheter is placed posterolaterally in the left pleural space, hemostasis is secured, and the incision is closed in layers.

Open Mitral Commissurotomy

After the usual preparations and median sternotomy, pericardial stay sutures are placed and a left atrial catheter inserted (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2). Using intraoperative TEE, chamber size is evaluated and mitral valve pathology confirmed, including degree of valve narrowing and any regurgitant jets. Often, subvalvar stenosis can be identified. Important tricuspid regurgitation or stenosis is noted.

The aortic cannula is inserted and venous cannulation accomplished with a single venous cannula, or bicaval cannulation may be used when the left atrium is small and exposure difficult. CPB is established and perfusate temperature lowered to 18°C to 20°C. A stab wound (part of the later left atriotomy) is made at the base of the right superior pulmonary vein for initial left atrial venting. A cardioplectic needle or aortic root catheter is placed in the ascending aorta, and a retrograde coronary sinus cardioplectic cannula may be introduced as well (see “Technique of Retrograde Infusion” in Chapter 3). The aorta is clamped, cold cardioplectic solution infused, and perfusate temperature stabilized at 28°C to 32°C. The left atrium is opened vertically from the right side (Fig. 11-7, A). This may be done after developing the interatrial groove in cases of minimal left atrial enlargement, or the incision may be started medially on the right superior pulmonary vein without dissecting the groove. Superiorly, the incision is extended beneath the superior vena cava after the right pulmonary artery is dissected away from the superior aspect of the left atrium. Inferiorly, the incision may be extended by cutting behind the freed vena caval—right atrial junction. Rarely, when exposure remains poor because of the small size of the left atrium, the superior vena cava is transected on the atrial side of the cannulation site and the incision carried farther to the superior aspect of the left atrium.

A Cooley left atrial retractor or Deaver retractor is inserted (Fig. 11-7, B). An intracardiac sump sucker placed through the incision is positioned in the orifice of one of the left pulmonary veins to keep the operative field dry.

The mitral valve is examined to determine its suitability for commissurotomy, and judgment is made as to whether the leaflets will be sufficiently pliable after commissurotomy to open adequately at a low left atrial pressure. Determination is straightforward when the leaflets are pliable and noncalcified and there is little or no coalescence of chordae. However, mitral commissurotomy can often yield reasonably good results when the valve is less ideal, and even when it is partially calcified.

Thus, if some reasonable degree of mobility remains in the central portion of the anterior leaflet, persistent attempts should be made to open the valve widely by commissurotomy. If commissurotomy is chosen, one stay suture can be placed in the midportion of the free edge of the anterior leaflet and another placed similarly in the posterior leaflet. Retraction on these sutures puts tension on the leaflets and their commissures. With a sharp-pointed scalpel (#11 blade), a stab incision is made in the fused anterolateral commissure next to the anulus (see Fig. 11-7, B). The incision is extended with the scalpel toward the valve orifice, in the groove of the commissural fusion. A 3- to 4-mm incision reveals the fan of underlying chordae, making it easy to stay in the middle of the commissural tissue over the center of the fan. The incision is then carried into the valve orifice. Alternatively, a blunt-ended, long-handled hook is placed beneath each leaflet, and by trial and error these hooks are positioned exactly in the spot that provides the best exposure for division of each commissure. With the scalpel, an incision is made at the anterolateral commissure beginning at the valve orifice and extended toward the anulus. The surgeon takes care to follow the true line of the commissure, which extends more anteriorly than might be thought. With either method, when fused chordae are present beneath the commissure, they can usually be separated with the knife or scissors. When appropriate, the incision is carried down into the center of the papillary muscles, dividing them into anterior and posterior halves (Fig. 11-7, C).

The posteromedial commissure is usually less well defined and fused for a shorter distance than the anterolateral commissure. Using one of the techniques just described, this commissural leaflet tissue is incised. Chordae are often more fused beneath this commissure, and their separation by sharp dissection may be needed together with longitudinal division of the papillary muscle. If the chordae are fused together to form a fanlike fibrous sheet beneath either leaflet at one or both commissures, this sheet is fenestrated by removing a wedge of tissue from its center using a sharp-pointed scalpel. Localized but bulky calcium deposits are removed from the leaflets with bone-nibbling forceps.

A firm plastic catheter with multiple side holes (ideally a 24F chest drainage tube) is placed through the valve into the LV and tied to the left atrial vent snare to secure it. Catheter placement frustrates the valve, and the side holes lying in the left atrium are an additional safeguard to prevent ejection by the LV into the aorta until de-airing is complete. The left atrium is closed with continuous 3-0 polypropylene suture, but with the loops left loose where the catheter exits through the left atrial incision. The left atrial vent is removed during this procedure to allow the left side of the heart to fill with blood. If return to the left atrium is inadequate, right atrial pressure is raised by returning blood to the patient (see “De-Airing the Heart” in Section III of Chapter 2). With the patient’s head down, the aortic clamp is released while suction is applied to the aortic vent needle. The heart is defibrillated if necessary, and the ventricle is allowed to eject into the left atrium and pericardium via the transmitral catheter until all air is clearly eliminated.

Alternatively, after completion of the commissurotomy, the left atrium is completely closed before beginning aortic root reperfusion and later removing the aortic clamp. Closure with 3-0 polypropylene suture is started at the superior angle, carried partway down, and held. With another suture, closure is begun at the inferior angle and carried superiorly until the other suture is reached. The closure must be done accurately because it is difficult to see the angles later. The sump sucker is removed, and the left atrium is filled with saline solution just before the suture line is completed. A small stab wound is made through a purse string in the ascending aorta and a small curved clamp placed through the hole to allow egress of blood and air from the LV before removing the aortic clamp. The venous line is partially clamped, and while the lungs are inflated, air is evacuated from the ascending aorta stab hole. Suction is placed on the aortic root catheter in the ascending aorta, the aortic clamp is released, and rewarming
Chapter 11 Mitral Valve Disease with or without Tricuspid Valve Disease

Figure 11-7 Open mitral commissurotomy. 

A, Exposure is through a median sternotomy. Left atrium is opened from right side in front of right pulmonary veins. 

B, Cooley left atrial retractor is positioned. With traction on stay sutures in each leaflet, valve is well exposed for commissurotomy. An incision is made from valve orifice into posteromedial commissure; line to be incised is located by staying in leaflet tissue overlying center of underlying nest of chordae to posterior papillary muscle (see text for details). Note that correctly placed incision curves anteriorly. As incision is made, chordae beneath commissure are separated. Incision is carried vertically down into the papillary muscles to attain a larger orifice. Key: IVC, Inferior vena cava; SVC, superior vena cava.
is begun (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2).

If the period of global myocardial ischemia has exceeded 30 minutes, the technique of controlled aortic root or retrograde perfusion may be used (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3). These maneuvers may aid in evacuating air from the coronary arteries. If careful observation reveals LV distention, a 13-gauge needle is inserted into the RV and across the septum into the LV. After good cardiac action has returned, the usual de-airing procedures are followed (see “De-Airing the Heart” in Chapter 2).

As rewarming progresses, two right atrial and two RV myocardial wires are placed. Before decannulation, examination by TEE should confirm no more than trivial or mild mitral regurgitation.

Repair of Mitral Regurgitation

Repair rather than replacement is the procedure of choice for treating mitral regurgitation, and current trends favor this approach. The proportion of patients undergoing repair for isolated mitral regurgitation rose from 51% in 2000 to 69% in 2007, as recorded in the Society of Thoracic Surgeons (STS) Adult Cardiac Surgery Database. However, not all cases are successfully managed in this fashion. Thus, at operation it must be determined whether repair will likely provide an acceptable result. This determination is aided appreciably by prebypass TEE. The magnitude and direction of the regurgitant jet can be assessed and the site of leaflet dysfunction accurately predicted. The abnormal valve physiology can often be characterized as restrictive, dilated, or prolapsing. These determinations allow informed decisions as to appropriate repair techniques. Repair can most confidently be performed when chordae are ruptured in a limited portion of the posterior leaflet and the anterior leaflet is essentially normal, or when there is simply prolapse of the posterior leaflet. Regurgitation from ruptured chordae to the anterior leaflet can be successfully repaired in most cases. Rheumatic mitral regurgitation can usually be repaired when distortion of the valve leaflets is minimal, as can certain cases of combined stenosis and regurgitation when commissurotomy precedes the repair. Nonrheumatic, noncalcific, almost pure mitral regurgitation in the adult, nearly always due to myxomatous degeneration, can usually be repaired. Regurgitation caused by infective endocarditis, with resultant chordal rupture or a perforated cusp, is repairable at times.

When regurgitation is associated with mitral valve prolapse, myxomatous degeneration, or chordal rupture, Carpentier’s techniques have proven reproducible and durable. Carpentier and Kumar (of Duran’s group) and their colleagues clarified the pathologic anatomy of the mitral valve. Their observations are fundamental considerations for a repair. As observed by echocardiography or at operation, the disease process of the mitral apparatus may be classified as restrictive, normal with annular dilatation, or degenerative (leaflet prolapse) (Fig. 11-8).

Thus, with the mitral valve exposed as usual and using saline distention, areas of prolapse and regurgitation are identified. With forceps and blunt hooks (crochet hooks), each element of the valve apparatus (anulus, leaflets, chordae, papillary muscle) is examined for pathologic changes. In particular, the normal primary chordae are distinguished from the abnormal stretched or ruptured chordae to the offending prolapsed portion. A rectangular excision of the prolapsed sector of the posterior leaflet is done (Fig. 11-9, A). This can involve 15% to 25% of the posterior leaflet. Further mobilization of the remaining leaflet may be accomplished by resecting some adjacent secondary and tertiary chordae. The resulting gap is bridged by a compacting (compression) suture at the base of the resected leaflet, beginning in atrial tissue just below the annulus. Alternatively, with a sliding plasty, adjacent normal portions of the posterior leaflet are incised at their bases and moved centrally to obliterate the gap (Fig. 11-9, B and C).

If a sliding plasty has been used, reconstruction is performed by suturing the mobilized leaflet to the posterior anulus and then reapproximating the cut edges of the leaflets with interrupted nonabsorbable sutures. Other techniques for closing the gap between the resected leaflets have been described, including the folding plasty technique. Usually an anuloplasty ring is then sutured into place to both support the repair and narrow the anulus (Fig. 11-9, D and E). Proper sizing of the anuloplasty ring (whether flexible or fixed) is essential to maintain competence and avoid postoperative LV outflow tract narrowing. Basically, the ring must recreate the normal anteroposterior depth of the anulus, which typically is the anteroposterior length of the splayed anterior leaflet. Thus, the size of the anterior leaflet rather than the intercommissural distance should be used to select the appropriate ring size. However, there is no uniform agreement about the technique or even the need to precisely measure anterior leaflet dimensions for ring selection. Brown and colleagues from the Mayo Clinic reported reproducibly good outcomes using a standard 63-mm posterior band in adult patients, without specific measurements.

Anterior leaflet prolapse repair (sector A₂) is more difficult and less often successful than posterior leaflet repair. A triangular wedge of the involved leaflet is resected, the leaflet is reconstructed, and a ring is placed (Fig. 11-10). To preserve available anterior leaflet for proper coaptation, the triangular resection should extend no more than one third of the distance between the free edge of the anterior leaflet and the mitral anulus. Often the repair involves other techniques described by Duran, Carpentier, Antunes, and Orszulak and their colleagues. These maneuvers are technically demanding and not as reliable as those applied to the posterior leaflet. Techniques include chordal shortening, chordal
Repair of mitral regurgitation caused by degenerative disease, with common form of ruptured chordae to posteromedial aspect of posterior leaflet ($P_2$).

A. After pathologic condition of valve is determined by careful inspection, the flail or prolapsing portion is isolated for excision. Projected incisions at base of posterior leaflet are also shown for closure of quadrangular gap by sliding plasty. Rectangular segment of leaflet tissue is excised back to annulus with lines of excision straight, not convex and outward.

B. After quadrangular resection, repair is accomplished in two phases. Anulus is narrowed at base of leaflet resection using a compression suture with or without pledgets, either figure-of-eight or horizontal mattress, with bites on ventricular and atrial aspects of annulus, to reapproximate the two sides of posterior leaflet.

C. Remaining segments of posterior leaflet are moved toward one another (sliding plasty) and reapproximated to base of leaflet. Leaflet repair is completed using fine interrupted, figure-of-eight, or continuous sutures.
Figure 11-9, cont’d  D, Carpentier-Edwards or similar anuloplasty ring is inserted. Size of ring is determined by height (depth) of anterior leaflet and by anterior intercommissural distance. Also, anterior leaflet is displayed using a crochet hook, and the two notches of sizer are approximated to anterolateral and posteromedial commissures. E, Anuloplasty ring is inserted using interrupted horizontal mattress sutures to create a purse-string effect at base of posterior leaflet, but using exactly matching intervals at base of anterior leaflet. Purse-string effect is attained both between the two arms of the suture and between each mattress suture. F, Completed ring insertion both narrows anulus and bolsters posterior repair. Only 10 to 12 double-armed mattress sutures are necessary to secure the ring.

Figure 11-10  Repair of mitral regurgitation from occasional isolated prolapse of anterior mitral leaflet or flail anterior leaflet from ruptured chordae. Valvuloplasty involves triangular resection, shown here for A, with repair of the leaflet using interrupted fine sutures (B), complemented by insertion of an anuloplasty ring (C). The triangular excision should not extend more than one third of the distance from the free edge to the anulus.
Dreyfus and colleagues have described an extensive experience with papillary muscle repositioning for anterior leaflet prolapse. The anterior head of the anterolateral papillary muscle is repositioned for A1/A2 prolapse, and the anterior head of the posteromedial papillary is repositioned for A2/A3 prolapse (Fig. 11-13).}

Alfieri and colleagues have described a simple technique that may be useful for anterior leaflet prolapse (Fig. 11-14). When the prolapse is near the commissure, the anterior and posterior leaflets are approximated “edge to edge” with one or two mattress sutures or, alternatively, with a figure-of-eight braided polyester suture. When the prolapse is in the central portion of the valve, one or two edge-to-edge leaflet-approximating sutures create a double-orifice mitral valve that functions adequately. Because mitral stenosis is a possible complication of this technique, it should probably be applied mainly in degenerative mitral valve disease. The resultant orifices should be at least 2 cm in diameter.

Figure 11-11 Repair of mitral regurgitation due to ruptured chordae to the anterior leaflet by chordal transfer. A, Area of anterior leaflet made flail secondary to ruptured chordae is resected. B, A small facing portion of normal posterior leaflet with its intact chordae is removed as a rectangular flap. C, Flap of posterior leaflet is flipped over to close defect in anterior leaflet, anchoring anterior leaflet with intact chordae. Base of flipped posterior leaflet segment is sutured to deepest aspect of anterior leaflet defect using fine polypropylene sutures. D, Quadrangular defect left in posterior leaflet is closed and the repair supported with an annuloplasty ring. (See Fig. 11-9, D and E.)
Use of 5-0 polytetrafluoroethylene (PTFE) sutures to create artificial chordae tendineae has largely supplanted chordal shortening or flip-over techniques as additions to classic mitral repair. Shown here is anterior prolapse with ruptured chordae to A. Offending primary chordae are resected, and occasionally, secondary chordae are freed. C-D, Double-armed 5-0 PTFE suture is passed in a figure-of-eight fashion, or buttressed with a pledget, through papillary muscle about 1 cm from its tip. Both arms of suture are then passed through leading edge of prolapsed leaflet, usually taking several over-and-over bites or anchoring suture over a pledget. E, Temporary guy-line stitch is placed through prolapsed leaflet area and through nonprolapsed apposing posterior leaflet. Tension applied to this guy suture determines appropriate height of anterior leaflet and length of artificial PTFE chord. PTFE suture is tied while maintaining tension on guy suture. Several such sutures are typically used.
Carpentier’s method, including an annuloplasty ring) has been the technique employed in most cases (see Fig. 11-9). When anuloplasty is necessary in young children with years of growth ahead, an anuloplasty ring is not used. Instead, an asymmetric measured anuloplasty is done by the technique described by Reed and colleagues\textsuperscript{R14,R16} (Fig. 11-15). This operation, as with most repairs of mitral regurgitation, is based on the fact that the central portion of the anterior mitral leaflet is usually pliable and of good quality. Its leading edge forms the line of closure for the repaired valve, both in the Reed repair and after insertion of a Carpentier ring.

Determining competence of the repaired valve while the left atrium remains open is imprecise. Yacoub’s maneuver involves perfusing warm blood into the aortic root proximal to the clamp through the cardioplegic needle or aortic root catheter so that function of the repaired valve can be inspected with the heart beating.\textsuperscript{Y1} A simpler method involves injecting saline under pressure through the valve into the LV. The distended leaflets and their opposing surfaces are examined, and areas of leakage, if present, are identified. The entire line of closure of the leaflets should be parallel to the mural part of the annulus—that is, to the hinge line of the posterior leaflet (or to this portion of the annuloplasty ring).\textsuperscript{C5} If all this is satisfactory, the left atrium is closed, de-airing is performed as described under Open Mitral Commissurotomy, and CPB is discontinued. At this point, competence of the valve is assessed by TEE. If more than mild regurgitation is present, CPB is resumed,\textsuperscript{M12} and the mitral valve is either re-repaired or replaced. In one institution, intraoperative TEE identified 26 of 309 patients (8%) undergoing repair for mitral regurgitation who had immediate failure of the procedure and required further repair or replacement at the same operation. Used in this manner, intraoperative TEE can limit the number of those who require late reoperation for failed repair.\textsuperscript{M8}

Repair of Mitral Regurgitation Associated with Submitral Left Ventricular Aneurysms

When there is bileaflet prolapse without anterior chordal pathology, often posterior leaflet resection and ring annuloplasty alone serve to correct the regurgitation, providing a durable repair without an additional procedure directed at the anterior leaflet.\textsuperscript{G14}

When repair rather than replacement is done for rheumatic mitral regurgitation in adults, annuloplasty (generally using CPB and myocardial management are as described for other mitral valve operations. The left atrium is opened from the right side. The aneurysmal sac is entered through an incision in the floor of the left atrium, parallel to and about 20 mm posterior to the hinge line of the posterior leaflet. The usually narrow pathway or “neck” between the LV and aneurysm is then easily visualized.\textsuperscript{A18} This pathway can be closed with interrupted pledgeted mattress sutures, bringing.
them anteriorly through the hinge line of the posterior leaflet. The opening from the left atrium into the aneurysm is then closed, draining the now-evacuated and exteriorized aneurysmal sac through its free wall into the pleural space if desired. Reparative operations can be performed for residual mitral regurgitation if indicated.

**Mitral Valve Replacement**

*Classic Procedure*

Mitral valve replacement begins with exposure of the mitral valve as described for mitral commissurotomy, using one or two valve hooks to display the leaflets. To excise the valve, an incision is begun with the knife in the center of the anterior mitral leaflet at approximately the 12-o’clock position about 2 mm from the anulus, because at that point the leaflet tissue is typically pliable and free of disease (Fig. 11-16). The incision is carried from this point leftward and rightward, either with the knife or scissors, and on to the commissural leaflet tissue at the anterolateral and posteromedial commissures. The incisions through the commissural leaflet tissue are kept next to the anulus so that the anterior and posterior leaflets stay together. The underlying papillary muscle and fused chordae are cut just in front of the incision for better exposure.

Classically, the excision is continued to the posterior leaflet from both sides. Ordinarily the posterior leaflet and its chordae are left in place when they are thin and pliable. Thus only the anterior leaflet is fully excised (but see “Chordal Sparing Procedure” later in this section). If this is not possible because of extensive disease, the secondary chordae that tether the posterior leaflet to the underlying ventricular myocardium are cut. When subanular calcification is present and can be excised without disturbing the anulus or the myocardium, it is removed. Otherwise, calcification is left in situ because overzealous efforts may damage the circumflex coronary artery or precipitate postrepair ventricular rupture.

The mechanical prosthesis or bioprosthesis can be sewn into place with interrupted simple sutures, but preferably with horizontal mattress sutures using pledgets on the atrial side, or with a continuous size 0 polypropylene suture (Figs. 11-17 and 11-18). All methods are associated with an extremely low
prevalence of periprosthetic leakage\textsuperscript{317} (see “Periprosthetic Leakage” under Modes of Death later in this section). A technique employing interrupted pledged mattress sutures with the pledgets on the ventricular side may be chosen when heavy calcification remains in some areas of the anulus or, rarely, when exposure is particularly difficult. With this technique, all sutures are placed in the heart first and then passed through the valve sewing ring. The prosthesis can then be lowered into position and the sutures tied. Protruding suture ends can damage the leaflets of bioprostheses.

After completing the valve insertion, a catheter is passed through the valve into the LV to act as a frustrator. The steps for exiting from the left side of the heart and de-airing are as described for mitral stenosis.

Chordal Sparing Procedure

Information based on experimental observation and clinical experience indicates that retention (rather than resection) of the mitral tensor apparatus at mitral valve replacement results in better LV function postoperatively\textsuperscript{1,12,25,30,31,32,325,316} (see “Cardiac Performance” later in this section). To insert a prosthesis while retaining both the anterior and posterior chordal attachments, the anterior leaflet may be split centrally and folded laterally and the posterior leaflet left as is. Alternatively, both the intact anterior and intact posterior leaflets can be folded toward their bases, then a prosthesis inserted (Fig. 11-19). These maneuvers (including folding the anterior leaflet) do not result in LV outflow tract obstruction or prosthetic obstruction when done for mitral regurgitation.\textsuperscript{116}

SPECIAL FEATURES OF POSTOPERATIVE CARE

In both the operating room and intensive care unit, patients may display a large \( v \) wave in the left atrial pressure pulse. This is \textit{not} a reliable indicator of mitral valve regurgitation, because the height of the \( v \) wave is related primarily to the level of mean left atrial pressure\textsuperscript{113} and in patients who have just undergone mitral valve repair or replacement, mean left atrial pressure is usually elevated. TEE can settle this issue.

Care of patients after mitral valve procedures is as described in Chapter 5. Ventricular unloading is an important aspect of the postoperative maintenance of optimal cardiac output in patients operated on for mitral regurgitation. Restoring mitral competence increases load-resisting shortening.\textsuperscript{34} Thus, by removing a parallel low-resistance circuit, myocardial oxygen requirement increases along with impairment of myocardial contractile reserve. Nitroglycerin, nitroprusside, and phosphodiesterase inhibitors are useful for decreasing afterload and improving cardiac performance.

Patients undergoing mitral valve replacement, including those receiving bioprostheses and often those undergoing commissurotomy or repair of mitral regurgitation, are begun on anticoagulant therapy using warfarin the evening of postoperative day 1 or 2 (day of surgery is postoperative day 0). For adults with a normal prothrombin time (PT), the initial dose is generally 7.5 to 15 mg, followed by daily doses in the hospital guided by daily PT measurements. The goal is prothrombin activity 20% to 30% of normal or PT twice the control value. This is best monitored and regulated using the international normalized ratio (INR) terminology. The INR allows standardizing the determination of PTs by accounting for differences among commercial thromboplas tin reagents.\textsuperscript{322} Optimal INR for patients after mitral valve replacement is 2.5 to 3.5.

When a mechanical valve has been inserted, this program is continued indefinitely, and the patient is educated about its extreme importance. Warfarin appears to be associated with a greater risk of excessive anticoagulation (hemorrhage) than reduced anticoagulation (thromboembolism and thrombosis). Thus, an appropriate recommendation is an INR of about 2.5 to 3.5.\textsuperscript{2,3,120,14} (See Special Situations and Controversies for additional details on long-term anticoagulation.)
Figure 11-17 Mitral valve replacement: continuous suture technique. A, One end of a double-armed size 0 polypropylene suture buttressed with a felt pledget is passed through mitral anulus just posterior to anterolateral commissure. Suture is then passed through prosthetic sewing ring, and valve without holder is lowered into place. Using about four throws, suture line is carried to the left, anteriorly passing stitches from anulus to sewing ring and taking deep bites, but avoiding noncoronary cusp of aortic valve. Suture is held midway across distance to posteromedial commissure. B, Other end of the suture, having been placed through mitral anulus as a mattress, is placed into prosthetic sewing ring and continued from anulus to sewing ring with four or five throws. It is helpful to move prosthesis in and out of anulus to accommodate needle passage. Suture is held. A second double-armed pledgeted suture is begun as a horizontal mattress just posterior to posteromedial commissure. Its ends are carried with four or five throws in each direction, first anteriorly and then posteriorly, to meet and tie with previously held ends. Knots then lie behind leaflet guards of the St. Jude Medical prosthesis depicted here.

When a bioprosthesis is inserted or anuloplasty or valvotomy performed, anticoagulation is continued for 2 to 3 months. Lower INR values (1.5-2.0) are acceptable during this period. Patients who undergo mitral valve repair and have paroxysmal or persistent atrial fibrillation should continue long-term anticoagulation with warfarin. Long-term treatment with low-dose aspirin (75-100 mg/day) is probably advisable for patients who remain in sinus rhythm after mitral valve repair. Patients who have undergone mitral valve repair or replacement should receive anti-endocarditis prophylactic antibiotics for medical procedures as indicated.

Evaluation of mitral valve repair or replacement by 2D and Doppler echocardiography should be routinely performed before hospital discharge or at first follow-up clinic visit. Assessment of right and left ventricular systolic function and identification of any residual mitral regurgitation will help guide afterload reduction therapy.
Figure 11-18  Mitral valve replacement: interrupted suture technique. A, Double-armed size 0 polyester sutures are generally placed with pledgets on atrial aspect of anulus. It is convenient to place one arm of a mattress suture just behind posteromedial commissure, reserving other end for placement later and holding suture for exposure. B, Posterior suture line proceeds counterclockwise beginning at anterolateral commissure. Sutures are placed from atrial side to ventricular side of anulus and may either be held or placed in prosthetic sewing ring. C, Anterior suture line usually proceeds clockwise from anterolateral commissure to posteromedial commissure. Along whole circumference, suture bites encompass base of residual leaflet. Clockwise from anterolateral commissure are the aortic cusps, conduction system, atrioventricular septum, coronary sinus, and circumflex coronary artery, which are at risk when bites are taken too deeply. With all sutures in place and on tension, valve is lowered into place and sutures tied, with about 12 mattress sutures used. Before tying, device struts are inspected to ensure that no suture is looped around a strut or caught within the device.
Figure 11-19 Mitral valve replacement: chordal sparing procedure. A, When it is appropriate to preserve anterior (and posterior) tensor apparatus, midportion of anterior leaflet is removed as a trapezoid or rectangle. Lateral and medial aspects of anterior leaflet remain and retain their chordal attachments. B, Residual portions of leaflet are folded back to be sutured to anulus. Leaving anterior leaflet totally intact may risk left ventricular outflow tract obstruction or, in the case of replacement for mitral stenosis, residual left ventricular inflow obstruction. Prosthesis is sutured into place using previously described interrupted (C and D) or continuous (E and F) suture technique. In either case, sutures surround retained leaflets, adding strength and purchase to the repair.
RESULTS

Mitral Commissurotomy

Survival

In an earlier era, mortality after closed commissurotomy was high. In the current era, hospital mortality after either closed or open commissurotomy approaches zero, and late survival is similar in risk-adjusted comparisons. A difference exists only in prevalence of postcommissurotomy mitral regurgitation (see “Mitral Regurgitation” in text that follows).

In many institutions, percutaneous catheter valvotomy has almost completely replaced surgical commissurotomy for isolated mitral stenosis. Procedure mortality approaches zero, and risk of complications (bleeding, severe regurgitation) requiring urgent operation is low.

Intermediate-term survival is good in those with favorable immediate hemodynamic results (Fig. 11-20).

Mitral commissurotomy is not curative with either open or closed (or balloon) commissurotomy, with survival progressively diverging from that of the general population. However, few late deaths result directly from the effects of recurrent or residual mitral stenosis or regurgitation. Rather, they result from thromboembolism or early or later sequelae of reoperation and mitral valve replacement.

Incremental Risk Factors for Premature Death

Few deaths occur early after mitral commissurotomy, and no risk factors are associated with these. Risk factors associated with later deaths include elevated Rp before commissurotomy, which directly affects survival rather than leading to reintervention, but its effect is moderate (Fig. 11-22 and Table 11-2). The aforementioned morphologic risk factors lead to recurrent symptoms and reintervention, usually valve replacement, and affect survival in this manner. Although not evident in a risk factor analysis using only preoperative variables, development of important mitral regurgitation after commissurotomy and occurrence of a thromboembolic event both adversely affect survival.

Mitral Regurgitation

Mitral regurgitation is a risk of mitral commissurotomy by any technique, but occurs in only 2% to 5% of patients who...
undergo open commissurotomy and in about 10% of patients who undergo closed commissurotomy. Rarely does the newly developed regurgitation require immediate operation, but it may lead to reoperation within a few months. Mild postcommissurotomy mitral regurgitation has little effect on survival or need for mitral valve replacement, but important postcommissurotomy regurgitation adversely affects both (Fig. 11-23).

Prevalence of new important mitral regurgitation is about 10% after percutaneous balloon mitral commissurotomy.

Cardiac Performance

Increase in calculated mitral valve area (or orifice size) produced by commissurotomy varies greatly and depends not only on the surgical opening but also on leaflet pliability and extent of subvalvar obstruction from fused chordae. Feigenbaum and colleagues found that closed mitral commissurotomy, usually with a transventricular dilator, increased mitral valve area by an average of 1.3 to 2.6 cm², with postoperative mitral valve areas ranging from 0.7 to 5.8 cm². Nakano and colleagues achieved valve areas of 2.52 ± 0.19 cm² in patients with pliable valves and minimal subvalvar disease, as well as good but smaller orifices in patients with extensive subvalvar diseases. Ben Farhat and colleagues reported an equivalent increase of mitral valve area (0.9-2.2 cm²) for open commissurotomy and percutaneous balloon valvotomy that was greater than for closed commissurotomy (0.9-1.6 cm²).

Younger patients tend to have a better functional result and experience greater increases in calculated valve area than older patients, perhaps because younger patients tend to have more pliable valves. The same general results are achieved by both open and closed commissurotomy and percutaneous balloon mitral valvotomy (Fig. 11-24). Enlargement after percutaneous balloon valvotomy results primarily from splitting of fused commissures.

Somewhat better orifices can be obtained by open than closed commissurotomy. Nakano and colleagues achieved valve areas of 2.52 ± 0.19 cm² in patients with pliable valves and minimal subvalvar disease, as well as good but smaller orifices in patients with extensive subvalvar diseases. Ben Farhat and colleagues reported an equivalent increase of mitral valve area (0.9-2.2 cm²) for open commissurotomy and percutaneous balloon valvotomy that was greater than for closed commissurotomy (0.9-1.6 cm²). The superior
hemodynamic results continued over a 7-year follow-up period (see Fig. 11-24).

A secondary effect of increased orifice size is lowering of left atrial pressure, although it frequently remains above normal. On average, left atrial pressure at rest is about 12 mm Hg after valvotomy, increasing to about 17 mm Hg on exercise. LV end-diastolic pressure often is modestly higher after commissurotomy. 

Cardiac output is usually increased by operation, and the amount of increase at rest and exercise correlates well with the increase in calculated valve area. RP usually falls immediately, especially in young patients, as verified by Block and Palacios during percutaneous balloon commissurotomy. 

Pulmonary artery pressure usually falls, which correlates well with the decrease in left atrial pressure and RP.

**Thromboembolism**

Successful mitral commissurotomy may reduce the likelihood of thromboembolism, although accurate comparisons are not available. About 90% of patients are free of a thromboembolic event 8 to 10 years after open commissurotomy. The linearized rate of thromboembolism has been reported at 1% to 2% per patient-year. This statistic is not very useful, however, because the hazard function for a first or subsequent thromboembolic event is not constant (Fig. 11-25). Atrial fibrillation, older age, and a history of thromboembolism preoperatively are reported risk factors for postcommisurotomy thromboembolism. Also, a postcommisurotomy thromboembolic event predisposes the patient to further events (Table 11-3). The type of surgical commissurotomy, open or closed, has not been shown to be a risk factor.

**Functional Status**

Successful open or closed mitral commissurotomy, in properly selected patients, results in dramatic relief of symptoms. More than 90% of patients are in NYHA functional class I or II during the first 1 or 2 postoperative years. Lack of permanent favorable results from mitral commissurotomy is evident in the gradual decline in functional status. Redevelopment of symptoms results from gradual loss of leaflet pliability as well as progression of subvalvar pathology and increase of valvar calcification. Although recurrence of rheumatic fever may accelerate this pathology, progression seems to occur even without further rheumatic episodes. Thus, NYHA functional class correlates well with estimated area of the mitral orifice late postoperatively; the mean value...

Data from Hickey and colleagues. Database is same as in Table 11-2. Variables entered into the analysis, ordinal logistic coefficients, and P values are provided in the original article.

Thromboembolism was considered to be a modulated renewal process (event), and thus the first, second, or third events (total of 44) are included.

Figure 11-25 Depiction of all postcommissurotomy thromboembolic events, not only the first episode. Format is as in Fig. 11-21. A, Cumulative event function for all thromboembolism. B, Hazard function for any thromboembolic event after mitral commissurotomy. (From Hickey and colleagues.)

Figure 11-26 Comparison of preoperative and postoperative New York Heart Association functional status in 123 patients surviving an average of 48 months after open mitral valvotomy. Key: Class IIa, Breathlessness with unusually strenuous activity; class IIb, breathlessness with ordinary activity. (From Smith and colleagues.)

Figure 11-27 Declining percentage of patients in New York Heart Association functional class I after open or closed commissurotomy. Changes across time of functional classes II and III are also shown. The longer the time since commissurotomy, the greater the percentage of patients undergoing mitral valve replacement. (From Hickey and colleagues.)

is 2.0 cm² in class I patients, 1.7 in class II, and 1.6 in class III. Immobility of valve leaflets and obstructive subvalvar agglutination of chordae are the main risk factors for a poor early functional result. Calcification of a portion of the leaflet(s) does not preclude a satisfactory result.

Despite excellent early and intermediate results in the current era, durability of results is limited. Scarring from the rheumatic process in the valve seems to progress gradually. Eventually, although not until 20 years postoperatively in some patients, most patients lose their good functional status and return with restenosis or new-onset regurgitation (Fig. 11-27). Absence of leaflet pliability in the presence of valvar calcification is a risk factor for the rate of decline in functional...
status after all types of commissurotomy. Type of surgical commissurotomy (open or closed) has not been shown to be a risk factor\textsuperscript{110} (Table 11-4).

**Reintervention**

Most patients undergoing mitral commissurotomy by any technique will require another procedure at some time, generally mitral valve replacement because of gradual loss of leaflet pliability, progression of subvalvar pathology, and increase of valvar calcification\textsuperscript{29,35,36,61,82} (see Fig. 11-27). About 20% of patients undergoing surgical commissurotomy require valve replacement within 10 years, and about half require it by 20 years (Fig. 11-28).

The same variables that cause survival to vary probably cause prevalence of postcommissurotomy mitral valve replacement to vary (Table 11-5). Again, type of surgical commissurotomy (open or closed) has not been demonstrated to be a risk factor for subsequent mitral valve replacement.\textsuperscript{111} Morphology of the mitral valve powerfully affects the time-related prevalence of mitral valve replacement after surgical commissurotomy (Fig. 11-29) as well as after percutaneous balloon valvotomy.\textsuperscript{81} At 7 years, freedom from restenosis was 93% for the open and balloon procedures vs. 63% after closed commissurotomy.

**Percutaneous Balloon Valvotomy**

Early hemodynamic, functional, and anatomic improvement after percutaneous mitral valvotomy is, as noted earlier, nearly equivalent to results following open surgical commissurotomy.\textsuperscript{316} Long-term outcomes are not available. There is a progressive decrease in valve area that closely parallels that seen historically and in concurrent studies for surgical approaches. Degree of deterioration can be predicted by variables related to preoperative functional class and morphologic features of the mitral valve.\textsuperscript{1118} (Table 11-6 and Fig. 11-30). Thus, long-term survival and need for reintervention after the catheter approach should be similar to results after the open surgical approach.

**Redo Mitral Commisurotomy**

Survival after a second mitral commissurotomy is surprisingly good in view of the more advanced valvar pathology usually present at reoperation. Peper and colleagues report 5-, 10-, and 15-year survival of 96%, 83%, and 63%, respectively, after repeat open commissurotomy. Also, 16 (31%) of 52 hospital survivors underwent still another mitral operation, usually a replacement, an average of 8.2 years later.\textsuperscript{76}

**Repair of Mitral Regurgitation**

In general, early, intermediate, and long-term results of repair of mitral valve regurgitation have been good.\textsuperscript{1113,84}

Survival

Early (Hospital) Death Hospital mortality after repair of isolated nonischemic mitral regurgitation is very low in the current era. Hospital mortality of 1% for isolated elective nonischemic mitral valve repair was reported in the STS Adult Cardiac Surgery Database in 2009.53

Time-Related Survival Time-related survival, including hospital deaths, of patients with mitral regurgitation undergoing repair with or without other cardiac procedures has been better than that of patients undergoing replacement. Most groups have reported similar findings, with 4- or 5-year survival after repair varying from 74% to 94%.10,30,32,23,14,15,16,30 Ten-year survival of one group of patients undergoing repair with or without other procedures was 59%.54

Variability in survival among reports and improved survival after repair compared with replacement are related in part to the differing prevalence of risk factors for death.57,63 Mayo Clinic surgeons reported surgical mortality of 2.6% for repair and 10% for replacement (P = .002).64 Late survival (in surgical survivors) at 10 years was 69% ± 6.0% vs. 58% ± 5.0% (P = .02), and late survival after valve repair did not differ from expected survival (Fig. 11-31). Again, the two groups differed mainly in degree of preoperative heart failure.65 A multicenter European study reported a 30-day mortality of 0.7% and a superior risk-adjusted 5-year survival with repair versus replacement (92% vs. 80%, P < .001).66 To address comparison of repair versus replacement, Gillinov and colleagues used propensity-score matching (see “Clinical Studies with Nonrandomly Assigned Treatment” in Chapter 6) and found that repair conferred a survival advantage in most (89%) patients that became evident after about 2 years.

Modes of Death
Modes of death early and late after mitral valve repair are similar to those after mitral valve replacement.54 The most common mode is cardiac failure.

Incremental Risk Factors for Premature Death
Incremental risk factors for premature death after repair of mitral regurgitation are the same as those after replacement (Table 11-7). In the UAB experience, neither procedure was a risk factor vis-à-vis the other. Akins and Dujardin and their colleagues, however, indicate that mitral valve replacement is a risk factor for late mortality compared with mitral repair in a univariable analysis, but not by multivariable analysis.10,23 In most studies, this reflects choice of replacement for those
patients who are older or in a more advanced NYHA functional class. However, Gillinov and colleagues found by both multivariable analysis and propensity adjustment that replacement was a risk factor.\textsuperscript{16,16}

**Residual or Recurrent Mitral Regurgitation**

Many patients have no residual mitral regurgitation after repair.\textsuperscript{4,7,29} Alvarez and colleagues reported that only 4.5% of 155 repair patients experienced repair failure within 6 months.\textsuperscript{15} In a group of more than 1000 patients analyzed for late failure, only 30 repair patients needed late reoperation (freedom from reoperation at 10 years 93%; CL 91%-94%).\textsuperscript{13} Recurrent regurgitation in these and other series is caused by either progression of disease or inadequate operation, including suture dehiscence.\textsuperscript{13} In most patients, residual regurgitation is present immediately after repair rather than developing later.\textsuperscript{13} Although reoperation may underestimate the prevalence of late regurgitation, various groups report freedom from reoperation of 80% to 96% at 10- to 15-year follow-up, suggesting satisfactory durability of repair.\textsuperscript{12,13,3,10,13,31,32}

A clear relationship has not been established between technique of repair and prevalence of residual regurgitation. However, repair is clearly more effective for patients with degenerative (myxomatous) disease than for those with restrictive (rheumatic) disease.\textsuperscript{12,17} (Fig. 11-32). The best results may be in patients with ruptured chordae to the posterior leaflet,\textsuperscript{5,16,29} although Orszulak and colleagues have found almost equally good results when the ruptured chordae belong to the anterior leaflet.\textsuperscript{3,27,33} For complex repairs and those involving the anterior leaflet, chordal replacement is superior to chordal shortening.\textsuperscript{17,39} Historically, surgical repair of posterior leaflet prolapse has been more durable than repair of anterior leaflet prolapse, but results of the latter have improved in the current era.\textsuperscript{3,30} Lawrie and colleagues reported a contemporary experience in which outcomes were equally

good for artificial chord replacement in anterior leaflet prolapse as in posterior leaflet prolapsed. In patients with isolated posterior leaflet prolapse, chordal replacement plus anuloplasty ring appears to provide midterm valve competence equivalent to that of traditional quadrangular resection plus ring. Others have extended leaflet resection to the severely prolapsing anterior leaflet with good midterm valve function. G8, S6 Gazoni and colleagues emphasize, however, that a triangular resection technique should be used, and the height of the resected leaflet segment should not exceed one third of the distance from the anulus to the free edge of the anterior leaflet.

**Cardiac Performance**

LV performance responds to mitral valve repair in the same general manner as it does to mitral valve replacement. Some regression of LV hypertrophy occurs, with decreased heart size, LV volume, and muscle mass. Preoperative LV systolic function is more or less preserved, although EF is often moderately decreased. However, some studies document LV performance to be better after mitral valve repair than after replacement. B30, C35 Corin and colleagues found that systolic and diastolic function returned to normal in mitral repair patients, but that global and regional systolic function as well as diastolic function were depressed in replacement patients. This difference is probably attributable to preservation of the tensor apparatus in the repaired valve (Fig. 11-33) but may also reflect earlier intervention in patients undergoing repair vs. replacement.

An important issue is the potential reversal of preexisting LV dysfunction following mitral valve repair (also see discussion of mitral valve repair in Chapter 20). Among patients with preserved EF preoperatively, large regurgitant volume (>80 mL by quantitative Doppler and proximal isovelocity surface area method) is predictive of LV dysfunction (EF < 50%) following mitral valve repair.

**Thromboembolism**

Patients undergoing mitral valve repair are generally free of late thromboembolic complications, even though they rarely receive anticoagulants. Duran and colleagues found 93% of patients free of thromboembolism within the first 4.5 years after repair, a prevalence similar to that for xenograft replacement in their experience.

**Left Ventricular Outflow Obstruction**

In about 5% to 10% of patients with mitral regurgitation associated with mitral valve prolapse, abnormal systolic anterior motion (SAM) of the mitral valve develops immediately after mitral anuloplasty with a Carpentier ring. Related to this, gradients of 60 mmHg across the LV outflow tract have been measured. This complication appears to be
limited to patients with myxomatous degeneration\textsuperscript{18,20,99} and excessive redundancy of the anterior and posterior leaflets, although presence of a small hyperdynamic LV and excessive ventricular hypertrophy may also contribute. SAM is now believed to be the result of anterior displacement of leaflet coaptation.\textsuperscript{15} LV outflow tract obstruction has not been observed in patients undergoing suture (rather than ring) mitral anuloplasty.\textsuperscript{95} Cosgrove and colleagues have shown that simple removal of the rigid anuloplasty ring abolished the obstruction while retaining competence of the mitral valve.\textsuperscript{37} Substitution of a larger ring, flexible ring, or half-ring or addition of a posterior leaflet sliding plasty may also eliminate SAM. Grossi and colleagues noted a prevalence of 6.4\% (CI 5.2\%-7.8\%) in their series of valve repair. All patients were treated medically, with resolution of gradients in all patients and resolution of SAM in half of patients within a year.\textsuperscript{30}

**Functional Status**

Functional status of most patients is excellent after repair or replacement of a regurgitant mitral valve, with greater than 90\% of surviving patients in NYHA class I or II.\textsuperscript{38,39,34}

**Reoperation**

Freedom from reoperation late after mitral valve repair is generally 85\% to 95\% at 10 years,\textsuperscript{16,20,47,81,83,84,14,15} similar to that after mitral valve replacement.\textsuperscript{27} Prevalence of reoperation is greater for anterior leaflet repair than for posterior leaflet repair.\textsuperscript{2,14}

Factors that may increase risk of reoperation late after repair include rheumatic disease (as opposed to degenerative disease; see Fig. 11-32), advanced degenerative changes involving the anterior leaflet, and residual regurgitation at completion of the initial procedure. When patients with 1+ or 2+ (of possible 4+) early postoperative regurgitation were compared with those with “echo-perfect” results (no regurgitation), Fix and colleagues found 83\% freedom from reoperation in the former group vs. 96\% in the latter group at late follow-up ($P = .07$).\textsuperscript{34} Type of repair appears to have no effect on prevalence of reoperation.\textsuperscript{29,29} Reed, Chauvaud, and Ohno and their colleagues showed mitral repair to be as successful in children as in adults\textsuperscript{20,22,24} (Fig. 11-34).

![Figure 11-34](image)

**Figure 11-34** Freedom from reoperation after mitral valve repair in children younger than age 12 years. Vertical bars represent one standard error. (From Chauvaud and colleagues.\textsuperscript{19})

The hazard function of reoperation after repair of mitral regurgitation is low, constant, and different from that of replacement (Fig. 11-35). Mitral valve repair does not have the peaking early hazard phase for reoperation, which in mitral replacement is related to periprosthetic leakage and prosthetic valve endocarditis. Furthermore, at least until now, no rising late hazard phase for reoperation after repair has been demonstrated, indicating the durability of this approach. In fact, in a 20-year experience reported by the Mayo Clinic, the absolute prevalence of reoperation in the current era was 5\% ± 2\% for posterior leaflet repair and 10\% ± 2\% for anterior leaflet repair at 10 years.\textsuperscript{27} A more recent analysis from the Mayo Clinic\textsuperscript{36} examined reoperations after mitral valve repair over 35 years. New pathology was the cause for reoperation in about 55\% of patients, and failure of mitral repair in most of the remainder. Mitral valve re-repair was possible in 44\% of patients.

**Infective Endocarditis**

Infective endocarditis is rare after repair of mitral regurgitation.\textsuperscript{41} No cases were found in the UAB experience, with a follow-up of 21 to 120 months.\textsuperscript{34} This complication is more common when the affected valve is replaced rather than repaired.\textsuperscript{44}

**Mitrval Valve Replacement**

**Survival**

**Early (Hospital) Death** Hospital mortality after primary isolated mitral valve replacement for nonischemic valve disease with preserved LV function is generally less than 2\% among patients without serious comorbidities in the current era.\textsuperscript{12} A hospital mortality of 5.7\% for isolated mitral valve replacement for any etiology, primary and reoperation, was reported from the STS Adult Cardiac Surgery Database during the years 2002 to 2006.\textsuperscript{11} Medicare sources indicated a hospital mortality of 14\% for isolated mitral valve replacement among patients older than age 65.\textsuperscript{65} Mortality after mitral valve replacement with tricuspid surgery is similar or slightly higher.\textsuperscript{12} When mitral valve replacement has been preceded by mitral valve repair, hospital mortality is not affected appreciably.
Time-Related Survival Considering both isolated mitral valve replacement and replacement done concomitantly with other procedures, 1-, 5-, and 10-year survival in an earlier era was 82%, 68%, and 55%, respectively. The hazard function had a rapidly declining early phase, but also a constant phase extending as long as patients had been followed (Fig. 11-36). Time-related survival has been higher in patients undergoing primary isolated mitral valve replacement than in those having replacement combined with other cardiac procedures (Fig. 11-37). Survivals similar to those reported here, including some 15-year survivals of 35% to 50%, have been reported by other groups.810,821,825,836-838,847 Both early and late survival after primary mitral replacement are considerably improved over that obtained in earlier eras.821,810,813 Improvement is related to better myocardial management,83 reduction in technical problems such as atrioventricular rupture and air embolization, and improved mechanical and bioprosthetic valve replacement devices.

Survival both early and late after reoperation is less than that after original valve replacement (Fig. 11-38). This is related not only to technical aspects of reoperation but also to the fact that prosthetic valve endocarditis is often the indication for reoperation, and reoperative patients as a group tend to have greater functional disability than those undergoing their first valve replacement.826

Mitral valve replacement in children and adolescents has low early mortality, and time-related survival is probably equal to or superior to that of adults. However, mitral replacement in the first year of life may carry a higher risk; 9 of 25 patients died (36%; CL 25%-48%) in the experience of Kadoba and colleagues.83 Seven of the deaths were in patients with atrioventricular (AV) septal defects. Recent experience with improved repair of the left AV valve in AV septal defects, better myocardial management, and supraannular placement of the prosthesis have reduced early risk in infants considerably (see Results in Chapter 34). Time-related morbidity is attributable to reoperation associated with bioprosthetic tissue degeneration and acquired prosthetic stenosis associated with somatic growth.

Modes of Death
Most early deaths are attributable to cardiac failure, usually acute and within a few days of operation. Subacute cardiac failure may be the mode of death in the hospital or within 1...
to 2 months after hospital discharge. It is characterized by stable but low cardiac output and consequent widespread subsystem failure, often including cool (rarely frankly ischemic) extremities, abdominal distention, and occasionally ischemic bowel, gastrointestinal bleeding, jaundice, poor renal function, and mental confusion. Infection may occur as a terminal event.

**Incremental Risk Factors for Premature Death**

Some of the incremental risk factors for death that existed during the earliest eras of mitral valve replacement have been neutralized by improvements in surgical technique, myocardial management (see Chapter 3), and perioperative care (see Chapters 4 and 5). Among specific improvements is sparing of the tensor apparatus, as demonstrated particularly by the Stanford group (see “Cardiac Performance” later in this section). Surprisingly, large size of the left atrium is a risk factor for poor outcome that approaches the risk imposed by LV enlargement. Presumably, marked LV enlargement connotes reduced ventricular contractility (see “Mitral Regurgitation” under Natural History earlier in this section), and this may actually be responsible for increased risk.

**Marked Left Ventricular Enlargement** LV enlargement is a risk factor for death early after repair (see Table 11-8). Presumably, marked LV enlargement connotes reduced ventricular contractility (see “Mitral Regurgitation” under Natural History earlier in this section), and this may actually be responsible for increased risk.

**Ischemic Mitral Regurgitation** Ischemic etiology is a greater risk factor for death late after mitral valve replacement than nonischemic etiology.

**Advanced Functional Disability** Expressed as NYHA functional class, advanced disability is an important risk factor for death in the early phase of hazard.

**Global Myocardial Ischemic Time** Prolonged global myocardial ischemic time using cold cardioplegia is an incremental risk factor for death in the early phase after operation. This can be seen from predicted 30-day mortality of 6% or less when global myocardial ischemic time is 120 minutes or shorter (Fig. 11-39). Almost all mitral valve operations, including those with concomitant coronary artery bypass grafting (CABG) and tricuspid anuloplasty, can be accomplished within that time.

**Nonischemic Mitral Regurgitation** In contrast to mitral stenosis, nonischemic mitral regurgitation is probably a risk factor for death (see Table 11-8), but not to the extent that might be predicted from the sudden increase in LV afterload imposed when the regurgitant mitral valve is made competent. This is probably because a number of the other sudden hemodynamic changes (e.g., reduction in LV stroke work) are favorable.

**Marked Left Ventricular Enlargement** LV enlargement is a risk factor for death early after repair (see Table 11-8). Presumably, marked LV enlargement connotes reduced ventricular contractility (see “Mitral Regurgitation” under Natural History earlier in this section), and this may actually be responsible for increased risk.

**Nonischemic Mitral Regurgitation** In contrast to mitral stenosis, nonischemic mitral regurgitation is probably a risk factor for death (see Table 11-8), but not to the extent that might be predicted from the sudden increase in LV afterload imposed when the regurgitant mitral valve is made competent. This is probably because a number of the other sudden hemodynamic changes (e.g., reduction in LV stroke work) are favorable.

**Marked Left Ventricular Enlargement** LV enlargement is a risk factor for death early after repair (see Table 11-8). Presumably, marked LV enlargement connotes reduced ventricular contractility (see “Mitral Regurgitation” under Natural History earlier in this section), and this may actually be responsible for increased risk.

**Left Atrial Enlargement** Surprisingly, large size of the left atrium is a risk factor for poor outcome that approaches the risk imposed by LV enlargement.

**Ischemic Mitral Regurgitation** Ischemic etiology is a greater risk factor for death late after mitral valve replacement than nonischemic etiology.

**Advanced Functional Disability** Expressed as NYHA functional class, advanced disability is an important risk factor for death in the early phase of hazard.

**Global Myocardial Ischemic Time** Prolonged global myocardial ischemic time using cold cardioplegia is an incremental risk factor for death in the early phase after operation. This can be seen from predicted 30-day mortality of 6% or less when global myocardial ischemic time is 120 minutes or shorter (Fig. 11-39). Almost all mitral valve operations, including those with concomitant coronary artery bypass grafting (CABG) and tricuspid anuloplasty, can be accomplished within that time.

**Incremental Risks of Concomitant Tricuspid Anuloplasty and CABG** are discussed separately under “Results” in Sections II and III.

### Devices

No device currently in use has been clearly shown to be a risk factor for premature death after mitral valve replacement. Earlier, the “high profile” of caged-ball valves was alleged to be an incremental risk factor because of its supposed obstructive effect and detrimental effect on LV function. This may have been true, in view of the superior early results from 1970 to 1973 using a stent-mounted aortic allograft valve, suggesting that a nonobstructive device with a central orifice flow pattern is optimal. Also, at least in the experience of Cohn and colleagues, survival after mitral valve replacement with a bioprosthesis of any type was higher than after replacement with a prosthetic disc valve, perhaps related. Undergoing mitral valve replacement for mitral regurgitation. Overall reported operative mortality in this age group in the United States exceeds 14%, and is notably higher (>20%) in low-volume centers.

### Nonischemic Mitral Regurgitation

In contrast to mitral stenosis, nonischemic mitral regurgitation is probably a risk factor for death (see Table 11-8), but not to the extent that might be predicted from the sudden increase in LV afterload imposed when the regurgitant mitral valve is made competent. This is probably because a number of the other sudden hemodynamic changes (e.g., reduction in LV stroke work) are favorable.
to fewer thromboembolic events and only infrequent anticoagulation in the former group\textsuperscript{228} (see “Mechanical Mitral Valve Replacement Devices” and “Bioprosthetic Mitral Valve Replacement Devices” later in this section).

Previous closed or open mitral valve repair or percutaneous balloon valvotomy cannot be considered incremental risk factors.

**Cardiac Performance**

Left AV valve function usually is greatly improved, but a transvalvar end-diastolic gradient is present in most patients following mitral valve replacement.\textsuperscript{519,515} Magnitude of the gradient depends on patient size and physical activity (e.g., cardiac output at rest and during exercise), size of device inserted, and its type.\textsuperscript{823} Gradients are small when devices larger than 29 mm can be used, but they vary according to the device and are typically present with 29-mm, 27-mm, and 25-mm sizes (Table 11-9). Zero-pressure fixation techniques may improve the performance of porcine bioprostheses by making the leaflets more pliable.\textsuperscript{842}

Response of LV performance to valve replacement in patients with mitral stenosis who have impaired function preoperatively has not been determined, but the abnormalities of compliance (which this type of impairment usually induces) probably remain.

Sudden ablation of mitral regurgitation by mitral valve replacement triggers a particularly complex LV response (see “Mitral Regurgitation” under Natural History earlier in this section).\textsuperscript{514,515,585} If the LV is normal, as usually occurs in acute experimental or clinical regurgitation, sudden correction of regurgitation immediately increases forward flow (cardiac output) despite increased afterload.\textsuperscript{531} After valve replacement for chronic mitral regurgitation, however, EF is lower, at least transiently, than preoperatively in most patients.\textsuperscript{85,510} When preoperative LV enlargement is only mild or moderate (with an end-diastolic dimension of 7 cm or less and an end-systolic dimension of 5 cm or less by echocardiography),\textsuperscript{510} reduced EF after valve replacement generally remains within the normal range.

In patients with a more than moderately enlarged LV at operation (with an echocardiographically determined end-diastolic dimension > 7 cm or an end-systolic dimension > 5 cm), a condition accompanied by decreased LV contractility and increased myocardial degenerative changes,\textsuperscript{511} EF is greatly reduced 2 weeks after valve replacement and at times deteriorates still further during the later postoperative period.

 Patients undergoing effective repair have generally better ejection indices postoperatively than similarly matched candidates after valve replacement. Tischler and colleagues reported reduction of rest and exercise EFs in 10 mitral replacement subjects, but no change in repair patients.\textsuperscript{75} Repair patients had a higher stroke volume and EF at rest and exercise, associated with lower end-systolic wall stress.

LV enlargement regresses after operation, with both end-diastolic and end-systolic dimensions returning toward normal.\textsuperscript{510} LV contractility is probably normal or near normal preoperatively and remains so after operation.\textsuperscript{510,516} In many patients, however, LV size is reduced early postoperatively (end-diastolic volume is less, and end-systolic volume is about the same), but increases late postoperatively (6-12 months after operation).\textsuperscript{510} LV wall hypertrophy does not regress.\textsuperscript{510} In such patients, the preoperative LV structural and contractile abnormalities not only show no regression after valve replacement but in fact progress and account for many recurrences of symptoms 2 to 5 years postoperatively and for many deaths 2 to 10 years postoperatively.

These findings apply to conventional mitral valve replacement in which the tensor apparatus (chordae tendineae) of the native valve is excised or transected (see “Chordal Sparing” under Technique of Operation earlier in this section). Experiments by Miller and colleagues have demonstrated that chordal division results in deterioration of LV systolic function in both isovolumic and ejecting heart preparations.\textsuperscript{115-117} These observations were extended to animals with surgically induced mitral regurgitation.\textsuperscript{75} Mitral valve replacement was performed with all chordae tendineae intact; LV systolic function was then assessed and subsequently remeasured after division of the chordae. End-systolic pressure volume (E\textsubscript{syst}V) and end-systolic stress volume (M\textsubscript{syst}) relationships decreased by 46% and 36% when the chordae were divided (P = .001 and .0001, respectively), indicating deterioration in LV energetics and mechanical efficiency (Fig. 11-40).

Miller termed the effect of an intact tensor apparatus on optimal global ventricular function “valvular-ventricular interaction.”\textsuperscript{515} Deterioration of function after division of the chordae resulted from an exacerbated mismatch of ventricular-arterial coupling with increased load-resisting shortening. In fact, chordal sparing was first suggested by Lillehei in 1964,\textsuperscript{112} then later disputed by some.\textsuperscript{85} However, David and colleagues in 1983 and later Daenen, Miki, Goor, and Hennein and their colleagues produced clinical results suggesting that chordal sparing during mitral valve replacement improved hospital survival and global LV function,\textsuperscript{51,D9,G2,G1,H1,M23} Carabello’s group again documented preservation of systolic ejection performance in mitral valve replacement with intact tensor apparatus compared with otherwise similar mitral valve replacement patients without chordal preservation.\textsuperscript{527} Preservation resulted in postoperative decrease in diastolic volume, reduced end-systolic stress, and no reduction of ejection indices. In analogous experiments in dogs, these investigators found individual myocyte contractile function normal when global contractile indices

*Rate 9.5% when multiple events included.
*In patients 51 to 65 years of age at insertion.

*Thromboembolism*

Table 11-10 shows the incidence of thromboembolism reported for selected mechanical and bioprosthetic valves (Fig. 11-41). In general, the incidence is somewhat less with bioprostheses. The incidence and importance of thromboembolism and anticoagulant-related hemorrhage are sufficient to have unfavorable effects on the life expectancy of patients with mechanical valves.

Adequacy of warfarin therapy appears to be the most important determinant of the rate of thromboembolism in patients with mechanical valves in the mitral position. With bioprosthesis, warfarin therapy for 3 months or aspirin indefinitely appear to be as effective as long-term warfarin therapy.

*Acute Thrombotic Occlusion*

Acute thrombotic occlusion of a mitral prosthesis occurs more often with a mechanical device (3 per 100 patient-years) than with a bioprosthesis (1.9 per 100 patient-years) (see “Mechanical Mitral Valve Replacement Devices” later in this section).

The problem in using linearized rates is well exemplified in the case of acute thrombotic occlusion. Linearized rates assume a constant hazard function (see “General Comments” under Time-Related Events in Chapter 6). However, at least in the case of the Bjork-Shiley tilting-disc valve, the hazard function for this event had a single peaking phase that returned to a low level by 4 years after operation. In addition to the scientific importance of this finding, the shape of
the hazard function and a limited clinical experience supports the use of thrombectomy (through both the left atrium and aorta) rather than valve replacement.

Acute thrombotic occlusion occurs primarily but not exclusively in patients receiving suboptimal anticoagulant therapy. A possible risk factor is female gender. Patients with this catastrophic complication usually become symptomatic only 1 to 3 days before admission to the hospital and present principally with extreme dyspnea and orthopnea. The patient may have noticed a decrease in intensity of prosthetic valve sounds about the time symptoms began. Many experience chest pain, and signs of shock usually appear. Although regurgitation is often present, an apical systolic murmur is rarely heard. A fluoroscopic finding of limited disc movement supports this procedure. 

Cardiac catheterization usually gives conclusive evidence of mitral obstruction, but such patients are usually too ill to withstand this procedure. Surgical thrombectomy often achieves a good result. Thrombolyis has been used with mixed results (see previous text and “Thrombosis” under Results in Chapter 14).

Complications of Long-Term Anticoagulation
Complications of long-term anticoagulation with warfarin or warfarin-like compounds appear to be independent of type of prosthesis. Certainly the quality of the surveillance program for patients receiving long-term anticoagulation affects both freedom from anticoagulant-related hemorrhage and prevalence of thromboembolic complications. Percentage freedom from first anticoagulant-related hemorrhage at 5, 10, and 15 years is about 87%, 79%, and 71%, respectively. Linearized rate of important hemorrhage is generally estimated to average 2.3 to 3.4 per 100 patient-years in patients with mechanical prostheses who are taking warfarin.

Figure 11-41 Summary of linearized rate of thromboembolism for mechanical mitral valve prostheses from reports published from 1989 to 2000, each containing at least 400 patient-years of follow-up. Vertical axis is linearized rate in units of percent per year (equivalent to events per 100 patient-years). Each symbol represents one series; height of symbol represents point estimate of event rate, and vertical bars show 95% confidence intervals. Series are grouped on the horizontal axis by valve model, shown below the axis by a two-letter abbreviation. Lower horizontal dashed line indicates the U.S. Food and Drug Administration’s Objective Performance Criteria (OPC). For approval of a new valve, the upper confidence limit should be less than twice the OPC (upper dashed line). Circles indicate that only late events were used to calculate the rates; diamonds indicate that both early and late events were used calculated to calculate the rates; diamonds indicate that both early and late events were used calculated to calculate the rates; diamonds indicate that both early and late events were used calculated to calculate the rates; diamonds indicate that both early and late events were used.

Prophylactic Valve Endocarditis
Prophylactic valve endocarditis is an uncommon but serious complication that results in the death of more than half of affected patients. Endocarditis strongly predisposes the patient to periprosthetic leakage. When it appears within 3 to 6 months of operation, prosthetic valve endocarditis is probably related to events in the operating room. When it develops later, it probably results from a new bacteremia (infective endocarditis is covered in detail in Chapter 15). When mitral prosthetic infection becomes evident within 6 months of implantation, prosthetic leakage is likely to occur, and the risk of death is high. Intensive antibiotic treatment followed by early prosthetic replacement in most patients is indicated. The organism and its antibiotic sensitivity should be identified and specific therapy used. In the unusual circumstance of excellent response to antibiotics, no evidence of peripheral embolization, and no evidence of peri-prosthetic leakage, reoperation may be deferred. The patient is followed closely under hospital conditions that permit immediate reoperation in the event any of these complications occur. When mitral prosthetic infection becomes apparent for the first time more than 6 months postoperatively, the same management protocols apply. More of these patients respond well to intensive medical treatment alone than those with infections occurring in the first 6 months after operation.

Periprosthetic Leakage
At UAB in an era when various suture techniques were used (1975 to July 1979), 13 of 452 (2.9%; CI 2.1%-3.9%) patients required reoperation for periprosthetic leakage. Currently, the incidence in uninfected patients approaches zero

---

1Prophylactic valve endocarditis and its abbreviation PVE are familiar, standard, and historical designations for infective endocarditis on any heart valve substitute. The rationale for a more appropriate term, replacement device endocarditis, is presented in Chapter 12.
when suture techniques described in this chapter are used. Preoperative infective endocarditis increases risk of prosthesis dehiscence with periprosthetic leakage. Anular calcification also increases risk.

Chronic Hemolysis
Well-functioning bioprosthetic and mechanical prostheses used in the current era rarely produce more than mild chronic hemolysis unless periprosthetic leakage is present. With periprosthetic leakage, hemolysis may be severe with any device; red cell trauma and fragmentation may be extreme under these circumstances. A mechanical prosthesis of small size relative to body size and hemodynamics may result in severe hemolysis.

Functional Status
Symptoms are reduced and functional capacity increased in most patients. However, prevalence of an excellent functional status after replacement is related to preoperative functional class. Only about half of patients with severe preoperative chronic functional disability return to NYHA functional class I. This finding suggests that many patients with mitral valve disease and advanced chronic disability have a secondary irreversible ventricular myopathy. Infrequently, a patient may display striking symptomatic improvement for 2 to 5 years, after which important symptoms and disability gradually reappear despite good function of the prosthetic device. This sequence is believed to result from progression of a secondary cardiomyopathy that was present before operation or occasionally from progression of other valve lesions.

Reoperation
Reoperation, usually for periprosthetic leakage with or without infectious endocarditis or for bioprosthetic degeneration, has been required within 5 years of the original operation in about 5% of patients. Prevalence, and particularly the hazard function for reoperation, are different for mechanical and bioprosthetic devices; only bioprostheses exhibit degeneration and a late-rising hazard function (Fig. 11-42). Risk of death after reoperation, both early and intermediate term

![Image](https://via.placeholder.com/150)

**Figure 11-42** Hazard function for reoperation for mechanical prostheses and bioprostheses, determined by separate analyses. Hazard function for mechanical prostheses has an early peaking phase and a constant phase. Hazard function for bioprostheses has an early peaking phase and a second, late rising phase. (From Blackstone and Kirklin.)

Summary
Although not free of complications in all patients, mitral valve replacement provides a considerably better prognosis than could be expected according to natural history. About 70% of patients are alive and without complications for at least 5 years after valve replacement.

INDICATIONS FOR OPERATION, SELECTION OF TECHNIQUE, AND CHOICE OF DEVICE

Mitral Stenosis
Patients with mitral stenosis and at least NYHA class II symptoms of heart failure should be considered for medical, interventional, or surgical therapy based on clinical, echocardiographic, and catheterization considerations. Useful algorithms for NYHA class II patients (Fig. 11-43) and class III and IV patients (Fig. 11-44) have been developed by the ACC/AHA. When an opening snap is prominent, when calcification cannot be demonstrated fluoroscopically, and when echocardiography demonstrates pliable leaflets and little or no subvalvar narrowing, good results from surgical mitral commissurotomy can usually be obtained. Under these circumstances, even mild symptoms (NYHA functional class II) in the presence of severe mitral stenosis are an indication for intervention (see Fig. 11-43). Percutaneous balloon mitral commissurotomy is often chosen, although surgical commissurotomy is a reasonable alternative. Particularly in young women, one acute episode of important paroxysmal nocturnal dyspnea or pulmonary edema in the presence of at least moderate mitral stenosis is an indication for intervention. It is particularly indicated before onset of atrial fibrillation. Intervention is also advisable when there is an important increase in Rp, even in the absence of symptoms. Asymptomatic patients with recurrent episodes of arterial emboli while receiving adequate anticoagulation are advised to undergo intervention if commissurotomy is a strong possibility; in this setting and in the presence of demonstrated thrombi in the left atrium, open surgical commissurotomy is advisable.

When mitral valve replacement seems likely (because of absence of an opening snap, immobile leaflets, heavy mitral valve calcification, severe subvalvar disease, or associated mitral regurgitation), a more symptomatic state is demanded as the indication for operation because of the added long-term imponderables introduced by the device inserted; these would be more severe chronic symptoms (NYHA functional class III or higher) or several acute episodes of symptoms of pulmonary venous hypertension.

Advanced disability, associated tricuspid valve disease, and associated coronary artery disease are not contraindications to operation, nor is severe pulmonary hypertension.

Mitral Regurgitation
At operation, mitral valve repair rather than replacement is chosen whenever possible: in 50% to 70% of all patients and in up to 90% of patients with mitral valve prolapse. Repair avoids the potential complications of long-term
Mitral Regurgitation

Management strategy for patients with mitral stenosis and mild symptoms. Mitral valve area (MVA) measurements may vary, and mean transmitral gradient, pulmonary artery wedge pressure (PAWP), and pulmonary artery systolic pressure (PASP) should also be taken into consideration. There is controversy regarding whether patients with severe mitral stenosis (MVA < 1 cm²) and severe pulmonary hypertension (PASP > 60 to 80 mmHg) should undergo percutaneous mitral balloon valvotomy (PMBV) or mitral valve replacement (MVR) to prevent right ventricular failure. Key: CXR, Chest radiograph, ECG, electrocardiogram; echo, echocardiography; LA, left atrial; MR, mitral regurgitation; MVG, mean mitral valve pressure gradient; NYHA, New York Heart Association; PAP, pulmonary artery pressure; 2D, two-dimensional. (From Bonow and colleagues.31)

Figure 11-43 Management strategy for patients with mitral regurgitation and gradually deteriorating LV function and/or may have only mild symptoms associated with long-term outcome. A strong predictor of valve reparability, operative mortality, and long-term survival and freedom from cardiovascular complications is a cardiographic anatomic and physiologic classification is a strong predictor of valve reparability, operative mortality, and long-term outcome.

Patients with mitral regurgitation may remain asymptomatic or may have only mild symptoms associated with long-standing disease and gradually deteriorating LV function because of the mitigating effect of regurgitant mitral flow on LV systolic function, reflected in EF. Thus, whereas the diagnosis and symptoms of mitral stenosis generally provide sufficient evidence for decision making, special attention must also be paid to the status of the LV in mitral regurgitation. A decline in LV contractility, assessed by end-systolic pressure-volume relationships or a similar method, portends a state of irreversibility and may be used to advise operation in relatively asymptomatic patients. Additionally, operation in most of these asymptomatic patients is well advised if repair is probable, because it has been well documented that postoperative LV systolic and diastolic LV function are preserved after mitral valve reconstruction.33,51

Reference has been made to more sophisticated methods of assessing the functional state of the LV in patients with mitral regurgitation (see “Mitral Regurgitation” under Natural History). Zile, Schuler, and their colleagues identified groups of patients with elevated end-diastolic dimensions, elevated systolic dimensions, and low-normal LVEF in whom symptoms were not relieved, heart failure was persistent, or high mortality followed operation.510,21 If LV end-systolic dimension exceeded 26 mm · m⁻² body surface area (BSA) and fractional shortening was less than 31%, consistent deterioration of LV function occurred postoperatively.21 Based on these findings, Ross has suggested operating on patients with few or no symptoms if LVEF is less than 55%, fractional shortening is less than 30%, and end-systolic diameter approaches 50 mm (26 mm · m⁻² BSA).225 These
failure to increase EF with exercise is an indication for surgical intervention if severe mitral regurgitation is present and repair appears likely. The role of left atrial enlargement in decision making is uncertain. More than moderate left atrial dilatation likely has a deleterious effect after valve repair or replacement and therefore favors operation.

The recommendation for early operation (assuming mitral valve repair is highly likely) in the asymptomatic patient with severe mitral regurgitation secondary to degenerative disease and normal LV function is supported by data from a European multicenter study (see also “Natural History of Mitral Regurgitation” earlier in this section). Early operation (within 1 year of diagnosis) resulted in an important reduction in subsequent heart failure and combined heart failure/cardiovascular mortality (Fig. 11-45).

The updated 2006 ACC/AHA guidelines also recommend that mitral valve repair be considered in asymptomatic patients with severe mitral regurgitation and preserved LV size and function in the presence of new-onset atrial fibrillation or pulmonary artery systolic pressure greater than 50 mmHg at rest or greater than 60 with exercise.

The adverse natural history of severe mitral regurgitation secondary to mitral valve prolapse with flail leaflet supports this condition as an isolated indication for operation, even in asymptomatic patients. The decision to recommend

---

Figure 11-44 Management strategy for patients with mitral stenosis and moderate to severe symptoms. Mitral valve area (MVA) measurements may vary, and mean transmitral gradient, pulmonary artery wedge pressure (PAWP), and pulmonary artery systolic pressure (PASP) should also be taken into consideration. There is controversy regarding which patients with less favorable valve morphology should undergo percutaneous mitral balloon valvotomy (PMBV) rather than mitral valve surgery. Key: CXR, Chest radiograph, ECG, electrocardiography; echo, echocardiography; LA, left atrial; MR, mitral regurgitation; MVM, mean mitral valve pressure gradient; MVR, mitral valve replacement, NYHA, New York Heart Association; 2D, two-dimensional. (From Bonow and colleagues.)

Recommendations were reaffirmed in the ACC/AHA Practice Guidelines for the Management of Patients with Valvular Heart Disease, which recommends operation for asymptomatic severe mitral regurgitation in patients with LVEF less than 60% and LV end-systolic dimension greater than 40 mm. Further evidence of contractile dysfunction in the presence of severe mitral regurgitation and normal EF was reported by Ahmed and colleagues, who noted evidence of myofibrillar degeneration on LV biopsy and persistence of wall stress/volume index abnormalities following mitral valve repair.

The magnitude of regurgitant volume may also refine the timing of intervention. Yamano and colleagues noted a strong correlation between large regurgitant volume and the likelihood of postoperative LV dysfunction (see “Cardiac Performance” under Results of Mitral Valve Repair in the Results section). Thus, if mitral valve pathology is such that successful repair is highly likely, operation is probably advisable if mitral regurgitant volume exceeds 80 mL before the onset of other established criteria for operation. Based on natural history studies, Enriquez-Sarano and colleagues from the Mayo Clinic recommended consideration for mitral repair in asymptomatic patients with an effective regurgitant orifice (by echocardiography) exceeding 40 mm².

Diminished response of EF with exercise also has been found to predict postoperative LV dysfunction. Thus, failure to increase EF with exercise is an indication for surgical intervention if severe mitral regurgitation is present and repair appears likely.

The role of left atrial enlargement in decision making is uncertain. More than moderate left atrial dilatation likely has a deleterious effect after valve repair or replacement and therefore favors operation.

The recommendation for early operation (assuming mitral valve repair is highly likely) in the asymptomatic patient with severe mitral regurgitation secondary to degenerative disease and normal LV function is supported by data from a European multicenter study (see also “Natural History of Mitral Regurgitation” earlier in this section). Early operation (within 1 year of diagnosis) resulted in an important reduction in subsequent heart failure and combined heart failure/cardiovascular mortality (Fig. 11-45).

The updated 2006 ACC/AHA guidelines also recommend that mitral valve repair be considered in asymptomatic patients with severe mitral regurgitation and preserved LV size and function in the presence of new-onset atrial fibrillation or pulmonary artery systolic pressure greater than 50 mmHg at rest or greater than 60 with exercise.

The adverse natural history of severe mitral regurgitation secondary to mitral valve prolapse with flail leaflet supports this condition as an isolated indication for operation, even in asymptomatic patients. The decision to recommend
operation in the subset of patients with mild or no symptoms is predicated on the assumption that a successful valve repair with mild or less postoperative mitral regurgitation can be accomplished with a likelihood of 90% or higher. Therefore, asymptomatic patients with severe mitral regurgitation and a floppy valve (prolapse as opposed to ischemic or restrictive functional anatomy) are excellent candidates for early operation, because operative mortality is low (<2%), reparability high (90%), and long-term survival good.\textsuperscript{11,12,13} In the case of chronic severe mitral regurgitation, the 2006 ACC/AHA guidelines present an algorithm for decision making that includes mitral valve repair for asymptomatic patients with preserved LV size and function (Fig. 11-46).

At the other end of the functional spectrum, advanced disability with NYHA functional class IV heart failure is not a contraindication to operation, although it is recognized that secondary LV myopathy associated with, and in part responsible for, this state has a deleterious effect on early and late results of operation. The 2006 ACC/AHA guidelines recommend that mitral valve repair be considered for patients with chronic severe mitral regurgitation secondary to severe LV dysfunction (EF < 30%) in the setting of NYHA functional class III or IV symptoms despite optimal therapy for heart failure, including biventricular pacing.\textsuperscript{13,14} If a stage of irreversibility can be securely identified by preoperative studies, valve surgery may be ineffective and cardiac replacement indicated.

Elderly patients with mitral regurgitation require special consideration because operative mortality is increased and late survival benefit reduced for patients older than about age 75 years, especially those with concomitant coronary artery disease\textsuperscript{5,15,20} (see “Older Age” under Incremental Risk Factors for Premature Death in the Results section). The increased operative risk is worth accepting in elderly patients with important symptoms that limit their quality of life. Otherwise, medical therapy is advisable.

Nonischemic Chordal Rupture

The decision about operation is more difficult in patients with mitral regurgitation from nonischemic chordal rupture of recent onset. If the symptoms of pulmonary venous hypertension are brought promptly under control by medical management, as often occurs, operation may be deferred and the patient reevaluated at frequent intervals (see Natural History earlier in this section). Thereafter, the criteria used in chronic mitral regurgitation apply. If the pansystolic murmur radiates into the aortic area and neck, however, and if echocardiographic evidence shows that the ruptured chordae belong to the posterior leaflet, indications for operation should be liberalized because a durable reparative operation can be done at low risk.

Infective Endocarditis

Mitral regurgitation may develop acutely as a result of infective endocarditis. If symptoms are initially mild or moderate and are brought under good control together with the infection, continuing in-hospital medical treatment is indicated. Surveillance must be close, however, because of possible rapid progression in severity of regurgitation. If this is suspected, operation is urgently indicated before hemodynamic deterioration occurs. Acute pulmonary edema, paroxysmal nocturnal dyspnea, or rising blood urea nitrogen or creatinine levels are indications for urgent operation. Systemic embolization during treatment or persistent active infection despite intense antibiotic treatment also indicate the need for operation (see Chapter 15).

Mixed Mitral Stenosis and Regurgitation

Patients with a mixture of important stenosis and mitral regurgitation usually have a clinical picture similar to that of patients with pure mitral stenosis. Valve replacement is usually required, and indications for operation are the same as in mitral stenosis.

Selection of Technique for Repair of Mitral Regurgitation

Anular dilatation is a central feature of degenerative mitral regurgitation, and therefore reduction anuloplasty is a standard component of most repairs. However, particularly in an era when percutaneous techniques for mitral valve repair (which do not include reduction anuloplasty) are being introduced, it is useful to consider situations in which reduction anuloplasty might not be needed. Maisano and colleagues used the concept of anular-to-leaflet mismatch to identify anular dilatation. The ratio of the septolateral (SL) dimension (distance between midpoint of the anterior mitral leaflet at the anulus to midpoint of the posterior leaflet at the anulus, measured during systole via TTE) to the anterior leaflet height (ALH) was used to define anular-to-leaflet mismatch. A ratio of SL/ALH greater than 1.4 corresponded to patients whose mitral anulus was reduced more than 20% by

Figure 11-45 Time-dependent analysis in asymptomatic patients with severe mitral regurgitation and normal ventricular function (n = 102) (after adjusting for age) shows favorable associations between prompt surgery (vs. no or delayed surgery) and heart failure and the combined endpoint heart failure/cardiovascular death (only cardiovascular death failed to reach statistical significance). Mitral valve repair in asymptomatic patients with normal ventricular function seems to prevent cardiac morbidity. Prompt surgery was defined as an operation performed less than 12 months after echocardiography (delayed surgery was longer than 12 months). Point estimates of hazard ratios are graphically depicted as circles, with their 95% CI (lines). Key: HR, Hazard ratio; MV, mitral valve. (From Grigioni and colleagues).\textsuperscript{26}
the anuloplasty procedure, which was termed “reductive.” “Nonreductive” anuloplasties (SL/ALH < 1.4) occurred in less than 20% of patients. Although good results have been reported following mitral valve repair without ring anuloplasty, the general consensus would favor placing a reductive partial or complete anuloplasty ring in patients with an enlarged anulus. By inference, less than 20% of patients with degenerative mitral valve disease would be expected to receive maximal benefit from techniques (including current percutaneous strategies) that do not include an anuloplasty ring. This inference is supported by a propensity-matched analysis by Gillinov and colleagues that demonstrated an accelerated return of mitral regurgitation when mitral valve repair was performed without an anuloplasty band or ring.

Coexisting Mild Aortic Stenosis
A number of patients treated by percutaneous or surgical valvotomy for mitral stenosis have mild aortic involvement at the time of the procedure. Most do not progress to severe disease even after long follow-up, and aortic valve replacement is rarely needed. Thus, at initial mitral operation, prophylactic aortic valve replacement is not indicated.

Choice of Device for Valve Replacement
Some surgeons routinely use one device or another for mitral valve replacement, but the valve of choice varies widely. Rabago and Cooley and others have reviewed a number of factors involved in the choice of device. Two of the most important considerations are durability and requirement for permanent anticoagulation.

Currently available xenograft bioprostheses degenerate more rapidly in young patients who would otherwise be good surgical candidates for tissue valves. Advanced age and atrial fibrillation increase the probability of thromboembolism even in patients with bioprostheses. Also, Warnes and colleagues reported that bioprostheses degenerate more rapidly in the mitral position than in the aortic position. Bioprostheses are in a state of evolution; continuing improvements will probably lead to increased durability.

Prosthetic mechanical valves are also evolving, but there is no evidence that a device that does not require lifelong anticoagulation will soon be available. Hemodynamic characteristics and performance of the mitral valve prosthesis may also influence choices, particularly in very young patients.

For patients undergoing mitral valve replacement, the basic decision is whether to use a mechanical valve or a...
bioprosthetic valve. In patients older than about 60 years, survival may be better with a bioprosthetic valve because of thromboembolic and anticoagulant-related problems associated with mechanical valves. Also, reoperation 7 to 15 years later may be preferable to lifelong anticoagulant (warfarin) therapy. In patients younger than age 60, survival may be better with a mechanical valve because of the more rapid degeneration of bioprostheses in the young, despite need for lifelong anticoagulation. Infrequently, a bioprosthesis is used in young women, with anticipated replacement after successful childbearing (see “Complications of Long-Term Anticoagulation” later in this section).

The newest approach to mitral valve substitute devices is use of a cryopreserved stentless allograft. Early reports suggest good hemodynamic performance and adequate freedom from thromboembolism (in the absence of anticoagulation). The important issue is durability. There are also scattered reports describing placement of a pulmonary valve autograft in the mitral position. The valve is implanted as a cylinder ("top hat") using two suture lines augmented with an atrial cuff.

Mechanical Mitral Valve Replacement Devices

The design of mechanical valve prostheses has evolved over the last 5 decades. A discussion of modern mechanical valves is complicated by two factors: (1) changing availability of specific valves because of continuing introduction and withdrawal of new models and (2) variability in prevalence of use in different countries, in part because of differing regulatory requirements. Here we discuss mechanical valves currently available and in use in at least several countries.

The major types of mechanical heart valves available are ball and cage (rarely used now), tilting disc, and bileaflet valves. Disc valves contain struts attached to the valve orifice (together called the valve housing) that guide and retain the occluder disc. Tilting disc valves contain a disc generally constructed from graphite with a coating of pyrolytic carbon. The valve opening is separated into two areas designated the major and minor orifices.

Bileaflet valves have variable design features, but all contain two leaflets that swing apart during opening, providing three separate flow areas. The leaflets are guided by a hinge or pivot mechanism that acts to retain the leaflets and defines their opening angle. Nearly all valves are rotatable following implantation to address potential impingement on leaflet closure by surrounding tissues.

Current mechanical valve design has focused on excellent hemodynamics, lifetime durability, and maximal resistance to thromboembolism. Transvalvar gradients are determined by orifice diameter, occluder characteristics, the opening angle, and leaflet or occluder orientation to the plane of the mitral orifice. A wide opening angle generally improves the effective orifice area and decreases the diastolic pressure gradient. Dynamic regurgitation is a feature of all mechanical prosthetic valves and is increased with larger effective orifice size and time needed for leaflet or disc closure. A small regurgitant volume is beneficial because it minimizes stasis and decreases platelet aggregation.

The Starr-Edwards (S-E) mitral ball-valve prosthesis (model 6120; Fig. 11-47), no longer available in the United States, was introduced in its current design in 1965. The occluder is a barium-impregnated silicone elastomer ball in a cobalt-chromium alloy cage. The sewing ring has a silicone rubber insert under seamless PTFE or polyester cloth.

Diastolic gradients across S-E prosthetic mitral valves in vivo are slightly greater, and effective orifice area slightly less, than for other available mechanical valves. No firm evidence indicates that projection of the valve cage into the LV is functionally disadvantageous, except when the ventricle is unusually small.

Thromboembolism is probably more common with the S-E valve than with other valves and more common after mitral valve replacement than after aortic valve replacement (see Table 11-10 and Fig. 11-41). The linearized rate of valve thrombosis in the mitral position is very low, about 0.2% per patient-year.

Mechanical failures in the current S-E silicone elastomer ball-valve prosthesis in the mitral position have not been reported. The valve is provided in sizes 5M (34 mm), 4M (32 mm), 3M (30 mm), 2M (28 mm), 1M (26 mm), 0M (22 mm), and 00M (20 mm).

The Björk-Shiley Monostrut valve (Fig. 11-48), introduced in April 1982, is commonly used in Europe but is not approved by the U.S. Food and Drug Administration (FDA).
for use in the United States. Earlier versions of the valve are no longer available. Its orifice ring and integral struts are constructed from a cobalt-chromium alloy as a single piece. The pyrolytic carbon convexo-concave disc opens to 70 degrees. Hemodynamics are good (see Table 11-9). Available information suggests that in the mitral position, the valve has a relatively low rate of thromboembolism (see Table 11-10 and Fig. 11-41). Daenen and colleagues found that freedom from thromboembolism was 86% ± 4% at 6 years. It is provided in odd-numbered external diameter sizes from 17 to 33 mm.

The Omniscience tilting-disc valve (Fig. 11-49) is an FDA-approved valve introduced in 1978 and distributed worldwide. It is a second-generation device based on modifications of the Lillehei-Kaster pivoting-disc valve. The pivoting occluder device consists of a free-floating convexo-concave disc of pyrolytic carbon within a one-piece titanium housing. The disc opens to 80 degrees. Hemodynamic performance is similar to that of other tilting-disc valves.

Thromboembolic complications have been the subject of considerable controversy. Several investigators have found linearized rates of thromboembolism to be higher with the Omniscience valve than with other mechanical prostheses, but others have found the rate to be low. The linearized rate of valve thrombosis was 3.1% ± 1.1% per patient-year, higher (P = .01) than for Medtronic-Hall and Bjork-Shiley tilting-disc valves. Scotten and colleagues found a smaller regurgitant volume with the Omniscience valve than with other mechanical prostheses, producing approximately 10% regurgitation. The original SJM was not rotatable, but the newer Masters Series allows rotation to an “anatomic” or “anti-anatomic” position of the leaflets. The sewing cuff on the mitral prosthesis has a supra-orifice area. The favorable hemodynamics in the smaller sizes is an advantage in small children. Regurgitant flow may be greater than optimal, particularly at low heart rates. Between 88% and 96% of patients with device placement in the mitral position are free from a thromboembolic event at 5 years after operation (Fig. 11-51; see Table 11-10). Linearized rate of the first thromboembolic event is about 1.5% to 1.75% per patient-year. Up to 75% of thromboembolic episodes occur when anticoagulation is inadequate (INR < 2.5). Thrombosis is uncommon. Incidence is approximately 0.1% per patient-year and is usually associated with inadequate anticoagulation. Mechanical failure is uncommon. The SJM
This solid pyrolytic carbon valve has a unique pivot design in which the pivot areas are entirely within the orifice ring, and the valve leaflets hinge on convex pivot guides on the ring. This differs from other mechanical valves that have cavities in the hinge area. The open pivot design feature is intended to decrease blood stasis and thrombus formation near the hinge points. The valve design minimizes overall valve height and generates a larger orifice area. Valve noise is reportedly reduced by this design.

The mitral prosthesis is available in sizes 27 to 33 mm. The On-X mechanical valve (Fig. 11-54), approved by the FDA in 2002, is a pure pyrolytic carbon leaflet valve prosthesis with a bileaflet design similar to other bileaflet prosthetic valves. The pure pyrolytic carbon structure is stronger than the silicon-alloyed pyrolytic carbon used in other mechanical prostheses. The On-X valve contains a flared inlet that produces a higher volume of flow with increased washing to minimize flow stagnation. The leaflets open 90 degrees, with "soft landing" leaflets designed to reduce blood element stress. The On-X mitral prosthesis comes in sizes 23 to 33 mm. It is available with an intra- and supra-anular sewing ring.

**Bioprosthetic Mitral Valve Replacement Devices**

A number of stent-mounted bioprosthetic devices are in clinical use for mitral valve replacement, including those with leaflets made of xenograft aortic valves, bovine or equine pericardium, and allograft aortic valves, fascia lata, and dura mater. Commercially available stented bioprosthetic mitral valves contain either porcine aortic valve leaflets or leaflets constructed from pericardium. These stented valves are designed to mimic flow characteristics of the in situ aortic valve. Pericardial prostheses have been greatly modified since the original Ionescu-Shiley valve, which demonstrated poor durability, manifested frequently by leaflet tearing. Bioprosthetic valves are preserved with glutaraldehyde, which cross-links collagen fibers and reduces normal turnover of extracellular matrix tissues. Glutaraldehyde fixation of porcine valves is achieved at high (60-80 mm Hg), low (<3 mm Hg), or zero pressure conditions. Lower fixation pressures in newer-generation porcine valves may reduce the tendency for calcification. Current pericardial valves include glutaraldehyde fixation at low pressure and mounting of the pericardium completely within the stent, producing less leaflet abrasion and potentially greater durability.

The major advantage of bioprosthetic mitral valves is their resistance to thromboembolism, which is sufficiently
PART III  Acquired Valvar Heart Disease

characteristics have been only partially evaluated, but the information available indicates that its performance is good.

The Carpentier-Edwards mitral porcine bioprosthesis is composed of porcine (xenograft) aortic valves preserved in buffered glutaraldehyde and mounted on a flexible lightweight frame made of cobalt-chromium-nickel alloy. The glutaraldehyde fixation reduces antigenicity and increases tissue stability. The suturing ring consists of a soft silicone rubber insert covered by porous seamless PTFE. An additional treatment removes phospholipids from the valve tissue. The mitral prosthesis (model 6625) is available in sizes 25 through 35 mm.

The Carpentier-Edwards Duraflex low-pressure porcine mitral valve prosthesis (model 6625LP; Fig. 11-56) employs low-pressure fixation techniques designed to preserve the natural flexibility of valve leaflets. It has a reported freedom from structural valve deterioration of 96% at 14 years for patients aged 70 and older. This model is available in sizes 27 to 35 mm. An extended sewing ring for the Duraflex valve is available in the same sizes (model 6625-ESR-LP).

The St. Jude Medical Biocor stented porcine heterograft (Fig. 11-57) incorporates three separate porcine leaflets with low-pressure fixation. Actuarial freedom from reoperation due to structural valve degeneration has been reported at 96% at 14 years for patients aged 70 and older. This prosthesis is characterized by low stent posts in the mitral position. The St. Jude Epic stented porcine valve carries the same design as the Biocor valve, with the addition of a proprietary anticalcification treatment designed to increase valve durability. To

date, there are no long-term data available on the effect of this anticalcification treatment on valve durability in humans.

The Carpentier-Edwards PERIMOUNT mitral pericardial valve (Fig. 11-58) is a glutaraldehyde-fixed stent-mounted valve introduced into clinical use in 1984 and approved by the FDA in 2000. It has a similar profile and configuration to the Carpentier-Edwards aortic pericardial device. Hemodynamic performance is comparable with other mitral bioprostheses. Ten-year freedom from thromboembolism was 93% ± 3.0% in the series reported by Poirier and colleagues.113 Freedom from structural valve deterioration at 10 years was 81% ± 7.0%, although no failures were noted in patients aged 70 years or older. The newer Magna mitral valve adds a nonreversible fixation process to reduce residual glutaraldehyde and phospholipids that contribute to periocardial leaflet calcification. In addition, the Magna Mitral bioprosthesis is designed with an asymmetric sewing cuff to maximize annular conformity.

SPECIAL SITUATIONS AND CONTROVERSIES

Alternative Surgical Approaches to Mitral Valve

Right Thoracotomy

Right thoracotomy was employed by Lillehei and colleagues in their first open operations for mitral valve disease and continues to be used by some surgeons.146 With this approach, the incision is through the left atrium just behind the interatrial groove, as in the median sternotomy approach. The chief disadvantages of right thoracotomy are the limited field provided by the anterolateral inter-space approach (with the patient positioned obliquely) and relative inaccessibility of the ascending aorta, both for cannulation and infusion of cardiopulmonary solution. The arterial cannula may have to be positioned in the external iliac (or femoral) artery. A particular advantage of this approach may be in reoperations after median sternotomy. With this approach, the mitral valve after commissurotomy or repair is easier. Closure of this incision is made in the roof of the left atrium as far as from the aortic root origin as possible (Fig. 11-59, C). The mitral valve is found to be very accessible; often, only stay sutures are required for retraction. Because of this, studying the competence of the valve after commissurotomy or repair is easier. Closure of this incision must be accurate, catching all layers (including the endocardium) with each stitch. Hemostasis should be secure before discontinuing CPB.

The superior approach is also useful when a short, limited upper sternotomy is used. A single-stage venous cannula is inserted through the right atrial appendage, and distal ascending aortic cannulation is used in combination with antegrade cardioplegia. Exposure is adequate.

Approach Across Atrial Septum

Approach through the right atrium and across the atrial septum can be used but may be unsatisfactory. Exposure is limited, and retraction is impeded by concern about injury to the AV node. Exposure can be improved by extending the incision onto the roof of the right atrium (Fig. 11-59, B). A variation of this approach is that of Guiraudon and colleagues (Fig. 11-60). Incision is begun high on the right atrial free wall and is extended caudally on the interatrial septum. It is completed by extending the septal incision to the superior aspect (roof) of the left atrium. Exposure is excellent, although closure is somewhat tedious. It is useful for patients with deep chests and those with small left atria.

Good results have also been reported with a “minitrans-septal” incision in the atrial septum extending from the inferomedial edge of the fossa ovalis up toward the medial base of the superior vena cava without incising the superior surface of the left or right atrium.110

Limited-Access Mitral Valve Strategies

Over the last 15 years, a gradually increasing number of cardiac surgical centers have gained experience with limited access approaches to the mitral valve, either with direct vision or video-assisted techniques (most recently with robotic technology). Successful repair of mitral regurgitation resulting from degenerative disease of the posterior leaflet, anterior leaflet, or both has been reported with a variety of these techniques. A single-stage venous cannula adds a nonreversible fixation process to reduce residual glutaraldehyde and phospholipids that contribute to periocardial leaflet calcification. In addition, the Magna Mitral bioprosthesis is designed with an asymmetric sewing cuff to maximize annular conformity.

Approach Through Superior Left Atrial Wall

Occasionally in large patients with small left atria, exposure is not optimal with the approach described earlier under Technique of Operation. The “superior approach” through the most superior aspect of the left atrium, where it appears in the transverse sinus, is an attractive alternative (Fig. 11-59). The superior vena cava is mobilized and retracted laterally, and the aorta is retracted to the left (after clamping it and injecting cardioplegic solution, because retraction may make the aortic valve regurgitant). A transverse incision is made in the roof of the left atrium as far as from the aortic root origin as possible (Fig. 11-59, C). The mitral valve is found to be very accessible; often, only stay sutures are required for retraction. Because of this, studying the competence of the valve after commissurotomy or repair is easier. Closure of this incision must be accurate, catching all layers (including the endocardium) with each stitch. Hemostasis should be secure before discontinuing CPB.

The superior approach is also useful when a short, limited upper sternotomy is used. A single-stage venous cannula is inserted through the right atrial appendage, and distal ascending aortic cannulation is used in combination with antegrade cardioplegia. Exposure is adequate.
PART III Acquired Valvar Heart Disease

522

the internal jugular vein with positioning by TEE, but this requires anesthesiologist expertise and is less reliable for routine use. A left atrial incision in the right interatrial groove anterior to the entrance of the right pulmonary veins provides exposure of the mitral valve. De-airing is facilitated by flooding the surgical field with CO₂, placing a urinary catheter or vent across the mitral valve during initial de-airing, and venting the ascending aorta through the antegrade cardioplegia catheter.

Under certain circumstances, mitral valve surgery on the beating heart at near normothermia has been advocated. As long as the necessary precautions for preventing ejection of air into the aorta are understood and followed, this technique can be an important option in the presence of prior CABG, severe LV dysfunction, or extensive arteriosclerotic disease of the ascending aorta.

Figure 11-59  Three incisions for exposing mitral valve. A, Classic approach involves retracting lateral right atrial wall. Groove between posterior right atrium (RA) and left atrium (LA) is developed, and inferior aspect of left atrium is freed from pericardium behind inferior cavoatrial junction. Incision extends cephalad behind superior vena cava (SVC) and caudad to the left under the inferior vena cava. B, Modification of DuBost transseptal approach. Vertical incision is made in lateral wall of right atrium. Interatrial septum is incised through the fossa ovalis, extending laterally to patient’s right to meet the right atrial incision and continuing to ventral aspect of right superior pulmonary vein. Atrial septal component must not extend inferiorly or medially, which could put the tricuspid anulus, atrioventricular septum, or bundle of His at risk. C, “Superior approach” involves retracting superior vena cava laterally and aorta to the left. Roof of left atrium is opened with incision directed leftward and posteriorly, leaving an adequate rim of atrial tissue anteriorly so as not to infringe on the mitral anulus.
In the evolution of limited-access approaches to the mitral valve, current surgical philosophies are divided between a greater emphasis on techniques for direct visualization using more standard surgical techniques and instrumentation, and video-assisted endoscopic or robotic approaches. Whether the enhanced visualization using thoracoscopic and robotic techniques provides sufficient benefit to justify the more expensive technology will await further long-term studies.

Mitral Valve Repair versus Replacement for Degenerative Disease in the Elderly

When successful reconstruction is feasible, repair is advisable for degenerative disease in the elderly to avoid risk of prosthesis-related complications. However, a propensity-matching analysis by Gillinov and colleagues demonstrated similar survival and freedom from reoperation in elderly patients undergoing mitral replacement or repair. Thus, in patients older than about age 70, mitral valve replacement with a bioprosthetic valve is an acceptable alternative to repair when the pathologic anatomy is suboptimal for repair (posterior anular calcification, marked prolapse of both anterior and posterior leaflets, valvar calcification).

Mitral Valve Replacement with Allograft

Acar and colleagues revitalized interest in mitral valve replacement with a mitral allograft using new techniques for fixation of the papillary muscles (side-by-side fine monofilament suture) and employing an anuloplasty ring in all cases (Fig. 11-61). Use of an allograft in the mitral position has a potential advantage in the setting of endocarditis.
Figure 11-61 Mitral valve replacement with mitral allograft using papillary muscle fixation and anuloplasty. 

A, Mitral valve is exposed in usual manner, and leaflets are completely resected at their bases. Chordae are excised at their papillary muscle origin. Muscular trabeculations attaching papillary muscles to free wall of left ventricle are divided. B, Cryopreserved mitral allograft, thawed and trimmed, is positioned for insertion. Interrupted 5-0 monofilament sutures (10-12) secure donor papillary muscle to recipient papillary muscle in side-by-side fashion. Donor papillary muscle is placed on mural (outside) aspect of recipient papillary muscle.

because of its known resistance to recurrent infection (see Chapter 15). Early enthusiasm for this technique was also, in the past, related to the possibility of better durability in younger patients than bioprosthetic valves.

An 8-year analysis of allograft mitral valve replacement (complete in 65 patients and partial in 39) by Ali, Acar, and colleagues underscored the important risk of early reoperation for valve dysfunction related to restriction of leaflet movement secondary to deep implantation of papillary muscles or an undersized allograft. Based on recommendations from Acar and colleagues, selection of allograft size was based on matching the height of the anterior leaflet. However,
Figure 11-61, cont’d C. Using continuous 4-0 polypropylene suture, donor anulus is sewn to bases of resected recipient leaflets beginning at left fibrous trigone and working clockwise anteriorly to right fibrous trigone, then in a counterclockwise direction posteriorly. A supporting annuloplasty ring is added.

Mitral valve replacement with a pulmonary autograft has been reported in a small number of patients, with good valve function at a mean follow-up of 6 years.\textsuperscript{K20}

### Surgical Plication of Giant Left Atrium

Massive enlargement of the left atrium can develop in patients with long-standing severe mitral regurgitation.\textsuperscript{P4} Surgical reduction has been recommended since the early days of cardiac surgery but has not been generally adopted.\textsuperscript{K6} Kawazoe and colleagues have used a special plication procedure designed to reduce bronchial compression and improve LV performance; their experience suggests effective results.\textsuperscript{K8} The procedure is probably indicated only when left atrial enlargement is causing severe compression of the left main bronchus.

### Left Ventricular Rupture Complicating Mitral Valve Replacement

Massive intrapericardial hemorrhage may occur shortly after discontinuing CPB or in the intensive care unit a few hours later. This complication is usually from LV rupture in or near the AV groove posteriorly. Nearly all patients die when the rupture occurs postoperatively, but some may be saved when it occurs while the chest is open.\textsuperscript{B23} LV rupture with hemorrhage is more likely to occur in women and in patients with small LVs.

There are several causes of LV rupture, but the surgeon must always assume that it is preventable. The most common contributing factors are (1) undue traction on the anulus during excision of the mitral valve or insertion of the prosthesis, (2) tearing of the anulus by sutures already placed when the heart is manually tilted up after the mitral prosthesis is in place, and (3) penetration of stitches into the left AV groove posteriorly.\textsuperscript{B21} These are particularly
dangerous problems because the surgeon is usually unaware of producing them during the operation, which may otherwise have been a technically simple procedure. In the initial report on this problem, Roberts and Morrow indicated that LV rupture can also result from (1) perforation of the LV wall as papillary muscle is excised and (2) perforation of the AV groove as a calcific deposit is being removed. stav1

Because of potential LV rupture, the surgeon must be very gentle in all maneuvers during mitral valve replacement. The heart should not be tipped up for air evacuation or ligation of the left atrial appendage or for routine inspection of the back of it after the prosthesis has been inserted. Excising only the chordae tendineae rather than the whole papillary muscle, and simply leaving in place deeply embedded calcific deposits in the anulus and placing sutures around them or only on their atrial side, should eliminate these causes of LV rupture. Alternatively, a chordal-sparing mitral valve replacement can be performed.

LV rupture can occur in the midportion of the posterior wall rather than in the region of the AV valve anulus. stav1 stav10

Whether the mechanism of this type of rupture is different is not certain, but LV trauma can be caused by penetration of a pillar of a stent-mounted valve.

Once massive hemorrhage has occurred, CPB must be reinitiated as quickly as possible while the hemorrhage is controlled digitally to the extent possible. A premature attempt to suture it will surely end in death, and even with proper management, the risk of death is great. After establishing CPB, clamping the aorta, and administering cardioplegic solution, the left atrium is reopened and the valve removed. An appropriately shaped piece of pericardium is fashioned and positioned as an onlay patch on the inside of the heart over the presumed or identified area of rupture, using multiple large, felt-pledgeted sutures. Even though every attempt is made to avoid the proximal circumflex artery, it may be compromised by these sutures, so the area of the circumflex artery must be carefully inspected before reinserting the valve.

If it is compromised, a saphenous vein bypass graft to a large marginal branch should be placed. The valve is then reinserted and the remainder of the procedure completed as usual. Great care must be taken with myocardial management throughout this procedure.

A small or moderate-sized hematoma is present in the left AV groove in 10% to 30% of all patients immediately after mitral valve replacement. If bleeding is not occurring, the patient’s condition remains good, and the hematoma does not increase in size, it should be left untreated and unsuspected, with nothing further done. The hematoma rarely results in LV rupture, but false aneurysms occasionally develop in this area.

Management of Antibiotic Prophylaxis with Prosthetic Valves

Prophylactic antibiotics against infective endocarditis are required for all patients with prosthetic heart valves. The details for specific situations are discussed in Chapter 15.

Management of Anticoagulation with Prosthetic Valves

The risk of thromboembolism is greater for prosthetic valves in the mitral position than in the aortic position (see Chapter 12 for recommendations about anticoagulation with aortic prosthetic valves). Long-term warfarin therapy is required for all patients with mechanical valves. In the mitral position, an INR of 2.5 to 3.5 is recommended. stav1 stav11 In patients with a mitral bioprosthetic valve, aspirin is recommended at 81 mg daily. Among patients with a bioprosthetic mitral valve and risk factors of atrial fibrillation, prior thromboembolism, LV dysfunction, or hypercoagulable conditions, warfarin (in addition to aspirin) is indicated to keep the INR at 2.0 to 3.0. stav11 When warfarin is indicated for mechanical or bioprosthetic valves and the patient cannot take warfarin, aspirin is indicated at a dose of 81 to 325 mg daily.

Among patients who experience a thromboembolic event while on recommended antithrombotic therapy, a more intensive regimen of warfarin or aspirin is advisable. stav1 stav1 If the warfarin INR is 2.0 to 3.0, it should be increased to 2.5 to 3.5; if the latter was used, it should be increased to 3.5 to 4.5 unless bleeding issues contraindicate this level of anticoagulation. If aspirin is used in the late regimen, it should be increased from 81 to 325 mg daily, or if the 325 mg daily is maintenance, addition of clopidogrel 75 mg daily should be considered.

When patients experience excessive anticoagulation (INR > 5), risk of hemorrhage is greatly increased. In the absence of bleeding, simply withholding warfarin until the INR is again therapeutic is usually sufficient. If more aggressive reversal is desirable, oral vitamin K (phytonadione) should be administered with caution because overcorrection may lead to a hypercoagulable state. Low-dose oral (1-2.5 mg) or intravenous (1 mg) vitamin K appears generally safe in this situation. stav4 stav13 In emergency situations, administration of fresh frozen plasma is preferable to high-dose vitamin K.

When patients with a mechanical mitral prosthesis require interruption of warfarin therapy for noncardiac surgery, invasive procedures, or dental work, warfarin is discontinued, and either intravenous heparin or low-molecular-weight heparin injections (twice daily) should be administered when the INR falls below 2.0. stav1 These agents should be stopped 4 to 6 hours before the procedure, resumed following the procedure when bleeding stability is appropriate, and continued thereafter until the INR with warfarin resumption reaches 2.0. Low-molecular-weight heparin is attractive because it may be administered on an outpatient basis.

Treatment of Valve Thrombosis

Thrombosis of a mechanical mitral prosthesis is uncommon but devastating, usually affecting patients who are inadequately anticoagulated. Thrombosis may be subacute or may present as an urgent event characterized by low cardiac output and pulmonary venous hypertension, and occasionally is preceded by thromboembolism. Although auscultation and cardiac fluoroscopy were appropriate elements for diagnosis in the past, echocardiography is by far the most reliable diagnostic study.

Optimal therapy is controversial. In general, surgical therapy is preferred for valve thrombosis, particularly for left-sided prostheses. In some patients, simple thrombectomy is appropriate. In most patients, however, thrombotic material may be adherent and often extends to the relatively inaccessible ventricular aspect of the prosthesis. Occasionally, thrombotic material is indistinguishable from the vegetations of
endocarditis. Thus, removal and replacement of the device is preferred. Mortality in these situations is 10% to 20%. Fibrinolytic therapy with urokinase, streptokinase, or recombinant tissue plasminogen activator has been successful, but the important risk of internal bleeding must be weighed against surgical intervention. Fibrinolytic therapy carries a major increased risk of active internal bleeding, recent trauma, history of hemorrhagic stroke, large or mobile thrombi, and recent surgery. In addition, lysis may be incomplete, with the potential for associated systemic embolization. Fibrinolytic therapy is perhaps most effective for valves in the tricuspid position, but is also effective in some cases of acute mitral prosthetic thrombosis. The 2006 ACC/AHA practice guidelines support consideration of fibrinolytic therapy as first line for patients with thrombosed right-sided prosthetic valves with NYHA class III/IV symptoms, thrombosed left-sided prosthetic valves, NYHA class I/II symptoms and a small clot burden, and thrombosed left-sided prosthetic valves with NYHA class III/IV symptoms if the risk of emergent surgical intervention is considered excessive. In the presence of excessive pannus formation, fibrinolytic therapy is ineffective.

Section II Mitral Valve Surgery with Coexisting Tricuspid Valve Disease

MORPHOLOGY

Slightly under half of patients undergoing mitral valve surgery exhibit some evidence of tricuspid regurgitation, which may be organic (rheumatic) in origin or, more frequently, functional. The importance of distinguishing between functional and organic tricuspid regurgitation in patients with mitral valve disease was illustrated by Duran and colleagues. When they ignored functional tricuspid regurgitation present at mitral valve surgery, tricuspid regurgitation was absent late postoperatively in all eight patients with low pulmonary vascular resistance (Rp) postoperatively, but was present in all nine patients with high Rp late postoperatively (P < .0001). Untreated functional tricuspid regurgitation disappeared in eight (47%; CL 32%-62%) of 17 patients undergoing mitral valve surgery. In contrast, ignored organic tricuspid regurgitation disappeared in none (0%; CL 9%-13%) of 14 patients undergoing mitral valve surgery (P = .005).

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Tricuspid regurgitation is apt to coexist when mitral regurgitation is rheumatic in origin and long-standing and when important symptoms have been present for more than about 6 years. In the absence of actual rheumatic involvement of the tricuspid valve, this finding is probably related to low RVEF (<30%), found in many patients with long-standing mitral regurgitation. Clinical features and diagnostic criteria of other forms of tricuspid regurgitation are discussed in Chapter 14.

NATURAL HISTORY

Patients with functional tricuspid regurgitation secondary to mitral valve disease who do not undergo repair of regurgitation at mitral valve surgery have a variable course late postoperatively (see also Chapter 14). Although Braunwald and others in an earlier era recommended against concomitant mitral valve and tricuspid valve surgery, the appearance of important late tricuspid regurgitation subsequently became apparent. Data from many sources have confirmed the deleterious late effects of failure to address severe tricuspid regurgitation at the time of surgery for the primary mitral valve lesion. Probably depending in part on the surgeon’s reason for not repairing the tricuspid valve at the original mitral valve operation, 6% (CL 4%-9%) to 35% (CL 23%-49%) have moderate or severe regurgitation late postoperatively. In most patients, tricuspid regurgitation is a persistent form of the preoperative condition, but some patients have a newly developed or worsening postoperative form despite surgically improved mitral valve function.

Clinically severe tricuspid regurgitation is present in one quarter to one third of patients undergoing surgery for rheumatic mitral valve disease. The presence and severity of tricuspid regurgitation late after mitral valve surgery is at least in part a function of the morphology (rheumatic vs. functional) of the tricuspid regurgitation and the type and severity of the mitral disease. By echocardiographic studies, evidence of at least moderate tricuspid regurgitation in patients with rheumatic mitral valve disease exceeds 60%. Moderate or severe tricuspid regurgitation is reported in more than 70% of patients 3 years after surgical repair of ischemic mitral regurgitation, but prevalence of late severe tricuspid regurgitation of less than 20% is reported following mitral valve repair with an added tricuspid anuloplasty. Late severe tricuspid regurgitation is less common after surgery for degenerative mitral valve disease, with a prevalence of less than 20% by 4 years.

Usually, late tricuspid regurgitation is secondary to anular dilatation (see Chapter 14). Although the probability of late progressive worsening of tricuspid regurgitation is unknown, Matsuyama and colleagues reported that among patients with grade 2 tricuspid regurgitation before mitral valve surgery who did not have tricuspid anuloplasty at time of that surgery, 37% developed late moderate to severe tricuspid regurgitation.

When pulmonary hypertension secondary to severe mitral stenosis is associated with moderate or severe tricuspid regurgitation, the regurgitation usually regresses after mitral valve surgery. Although pulmonary arteriolar medial hypertrophy can cause permanent major pulmonary hypertension, reactive pulmonary vasoconstriction usually regresses and pulmonary artery pressure progressively falls in the weeks or months following successful mitral valve surgery. Perhaps predictably, patients with severe preoperative tricuspid regurgitation associated with marked pulmonary hypertension have less late tricuspid regurgitation after successful mitral valve surgery than patients with severe preoperative tricuspid regurgitation and mild or moderate pulmonary hypertension.

Other predictors of improvement in tricuspid regurgitation after mitral valve surgery without tricuspid anuloplasty include younger age, functional (as opposed to organic) tricuspid regurgitation, and absence of atrial fibrillation.
Incremental risk factors for persisting or worsening tricuspid regurgitation after mitral valve repair or replacement without surgery on the tricuspid valve include:

- Persistent or recurrent mitral disease predisposes the patient to continuing or increasing tricuspid regurgitation. The more severe the un repaired tricuspid regurgitation, the more likely it is to persist or increase late after mitral valve surgery. Thus, tricuspid regurgitation judged mild at operation rarely persists or progresses after adequate mitral valve surgery, whereas moderate or severe regurgitation may progress.\(^{8,9}\)
- When there is no remaining left-sided stenosis or regurgitation, progression is most frequently related to persistent pulmonary hypertension or worsening secondary RV dysfunction. Long-standing and perhaps irreversible RV enlargement secondary to mitral or pulmonary vascular disease predisposes the patient to persistent tricuspid regurgitation. Such situations likely interfere with systolic shortening of the tricuspid anulus. Thus, tricuspid regurgitation that does not disappear promptly with intensive decongestive treatment preoperatively and is therefore fixed rather than variable is more likely to persist late postoperatively if not repaired.\(^{59}\)
- Organic (rheumatic) tricuspid regurgitation, usually associated with some stenosis, is more likely to persist than functional regurgitation.

De Bonis and colleagues\(^{312}\) identified RV dilatation, preoperative RV dysfunction, higher tricuspid regurgitation grade at discharge, and pulmonary hypertension as strong predictors of late significant tricuspid regurgitation. Presence of atrial fibrillation at the first operation and rheumatic etiology are also risk factors for late tricuspid regurgitation.\(^{527}\) A dilated tricuspid anulus (≥3.5 cm in adults) is also predictive of important tricuspid regurgitation, irrespective of level of regurgitation at operation.\(^{517}\) In fact, tricuspid anular dilatation is probably the most important factor in development of late tricuspid regurgitation.\(^{534}\) Normal dimensions of the tricuspid valve are discussed in Chapters 1 and 14.

Presence of tricuspid regurgitation late after mitral valve surgery is clearly associated with poor long-term survival and reduced functional capacity.\(^{519}\) Whether the reduced survival is caused by the tricuspid regurgitation itself or the pathogenic factors that produce late regurgitation (see Morphology earlier in this section) is unknown, but it is likely a combination of both. Among patients with moderate or severe tricuspid regurgitation late after mitral valve surgery, pulmonary artery systolic pressure greater than 40 mmHg, depressed LV function (EF < 50%), depressed RV function, and RV dilatation are predictive of reduced survival.\(^{517}\) In the setting of balloon valvuloplasty for rheumatic mitral stenosis, increasing severity of tricuspid regurgitation at time of the procedure is associated with a progressive decrement in midterm survival.\(^{519}\) (Fig. 11-63).

**RESULTS**

Assessing the results of repair of functional tricuspid regurgitation in patients undergoing mitral valve surgery is difficult because of insufficient information regarding the outcome had the patient’s tricuspid regurgitation been left untreated. The effect of tricuspid anuloplasty in preventing late tricuspid regurgitation was examined by Song and colleagues\(^{526,527}\) in a large cohort of patients with mitral stenosis and severe tricuspid regurgitation who underwent either balloon valvotomy or mitral and tricuspid valve surgery. At 7 years, 98% of patients in the surgery group had less than grade 2+ tricuspid regurgitation compared with 46% in the balloon valvotomy group. Furthermore, event-free survival was superior in the surgical group.

It has been reported that tricuspid anuloplasty is performed in 10% to 20% of patients undergoing mitral valve replacement. Less than 1% of these patients undergo subsequent tricuspid valve replacement.\(^{519,533,534,535}\) The early benefit likely relates to associated comorbidities or severity of the rheumatic process (making the valve unsuitable for repair), but the late disadvantages of valve replacement are clear (see Chapter 14).
