Intermediate-term survival is lower in patients undergoing concomitant mitral valve replacement and tricuspid anuloplasty than in those undergoing isolated mitral valve replacement (see Fig. 11-37). When multivariable analysis accounts for other differences between patients undergoing mitral valve replacement alone and those undergoing concomitant tricuspid valve repair, important tricuspid regurgitation treated by anuloplasty is not a strong risk factor for death early after operation, but it is later after repair (see Table 11-8). These relationships are also reflected in the higher hazard function for death 3 or more months after operation for those undergoing mitral valve replacement plus tricuspid anuloplasty. The inference is that despite tricuspid valve repair, the RV dysfunction usually associated with important preoperative tricuspid regurgitation persists in some patients and is a risk factor for death after mitral valve surgery. Nonetheless, survival is probably better than if

**TECHNIQUE OF OPERATION**

Techniques of concomitant tricuspid valve surgery are discussed in detail under Technique of Operation in Chapter 14.
the tricuspid regurgitation had been left untreated, although this has not been proven.

The functional result in patients surviving at least intermediate term after mitral valve replacement plus tricuspid valve repair is good. However, the prevalence of return to an excellent clinical status (NYHA functional class I or II) is less than when only mitral valve replacement is deemed necessary. This finding again suggests that in general, patients requiring concomitant tricuspid anuloplasty have a more advanced cardiac condition than those requiring only mitral valve replacement. The tendency for gradual progression of tricuspid regurgitation even after prosthetic ring anuloplasty underscores the importance of other RV factors in determining late tricuspid regurgitation.11

When patients undergo tricuspid anuloplasty or replacement late after mitral valve surgery, perioperative mortality is high, often exceeding 20%22 (particularly with rheumatic heart disease), late survival is poor, and functional capacity is frequently unchanged.22,23,88 Poor late outcomes undoubtedly reflect the adverse effect of long-standing poor RV function.

INDICATIONS FOR OPERATION

When surgery is planned for mitral valve disease, tricuspid repair should be considered if important tricuspid regurgitation is present at the time of the mitral surgery.24,25,88 However, there remains uncertainty in estimating the presence and magnitude of tricuspid regurgitation both preoperatively and intraoperatively. Fournier, Carpentier, and Duran and their colleagues have emphasized that digital estimation at operation, with a finger through the right atrial appendage, is unreliable.28,29 In the current era, evaluating tricuspid regurgitation during anesthesia induction as well as before and after CPB is most reliably accomplished with TEE. The value of anuloplasty is less certain in patients whose tricuspid regurgitation is less than severe. Consensus is emerging that patients with tricuspid anular dilation (>2 to 5 cm · m⁻² or 3.5 cm in the average adult) should undergo tricuspid anuloplasty whether or not important regurgitation is present.24,25

Further details regarding indications for operation and current ACC/AHA guidelines are found under Indications for Operation in Chapter 14.

Tricuspid anuloplasty is generally not indicated when the tricuspid anulus is not dilated and (1) tricuspid regurgitation is variable preoperatively and is absent during periods of good medical control of heart failure, (2) organic tricuspid disease is excluded based on digital or echocardiographic examination of the valve at operation, (3) a good repair or replacement can be done for the mitral disease, and (4) Rp is low. If regurgitation is more severe (moderate or severe by intraoperative TEE) and has been important and constant, anuloplasty is indicated.29,30 Because the left-sided disease is usually long-standing and the possibility of irreversible left and right ventricular dysfunction high, a procedure directed at the tricuspid valve may decrease postoperative morbidity and avoid a second operation.

If tricuspid regurgitation has been left unrectified, if right atrial pressure is the same or higher than left atrial pressure immediately after CPB, and if tricuspid regurgitation is assessed as moderate or severe by TEE (grade 3 or more), tricuspid anuloplasty is indicated provided that temporary acute RV dysfunction (usually from right coronary air embolization) can be excluded. This exclusion can be made by resuming CPB; a vasoconstrictor is then given to ensure normal arterial blood pressure (see Chapter 4), the heart is “unloaded,” and CPB is continued for 5 to 10 minutes.

Organic (rheumatic) tricuspid disease virtually always requires intervention, either repair or replacement at the time of mitral valve surgery.

Indications for isolated tricuspid repair late after mitral valve surgery are more problematic (see discussion in Chapter 14).

Section III Mitral Valve Surgery with Coexisting Ischemic Heart Disease

MORPHOLOGY

In recent years, about 15% to 20% of patients undergoing mitral valve replacement for nonischemic mitral valve disease have undergone concomitant CABG.

NATURAL HISTORY

Reliable assessment of the results of isolated mitral valve surgery (without CABG) in patients with coexisting coronary artery disease is not available. Studies by Czer and Chaffin and their colleagues, however, suggest that survival is less satisfactory in these situations when operation is restricted to the mitral valve.24,25

TECHNIQUE OF OPERATION

Primary considerations in CABG accompanying mitral valve replacement or repair are (1) planning the operation to limit duration of CPB and global myocardial ischemia (aortic clamping) and (2) reducing the need to tilt the heart up after the valve is inserted or repaired (see “Left Ventricular Rupture Complicating Mitral Valve Replacement” in Section 1). Two methods can be recommended.

In one method, operation is begun by performing the distal anastomoses of vein grafts and in situ internal thoracic artery (see “Internal Thoracic Artery” under Technique of Operation in Chapter 7). After administering an additional dose of cardioplegia, the left atrium is opened from the right side and the mitral valve procedure performed. The left atrium is closed. After aspiration of air from the ascending aorta and with strong suction on the aortic needle vent, the aortic clamp is removed and rewarming begun. Venous and arterial grafts are routed as usual, and the venous grafts are anastomosed to the openings in the exteriorized portion of the aorta. After the side-biting clamp is removed, the usual de-airing procedures are performed (see “De-Airing the Heart” in Section III of Chapter 2). Operation is then completed in the usual manner. To avoid ventricular rupture, unless urgently indicated, the heart should nor be tipped up for inspection of the posterior anastomoses. Alternatively, the proximal anastomoses are made with the aortic clamp still in place. Operation proceeds as in isolated CABG, using the technique of initially hyperkalemic controlled aortic root
reperfusion (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3).

In the second method, proximal anastomoses are made directly after initiating CPB. Cardioplegic solution is then administered, and distal anastomoses are performed as usual. Care is taken to ensure that the vein graft coursing to the right of the right atrium is slightly more redundant than usual to avoid damage from retraction during the mitral procedure. Particular care is taken to ensure the anastomoses are hemostatic, again to avoid the potentially dangerous maneuver of tilting up the heart after the mitral valve prosthesis is inserted. After infusing another dose of cardioplegic solution, small bulldog clamps are placed very proximally on each vein graft (they must be removed later, a minute or so after release of the aortic clamp) to prevent air that enters the aortic root during mitral replacement from entering the vein graft. Thereafter, the left atrium is opened and mitral valve repair or replacement carried out as usual. After the left atrium is closed, controlled aortic root reperfusion is begun, and the operation proceeds as in an isolated mitral valve procedure.

In both methods, TEE is useful to assess the adequacy of air removal from the cardiac chambers.

**RESULTS**

**Early (Hospital) Death**

Hospital mortality of patients undergoing mitral valve replacement and concomitant CABG is higher than that of patients undergoing isolated mitral valve replacement, with or without concomitant tricuspid valve anuloplasty. In an analysis by Gillinov and colleagues at the Cleveland Clinic, factors associated multivariably with greater likelihood of repair included isolated posterior chordal rupture ($P < .0001$), more recent date of operation ($P < .0001$), and younger age ($P = .0003$). Factors associated with a greater likelihood of replacement were bileaflet prolapse ($P < .0001$), retracted leaflet from abnormal chordal mesh ($P = .01$), and previous cardiac surgery ($P = .008$).

**Time-Related Survival**

Intermediate-term survival is less satisfactory, and the hazard function for death in the constant phase is greater in patients undergoing mitral valve surgery and concomitant CABG than in those undergoing mitral surgery without concomitant CABG and thus presumably without coexisting ischemic heart disease (see Fig. 11-37). This finding is partly explained by coexistence of two diseases, but also partly by older age at operation of patients with the two existing diseases, and the longer global myocardial ischemic time when the two procedures are performed concomitantly. In the study by Gillinov and colleagues, for the mitral repair group, survival was 79% and 59% at 5 and 10 years, and for the mitral replacement group, it was 70% and 37%, respectively (Fig. 11-64, A). The unadjusted survival curves diverged at about 4 years because of earlier divergence ($< 2$ years) of the late-rising phase of hazard (Fig. 11-64, B), with patients undergoing mitral valve replacement having a marked increase in mortality risk compared with those undergoing repair.

**Incremental Risk Factors for Death**

Because patient characteristics differed between those undergoing mitral repair vs. replacement, a propensity score was used by Gillinov and colleagues to adjust the multivariable risk factor analysis for these differences (see “Clinical Studies with Nonrandomly Assigned Treatment” in Section I of Chapter 6). After using the propensity score to adjust for dissimilarities in patient characteristics, replacement was identified as a risk factor for death in the late hazard phase, beginning about 2 years after surgery.

**Functional Status**

Prevalence of good functional status (NYHA functional class I or II) among patients surviving at least the intermediate term after mitral valve replacement and concomitant CABG is as high as after isolated mitral valve replacement. This finding is probably related to coexisting coronary artery disease in this group of patients generally being moderate and well treated by CABG.

---

1 At UAB, age of patients undergoing isolated mitral valve replacement was $52 \pm 14$ [SD] years vs. $61 \pm 8.2$ years in those with both diseases, $P < .0001$. 

2 Prevalence of good functional status (NYHA functional class I or II) among patients surviving at least the intermediate term after mitral valve replacement and concomitant CABG is as high as after isolated mitral valve replacement. This finding is probably related to coexisting coronary artery disease in this group of patients generally being moderate and well treated by CABG.
INDICATIONS FOR OPERATION AND SELECTION OF TECHNIQUE

Chapter 10 discusses the special topic of ischemic mitral regurgitation.

Proper surgical procedure for patients with coronary artery disease who require mitral surgery for nonischemic mitral valve disease has been debated in the past. However, ignoring coronary artery disease increases the risk of death.\textsuperscript{12} In view of this finding and good results achieved in treating both diseases, important coronary artery disease should be treated surgically at the time of mitral repair or replacement.

Selection of Technique

Whether a patient should undergo repair or replacement of the mitral valve depends on the feasibility of repair and possible survival benefit if repair is done. The probability of valve calcification, for example, increases beyond about age 60. As noted previously, important valve calcification strongly favors replacement over repair. Although their analysis includes patients undergoing operation between 1973 and 1999, and therefore likely not directly applicable in the current era, Gillinov and colleagues developed an algorithm to assist in decisions regarding mitral valve repair or replacement for degenerative disease and concomitant CABG.\textsuperscript{13,14}

DEFINITION
This chapter describes the surgical aspects of aortic valve disease, excluding congenital aortic stenosis in infants and children (see Chapter 47) and aortic regurgitation with either ventricular septal defect (see Chapter 35) or sinus of Valsalva aneurysm (see Chapter 36).

HISTORICAL NOTE
In 1947, Smithy and Parker at the University of South Carolina in Charleston first reported an experimental study of aortic valveotomy. During the early 1950s, Bailey and colleagues in Philadelphia used closed methods—either a dilator introduced transventricularly or a digital approach through a “poncho” sewn onto the ascending aorta—in clinical attempts to relieve severe aortic stenosis. Modest success in some patients was obtained by them and by Ellis and Kirklin. In 1951, Hufnagel in Washington, D.C., developed a ball valve prosthesis for rapid insertion into the descending thoracic aorta. (From his work with Gross in developing the coarctation operation, Hufnagel was well aware of the risk of paraplegia with aortic clamping and therefore emphasized the rapidity of insertion of his device; see Chapter 24.) The prosthesis could be inserted quickly because of two multipoint fixation rings, each placed around the aorta and over the end of the prosthesis lying within the aorta. Hufnagel and Harvey, Ellis and Kirklin, and others obtained fairly good palliation of severe aortic regurgitation in some patients with this device. However, upper body signs of aortic regurgitation became severe. During the early 1950s, Bailey and Likoff developed and used a number of ingenious but unsuccessful closed methods of overcoming aortic regurgitation.

A more effective approach to surgical treatment of aortic valve disease in adults began with the advent of clinical cardiopulmonary bypass in 1954 and 1955 (see Chapter 2). At first, aortic valvotomy and removal of calcific deposits were all that could be done. Then Bahnson and colleagues and, independently, Hufnagel and Conrad developed a single-leaflet prosthesis that was commercialized. Generally, the leaflets were used to partially replace the aortic valve, but three leaflets could be used together for total aortic valve replacement. Probably the first single-unit prosthesis for total aortic valve replacement was the polytetrafluoroethylene (PTFE) sleeve prosthesis developed and first used by McGoon at the Mayo Clinic in 1961. Although this device was successful in terms of early results, competence was sometimes not achieved, leading to appreciable hospital mortality. Introduction of the ball valve prosthesis by Harken and colleagues and Starr and colleagues in 1960 and reported in 1963 established aortic valve surgery on a firm basis. Many types of prosthetic valves have subsequently appeared.

In 1956, Murray demonstrated that the aortic valve could be used as an allograft valve transplant in the descending thoracic aorta in patients with aortic regurgitation, and Kerwin and colleagues reported 6-year follow-up. The first orthotopic insertions of an allograft valve using the double-suture-line technique were performed in 1962 by Barratt-Boyes and separately by Ross using a single-suture-line technique described by Duran and Gunning. At first, cadaveric valves were collected aseptically and implanted within a few days or weeks, but for logistic reasons this technique was soon replaced by unsterile collection and sterilization by β-propiolactone, ethylene oxide, or irradiation. The allografts were then stored either in Hanks’ balanced salt solution at 4°C or frozen and dried. In 1968, because of high occurrence of cusp rupture with these techniques, antibiotic sterilization was introduced.

Cryopreservation rather than wet preservation was introduced in 1975 by O’Brien and colleagues. Yacoub and colleagues and Ross and colleagues expanded the use of allografts to include combined aortic valve and ascending aorta replacement.

In 1967, Ross and colleagues introduced the pulmonary autograft for aortic valve replacement, after Lower and colleagues had shown the feasibility of the procedure experimentally in 1960. Subsequently, the pulmonary valve and trunk were introduced as autograft composite conduits (cyinders) for replacing the aortic valve and ascending aorta.

Other biological valves were introduced. Senning in Zurich replaced the aortic valve clinically with individual cusps made of the patients’ fascia lata. Because of high late postoperative occurrence of infective endocarditis, however, this method was abandoned. Use of autologous fascia lata mounted on a frame was described by Ionescu and Ross but abandoned because of late dehiscence. Allograft dura mater valves, stent-mounted and preserved in glycerol, were used for aortic valve replacement by Zerbini and colleagues in Brazil. Bovine pericardium, glutaraldehyde treated and frame mounted, was introduced by Ionescu and colleagues at Leeds, England, in 1971.

In 1965, Binet and colleagues in Paris implanted porcine xenograft aortic valves, sterilized and preserved in a special formaldehyde solution, directly into the aortic root. The valves degenerated rapidly, most likely because of suboptimal tissue preservation. This led to abandoning direct xenograft valve implantation in favor of xenograft valves mounted on a stent frame. Stent-mounted bioprostheses are manufactured to provide a standard device that is easily implanted and provides reproducible results in the aortic position. Glutaraldehyde-preserved stent-mounted porcine valves were introduced by Carpentier and colleagues in Paris in 1967.

David and colleagues revived the concept of direct insertion of nonstented porcine xenografts into the aortic root. This valve was manufactured on a limited trial basis by Hancock Laboratory and by St. Jude Medical as the Toronto SPV (stentless porcine valve).

In April 2002, Professor Alan Cribier at the University of Rouen, France, performed the first percutaneous aortic valve replacement for aortic stenosis in a 62-year-old man who was not a candidate for surgery. Cribier used the antegrade transseptal approach through the femoral vein. The second percutaneous aortic valve insertion was in a 30-year-old man with severe aortic regurgitation who had no contraindication for surgery.

Beginning in 1979, Yacoub and colleagues developed the remodeling method of aortic valve-sparing root replacement for patients with aneurysms of the ascending aorta and root (including those associated with Marfan syndrome) and aortic dissection. In 1988, David and Feindel described an aortic valve-sparing operation (subsequently termed the reimplantation technique) for patients with aortic regurgitation and aneurysm of the ascending aorta in which the aortic valve is reimplanted within a polyester tubular graft.
**MORPHOLOGY**

**Aortic Valve Stenosis**

**Calcific Aortic Stenosis (Congenital)**

Calcific aortic stenosis implies stenosis secondary to heavy dystrophic calcification of a congenitally abnormal valve (Fig. 12-1, A and B). Calcification is rarely present before age 20; thereafter it is slowly progressive and results in important stenosis, most often in the fifth and sixth decades of life, earlier in unicommissural than bicuspid valves, and earlier in men than women. The calcification presents as a bulky califlower-like mass within the cusps, maximal at sites of commissural fusion or congenital buttress formation, often extending into the anulus (left ventricular [LV]-aortic junction) and adjacent aorta. Retrograde extension of calcification into the region beneath the right noncoronary cusp commissure adjacent to the membranous septum may lead to complete heart block. The valvar orifice is slitlike, often eccentrically located and oriented in a sagittal (most often) or transverse plane, and fixed, which often results in trivial or mild aortic regurgitation. (For description of critical congenital aortic stenosis, see Morphology in Chapter 47, Section I.)

**Bicuspid Aortic Valve**

Bicuspid aortic valve is considered the most common congenital heart anomaly, reported in 0.5% to 2% of the general population. The valve has two cusps of unequal size, the larger one containing a central raphe. The raphe results from commissural fusion (type 1). The most common pattern involves fusion of the right and left cusps and is associated with coarctation of the aorta. Rarely, the cusps are symmetric without residual commissure or raphe (type 0). Even less common is two raphes (type 2), usually with a well-developed commissure between the left and noncoronary sinuses.

Among patients with a bicuspid aortic valve, structural abnormalities exist at the cellular level that are independent of hemodynamic effects. The thoracic aorta typically shows reduced fibrillin-1, and increased matrix metalloproteinases are associated with smooth muscle cell detachment, matrix disruption, and cell death. The genetics of bicuspid aortic valve is complex and likely involves multiple pathways. Mutations in the signaling and transcriptional regulator NOTCH1 and in the ACTA2 gene (which encodes vascular smooth muscle cell B-actin) are linked with bicuspid aortic valve and familial thoracic aortic aneurysms. Numerous cardiac malformations are associated with bicuspid aortic valve: coarctation, Shone syndrome, William syndrome, Turner syndrome, and hypoplastic left heart syndrome. Abnormalities of the aorta (aortopathy) are the most frequent cardiac anomalies (with a male predominance of 3:1). Although ascending aortic dilatation is most common, aortic root and arch involvement are also frequent.

Controversy exists regarding the contribution of genetic mutations vs. flow characteristics in the genesis of the aortopathy. Using magnetic resonance imaging (MRI), Hope and colleagues demonstrated two distinct flow patterns specific to the two most common cusp fusion types and related these to location of thinning and dilatation of the ascending aorta. Asymmetric distribution of wall stress in patients with a bicuspid aortic valve (likely superimposed on genetically conferred aortic wall weakness) has been linked with asymmetric aortic smooth muscle cell apoptosis that could be flow mediated.

**Degenerative Aortic Stenosis**

Degenerative disease is often present in stenotic aortic valves of patients older than 65 years of age, and its prevalence increases with age. In a series of patients whose mean age was older than 70, prevalence of degenerative aortic valve stenosis exceeded 70%. The valve is tricuspid, without commissural fusion; the cusps are held in a closed position by deposits of diffuse nodular or eggshell calcification (Fig. 12-1, D). These deposits are not bulky and may also involve the sinuses of Valsalva and ascending aorta. Although degenerative (senile) aortic stenosis is presumed to be arteriosclerosis, Hoagland and colleagues found no correlation between aortic stenosis in adults over age 50 and systemic hypertension, elevated serum cholesterol, smoking, or diabetes. A more recent study of 5201 subjects older than 65, however, found that clinical factors associated with aortic sclerosis and stenosis are similar to risk factors for arteriosclerosis. Aortic valve sclerosis was present in 26% and aortic valve stenosis in 2% of the entire study cohort. In patients over age 75 the prevalence of aortic sclerosis was 37% and stenosis 2.6%. Smoking increased the risk by 35% and hypertension by 20%. Other factors associated with increased risk of aortic valve disease were high lipoproteins, elevated low-density cholesterol levels, and diabetes mellitus. Older age was directly associated...
with risk, with a twofold increase in risk for each 10-year increase in age.

Mitral annular calcification is common in elderly patients with calcific aortic stenosis. Presumably, both are degenerative in origin.

**Rheumatic Aortic Stenosis**

Rheumatic aortic stenosis is characterized primarily by diffuse, prominent fibrous cusp thickening of a tricuspid valve (Fig. 12-1, C), with fusion to a variable extent of one or two commissures (rarely all three). The orifice is approximately central and irregular in shape. Calcification other than a mild form is rarely present except in elderly patients, but is bulkiest at sites of commissural fusion. Rheumatic aortic stenosis is seldom if ever isolated, although at the patient’s first operation this may appear to be the case. In surgical series of apparently isolated aortic stenosis, prevalence of rheumatic etiology is low compared with that when patients with important mitral valve stenosis are included.

About half of patients with so-called rheumatic aortic stenosis fail to report a history of rheumatic fever, suggesting other unrecognized inflammatory processes as the cause. However, with the decline in incidence of rheumatic fever in the United States and other developed countries, rheumatic aortic stenosis decreased from a prevalence of 30% to 18% by the 1980s (and senile degenerative disease increased from 30% to 46%).

**Aortic Valve Regurgitation**

The terms aortic regurgitation, aortic incompetence, and aortic insufficiency are used interchangeably. Regurgitation is the preferred and most descriptive term. Morphologic characteristics of aortic regurgitation depend on etiology. These characteristics are not as easily categorized as in aortic stenosis.

**Relevant Aortic Root Anatomy**

Basic anatomy of the aortic root is detailed in Chapter 1. This section provides additional details about aortic root anatomy and relationships that are relevant to aortic root reconstruction and valve-sparing aortic root replacement (discussed later in this chapter). The aortic root is that part of the aorta bounded proximally by the bases of the aortic valve cusps and distally by the sinutubular junction. McAlpine conceptualizes a continuous membrane covering the ostium or opening of the LV (the aortoventricular membrane) that contains the anulus of the mitral valve and the aortic anulus and adjacent fibrous components. The left anterior fibrous trigone is a membrane between the left and right cusps and the ostium of the LV. The remaining structures related to the aortic root result from thickening of the aortoventricular membrane (at the aortoventricular membrane, and these are the right anterior fibrous trigone, the ventricular and atrial segments of the membranous septum, intervalvar trigone, right fibrous trigone, and fila coronary (the portion of the aortoventricular membrane between the ostium of the LV and the left atrial attachment, which comprises about 75% of the mitral anulus). The region where the aortic valve cusps are in fibrous continuity with the anterior leaflet of the mitral valve (aortomitral anulus) is thickened at each end to form a left and right fibrous trigone. The right fibrous trigone is in continuity with the membranous portion of the septum, and these two structures form the central fibrous body. The left anterior fibrous trigone, right anterior fibrous trigone, and intervalvar trigone are also termed intercusp triangles. The membranous septum is divided into the ventricular membranous septum and atrial membranous septum by attachment of the tricuspid valve septal leaflet to the aortoventricular membrane (Fig. 12-3). Attachment of the right ventricle (RV) to the aortoventricular membrane is in close relationship to the left and right anterior fibrous trigones (Fig. 12-4).

The aortic root forms the outflow tract from the LV and contains the aortic valve cusps, sinuses of Valsalva, and intercusp triangles (trigones). Morphology of the aortic valve cusps reflects their exposure to the mechanical stress of diastolic pressure. They have three distinct layers. The outflow surface is the fibrosa, comprising bundles and sheets of collagen aligned in the circumferential direction. The cusp has a coaptional portion (where the collagen bundles are discontinuous) and a noncoaptional surface or cusp belly (where the collagen bundles are continuous). The ventricular surface of the cusp is composed of the ventricularis, which is another fibrous layer. It is a mixture of both collagen and elastin (although the elastin is not as important as the collagen from a biomechanical standpoint). The fibers are arranged
PART III Acquired Valvar Heart Disease

The tissue in between the attachment of the aortic valve cusps to the aortic wall is the intercusp triangle, a layer composed of circularly oriented collagen fibers. The base of two of the intercusp triangles is LV muscle, and the intercusp triangle beneath the commissure of the left and right cusps is fibrous (left anterior fibrous trigone). Attachment of the base of the aortic root is approximately 55% fibrous and 45% muscular. The intercusp triangles are exposed to ventricular hemodynamics, and they may function in part to allow each of the sinuses to act independently.

An important surgical point regarding the ventricular-aortic junction is the site of attachment of prosthetic valves, which are largely circular structures. Prosthetic valves are actually attached to the anatomic ventricular-aortic junction and do not follow the cusp attachment, although this is usually regarded as the “anulus.”

Aortic Regurgitation Related to Aortic Root Pathology
A spectrum of aortic pathology may result in aortic regurgitation due to alterations in the geometry of the sinutubular junction, sinuses, and the ventricular-aortic junction. Ascending aortic aneurysms and aortic root disease may be distinct processes, or they may coexist as a blending of morphologic manifestations.

Many different pathologies may result in ascending aortic aneurysms (see Chapter 26). These include long-standing hypertension, arteriosclerosis, aneurysms associated with bicuspid aortic valves, and extreme forms of post-stenotic dilatation of a stenotic aortic valve. Ascending aortic aneurysms may also result from inflammatory processes causing aortitis, including rheumatoid arthritis, ankylosing spondylitis, and Reiter syndrome. Ascending aortic aneurysms and aortic root disease may arise from clearly defined genetic syndromes, including Marfan syndrome, Loeys-Dietz syndrome, Ehlers-Danlos syndrome, and filamin A mutations. Most patients with thoracic aorta disease and aortic dissections do not have a clearly defined genetic disorder, but many have an inherited predisposition to the process.

Marfan syndrome, one of the most common connective tissue disorders, is an autosomal dominant condition affecting about 1 in 3000 to 5000 people. Most patients with the typical Marfan phenotype have mutations involving the FBN1 gene that codes for fibrillin-1, an extracellular matrix protein.

Figure 12-3 Components of the ventriculoarterial membrane from within left ventricle, with aortic valve opened through the right aortic sinus. Key: L, Left noncoronary sinus; LA, left atrium; LAF, left anterior fibrous trigone; LF, left fibrous trigone; N, noncoronary sinus; R, right noncoronary sinus; RA, right atrium; RV, right ventricle; TV, tricuspid valve. (From McAlpine.)

Figure 12-4 Attachment of right ventricle and tricuspid valve anulus to the ventriculoarterial membrane. Right ventricular outflow tract has a very close relationship and fibrous attachment to the left anterior trigone (which is of particular importance to the operation of aortic valve-sparing root replacement). There is a further attachment of the posterolateral wall of the right ventricle together with the septal leaflet of the tricuspid valve to the ventriculoarterial membrane. The dashed line indicates demarcation between right and left ventricles. (From McAlpine.)

randomly, and therefore when the ventricularis is under load, the fibers realign in the direction of the applied load and only then resist further extension. The spongiosa layer between the fibrosa and ventricularis is composed principally of glycosaminoglycans, which are responsible for energy dissipation and lubrication of the movements between fibrosa and ventricularis. The biomechanical properties of the fibrosa and ventricularis allow radial extension of the cusp to form a large coaptational area.

The sinuses of Valsalva are the bulging portions of the aortic root from which the coronary arteries arise. They accommodate the open cusps of the aortic valve and generate vortices that are important for aortic cusp closure. The base of the aortic cusp attachment forms a coronet-like structure (Fig. 12-5).
glycoprotein that contributes to structural integrity of connective tissue. In a minority of cases, an FBN1 mutation is not found. Fibrillin-1 is an important component of both elastic and nonelastic connective tissue. In about 10% of Marfan phenotypes, mutations have been noted in transforming growth factor (TGF)-β receptor genes. Criteria for diagnosis of Marfan syndrome involve genetic studies, family history, and major and minor clinical manifestations. Because of the linkage between these genetic entities and phenotypes that overlap with typical Marfan syndromes, the clinical diagnosis requires specific combinations of criteria. Histologic features of the ascending aorta media in Marfan patients include fragmentation of elastic lamellae, loss of smooth muscle cells, fibrosis, and cystic medial necrosis (a misleading term coined to describe the lacunar appearance of medial degeneration when, in fact, cystic changes and necrosis are absent).

Other connective tissue disorders that predispose to aortic aneurysmal disease and dissection include Loeys-Dietz syndrome and the vascular type of Ehlers-Danlos syndrome. \(^{P1}\) Loeys-Dietz syndrome is an autosomal dominant aortic syndrome resulting from mutations in genes for the cytokine (TGF)-β receptor (TGFBR) type I or II. Arterial tortuosity and aneurysms, hypertelorism, and bifid uvula or cleft palate characterize the disease phenotype. Skeletal features are similar to those of Marfan syndrome. The aortic disease in this syndrome is particularly aggressive, and 98% of patients develop aortic root aneurysms that have a high propensity for dissection. \(^{L15,W11}\) Mean age of death with this syndrome is 26 years. \(^{L15}\) In children affected with Loeys-Dietz syndrome, prominent craniofacial features are associated with more severe aortic disease. Because these patients are prone to aneurysm development in other locations, yearly MRI or computed tomography (CT) is advisable from the pelvis to the brain.

The vascular form (type IV) of Ehlers-Danlos syndrome is a rare autosomal dominant disease caused by a defect in type III collagen, encoded by the COL3A1 gene. Prominent clinical features include easy bruising, thin skin, characteristic facial features, and tendency for rupture of arteries, uterus, or intestines. \(^{P1}\) The role of prophylactic aortic replacement surgery to prevent aortic rupture or dissection is less clear than for Marfan or Loeys-Dietz syndromes. Of importance, these patients typically have extreme tissue fragility, so if aortic aneurysms or aortic regurgitation require cardiac surgery, reinforcement of suture lines with felt pledgets or strips is recommended. \(^{S47}\)

Anuloaortic ectasia can produce aortic regurgitation of varying but sometimes severe degree even though the cusps are normal. \(^{S8}\) It is most often caused by cystic medial degeneration of the aorta and may be associated with Marfan syndrome. Even in the absence of Marfan syndrome, anuloaortic ectasia appears to be a genetic disease. \(^{S48}\) It begins in the sinuses of Valsalva; at this stage, regurgitation is usually not present. With time, the process extends to involve the proximal ascending aorta, producing a symmetric, pear-shaped aneurysmal enlargement. Regurgitation now appears and progresses because dilatation of the aortic wall at the sinutubular junction separates the commissures and tightens the free cusp edges, preventing coaptation during diastole. As dilatation of the aorta progresses, central aortic valve regurgitation increases. The LV-aortic junction usually does not increase in size, even in patients with large aneurysms associated with anuloaortic ectasia. Size of the aortic valve prosthesis used in these patients (if indicated) is generally similar to that used for replacement in patients with rheumatic or other disease. \(^{S26}\)

The aneurysmal process eventually involves the entire ascending aorta, but usually stops just before the level at which the brachiocephalic artery originates, although the remainder of the arch may show cystic medial degeneration. The aneurysms are thin walled with a smooth lining. Dissection may begin within the aneurysms, extending proximally and distally or remaining localized (although most acute aortic dissections occur in the absence of an aortic root aneurysm). In patients with Marfan syndrome, about 30% of those operated on for anuloaortic ectasia and aneurysm of the ascending aorta have an aortic dissection. It is limited to the ascending aorta in about half the patients and extends into the transverse and descending aorta in the rest. \(^{S15}\) Frequently, dissection is unexpectedly found at operation. With proximal extension of this dissection, the commissural attachment of the valve becomes separated from the outer aortic wall such that the valve prolapses centrally, and regurgitation may abruptly increase (see Chapter 25).

Arteriosclerotic and Syphilitic Ascending Aortic Aneurysms

Ascending aortic aneurysms also produce valvar regurgitation because of thickening of the free edges of the cusps that results from aortic dilatation. In syphilitic ascending aortic aneurysm, aortic regurgitation is exacerbated by a valvulitis that produces thickening and retraction of the cusp edge. Neither condition, however, is generally associated with aortic dissection.
Aortitis
In some patients with rheumatoid arthritis, ankylosing spondylitis,\textsuperscript{537} or Reiter disease, an aortitis occurs that may lead to aneurysmal dilatation of the ascending aorta and aortic valvar regurgitation.\textsuperscript{58} The aortitis is characterized by dense adventitial inflammatory fibrosis involving the sinuses of Valsalva and proximal aorta, especially adjacent to the commissures.\textsuperscript{667} The process may extend below the base of the aortic valve to form a characteristic subvalvar ridge and may involve the base of the anterior mitral leaflet or even the adjacent ventricular septum, causing conduction disturbances. Particularly in rheumatoid arthritis, the cusps may be thickened and shortened and show rheumatoid nodules histologically.\textsuperscript{R12}

Rheumatic Aortic Regurgitation
Rheumatic aortic regurgitation results from a different response of the valve to the rheumatic process than occurs when stenosis develops. Commisural fusion is minimal or absent, and the cusps are only slightly thickened. Minor calcification is present in about 10% of affected valves. The major pathologic process is cicatricial shortening of the cusps between their free edge and their anular attachment, with rolling of the free edge. As time passes, the aortic root widens in response to the regurgitation, further increasing central valvar regurgitation.

Native Valve Endocarditis
Native valve endocarditis, which may occur on a structurally normal valve or on congenitally or rheumatically deformed valves, is a common cause of aortic regurgitation. The regurgitation may result from a destroyed commissure and consequent cusp prolapse or from a perforation in the belly of the cusp. An infected pannus may appear below the cusps, or extensive destruction of the aortic root may occur, with a periaortic root abscess sometimes extending into the mitral anulus and anterior mitral leaflet. Mitral regurgitation may also develop because of perforation of the anterior leaflet by a “drop lesion” caused by the infected regurgitant stream from the diseased aortic valve.

Congenital Aortic Valve Disease
A congenitally bicuspid or unicuspid valve can produce regurgitation from prolapse of the free edge of a redundant cusp.\textsuperscript{513} In such patients, the regurgitation may be aggravatad by infective endocarditis or an improper valvotomy (see Chapter 47). Lack of support of the aortic anulus in association with ventricular septal defect may result in aortic valve prolapse and regurgitation (see Chapter 35).

Flappy Aortic Valve
Occasionally, aortic regurgitation may be caused by prolapse of redundant aortic cusps that are mildly thickened and myxomatous. The aortic root may be normal or dilated, usually with cystic medial necrosis, and mitral valve prolapse may also occur.\textsuperscript{B27,W16}

Iatrogenic Aortic Valve Disease
Aortic valve regurgitation may be caused by a number of physician-related interventions. Perforation of the aortic valve cusps may result from diagnostic or balloon dilatation catheters. Even with newer methods and lower doses of mediastinal irradiation, occasional cases of mediastinal fibrosis occur, with injury to the pericardium, cardiac valves, coronary arteries, and myocardium. Cardiac valve disease has also been associated with migraine medications (ergotamine, methysergide) and appetite suppressants (fenfluramine, with or without phentermine)\textsuperscript{233} (Fig. 12-6).

Other Types of Aortic Regurgitation
Other causes of aortic valve regurgitation include spontaneous cusp rupture,\textsuperscript{O1} rupture caused by severe closed-chest trauma,\textsuperscript{M16,R8} and severe long-standing systemic hypertension with aortic root dilatation. In patients with long-standing hypertension, regurgitation may result from typical myxoid degeneration of the valve.\textsuperscript{A6,12,712} Some instances of regurgitation are probably related to arthropathies with minimal joint involvement or to hypertension, psoriasis, giant cell aortitis,\textsuperscript{527} or Takayasus disease. Occasionally the etiology of regurgitation is not apparent.

Combined Aortic Stenosis and Regurgitation
The etiology and morphology of combined aortic stenosis and regurgitation are similar to those of aortic valve stenosis. In some cases, an episode of endocarditis produces regurgitation of a previously stenotic valve.

Changing Etiology and Morphology
A time-related change in etiology and morphology has been observed at operation in patients with aortic valve disease. Although the overall prevalence of bicuspid aortic valves in the general population has not changed over the past 50 years,\textsuperscript{8} its relative frequency in the surgical population has decreased (Table 12-1). In surgical patients at the Mayo Clinic the relative frequency of bicuspid aortic valves fell from 49% in 1965 to 36% in 1990.\textsuperscript{D1,S42} The relative frequency of patients with degenerative aortic valve disease increased greatly, however, and the prevalence of aortic stenosis doubled from 32% to 65%. Mean age at operation increased from 49 years in 1965 to 66 years in 1990 and continues to rise.\textsuperscript{D1,S99,P96,S41,S42}

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA
Aortic Stenosis
Patients with aortic stenosis are usually symptomatic when first seen. They may present without symptoms, however, having been referred because of a cardiac murmur. The classic triad of effort dyspnea, angina, and syncope is present in 70% of patients.\textsuperscript{E12} Understanding and recognizing the symptoms of aortic stenosis is particularly important because of the heavy reliance on symptoms in decisions regarding advisability of operation (see Indications for Operation, Selection of Technique, and Choice of Device later in this chapter).

Angina pectoris is present as the only symptom or is combined with others in 50% to 70% of patients.\textsuperscript{B20,E1} It is more common in patients with combined aortic stenosis and coronary artery disease than in those with isolated aortic stenosis.\textsuperscript{1,24} Angina in patients without coronary artery disease presumably results from an imbalance between coronary blood flow and oxygen demand in the hypertrophied LV. Angina appears to occur more frequently in patients with severe...
Figure 12-6  Iatrogenic aortic valve disease. Aortic valve regurgitation caused by physician intervention. A, Aortic valve affected by fenfluramine/phentermine (Fen/Phen). One cusp is contracted due to a fibrotic plaque. The other two cusps are normal. B, Echocardiogram of Fen/Phen iatrogenic aortic valve disease. A regurgitant jet indicates moderately severe aortic valve regurgitation before repair. Repair consisted of débridement of fibrotic plaques from the valve cusps and narrowing of the sinutubular junction by a prosthetic band. After repair, there is trivial aortic valve regurgitation.

Data from William D. Edwards, MD, based on references D1, O9, P6, S41, S42 and surgical patients at the Mayo Clinic.

A few patients (10%) survive typical symptoms long enough for secondary RV failure to develop. These patients present with a clinical picture dominated by elevated right atrial and jugular venous pressure, hepatomegaly, cardiac cachexia, and rarely, tricuspid regurgitation. Patients often appear to have combined aortic stenosis and mitral regurgitation as well.

Diagnosis of important aortic stenosis can often be made by physical examination with reasonable certainty when, in addition to the presence of an aortic ejection murmur (usually best heard in the second right intercostal space beside the sternum and transmitted to the carotids, but also often at the apex and in the second left intercostal space), the arterial pulse is of small volume with a slow upstroke. Support for the diagnosis may be obtained from expiratory splitting of the second heart sound and from evidence of LV hypertrophy provided by the character of the apex beat and electrocardiogram (ECG). Usually the ECG provides evidence of LV hypertrophy, with or without inverted T waves in lead V6 (the so-called strain pattern). When chest radiography or fluoroscopy also shows calcification of the aortic valve and convexity along the upper part of the LV silhouette produced by LV hypertrophy, the diagnosis of calcific aortic stenosis becomes a near certainty.

Data from Bonow and colleagues.⁶³⁰

¹Valve gradients are flow dependent and, when used as estimates of severity of valve stenosis, should be assessed with knowledge of cardiac output or forward flow across the valve.

Key: Cath, Cardiac catheterization; echo, echocardiogram; LVOT, left ventricular outflow tract.

At times, physical findings are less diagnostic. Systemic hypertension or, in older patients, inelasticity of aortic and arterial walls may alter the character of the arterial pulse wave and prevent development of a clinically recognizable slow upstroke or soft, weak pulse (pulsus parvus). Absence of the aortic component may prevent assessment of the respiratory behavior of the second heart sound, whereas in patients with right or left bundle branch block, splitting of this sound is of no value as a guide to the severity of aortic stenosis. In older patients especially, the character of the cardiac apex may be unreliable as a clinical guide to presence and degree of LV hypertrophy. The ECG also may fail to show the degree of LV hypertrophy associated with severe aortic stenosis and occasionally remains normal without showing evidence of LV involvement.

In these patients, judicious use of graded exercise testing may uncover a clinically silent state of LV dysfunction and functional aerobic impairment. Exercise has generally been considered dangerous in patients with severe aortic valve stenosis because of effort syncope. Experience has shown, however, that graded exercise testing is not a risky procedure in patients with aortic stenosis who are asymptomatic, but it is not advised in symptomatic patients. Impaired exercise tolerance (as by 6-minute walk testing), occurrence of symptoms, inadequate blood pressure increase (10 mmHg · 30 watts⁻¹ or less) or blood pressure drop (≥10 mmHg), bradycardia, arrhythmia, conduction disturbance, and ST-segment depression (≥0.2 mV) indicate impaired aerobic or LV function. This information may be helpful in deciding on operative intervention or, if continued observation is advised, recommendations concerning vocational, recreational, or sports participation. Finally, in the terminal stages of low-output heart failure, the murmur may be so faint that aortic stenosis is not suspected, particularly in adult patients in whom the heart sounds are distant either because of chest wall thickness or inelastic and voluminous lungs.

Doppler echocardiography is a reliable means of establishing the presence of aortic stenosis and is usually performed in patients suspected of having aortic valve disease. In most patients with aortic stenosis, the degree of obstruction to outflow, aortic valve peak and mean gradient, and valve area can be reliably determined. It is the main modality for serial evaluation. Maximal instantaneous gradient is obtained by applying the modified Bernoulli equation to peak aortic velocity; this may be 30% to 40% higher than gradient determined by cardiac catheterization (Table 12-2). Using continuous wave Doppler, the simplified Bernoulli equation can be applied to obtain the peak instantaneous gradient: Peak pressure gradient (mmHg) = 4 × peak velocity². The mean gradient across the aortic valve is obtained by planimetry of the continuous wave signal. Mean gradient is more useful clinically than instantaneous gradient. Mean pressure gradient is the arithmetic mean of the derived instantaneous gradients; it correlates well with mean pressure gradient obtained by cardiac catheterization. Aortic valve area may also be determined by echocardiography based on the continuity principle, which states that flow through a nonstenotic region of the heart should equal flow through a stenosis (assuming no regurgitation or shunt). Aortic valve area derived by cardiac catheterization is well correlated with this.

Hemodynamic data derived by Doppler echocardiography or cardiac catheterization can provide a grading of degree of stenosis (see Table 12-2). The aortic valve area must be reduced to about one fourth its normal size before important changes occur in the circulation. The normal adult aortic valve area is 3.0 to 4.0 cm². Thus, an area of less than 1.0 cm² is likely to produce clinical symptoms. The American College
of Cardiology/American Heart Association (ACC/AHA) Task Force on Practice Guidelines states that aortic valve stenosis is mild when aortic valve area is greater than 1.5 cm² (with transvalvar gradient < 25 mmHg), moderate when 1.0 to 1.5 cm², and severe when less than 1.0 cm² (see Table 12-2). Because pressure gradient is flow dependent, stenosis is considered severe when mean gradient is 40 mmHg or higher and cardiac output is normal. However, when cardiac output is low, severe aortic stenosis may be present with a lower transvalvar gradient.

These hemodynamic criteria are helpful, but therapeutic decisions related to operative intervention are largely based on presence or absence of symptoms.

In patients over age 40, coronary arteriography is also performed when operation is being considered, because coronary artery disease coexists in many of these patients whether or not angina is present. At the time of coronary arteriography, systolic pressure gradient across the aortic valve is measured. Cardiac output can be measured and the valve area calculated by the Gorlin equation.

Hematologic abnormalities associated with severe aortic stenosis include impairment of platelet function and decreased levels of von Willebrand factor, which correlate with severity of stenosis. Clinical bleeding is observed in about 20% of patients with severe aortic stenosis, most often epistaxis or ecchymoses. Coagulation abnormalities usually disappear after aortic valve placement.

Aortic Regurgitation

Patients with aortic regurgitation present more frequently without symptoms than do those with aortic stenosis, perhaps because of the more dramatic physical and radiographic findings and relatively long asymptomatic phase of regurgitation. In most patients, the dominant symptoms reflect pulmonary venous hypertension (dyspnea, orthopnea, paroxysmal nocturnal dyspnea, pulmonary edema). Angina pectoris is often part of the presenting complaint, but is the chief complaint in less than one fourth of patients and is more common in older patients. Coronary artery disease is present in about 20% of patients with angina pectoris. Syncope is rare.

In severe aortic regurgitation, the LV apex is usually displaced and overactive in character. The carotid and other pulses are jerky to palpation in moderate regurgitation and collapsing or “water-hammer” in severe regurgitation because of the wide pulse pressure and rapid rise and fall of the pulse wave. Blood pressure measured by Korotkoff sounds may reach 200 to 250 mmHg systolic and 50 to 0 mmHg diastolic. Normally, brachial or radial pulse pressure measured by an arterial needle is less than that measured by Korotkoff sounds, and central aortic pulse pressure is even less. These phenomena, including systolic amplification between central aortic and radial artery blood pressures, are related to standing waves created by the pulsatile ejection of an unusually large LV stroke volume into the aorta and remainder of the arterial tree. If cardiac output is low because of severe cardiac failure, these phenomena are minimal.

Auscultation in the aortic area reveals an early diastolic murmur that radiates toward the apex of the heart. Intensity of the murmur has been shown to correlate with degree of aortic valve regurgitation. Murmur grade 3 or greater predicts severe aortic regurgitation in 71% of patients, whereas murmur grade 1 or less predicts that aortic regurgitation is not severe in 100% of patients. Often a systolic click or ejection murmur is present as well. At the apex a mid-diastolic murmur is frequently caused by fluttering of the anterior mitral leaflet from a prominent regurgitant jet (Austin Flint murmur). This may be difficult to distinguish from the murmur of mitral stenosis, although in the latter an opening snap is often present. When mitral stenosis coexists, the ECG usually shows P mitrale and the left atrium is enlarged, although in severe and long-standing pure aortic regurgitation, the ECG may also show P mitrale. Two-dimensional echocardiography is useful in making the distinction between mitral stenosis and merely an Austin Flint murmur (Fig. 12-7). The chest radiograph confirms LV enlargement; the left atrium is usually normal or slightly enlarged. Radiographic evidence of pulmonary venous hypertension may or may not be present. Enlargement of the shadow of the ascending aorta to the right suggests an accompanying aneurysm of the ascending aorta, but an aneurysm can be present without this sign. The ECG shows evidence of LV
enlargement, often with the high-peaked T waves and prominent Q waves of LV volume overload. T-wave inversion and ST-segment depression are seldom present until the LV is extremely large.

Diagnosis of aortic valve regurgitation can usually be made on the clinical findings, but other abnormalities in the aortic root allowing a rapid aortic runoff (e.g., ruptured sinotubular junction, large patent ductus arteriosus with pulmonary valve regurgitation) cannot be entirely eliminated without special studies. Color flow Doppler echocardiography firmly establishes the diagnosis.

Doppler echocardiography can be used to quantify aortic valve regurgitation (see Table 12-2). Measurements are made of regurgitant volume (volume regurgitated per heart beat) and of regurgitant fraction (proportion of total ejection of the LV). These measurements are highly dependent on technical experience, with overestimation the rule at first. Size of the jet visualized by color Doppler echocardiography may not represent the degree of aortic regurgitation. It is possible to measure the vena contracta, which is the size of the regurgitant jet within the regurgitant aortic valve orifice. This measurement correlates well with effective regurgitant orifice size. The width of the vena contracta just below the flow convergence is measured using the parasternal long-axis view. The vena contracta of 7 mm or greater uniformly favors severe aortic valve regurgitation, whereas measurements of 5 mm or less correspond to less regurgitation. The degree of aortic regurgitation may also be quantified by cineangiography using an aortic root contrast injection in the right anterior oblique projection, but this method is difficult and often unreliable.

Coronary arteriography is indicated in patients over age 40.

Combined Aortic Stenosis and Regurgitation

Although many patients with severe aortic stenosis have mild regurgitation and a few patients with severe regurgitation have some stenosis, a small group of patients have virtually balanced lesions. Their symptoms are generally similar to those associated with aortic stenosis. This group may have a particularly unfavorable prognosis because there is both volume and pressure overload on the LV.

NATURAL HISTORY

Aortic Stenosis

The natural history of adults with aortic valve disease is incompletely known, although it is evident that severity of the stenosis gradually increases. Synthesis of four echocardiographic studies indicates that once moderate aortic stenosis is present (jet velocity by echocardiography > 3.0 m · s⁻¹), the average rate of progression in mean pressure gradient is about 7 mmHg · y⁻¹, an increase in jet velocity of 0.3 m · s⁻¹ · y⁻¹, and a decrease in valve area of 0.1 cm² · y⁻¹. Aortic stenosis appears to progress more rapidly in patients with degenerative disease than in those with congenital or rheumatic etiology. A complicating factor is that some degree of stenosis may have existed in childhood, often with associated regurgitation. The natural history in these patients may be more favorable than when the disease develops de novo and more rapidly later in life.

Medical therapy has generally been regarded as ineffective in preventing or retarding disease progression in aortic stenosis. Research over the past decade indicates that aortic valve disease of the elderly is not just a passive “wear-and-tear” process, but an active inflammatory process with histologic changes similar to arteriosclerosis. An evaluation of statin therapy (based on its efficacy in arteriosclerosis stabilization) in the Simvastatin Ezetimibe Aortic Stenosis (SEASten) and Scottish Aortic Stenosis and Lipid Lowering Trial, Impact on Regression (SALINE) prospective randomized trials failed to identify a favorable effect of statins on progression of aortic stenosis. Ongoing research efforts may clarify the potential role of these and other agents in ameliorating disease progression.

Survival

Grant reported that 35% of unoperated patients with usual symptoms of aortic stenosis are alive at 10 years. Wood stated that 46% of such patients were alive 1 to 7 years later. Frank and Ross reported that of 12 unoperated patients with severe aortic stenosis, only 18% were alive 5 years later. Based on their data, Ross and Braunwald concluded that average survival after onset of angina or syncope is 3 years and after onset of heart failure about 1.5 years. ACC/AHA guidelines suggest that after onset of symptoms, average survival is less than 2 to 3 years, with a high risk of sudden death. Thus, development of symptoms identifies a critical point in the natural history of aortic stenosis. O’Keefe and colleagues followed 50 symptomatic patients with severe aortic stenosis in whom operation was declined or deferred. Average age of these patients was 77 (60-89) years. Survival was 55%, 37%, and 25% at 1, 2, and 3 years, respectively, compared with a matched general population of 93%, 85%, and 77%. Death was from cardiac causes in all cases except one. Of 179 patients aged 83 ± 8.3 years deemed inoperable in the PARTNER IB cohort, 1-year survival was 49%.

Although it is impossible to rigorously assemble such disparate data, a likely survival curve for adult patients with severe, unoperated aortic stenosis is estimated in Fig. 12-8.

![Figure 12-8](image-url) Nonrigorously derived survival curves for patients with surgically untreated severe aortic stenosis (solid line) and severe aortic regurgitation (dashed line). Time zero is the time of developing an important hemodynamic effect. Survival of patients with aortic stenosis reported by Wood, Frank and Ross, and Grant is shown by filled circles.
Deaths within the first 1 or 2 years are likely to be sudden, presumably associated with ventricular fibrillation (15%-20% of all deaths in aortic stenosis are sudden\textsuperscript{[10]}), or, after a few hours or days of acute pulmonary edema, from sudden LV failure. Most unoperated patients die in the latter mode within about 5 years of diagnosis. Beyond 5 years of follow-up, some die of gradually worsening cardiac failure, with low cardiac output and gradually worsening symptoms of pulmonary venous hypertension. Moderate pulmonary artery hypertension develops in some patients who exhibit these findings; in a few, typical symptoms and signs of RV failure become prominent.

Asymptomatic patients with severe aortic stenosis usually develop symptoms within a few years of diagnosis. Otto and colleagues showed that about one fourth of initially asymptomatic patients with aortic valve stenosis had developed symptoms,\textsuperscript{[13]} half by 3 years and three fourths by 4 years. When the Doppler outflow velocities were initially 4.0 m · s\textsuperscript{-1} or greater, progression was more rapid, with three fourths of patients symptomatic by 2 years. Thus, even in initially asymptomatic patients with aortic stenosis, progression to symptoms may be rapid, and patients should be monitored closely for progressive disease. Sudden death is uncommon in asymptomatic patients with aortic stenosis, occurring in less than 1% per year.\textsuperscript{[550]} However, as noted by Freed and colleagues, failure to identify subtle symptoms of severe aortic stenosis is common, and the subsequent mortality without surgery may exceed 10% in the ensuing 1 to 1.5 years.\textsuperscript{[512]}

Left Ventricular Structure and Function
The LV hypertrophies progressively in the presence of important aortic stenosis, which usually develops over decades. The increase in wall thickness is usually enough to counter the high intraventricular systolic pressure and maintain normal ventricular volume.\textsuperscript{[41,56]} In this circumstance, LV wall stress (afterload) remains within normal range, and EF remains preserved (given the inverse relationship between systolic wall stress and EF).\textsuperscript{[236]} However, when the hypertrophic response is not adequate for progressively higher intracavitary pressures, the increased afterload can cause a decrease in EF, which is generally reversible with valve replacement.\textsuperscript{[512,513]}

Myocardial hypertrophy in aortic valve stenosis is caused by new myofibrils added in parallel to myocytes. No new myocytes are added, but existing myocytes become thicker, not longer, compared with normal myocytes. The hypertrophy of myocardial cells (increased myocardial cell diameter) is a determinant of both increased systolic load stress and decreased LV diastolic function found in aortic stenosis,\textsuperscript{[514]} and is also related to reduction in EF.\textsuperscript{[535]} Myocardial fibrosis exerts little effect.

Schwartz and colleagues found good systolic function and only hypertrophic myocardial cells when LV mass was less than 200 g · m\textsuperscript{-2}.\textsuperscript{[515,537]} When it was 200 to 300 g · m\textsuperscript{2}, degenerative changes were present but mild. When LV mass was greater than 300 g · m\textsuperscript{2}, systolic function was greatly depressed and multiple degenerative changes in ultrastructure were present (mitochondrial changes, disruption of sarcomeric units, nonoriented growth of fiber components, disappearance of organelles). Maron and colleagues also described these degenerative changes in detail.\textsuperscript{[536]} Krayenbuehl and colleagues found degenerative changes in the form of increased interstitial nonmuscular tissue in association with myocardial cellular hypertrophy.\textsuperscript{[535]} These changes are probably the morphologic basis for loss of inotropic (contractile) strength and irreversibility.

Thus, during the compensated phase, thickening of the LV wall keeps LV afterload (systolic wall stress) more or less normal (see “Ventricular Afterload” under Cardiac Output and Its Determinants in Section I of Chapter 5), preserving LV systolic function. LV compliance and diastolic function are gradually impaired, to a degree primarily related to extent of LV hypertrophy.\textsuperscript{[10]} At a more advanced stage, hypertrophy and wall thickness may increase less than LV systolic pressure (afterload mismatch\textsuperscript{[512]}); the resulting increase in afterload impairs LV systolic function. The degree of LV hypertrophy and decrease in contractility that ultimately develop are more often the cause of declining cardiac function.\textsuperscript{[614]} As indices of systolic function (EF, end-systolic volume, LV fractional shortening, velocity of circumferential shortening) decline, cardiac output decreases gradually or acutely, and LV diastolic function decreases with a consequent increase in LV end-diastolic pressure.\textsuperscript{[514]} By this time the condition is advanced, and chronic heart failure is present.

The atrial contribution to ventricular filling is of great importance with a thickened noncompliant ventricle. As long as sinus rhythm is maintained, left atrial and pulmonary venous pressure can remain near normal. However, loss of atrial contraction with the onset of atrial fibrillation can induce rapid clinical decompensation.\textsuperscript{[53]}

The hypertrophied ventricle may have reduced coronary perfusion per gram of muscle with diminished coronary vaso-vodilator reserve. Added myocardial oxygen demands with exercise or tachycardia may induce subendocardial ischemia and angina in the absence of coronary artery disease.\textsuperscript{[53,535]}

Occasionally, complete heart block develops in patients with extensive calcification of the stenotic aortic valve. It may be the result of gradually increasing pressure on the bundle of His by calcific deposits beneath the commissural area between the noncoronary and right coronary cusps.\textsuperscript{[58]} However, complete heart block sometimes occurs without calcific pressure on the bundle of His.\textsuperscript{[111]} Pressure in the LV is hypothesized to play a role. Rarely, relief of aortic stenosis relieves the heart block.\textsuperscript{[82]}

Aortic Regurgitation
Aortic regurgitation may develop acutely or more gradually as a chronic condition. Acute onset of severe regurgitation imposes a sudden large regurgitant volume on the LV, which has been normal.\textsuperscript{[556]} There is little time to accommodate to the volume load, and LV end-diastolic and left atrial pressures increase rapidly. Tachycardia is the primary compensatory mechanism but may be insufficient, and the clinical situation may quickly deteriorate to pulmonary edema and circulatory shock.

Patients presenting with chronic aortic regurgitation have combined volume and pressure overload of the LV.\textsuperscript{[550]} Compensatory mechanisms are primarily recruitment of preload reserve and LV hypertrophy. Most patients remain asymptomatic through a long compensatory phase that may last for decades.\textsuperscript{[550]}

The natural history of patients with aortic regurgitation depends primarily on its severity.\textsuperscript{[537]} Mild or moderate aortic regurgitation appears to affect activity and life expectancy minimally. LV structure and function begin to be adversely
affected, symptoms develop, and prognosis becomes more limited as severity of the regurgitation increases.

**Survival**

Even when aortic regurgitation becomes severe, there may be a long latent period (3-10 years), during which LV enlargement is only mild, symptoms are absent or mild, and the prognosis is good as long as the findings remain unchanged. Bonow and colleagues followed patients with chronic aortic regurgitation and normal EF. They found that 81% were alive without need of aortic valve replacement 5 years later. Less than 6% per year required aortic valve replacement because of symptoms or LV dysfunction at rest, less than 3.5% per year developed asymptomatic LV systolic dysfunction, and less than 0.2% per year died suddenly. Vasodilator therapy using nifedipine may benefit such patients and delay surgical intervention. When important symptoms develop, however, prognosis becomes severely limited (see Fig. 12-8).

The probability of death increases with development of specific risk factors. Symptoms of cardiac failure, development of ventricular premature beats, marked cardiomegaly (cardiothoracic ratio > 0.6), and ECG evidence of severe LV hypertrophy all increased the risk of death in a group of 180 surgically untreated patients with isolated severe aortic regurgitation of rheumatic etiology.

When severe aortic regurgitation develops acutely, as from infective endocarditis, the natural history is much less favorable. Only 10% to 30% survive more than 1 year after onset.

**Left Ventricular Structure and Function**

Cardiac size gradually increases in the presence of important aortic regurgitation. Quantitative angiography has shown that increased LV end-diastolic volume is directly related to the magnitude of aortic regurgitant flow.

Bonow and colleagues found a higher-risk subgroup within patients who are asymptomatic and have normal LV systolic function. Progressive enlargement (dilatation) of the LV or reduction in resting EF identified by serial echocardiography heralds onset of symptoms. Patients at risk for sudden death are those with extreme LV dilatation or an LV cavity dimension of 75 mm or more at end-diastole and 55 mm or more at end-systole (normal values are ≤55 mm and ≤35 mm, respectively). As LV size and end-diastolic volume steadily increase, eventually there is loss of LV reserve, and LV end-diastolic pressure then rises rapidly.

As the LV enlarges, LV hypertrophy begins to develop. In addition, the LV undergoes an increase in mass and wall thickness, and its shape and ultrastructure change. The myocardial cell hypertrophy and increase in interstitial nonmuscular tissue found in the pressure-overloaded LV of aortic stenosis are similar in the volume-overloaded LV of aortic regurgitation. Concomitant with hypertrophy, LV compliance decreases, compromising diastolic function. Finally, LV end-diastolic and left atrial pressures become elevated, with further increases during exercise.

At some point, LV stroke work fails to respond to increased wall stress (e.g., afterload increase by infusion of angiotensin). As LV systolic function decreases, LV end-systolic dimension steadily increases, and even in asymptomatic patients the rate of increase is about 7 mm per year.

Despite these changes and because of the complex interaction between aortic regurgitation and decreasing systemic vascular resistance, LVEF response to exercise is favorable for a considerable time. Eventually, however, it declines, and systolic function may even decrease during stress. Symptoms then worsen, and the decline in LV function accelerates.

**Bicuspid Aortic Valve**

Bicuspid aortic valve disease is usually asymptomatic in childhood, although rarely the presentation and natural history may take the form of critical congenital aortic stenosis (see Chapter 47). The clinical manifestations relate to the functional state of the valve (stenosis, regurgitation, or both), the aortopathy (aneurysm or dissection), and the potential for endocarditis. Longitudinal studies indicate that 25% to 40% of affected patients will have cardiac events (onset of heart failure, symptomatic aortic stenosis, stroke, endocarditis, or cardiac surgery) by age 50. More than one fourth of patients who are free of important aortic stenosis or regurgitation at initial diagnosis will require cardiac surgery within 20 years. Thus, many if not most patients with bicuspid aortic valve will eventually require surgical or catheter intervention.

Among adults, cusp calcification progressing to aortic stenosis is thought to be initiated by endothelial dysfunction and inflammation, lipoprotein deposition, and fibrosis, and contributed to by turbulent flow. Calcification is frequently present by age 40, and stenosis is often then progressive.

The natural history of aortic dilatation in patients with unoperated bicuspid aortic valve has been studied by Davies and colleagues. Compared with patients having a tricuspid aortic valve, aneurysm progression is greater (0.19 cm · y⁻¹ vs. 0.13 cm · y⁻¹), nearly twice as many undergo aortic surgery, and surgery occurs at a younger age. In a study using MRI and CT, additional involvement of the aortic root, aortic arch, or both was present in more than half the patients. Those with a bicuspid aortic valve are reported to have a ninefold increase in risk of acute ascending aortic dissection compared with those with a tricuspid valve, but the incidence of dissection remains low: 0.1% per patient-year of follow-up. Despite the risk for adverse cardiac events, 20-year survival in adults without important valve dysfunction at initial observation is equivalent to that of the general population.

**TECHNIQUE OF OPERATION**

**Isolated Aortic Valve Replacement**

**Initial Steps**

After the usual preparations and median sternotomy, cardiopulmonary bypass (CPB) is established at 34°C using a single two-stage venous cannula. A cardioplegia infusion catheter is positioned in the ascending aorta, and a coronary sinus perfusion catheter may be passed through a purse-string stitch in the right atrium and positioned in the coronary sinus. The cardioplegia infusion catheter, on one arm of a Y assembly on the cardioplegia infusion tubing filled with cardioplegic solution, is positioned in the ascending aorta. The other arm of the Y assembly, now clamped, also has two arms. One is connected to a second Y assembly, on each arm of which is an O-ring cannula to be used for direct cardioplegic infusion into the coronary ostia. The other arm can be attached to the
coronary sinus retrograde perfusion catheter (see Technique of Retrograde Infusion in Chapter 3).

Perfusate temperature is lowered and adjusted to 25°C to 28°C. The ascending aorta is occluded, promptly if ventricular fibrillation occurs, to prevent LV distention. The operation may be performed without a vent; alternatively, a vent may be introduced into the left atrium from the right side through the right superior pulmonary vein and advanced into the LV. The vent catheter may be introduced before aortic occlusion if ventricular fibrillation occurs or aortic regurgitation produces ventricular distension during cooling. Following aortic clamping, antegrade cold blood cardioplegia may be infused into the aortic root provided there is no aortic regurgitation. Even the slightest leak at the aortic valve will cause ventricular filling, although a properly functioning LV vent may prevent ventricular distention. Subsequent to cardiac electromechanical arrest, cold cardioplegia may be infused into the coronary sinus. Cardioplegic arrest may be accomplished by exclusive perfusion of the coronary sinus in the presence of important aortic regurgitation. A small aortotomy should be made or the aortic root vented when coronary sinus perfusion is performed. Alternatively, in the presence of aortic regurgitation, topical and systemic cooling of the vented LV may intentionally induce ventricular fibrillation, after which the aorta is promptly clamped, an aortotomy made, and direct coronary artery cardioplegia administered.

An initial aortotomy is made about 15 mm downstream from the origin of the right coronary artery. Its precise location is very important not only for surgical exposure but also because of space for intraaortic positioning of an allograft, autograft, or prosthetic valve, ease and security of closure, avoiding damage to the right coronary artery or its ostium, and facilitating aortic root enlargement if necessary. Exposure for this incision is facilitated by the first assistant’s retraction of the fat pad along the right atrioventricular groove over the aortic root. The pulmonary trunk may also need to be partially dissected from the aorta to avoid incising it. The initial incision is made directly anteriorly with scissors, facilitated by the collapsed state of the aorta. Once this small incision is made, the inside of the aortic root is visualized and a decision made as to whether an allograft, a pulmonary autograft valve, or a prosthesis will be used or repair performed (see “Nonreplacement Aortic Valve Operations in Adults” under Special Situations and Controversies later in this chapter).

The incision is extended. The surgeon has a choice depending on the operation to be performed:

- Extend the incision transversely (Fig. 12-9, A). This is the most common approach and has the advantage of providing good exposure of the aortic root without distorting it. The sinutubular junction is not disturbed. Exposure at the level of the aortic valve and below into the left ventricular outflow tract (LVOT) is usually very good.
- Extend the incision into the posterior commissure between the left and noncoronary cusps if posterior enlargement of the aortic root is required.
- Extend the incision obliquely (Fig. 12-9, B) into the noncoronary sinus to a point near the aortic anulus, to provide maximal exposure at the level of the aortic valve and below into the LVOT. This incision, which divides the sinutubular junction, can be extended into the anterior leaflet of the mitral valve for posterior aortic root enlargement.
- Extend the incision to divide the aorta (Fig. 12-9, C). This incision provides optimal exposure of the aortic root because the proximal aortic structures can be easily moved and displaced inferiorly and anteriorly so that the surgeon may visualize the intact aortic root and look directly into it. This incision is best for placing aortic allografts and stentless porcine bioprostheses inside the aortic root, as well as for aortic valve replacement with a pulmonary autograft or other procedures requiring replacement of the complete aortic root. It also provides excellent exposure for routine prosthetic valve implantation. Traction stitches are placed just above the aortic valve commissures for optimal exposure of the aortic root structures, regardless of type of incision.

The aortic valve is removed (Fig. 12-10, A). Unless the aortic valve disease is noncalcific, a short strip of narrow packing gauze can be inserted through the valve orifice into the LV (and some foolproof system is used to ensure its removal) to trap all calcific fragments that may escape during valvectomy. Neat, complete removal of the valve, particularly when heavily calcified, without damage to the LV-aortic junction, ventricular septum, or aortic wall, is one of the operation’s critical aspects. Usually an area exists in about the midportion of the right coronary cusp where an initial scissors cut can be made from the free edge to the point of cusp attachment. This incision allows entry of a knife blade to incise precisely along the attachment of the right coronary cusp toward the commissure between left and right coronary cusps. This commissure may also be calcified, but the incision can usually be carried between it and the aortic wall, often with scissors. The incision is then carried along the attachment of the left coronary cusp, stopping at a point about two thirds of the distance to the left coronary–noncoronary cusp commissure, because beyond that point, there is a tendency to carry the incision into the aortic wall or LV-aortic junction.

Returning to the right coronary cusp, the incision is extended toward the right coronary–noncoronary cusp commissure. In this area and in this commissure the calcification is often especially abundant, sometimes extending onto the underlying ventricular septum or, especially at the commissure, onto the aortic wall or underlying membranous septum. Thus, in dissecting this area, great care must be taken in deciding whether to cut through the calcific cusp attachment to the aortic wall or to go around some of the calcific material and leave it for later piece-by-piece removal. To the extent possible, one-piece removal is preferable, but perforation of the septum, LV-aortic junction, or aortic wall should not become a risk.

When the aortic valve is completely replaced by calcium deposits, or when the deposits extend into the sinus aorta or anterior leaflet of the mitral valve, it is useful to mobilize the calcified tissues by the endarterectomy technique. Using a scalpel, a shallow incision is made in the aortic intima along the calcified deposit. This allows insertion of an endarterectomy spatula (Freer septum elevator) to lift the intact hard deposit away from the soft underlying aortic or mitral valve tissues without fragmenting the calcified material. The incision is carried down along the attachment of the noncoronary
Figure 12-9  Initial steps for aortic valve replacement.  

**A.** Initial transverse incision into ascending aorta (*dashed line*) is 15 mm above right coronary artery. Lengthened just a little, it suffices for evaluating the aortic valve and deciding on procedure to be used. Lengthened further, it is sufficient for aortic valve replacement.  

**B.** Incision is extended into middle of noncoronary sinus of Valsalva, providing excellent exposure of aortic valve for its replacement with prosthetic device.  

**C.** Transverse incision may be extended to divide aorta above sinutubular junction. This permits working within the intact aortic root for correct positioning of aortic valve allografts or stentless xenografts below the coronary arteries (subcoronary technique).
Figure 12-10  Excision of aortic valve and débridement. A, A scissors cut is made in aortic valve cusp, extending to, but not into, aortic wall. Valve excision is along hinge line of aortic valve cusp. Careful excision of valve usually includes removing most calcium deposits along with the valve. B, Residual calcium deposits are débrided from aortic anulus and sinus aorta. Sellman or other forceps and bone rongeurs are instruments commonly used to accomplish this.
cusp, stopping about two thirds of the distance to the commissure between the noncoronary and left coronary cusps. The latter commissural area, which is at particular risk of junctional or aortic wall perforation during valvectomy, can then be approached with excellent visibility from both sides; the incision is carried through this area with firm upward traction on the valve.

After the valve is excised, the bed is examined and any loose calcific particles removed. Any remaining fragments are grasped with forceps or small rongeur and gently enucleated with a twisting motion (Fig. 12-10, B).

The downstream area of aorta is irrigated and examined for any loose calcific fragments, and the valve bed is wiped with gauze and irrigated with cold saline solution to remove any tiny fragments. The LV vent is turned off so that it will not suck fragments into the inaccessible depths of the ventricle, and the gauze is carefully removed from the LV cavity, most likely having trapped a few small calcific fragments. The LV cavity is then vigorously irrigated and aspirated with high suction and inspected for fragments. Generally, no fragments are found. With the precautionary measures against calcific embolization complete, the LV vent is again activated.

Prosthetic Aortic Valve
Insertion of a prosthetic aortic valve is the most common operation for replacing the aortic valve. The anulus is sized and an appropriate-size prosthesis selected. There is no advantage in choosing an oversized prosthesis that will erode the aortic anulus. Instead, if the aortic anulus is too small to accommodate a prosthesis that will provide adequate hemodynamic performance, a supraanular device may be chosen or the anulus enlarged (see “Managing the Small Aortic Root” under Special Situations and Controversies later in this chapter).

Interrupted Suture Technique Synthetic suture material is used, with a compressed PTFE pledget placed centrally and needles at each end. Alternating suture colors (green, white) simplifies sorting so that sutures may be held together as a group for each aortic sinus. Mattress stitches are taken through the aortic valve anulus beginning at the commissure between the left and right coronary cusps. The suture is placed through the sewing ring of the prosthesis after completing each anular pass. Stitches are placed in the right coronary anulus working clockwise toward the commissure between the right and noncoronary sinus (Fig. 12-11, A). Separate stitches are placed close to one another, and the space along the anulus is taken beneath the pledget of the mattress stitch. The prosthesis is held away from the aortic anulus until all stitches have been placed.

The anulus of the left coronary sinus of Valsalva is then approximated to the sewing ring of the aortic valve prosthesis, working counterclockwise from the commissure between the left and right coronary cusps (Fig. 12-11, B). The anulus of the noncoronary sinus of Valsalva is then approached to the valve prosthesis, working clockwise from the commissure between the right and noncoronary cusp toward the commissure between the left and noncoronary cusp (Fig. 12-11, C). Needles are passed through the anulus in a backhand manner. The three groups of sutures are then strongly retracted so that the prosthesis may be slid over the suture loops into the aortic anulus. Position of the occluder mechanism may be adjusted before the valve holder is removed.

Sutures are sorted and tied down in order, working first in the noncoronary sinus in a counterclockwise approach. The first suture in the left coronary sinus closest to the commissure between the left and right coronary cusps is tied to secure seating of the prosthesis directly across the anulus from those sutures already tied in the noncoronary sinus. The sutures of the left coronary sinus are tied down counterclockwise. Sutures are tied in the right sinus, working clockwise to complete the procedure (Fig. 12-11, D). For valve prostheses that have any part of the device projecting below the sewing ring, such that it is positioned partially below the anulus in the LVOT, the order of tying should be altered so that the prosthesis is first secured adjacent to the portions of the device below the anulus.

An alternative technique for placing the pledget stitches is used for the small aortic anulus (Fig. 12-11, E). Pledgets are placed below the anulus in the LVOT by passing a double-needle suture with center pledget as a mattress stitch from below the anulus and up through the prosthesis. A larger prosthesis is thereby secured above the anulus as the anulus is compressed between the pledget and device.

Continuous Suture Technique Continuous suture technique provides the advantage of tight approximation of the prosthesis to the aortic anulus, because the suture loops can slip through the tissues so that tension is equalized with heart motion. Inserting a slightly larger prosthesis may also be possible because an interrupted mattress suture technique may bunch tissues together.

The aortic anulus is divided into three segments by the commissures. During valve replacement, the anulus is further subdivided into six subsegments at the midpoint on the anulus between the commissures. Polypropylene suture (2-0) is used, with needles at each end and a compressed PTFE pledget in the center of the suture. An initial mattress stitch is placed at the center of the sinus of Valsalva through the anulus of the aortic valve and brought through the sewing ring of the prosthesis (Fig. 12-12, A). The prosthetic valve is held away from the anulus and positioned and retracted for added exposure. Exactly three stitches are placed between the initial pledgeted stitch and the commissure on each side of the sinus. The final stitch at each end is secured to the wound drapes by a hemostat. A loop of size 0 suture is placed around the polypropylene suture as the first suture loop is completed through the prosthesis in each subsegment. This suture loop is held by a hemostat to be used to adjust tension on the suture line.

Sutures in the right coronary anulus are placed from the center toward the commissures in the first and second subsegments. The initial stitch in the left coronary sinus passes through the sewing ring of the prosthesis opposite the last stitch of the second subsegment. Working from the center to the commissures in the left coronary sinus, the third and fourth subsegments are approximated to the prosthesis, and then the fifth and sixth subsegments are completed in the noncoronary sinus.

Traction is placed on the six size 0 silk loop sutures to pull the prosthesis into the anulus of the aortic valve (Fig. 12-12, B). The occluder of the prosthesis is opened, and the area below the prosthesis is checked to ensure that no loose suture loops exist in the LVOT beneath the prosthesis.
Aortic valve replacement with mechanical prosthesis or stent-mounted bioprosthesis, interrupted suture technique. 

**A**, Polytetrafluoroethylene felt pledget–reinforced 2-0 braided polyester suture is placed as interrupted horizontal mattress stitches passed from aortic side through aortic annulus. Needles are then passed through sewing cuff of replacement device. Suturing begins at commissure between left and right sinus of Valsalva and proceeds clockwise in right coronary sinus to commissure between right and noncoronary sinus. Alternating color of suture aids suture sorting.

**B**, Suturing continues in left coronary sinus of Valsalva in a counterclockwise fashion to commissure between left and noncoronary sinus.

*Continued*
Sutures surrounding anterior commissure should not penetrate tissues of membranous septum, to protect the His bundle from injury. Suturing is completed in noncoronary sinus of Valsalva. Prosthesis is passed over sutures into position on aortic anulus. Sutures are sorted and tied to fix prosthesis to aortic anulus.
because of the thickness of its wall. Therefore, it must be 1 to 2 mm smaller in internal diameter than the measured aortic anulus. This will allow some redundant aortic valve cusp to provide a larger than normal coaptation surface to accommodate the expected tissue shrinkage for several weeks after implantation.

The aortic allograft is removed from the liquid nitrogen freezer valve bank and thawed by protocol. The septal muscle is excised, with a finger placed inside the aorta to stabilize the graft, gauge the thickness of the trimmed graft, and remove endothelial cells that are antigenic. Excess aorta is trimmed from the valve cusps, leaving a 3- to 4-mm rim of aorta beyond attachment of the cusps. Most of the sinus aorta is removed from the right and left coronary sinuses, leaving the noncoronary sinus intact (Fig. 12-13, A). This technique was described by Ross and colleagues in London and has been used successfully for many years.

The allograft is implanted in anatomic position. Three stitches are used to attach it to the outflow tract. The first suture is 3-0 or 4-0 polypropylene, placed using two small (17-mm) strong half-circle needles. This suture is chosen for high needle strength and low tissue drag. The suture is placed through the patient’s aortic outflow tract below the medial commissure between the right and left coronary sinuses and through the septal myocardium below the corresponding commissure in the graft; the stitch is placed below the anulus of the aortic valve. The other two stitches are simply stay sutures placed to assist in aligning the allograft to the patient’s

Allograft Aortic Valve
Replacing the aortic valve with a transplanted human aortic valve became more feasible and available to surgeons because of improved commercial cryopreservation techniques.

Subcoronary Technique Because with this technique the graft is to be sewn in “freehand” using the natural aorta for support, a clear understanding of the anatomy and spatial relationships of the aortic root is essential. Important deformity of the aortic sinuses should be appreciated and corrected or the procedure abandoned in favor of conventional valve replacement or aortic root replacement techniques.

A transverse aortotomy is made initially. After assessing aortic valve morphology and anatomy of the aortic root, the incision is extended to transect the aorta (see Fig. 12-9, C). The aortic valve is excised and anulus débrided by usual techniques. Diameter of the aortic root at the level of the ventricular-aortic junction (anulus) is determined using standard sizing devices. This dimension must be accurately measured and clearly visualized. The aortic valve allograft to be placed inside the aortic root will consume space simply because of the thickness of its wall. Therefore, it must be 1 to 2 mm smaller in internal diameter than the measured aortic anulus. This will allow some redundant aortic valve cusp to provide a larger than normal coaptation surface to accommodate the expected tissue shrinkage for several weeks after implantation.

The aortic allograft is removed from the liquid nitrogen freezer valve bank and thawed by protocol. The septal muscle is excised, with a finger placed inside the aorta to stabilize the graft, gauge the thickness of the trimmed graft, and remove endothelial cells that are antigenic. Excess aorta is trimmed from the valve cusps, leaving a 3- to 4-mm rim of aorta beyond attachment of the cusps. Most of the sinus aorta is removed from the right and left coronary sinuses, leaving the noncoronary sinus intact (Fig. 12-13, A). This technique was described by Ross and colleagues in London and has been used successfully for many years.

The allograft is implanted in anatomic position. Three stitches are used to attach it to the outflow tract. The first suture is 3-0 or 4-0 polypropylene, placed using two small (17-mm) strong half-circle needles. This suture is chosen for high needle strength and low tissue drag. The suture is placed through the patient’s aortic outflow tract below the medial commissure between the right and left coronary sinuses and through the septal myocardium below the corresponding commissure in the graft; the stitch is placed below the anulus of the aortic valve. The other two stitches are simply stay sutures placed to assist in aligning the allograft to the patient’s
Figure 12-12 Aortic valve replacement with mechanical prosthesis or stent-mounted bioprosthesis, continuous suture technique. A, Polytetrafluoroethylene felt pledget–reinforced 2-0 polypropylene suture is placed through aortic anulus as a horizontal mattress stitch at midpoint of right coronary sinus. Stitch is brought through sewing cuff of prosthesis. Exactly three suture loops are placed through aortic anulus and sewing cuff between initial stitch and commissure. Tension loop is placed around first suture loop. After suturing right sinus, prosthesis is attached to left coronary sinus and finally to noncoronary sinus. B, Prosthesis is approximated to anulus of aortic valve by pulling up suture loops. Tension loops are pulled up to tightly approximate sewing cuff to deepest point in sinus of Valsalva. Suture ends at commissures are then pulled up to seat the valve in aortic root. Sutures are joined at commissures.
Figure 12-13  Aortic valve replacement with aortic valve allograft, subcoronary technique. A, Aortic allograft is chosen that is no more than 2 mm smaller in internal diameter than left ventricular (LV) outflow tract at aortic anulus. Cryopreserved aortic allograft is taken through the standard controlled thawing process. Its septal myocardium is thinned out and anterior leaflet of mitral valve removed along with tissues below aortic valve to create a level plane. Allograft aorta is removed from right and left coronary sinus of Valsalva, leaving 3 to 4 mm of aorta beyond hinge point of valve. Noncoronary sinus remains intact, maintaining relationships of commissures on each side of sinus. B, Patient’s aorta is divided above sinutubular junction so that valve replacement may proceed within the intact aortic root. Traction stitches are placed above each commissure. Allograft is inverted through its anulus into patient’s left ventricular outflow tract (LVOT). Allograft is attached to aortic anulus and below commissures in a generally level plane using continuous stitches of 3-0 polypropylene suture. C, Allograft is pulled back into aorta. Sinus aorta of allograft is attached to patient’s sinus aorta below the coronary ostia. Sutures proceed progressively up commissures to accurately recreate relations of aortic valve within aortic root. Suturing begins at lowest point of sinus of Valsalva and proceeds to top of each commissure. Separate sutures are used for each sinus and are joined at top of commissures. Intact noncoronary sinus of graft is sewn to patient’s aorta by continuous suture.
aortic root. These sutures will be removed because the primary suture line includes their position. They are placed beneath the appropriate commissure of the allograft and directly below the anterior and posterior commissures of the patient’s aorta.

The allograft valve is lowered into position in the patient’s aortic root. Commissures of the allograft are inverted through its anulus into the patient’s LV so as to expose the subvalvar edge of the allograft. A knot is placed in the primary suture, and the stay sutures are tightened to align the allograft with the LVOT. Stitches are placed between the allograft and the LVOT at or below the level of the anulus, attempting to make a level suture line (Fig. 12-13, B). Because the aortic anulus is not circular but crescent shaped, the stitches are well below the fibrous anulus in the subcommissural region and through this fibrous tissue of the anulus at the midpoint of the aortic sinus (see “Cardiac Valves” in Chapter 1). The stitches below the left coronary sinus are placed first. The suture line is taken to a point below the posterior commissure. Using the opposite needle, the stitches between the allograft and LVOT are placed below the right coronary sinus and completed below the noncoronary sinus (Fig. 12-13, B). Alternative suture techniques are equally effective, such as using three separate polypropylene sutures to facilitate placing multiple suture bites without “snuggling” the suture line to improve exposure, after which the sutures are tightened with a blunt nerve hook prior to tying. In the small aortic root, simple sutures of 4-0 polypropylene are also effective.

The commissures of the allograft are pulled out of the LV so that the allograft assumes its normal position and configuration. The allograft commissures are attached to the patient’s sinus aorta using continuous 4-0 or 5-0 polypropylene sutures. Separate sutures are used for each aortic sinus. The first stitch is taken deep in the sinus aorta at mid-position in the sinus slightly above the aortic anulus and then passed through the allograft. Suturing proceeds along the sinus aorta toward the commissure, so as to place the allograft flat against the patient’s aortic wall. The final stitch is placed at the top of the commissure, leaving the suture to be secured later (Fig. 12-13, C). Suturing proceeds in each aortic sinus until the allograft is completely attached. Either the right or left coronary sinus is completed first, sewing from the center point of the sinus to each of the commissures using opposite ends of the suture. The repair is completed in the noncoronary sinus by shortening the allograft aorta to approximate the height of the patient’s intact noncoronary sinus. The two edges of the aorta are simply oversewn by continuous suture so that the intact noncoronary sinus of the allograft is completely enclosed within the aorta. Optionally, the space between the allograft noncoronary sinus and the underlying native aortic wall can be partially obliterated with mattress sutures that are tied outside the native aorta. The ends of the patient’s aorta are then reanastomosed by continuous suture.

Intraoperative echocardiography is used to confirm aortic valve competence.

Root-Enlarging Technique An aortic allograft may be used for valve replacement as part of a root-enlarging operation. A transverse incision is made in the patient’s aorta. The incision is extended to the posterior aspect of the aorta and into the posterior commissure between the left and noncoronary sinuses. Incision into the triangular space of the commissure between the fibrous attachment of the native aortic valve opens the aortic root where there is little fibrous support so that the edges of the aortotomy will separate widely. The incision is taken to the upper edge of the anterior leaflet of the mitral valve, but it does not need to enter the leaflet tissue to provide the desired separation of the edges of the incision. The increased diameter of the patient’s aortic root is measured and an appropriately sized aortic allograft chosen. The allograft is trimmed, leaving the noncoronary sinus intact. The sinus aorta is removed from the left and right sinuses, leaving a few millimeters attached to the fibrous support of the cusps. The allograft is attached to the rim of the aortic-mitral anulus (without entering the actual anterior leaflet of the mitral valve) and superior aspect of the left atrium with interrupted 3-0 or 4-0 polypropylene sutures. The stitches are placed in the corresponding mitral valve and left atrium of the allograft’s noncoronary sinus. A PTFE felt strip is fashioned to slightly more than the length of the unsupported area of the separated aortotomy. The sutures of the noncoronary sinus are then tied down over the felt strip so as to incorporate it and fill in any potential defects in the suture line. The commissures of the valve are inverted into the LVOT, and the rest of the repair is completed according to the approach previously described under “Subcoronary Technique.” The allograft’s intact noncoronary sinus is used to close the aortotomy and widen the aortic root.

When greater enlargement of the LVOT is required, or when there is infective endocarditis with extension of anular abscess into the anterior leaflet of the mitral valve, the incision in the aorta is extended across the mitral valve anulus into the middle of the valve’s anterior leaflet. Anular abscesses are thoroughly débrided and much of the anterior leaflet of the mitral valve removed (Fig. 12-14, A). The anterior leaflet of the mitral valve is left attached to the aortic allograft and used to widen the LVOT or repair defects in the patient’s mitral valve (Fig. 12-14, B). The defect in the roof of the left atrium is closed with a patch taken from the aorta of the allograft or with bovine pericardium.

Aortic Root Replacement Technique An aortic allograft may be used to replace the patient’s aortic root completely when gross deformity is caused by infection or congenital anomaly, or it may be used to enlarge the root. Many surgeons use this technique routinely because aortic valve competence is virtually assured due to retention of the valve relationships within the intact aortic root of the allograft.

An initial transverse aortotomy is made (Fig. 12-15, A). After decision to proceed with aortic root replacement, the patient’s aorta is transected (Fig. 12-15, B). The sinus aorta is removed except for a rim surrounding the ostia of the coronary arteries. The aortic valve is removed and an appropriately sized aortic allograft selected. The allograft is used intact and in natural anatomic orientation, with only the excess of septal myocardium and the anterior leaflet of the mitral valve removed. Size match is not nearly as important as it is for freehand subcoronary valve replacement, but if the aortic anulus is more than 3 mm larger in diameter than the largest available aortic allograft, the patient’s aortic root should be narrowed to approximate the size of the allograft. This can be done conveniently by placing a pledged mattress stitch through the aortic anulus alongside the commissures so that when tied, the intecusp triangle below the commissure is obliterated (see “Method for Reducing Diameter of Dilated Aortic Anulus” later in this chapter).
Figure 12.14  Aortic valve replacement with allograft, aortic root enlarging technique, or repair of anular abscess. A, Aortotomy is extended through posterior commissure into abscess of patient’s mitral valve anterior leaflet. Abscess is débrided or simply incised if procedure is used to widen left ventricular outflow tract (LVOT). B, Anterior leaflet of mitral valve is left attached to allograft and used to widen, LVOT or repair defects caused by endocarditis. Anterior leaflet repair is done with interrupted stitches for greatest security. Defect in left atrium is closed with a patch of aorta from the allograft.
Figure 12-15  Aortic valve replacement, aortic root replacement technique. A, Transverse aortotomy is made. B, Traction stitches are placed in aorta above each commissure, and aortic valve is excised. When decision is made to proceed with complete replacement of aortic root, aortotomy is extended to divide aorta. Aorta is removed from sinuses of Valsalva, except for generous buttons around coronary artery ostia. C, Aortic allograft is minimally trimmed, removing anterior leaflet of mitral valve. Allograft root is attached to anulus of patient’s aortic valve with interrupted stitches of 3-0 or 4-0 polypropylene suture. Simple stitches are used.
D, Suture loops are tied down over a narrow strip of polytetrafluoroethylene felt or pericardium to support and fix diameter of aortic anulus and seal spaces between stitches. E, Left coronary artery button is anastomosed to opening in allograft created by excising left coronary artery of graft. Continuous stitches of 4-0 or 5-0 polypropylene are used, depending on thickness of tissues. F, Opening is made in allograft at position of right coronary artery unless patient’s aortic root was greatly dilated. Dilatation of aortic root displaces right coronary artery; in this case, it is advisable to complete the aortic anastomosis so that aorta may be filled under pressure to properly locate position for anastomosis of right coronary artery. G, End-to-end anastomosis of allograft to patient’s aorta completes the repair.
Figure 12-16  Aortic valve replacement, porcine xenograft stentless bioprosthesis. A, St. Jude Medical Toronto SPV bioprosthesis is presented with sinus aorta removed from all three sinuses of Valsalva. Device is covered with polyester fabric. Medtronic Freestyle porcine xenograft bioprosthesis is presented with intact aortic root with less fabric. There is an inflow sewing ring, and fabric covers portions of septal myocardium on aortic root. Aorta is removed by the surgeon from right and left coronary sinuses of Valsalva, leaving noncoronary sinus intact. B, Inflow sewing cuff of bioprosthesis (Freestyle) is attached to aortic valve anulus with continuous stitches of 3-0 polypropylene suture. Tension loops are placed around every third suture loop to make it easier to tighten suture and approximate bioprosthesis to aortic anulus. Alternatively, simple interrupted stitches of 2-0 or 3-0 braided polyester are used.
The allograft is attached to the LVOT at the aortic anulus and below the commissures by simple interrupted stitches of 3-0 or 4-0 polypropylene (Fig. 12-15, C). The key to a hemostatic proximal suture line is use of a PTFE felt collar. The felt is approximately 5 mm wide and long enough to encircle the allograft. The allograft is slipped over the sutures into the desired position in the LVOT. The sutures are then tied down, incorporating the felt strip within the suture loops (Fig. 12-15, D).

An alternative hemostatic method is to incorporate a double-suture-line technique in which the first suture line uses three separate polypropylene continuous sutures (one for each sinus), placing the sutures as in the interrupted technique. They are gently tightened with a nerve hook and tied. A second suture line incorporates the cut edge of the aortic wall adjacent to the anulus and the adventitia of the allograft immediately above the prior suture line.

The coronary ostia on the allograft are removed to create openings 5 to 10 mm in diameter (Fig. 12-15, E and F). The coronary arteries are anastomosed to the allograft by continuous 4-0 or 5-0 polypropylene suture using a small needle (exact size depends on thickness of the tissues). The left coronary anastomosis is created first (Fig. 12-15, E), followed by the right coronary anastomosis (Fig. 12-15, F). Repair is
completed by end-to-end anastomosis of the distal end of the allograft to the patient’s aorta (Fig. 12-15, G). Continuous stitches of 3-0 or 4-0 polypropylene are used.

**Cylinder Technique** The aortic valve allograft may be inserted as a cylinder within the aortic root, using a technique described by O’Brien and colleagues.\(^3\)

Buttons of sinus aorta are excised, including the ostia of the left and right coronary arteries of the allograft.\(^3\) The resultant opening may need to be extended proximally because the allograft valve now lies a little downstream from its native position.\(^3\) This technique has the potential disadvantage of too much open space between the allograft and native aortic walls.

In a slight modification of the cylinder technique, the center of each sinus is removed before inserting the cylinder of allograft, leaving an intact strut of aortic wall over each sinus.\(^8\) This approach maintains the integrity and special relationships of the allograft until the majority of the second (downstream) suture line of each sinus is complete and the bar over that sinus excised.
Porcine Xenograft Stentless Bioprosthesis

Several manufacturers supply porcine xenograft stentless aortic valves. The devices most frequently used are manufactured by St. Jude Medical and Medtronic (Fig. 12-16, A). The St. Jude medical device (Toronto SPV) is supplied for subcoronary valve replacement with the sinus aorta removed from all three sinuses of Valsalva. The device is covered with a thin polyester mesh. Proper insertion depends on near-normal diameter relationships of the aortic anulus and the sinutubular junction. The Medtronic device (Freestyle) is presented as the entire untrimmed aortic root.

Subcoronary Technique

The implant technique is similar to aortic valve replacement with aortic allografts. The aorta is divided about 1 cm above the sinutubular junction, or a transverse aortotomy is made in the same location. The proper size of xenograft is chosen using the sizing devices supplied by the manufacturer. The diameter of the aortic anulus is measured, and the same-size xenograft is chosen for implantation. Downsizing is not required because the xenografts are sized according to outside diameter of the device, in contrast to aortic allografts, which are sized according to inside orifice diameter. Some surgeons choose a xenograft 1 or 2 mm larger than the anulus because these flexible stentless bioprostheses fit easily into the aortic root. However, no advantage exists to greatly oversized xenografts increase the gradient across the valve.

The Medtronic Freestyle bioprosthesis requires trimming before implantation (see Fig. 12-16, A). The sinus aorta is removed from the right and left sinuses of Valsalva. The noncoronary sinus remains intact to fix the position of two of the three commissures of the valve. The lower edge of the aortic root of the xenograft is covered with polyester cloth to assist with implantation and to prevent shrinkage when xenograft septal myocardium is absorbed. This cloth limits how deeply the sinus aorta may be excised, especially in the right coronary sinus. Care should be taken not to disrupt the cloth covering.

The aortic valve is excised in the usual manner, and all calcific deposits are removed from the aortic anulus and sinus aorta. Exposure is enhanced by traction sutures placed at the sinus rim above each commissure. Markings on the cloth covering the lower edge of the xenograft correspond to each commissure. Continuous 3-0 polypropylene suture is used to attach the lower edge of the xenograft to the patient’s aortic anulus. A small needle with a taper-cut design is best to allow easier penetration of the polyester fabric. The suture line is started in the intercusp triangle below the commissure between left and right sinuses.

The prosthesis is held away from the anulus as suture loops are placed (Fig. 12-16, B). A heavy suture (0 or 2-0) is passed around every third suture loop to act as a tension-adjusting loop suture. These tension loops are secured by a small hemostat. Suturing proceeds below the right sinus to the commissure below the right and noncoronary sinuses. Stitches are placed mostly through the thick fibrous hinge of the aortic valve (anulus), attempting to level the plane of the suture line rather than strictly following the semilunar plane of the valve hinge (Fig. 12-16, C). From the midpoint of the right coronary sinus to the commissure between the right and noncoronary sinuses, the stitches must be through the anulus, not below and into the myocardium, to protect the conduction system from injury.

Suturing continues below the left sinus of Valsalva until below the commissure between the left and noncoronary sinuses. A separate suture is used for noncoronary sinus repair. Tension loops are placed around every third stitch. The prosthesis is seated in the aortic root by sequentially pulling up on the tension loops to approximate the fabric of the xenograft to the aortic anulus. Alternatively, the inflow suture line may be simple interrupted stitches placed with the xenograft held away from the anulus (see Fig. 12-16, B). Many surgeons prefer the interrupted stitch technique because it is similar to implanting prosthetic devices and avoids the possibility of a purse-string effect.

The sinus aorta of the xenograft is attached to the patient’s sinus aorta by continuous stitches of 4-0 polypropylene (Fig. 12-16, D). The initial stitch is placed in the patient’s sinus aorta just below the right coronary ostia. The suture line comes very close to the coronary ostia to achieve proper fit of the xenograft tissues to the patient’s sinus aorta. This is especially true for the right coronary sinus of the xenograft, which is covered with cloth quite high on its external surface. The commissure between the right and left sinuses of the xenograft must be carefully located so as not to distort the xenograft. Suturing continues beneath the left coronary artery to the top of each adjacent commissure (Fig. 12-16, E).

The noncoronary sinus repair is accomplished by trimming the xenograft to the same height as the patient’s noncoronary sinus aorta. The two edges of tissue are approximated by direct suture (see Fig. 12-16, E). Sufficient space usually exists in the patient’s noncoronary sinus of Valsalva to accommodate the xenograft without distortion. If the diameter (length) of the aorta at the sinutubular junction in the noncoronary sinus is greater than that of the sinutubular junction of the xenograft, the discrepancy can be compensated for by placing stitches more closely on the xenograft than the patient’s aorta. The repair is completed by anastomosis of the aorta or closure of the transverse aortotomy.

Aortic Root Replacement Technique

The Medtronic Freestyle device may be implanted as a complete aortic root replacement (Fig. 12-16, F). This method is employed when the aortic root is distorted or when it is dilated enough that support for the xenograft as a subcoronary valve implant will be inadequate. The aorta is divided just above the sinutubular junction. The left and right coronary arteries are mobilized, retaining a generous rim of sinus aorta around the coronary ostia, and the noncoronary sinus aorta is excised. The device is implanted as a complete root. The infow suture line is placed as for subcoronary implantation using continuous 2-0 polypropylene. The suture line is started in the intercusp triangle below the commissure between left and right sinuses.

The prosthesis is held away from the anulus as suture loops are placed (Fig. 12-16, B). A heavy suture (0 or 2-0) is passed around every third suture loop to act as a tension-adjusting loop suture. These tension loops are secured by a small hemostat. Suturing proceeds below the right sinus to the commissure below the right and noncoronary sinuses. Stitches are placed mostly through the thick fibrous hinge of the aortic valve (anulus), attempting to level the plane of the suture line rather than strictly following the semilunar plane of the valve hinge (Fig. 12-16, C). From the midpoint of the right coronary sinus to the commissure between the right and noncoronary sinuses, the stitches must be through the anulus, not below and into the myocardium, to protect the conduction system from injury.
Figure 12-17  Aortic valve replacement with pulmonary autograft (Ross procedure), aortic root replacement technique. A, Ascending aorta is divided, aortic valve is removed, and all aorta from sinuses of Valsalva is excised except for generous buttons around coronary artery ostia. Traction stitches are placed above each commissure. B, Pulmonary trunk is divided at bifurcation. Pulmonary valve is inspected to assure normal morphology. C, Dissection between medial commissure of aortic valve and pulmonary trunk enters infundibular septum. Plane between infundibular septum and right ventricular outflow tract (RVOT) is identified and dissection carried as far behind pulmonary trunk as is convenient. D, RVOT is opened anteriorly 5 mm below pulmonary valve.
E, Incision of RVOT is extended posteriorly to extent of previous dissection (C). F, Shallow incision is made below pulmonary valve posteriorly in RVOT, joining extent of RV incisions. Angle of scalpel is changed so that ventricular myocardium may be shaved off infundibular septum without injuring underlying first septal branch of left anterior descending coronary artery. G, Pulmonary autograft trunk is transferred to aortic position. Simple interrupted stitches of 3-0 polypropylene are used to attach pulmonary autograft to aortic anulus (see Fig. 12-15, B).
H, Narrow strip of polytetrafluoroethylene felt or pericardium is placed within suture loops. Pulmonary autograft is partially inverted into left ventricular outflow tract (LVOT). Sutures are tied to secure pulmonary autograft to anulus of aortic valve, making sure that there is direct tissue approximation and keeping support strip to the outside. I, An opening is made in posterior sinus of Valsalva of pulmonary trunk and a narrow strip of tissue removed from one side to create a site for anastomosis of left coronary artery. J, Left coronary artery is anastomosed to pulmonary trunk using continuous stitches of 5-0 polypropylene. K, Pulmonary trunk is anastomosed in end-to-end fashion to ascending aorta. Aortic occlusion clamp is removed temporarily to fill pulmonary autograft under pressure so that proper position for right coronary artery anastomosis can be located. A small opening is made into graft, and right coronary artery is anastomosed to it.
Figure 12-17, cont’d  L, A cryopreserved pulmonary allograft of appropriate size, having previously been selected and thawed, is anastomosed in end-to-end fashion to pulmonary artery bifurcation. Exposure for this anastomosis may sometimes be better if it is performed before aortic anastomosis. Proximal end of pulmonary allograft is anastomosed to RVOT using continuous stitches of 3-0 polypropylene. Stitches are placed through only partial thickness of infundibular septum posteriorly over location of first septal branch of left anterior descending coronary artery. M, Completed repair: aortic valve replacement with pulmonary autograft, pulmonary trunk replacement with pulmonary allograft.
in the porcine aortic root are closer together than in humans. It is usually necessary to create another opening into the right coronary sinus of the graft at an appropriate location to prevent kinking of the patient’s right coronary artery. The position is usually to the right of the right coronary artery of the porcine root, although it may be placed on part of the base of the porcine right coronary artery. Proper location of the right coronary artery is facilitated by filling the RV with blood from the pump-oxygenator. Any evidence of myocardial ischemia after aortic root replacement indicates need for revision of the location of the coronary anastomosis or for coronary artery bypass grafting.\textsuperscript{119}

**Autograft Pulmonary Valve**

The aortic valve may be replaced with the patient’s own pulmonary valve (pulmonary autograft) and a pulmonary allograft used to replace the pulmonary valve. This operation was devised by Ross and carries his name.\textsuperscript{119} The operation has the advantage of placing autogenous tissue in the high-pressure aortic position that theoretically should last indefinitely, assuming the procedure is technically correct. (See “Selection of Technique and Choice of Device for Isolated Aortic Valve Replacement” later in this chapter). The allograft tissue is placed in the low-pressure pulmonary position, where even if it should fail, valve regurgitation is tolerated for a long time.

CPB is established using two cannulae for venous drainage. A right-angle cannula is placed directly into the superior vena cava at the pericardial reflection. The other is placed in the inferior vena cava through the right atrium at the diaphragm (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2). Alternatively, a single two-stage venous uptake cannula may be used, placing the second-stage opening low in the right atrium near the inferior vena cava orifice. Vacuum-assisted venous return provides more safety and reserve when the single-cannula technique is used, reducing the risk and consequences of air lock, which may occur in a gravity drainage system when the RV is opened (see “Vacuum-Assisted Venous Return” in Section I of Chapter 2). Oxygenated blood is returned to the ascending aorta.

**Pulmonary Autograft Technique**

The aortic root is explored through the usual transverse incision. Once it is determined to proceed with the pulmonary autograft operation, the ascending aorta is divided, the aortic valve removed, and the entire sinus aorta excised except for a generous rim around the coronary ostia (Fig. 12-17, A). Traction stitches on the aorta above the coronary arteries are helpful. Only the fibrous connection of the aortic cusps remains for attachment of the pulmonary autograft. Traction stitches are placed above each commissure. Diameter of the aortic anulus is measured using Hegar dilator sizers.

The pulmonary trunk is separated from the aorta up to its bifurcation. It is divided at the bifurcation, taking care not to shorten the right pulmonary artery (Fig. 12-17, B). The pulmonary valve is inspected from above. If it is normal, operation may proceed. If it is abnormal, the pulmonary artery is reanastomosed and an aortic allograft used to replace the aortic root.

Dissection between the medial commissure of the aorta and the pulmonary trunk comes down onto the muscle of the right ventricular outflow tract (RVOT; Fig. 12-17, C). Thorough dissection between the aorta and pulmonary trunk, especially low onto the RV in the plane between the RVOT and the infundibular septum, makes removing the pulmonary trunk much easier.

The anterior intercusp triangle below the anterior commissure is identified as a reference point for opening the RVOT. A small right-angle clamp is placed precisely in the anterior intercusp triangle and pushed through the anterior wall of the RV. The small opening is carefully enlarged. The pulmonary trunk is separated from the RV, looking inside frequently to maintain appropriate length of the ventricle below the pulmonary valve (Fig. 12-17, D). Incision of the RVOT continues on the right side and posterior to the extent of previous dissection (Fig. 12-17, E).

The critical and unique part of the Ross operation is separating the pulmonary trunk from the RVOT above the infundibular septum. When done correctly, this part of the procedure makes the entire operation safe. Anatomy of the subpulmonary infundibulum is described in “Right Ventricle” under Cardiac Chambers and Major Vessels in Chapter 1. Injury to the underlying first septal branch of the left anterior descending coronary artery during dissection of the pulmonary trunk is a major source of morbidity in this operation. A shallow incision of the endocardial surface is made to join both ends of the partly excised pulmonary trunk (Fig. 12-17, F). The incision extends completely across the remaining undivided RVOT. The angle of the scalpel is immediately changed to shave off the ventricular myocardium almost parallel to the endocardial surface. This shaves off the pulmonary trunk without injuring the underlying first septal branch. This part of the operation should be performed deliberately and under precise control. The septal excision eventually separates the pulmonary trunk completely, leaving the left main coronary artery and the first septal branch behind and protected by a generous layer of tissue. The septal artery is occasionally seen in the myocardium.

The separated pulmonary trunk is placed in the pericardial sac for immediate use. The trunk is not removed from the operating field, to prevent its misplacement or inadvertent mixture with the allograft. At this point it is convenient to measure the dimensions of the pulmonary anulus using standard prosthetic valve sizers and to choose a pulmonary allograft for preparation for later use.

The pulmonary autograft is attached to the unmodified LVOT, using interrupted stitches of 3-0 polypropylene (Fig. 12-17, G). Size discrepancy between the pulmonary autograft anulus and aortic anulus should not exceed 2 mm. A larger discrepancy indicates the need to adjust the anulus of the aorta to match that of the pulmonary autograft (see “Method for Reducing Diameter of Dilated Aortic Anulus” later in this chapter). The autograft is marked below each of the commissures for orientation. The anterior commissure of the autograft is oriented to approximate the commissure between the right and noncoronary sinuses. Suturing proceeds below each sinus, separating the stitches into three groups. Stitches are placed through the strong fibrous tissue of the aortic anulus, keeping the plane of repair as level as possible. A strip of PTFE felt about 5 mm wide is used to fix the diameter of the proximal suture line and to ensure hemostasis between the sutures (Fig. 12-17, H). A strip of autogenous pericardium may also be used. A “supported” repair is favored to prevent dilatation of the pulmonary autograft at the proximal suture line. Some surgeons prefer a continuous suture line using absorbable stitches without prosthetic material, especially for children in whom growth of the pulmonary autograft is
desired. However, the accuracy of carefully spaced individual stitches and fixation support of the anulus seem best in adult patients. The felt or pericardial strip is placed within the suture loops so that it is incorporated as the sutures are tied down. The pulmonary autograft is partially inverted into the LVOT as the sutures are tied to ensure that tissue approximation is accurate and that the support ring is to the outside rather than interposed between the tissues of the autograft and the aortic anulus.

An opening is made into the left coronary sinus of the autograft using a scalpel (Fig. 12-17, J). Only minimal sinus tissue is excised, because the delicate pulmonary artery dilates and separates readily. The sinutubular junction of the autograft is preserved to maintain proper relationships of the commissures and cusps.

The left coronary anastomosis proceeds, working on the outside of the pulmonary autograft (Fig. 12-17, J). Continuous stitches of 5-0 polypropylene are used. As a practical matter, it is best to perform the right coronary anastomosis after completing the aortic anastomosis so that the pulmonary trunk can be distended by temporarily removing the aortic clamp (Fig. 12-17, K). The right coronary anastomosis typically fits high in the right sinus or even above the sinutubular junction on the anterior wall of the pulmonary trunk. It may also be advisable to anastomose the pulmonary allograft to the bifurcation of the pulmonary trunk before the aortic anastomosis if the medial aspect of the pulmonary anastomosis might be obscured by the overlying aorta (Fig. 12-17, L). Often the diameter of the aorta is larger than that of the pulmonary trunk, but the pulmonary trunk is usually sufficiently long that a bevel can be created to take up any size discrepancy. With gross aortic enlargement or aneurysm, the entire ascending aorta may be removed and the pulmonary trunk extended with a prosthetic graft (see “Method for Extending Pulmonary Autograft” later in this chapter).

**Pulmonary Allograft Technique** The cryopreserved pulmonary allograft is trimmed minimally. An end-to-end anastomosis of the allograft to the pulmonary bifurcation is performed using continuous stitches of 4-0 polypropylene (see Fig. 12-17, L). Retracting the LV inferiorly and placing the graft in the space between the pulmonary bifurcation and the RV makes it easier to perform the anastomosis of the posterior wall of the pulmonary arteries. It is sometimes preferable to perform this anastomosis before constructing the aortic anastomosis. The proximal end of the allograft trunk is anastomosed to the RVOT (see Fig. 12-17, L). Continuous stitches of 3-0 polypropylene are used. Needle penetration must be through only part of the thickness in the infundibular septum to avoid injury to the underlying first septal branch of the left anterior descending coronary artery. A potentially weak point on the anastomosis at the transition from the infundibular septum to the medial aspect of the RV free wall may be reinforced with a PTFE pledget worked into the suture line. The completed repair produces a remarkably normal anatomic appearance (Fig. 12-17, M).

**Method for Lengthening Pulmonary Allograft** The pulmonary allograft may be tailored to achieve greater length, reducing the chance that the graft will be too tight between the RVOT and pulmonary artery bifurcation. The entire left pulmonary artery may be retained on the graft. The right pulmonary artery is removed and closed by direct suture using 5-0 polypropylene to lengthen the graft (Fig. 12-18, A). The left pulmonary artery is cut back to the bifurcation to create a large circumference for anastomosis. Making the pulmonary allograft long or even slightly redundant may be important in maintaining proper allograft length, because myocardium below the pulmonary allograft valve is resorbed and replaced with contracting scar.

**Method for Reducing Diameter of Dilated Aortic Anulus** When the patient’s LVOT at the level of the anulus is more than 2 mm in diameter greater than the pulmonary autograft, the patient’s anulus may be narrowed to fit the autograft, taking up this variance in anular diameters. Interrupted mattress stitches of 2-0 braided suture reinforced with PTFE pledgets are placed through the fibrous tissue that supports the aortic cusps alongside each of the commissures. The stitches are placed across the intercusp triangle so that the triangle is obliterated after tying down the suture (Fig. 12-18, B).

**Method for Extending Pulmonary Autograft** When the ascending aorta is greatly dilated or aneurysmal, it is advisable to remove the affected aorta. A polyester tubular graft with the same diameter as the pulmonary autograft’s distal end at the sinutubular junction is selected for replacement of the ascending aorta as an interposition graft (Fig. 12-18, C).

**Method for Fixing Sinutubular Junction** Evidence indicates that the pulmonary trunk may dilate up to 30% in diameter and length when exposed to systemic arterial pressure. Schmidtke and colleagues found that the pulmonary trunk in the aortic position as a freestanding root assumed a diameter of 41 mm at the sinus level, compared with 32 mm when the autograft was placed within the natural aorta. When the pulmonary trunk may also dilate in the clinical setting of bicuspid aortic valve with dilated ascending aorta. Fixing the diameter of the sinutubular junction of the pulmonary autograft is desirable and may prevent or correct pulmonary autograft regurgitation. A segment of tubular polyester vascular prothesis equal to, or 1 to 2 mm greater than, the diameter of the pulmonary autograft sinutubular junction (10% larger) is placed on the outside of the autograft to fix its diameter at its normal dimension. The polyester segment is attached to the pulmonary autograft with a few simple stitches to prevent migration (Fig. 12-18, D). A PTFE felt strip works equally well, but the diameter of the finished band is more difficult to control. Surgeons not wanting to fix the diameter of the pulmonary autograft at the sinutubular junction may find that narrowing the graft with a felt strip corrects possibly important autograft regurgitation (Fig. 12-18, E). Because of the known tendency for the pulmonary autograft to dilate, some have advocated reinforcing the entire autograft with bovine pericardium, polyester, or as an intraaortic cylinder within the native aortic root.

**Replacement of Aortic Valve and Ascending Aorta, En Bloc**

Replacement of the aortic valve and ascending aorta, en bloc, is most frequently performed for anulaoortic ectasia and ascending aortic aneurysm accompanied by aortic valve regurgitation. Occasionally, en bloc replacement is performed for infective endocarditis of the aortic root with extensive abscess formation and in the setting of acute or chronic aortic dissection with aortic valve regurgitation, for which the technique of distal anastomosis may be somewhat different.
Figure 12-18  Methods for adjusting Ross operation in specific situations. **A,** Method for lengthening pulmonary allograft to prevent tension on graft between right ventricular outflow tract and bifurcation of pulmonary artery as right ventricular myocardium on allograft is reabsorbed and replaced with scar tissue. Left pulmonary artery is retained with pulmonary trunk; it may be cut back (broken line) to pulmonary bifurcation to create a large opening. Right pulmonary artery is removed and its origin closed by continuous suture. **B,** Method for reducing diameter of dilated aortic anulus for proper size match with pulmonary autograft. Pledget-reinforced horizontal mattress stitches are placed through the fibrous tissue adjacent to intercusp triangles posteriorly and medially to obliterate triangular space, thereby reducing anular diameter.

**Initial Steps**
The early steps of the en bloc operation differ somewhat from those of simple aortic valve replacement. The arterial cannula may need to be placed in the common femoral artery (see “Cardiopulmonary Bypass Established by Peripheral Cannulation” in Section III of Chapter 2). When the ascending aortic aneurysm stops short of the brachiocephalic artery origin, the distal ascending or proximal transverse arch can be cannulated in the usual manner.

A limited dissection is done, separating the right and contiguous portion of the pulmonary trunk from the back of the aorta and the aneurysm. This approach affords safe placement of the aortic occlusion clamp just proximal to the brachiocephalic artery. The procedure involves clean surgical separation of the right and contiguous portion of the pulmonary trunk from the back of the aorta and from the aneurysm, if possible.

CPB is established at 34°C using a single two-stage venous cannula and left atrial vent. The perfusate temperature is lowered to bring body temperature to 28°C. The aorta is occluded just proximal to the brachiocephalic artery. The ascending aorta is opened transversely in its midportion, stay sutures are applied, and cardioplegia is given.

The patient’s aortic root is disconnected from the LVOT and left atrium–mitral valve complex. The sinus aorta surrounding the coronary arteries is retained. The remaining
Figure 12-18, cont’d  
C. Method for extending pulmonary autograft when there is aneurysm or dilatation of ascending aorta. Aneurysmal aorta is removed. Pulmonary autograft is lengthened by attaching a tubular polyester graft of exactly the same diameter as the pulmonary trunk just above valve commissures. D, Method of fixing sinutubular junction of pulmonary autograft to prevent dilatation. A segment of tubular polyester vascular prosthesis 10% smaller than measured diameter of pulmonary valve is placed around outside of autograft at level of sinutubular junction. A few interrupted stitches are placed to attach graft to pulmonary trunk to prevent migration. E, Echocardiogram of pulmonary valve before aortic valve replacement with pulmonary autograft shows typical trivial central valve regurgitant jet. After pulmonary trunk is transferred to aortic position and subjected to systemic arterial pressure, there is moderate (2+) valve regurgitation. Narrowing the sinutubular junction with an external band restores valve to preoperative state of trivial regurgitation.

sinus aorta is excised, leaving only fibrous aortic valve attachments, which are normal and uninvolved with the disease process being treated. The ascending aorta is divided by extension of the transverse aortotomy.

Allograft Aortic Valve Cylinder
When the ascending aorta is replaced along with the valve, sizing of the allograft valve is less critical than in the case of isolated aortic valve replacement. Aorta is usually sufficient on the allograft to replace the ascending aorta. Length of the retained ascending aorta and arch are considered when choosing the graft (see Fig. 12-14). The distal aorta is tailored to fit the native aorta. The distal anastomosis is performed directly or under circulatory arrest with the patient’s body temperature at 18°C.

Autograft Pulmonary Valve Cylinder
In young patients it may be desirable to use a pulmonary autograft as part of the en bloc operation. The pulmonary autograft is used as an intact pulmonary trunk to replace the aortic root as described earlier for isolated aortic valve replacement (see Fig. 12-18, C). The abnormal dilated or
aneurysmal ascending aorta is excised. A crimped polyester tubular graft, collagen coated and of the same diameter as the distal end of the pulmonary autograft, is selected for replacing the ascending aorta. This graft is anastomosed to the distal end of the pulmonary trunk. The graft is shortened and beveled appropriately for end-to-end anastomosis to the distal ascending aorta.

**Composite Valve Conduit**

Replacing the aortic valve and ascending aorta as an en bloc procedure is most often done with a composite prosthesis containing a mechanical or bioprosthetic cardiac valve enclosed within a slightly larger tubular polyester graft. This operation is frequently referred to as the Bentall procedure. These grafts have a collagen or gel coating that makes them impervious to blood.

The patient is placed on CPB using a single venous two-stage cannula, with oxygenated blood returned to the femoral artery in most cases. Occasionally, the amount of ascending aorta is sufficient to allow it or the transverse portion of the aortic arch to be perfused. The ascending aorta is occluded by a vascular clamp, and a vent catheter is placed through the right superior pulmonary vein to the left atrium and LV. A vertical incision is made in the ascending aorta aneurysm. Cold cardioplegic solution is administered to the coronary sinus by a retrograde coronary perfusion cannula. Traction stitches are placed above each aortic valve commissure to expose the aortic root (Fig. 12-19, A). The aortic valve is excised. The coronary arteries are mobilized, retaining a generous button of sinus aorta. A limited dissection of the coronary artery is sufficient to ensure that excision of the coronary artery is complete and that the coronary button will move easily up to the composite prosthesis without kinking or creating undue tension on the artery. The remaining sinus aorta is removed.

Diameter of the anulus is calibrated, and an appropriately sized composite prosthesis, including the prosthetic aortic valve and attached crimped polyester tubular prosthesis, is selected. Stitches are placed through the anulus of the aortic valve and brought up through the sewing ring of the prosthetic valve is avoided. Ten-millimeter diameter of the anulus is calibrated, and an appropriately sized composite prosthesis is constructed by placing a prosthetic valve within a tubular polyester graft so that there is a short length of tubular graft extending below and a longer length of graft extending above the sewing ring of the valve (Fig. 12-19, C). The graft collar is used to cover the completed anastomosis for hemostasis (Fig. 12-19, D). Modifications are required when coronary artery ostia are either close to the anulus or widely separated laterally by an aortic aneurysm. When coronary artery ostia are bound tightly to the aortic anulus, usually by prior operation or valve replacement, it is impossible to create an accurate anastomosis to the tubular portion of a composite graft because the valve sewing ring may impinge on the coronary ostia. In this situation, a composite valve prosthesis is constructed by placing a prosthetic valve within a tubular polyester graft so that there is a short length of tubular graft extending below and a longer length of graft extending above the sewing ring of the valve (Fig. 12-19, D). The graft and sewing ring of the prosthetic valve are attached by continuous suture. The extension of the tubular graft below the prosthetic valve is attached to the aortic anulus, displacing the level of the prosthetic valve cephalad above the bound down coronary ostia. Obstruction of the coronary ostia from contiguous placement of the thick sewing ring of the prosthetic valve is avoided. Ten-millimeter extension grafts from the aortic graft above the prosthetic valve to the coronary ostia complete the repair.

When the coronary artery ostia have been carried laterally and superiorly from the usual location relative to the aortic
Figure 12-19 Replacement of aortic root and ascending aorta (en bloc) with composite prosthetic valve conduit. A, Aortic valve is excised. Aorta is removed from sinuses of Valsalva except for generous buttons around coronary ostia. Abnormal ascending aorta is removed. B, Composite prosthetic valve conduit is attached to anulus of aortic valve with pledget-reinforced horizontal mattress stitches of 2-0 braided polyester. Continuous suture technique may also be used. C, Sutures are tied to tightly approximate prosthesis to aortic anulus. D, An opening is made into graft posteriorly. Left coronary artery is anastomosed to graft using continuous stitches of 3-0 or 4-0 polypropylene.

Continued
Figure 12-19, cont’d  E, An opening is made into graft anteriorly. Right coronary artery is anastomosed to graft.  F, Generally, coronary arteries may be anastomosed to the graft directly, without special treatment. Dissection of aorta around coronary ostium may require repair with polytetrafluoroethylene (PTFE) felt “washers” placed on endothelial and adventitial surfaces to sandwich the aortic tissue. Biological glue may also be applied. When coronary ostia are widely displaced, a short segment of tubular polyester or PTFE graft may be placed between aortic graft and coronary ostium. A short segment of saphenous vein may be used as an interposition graft.
anulus by aneurysm or dilatation of the aortic root, it is necessary to create an extension from the composite prosthesis to the coronary arteries. Ten-millimeter tubular polyester grafts are attached to the coronary arteries and brought up to the anterior aspect of the composite prosthesis (Fig. 12-19, K).

Repair of Aortic Valve Regurgitation due to Aortic Dilatation or Aneurysm (Valve-Sparing Aortic Root Replacement)

Kunzelman and colleagues studied the relationships of the diameters at various levels in the aortic root, showing that the diameter at the sinutubular junction should be about 15% less than that at the base (anulus or ventricular-aortic junction)\(^{37}\) (Fig. 12-20). Grande and colleagues showed that minor dilatation of the aortic root (5%-15%) caused increased stress on aortic valve cusps.\(^{17}\) In response to dilatation of the aortic root, strain on the valve cusps changes in order to maintain coaptation. This method of compensation fails at 30% to 50% dilatation of the aortic root, and cusp tissue is insufficient to maintain coaptation, resulting in aortic valve regurgitation. Frater demonstrated that simply adjusting the dimensions of the sinus rim or sinutubular junction can correct such regurgitation.\(^{11}\)
Remodeling versus Reimplantation Procedures

Remodeling Procedure  The remodeling operation consists of removing the sinus aorta except for a small rim of aortic tissue around the coronary ostia and a rim of about 5 mm of aortic wall above the aortic valve anulus. Commissures are positioned to achieve good coaptation of the aortic valve cusps.

Choo and Duran point out that the aortic root is dynamic, responding to pressure changes during the cardiac cycle that expand the aorta at the sinutubular junction by 35%, but the area at the base (anulus) by only 5%. Thus, they propose measuring the aortic root diameter at the base of the cusps as the most reliable method for appropriate graft sizing. The method proposed here is based on the measured diameter of the aortic anulus and simple arithmetic. When the diameter of the aortic anulus is normal, a graft is chosen that will narrow the sinutubular junction by 10% to 15%. When the diameter of the aortic anulus is enlarged, it is adjusted to normal diameter for body size using a graft diameter approximately 10% less than the desired aortic anular diameter. The
geometry conveniently allows strips of the graft to support a reduction anuloplasty of five-sixths the circumference of the anulus (avoiding the conduction system) while the graft adjusts the diameter of the sinutubular junction.

David recommended that when aortic root remodeling procedures, such as the Yacoub operation, are performed in patients with Marfan syndrome, or when the aortic anulus is dilated, an aortic anuloplasty should be performed. A strip of prosthetic material is used on the outside of the LVOT below the aortic valve to correct dilatation of the fibrous components of the LVOT resulting from myxomatous changes in these tissues.

Reimplantation Procedure In this procedure, the aortic valve is reimplanted within a polyester tubular graft. The graft is secured to a level plane in the LVOT just below the valve, except in the one sixth of the circumference occupied by the conduction system. This fixes the diameter of the LVOT, but one may reduce the diameter if necessary. The aortic valve is attached (reimplanted) to the inside of the prosthetic graft. The graft determines the diameter of the sinutubular junction.

The reimplantation procedure has undergone a number of modifications by both David and other surgeons. However, the basic concept has been retained. Cochrane and colleagues modified the David operation to create pseudosinuses in the graft by removing three symmetric scallops from it, thereby lengthening the proximal suture line and restoring proper relationships at the sinutubular junction. The pseudosinus method (Cochrane) and sinus-tailored method (Yacoub) result in simulated cusp stresses that are closer to normal than does David’s cylindrical technique.

The graft is usually 30 to 32 mm in diameter, although 28- or 34-mm grafts are occasionally used.

Technique of Operation

After induction of anesthesia and before incision, intraoperative transesophageal echocardiography (TEE) is used to measure aortic root dimensions at the sinutubular junction and ventricular-aortic junction. Operations are performed on CPB using a single two-stage cannula for venous uptake, with oxygenated blood returned to a cannula placed high in the ascending aorta or arch or in the femoral artery. Hypothermic circulatory arrest is used when the aneurysm extends beyond the ascending aorta.

The aorta is divided above the sinutubular junction and the aortic valve thoroughly examined. Normal aortic valve cusps suggest the possibility of a valve-sparing operation. Diameters of the sinutubular junction and ventricular-aortic junction are measured using Hegar dilators or accurate valve sizers. Alterations of aortic root dimensions are noted and will guide the steps taken to restore dimensions to normal.

Aortic Anulus Normal, Normal Sinuses of Valsalva, Sinutubular Junction Enlarged A normal aortic anulus with enlarged sinutubular junction is found in patients with aortic ectasia and aneurysm of the ascending aorta not involving the aortic sinuses. The coronary arteries are not displaced from their usual location in relation to the anulus.

A vascular graft the same diameter as the aortic anulus is selected. A 4- to 5-mm segment of the graft is prepared for placement on the outside of the aorta at the sinutubular junction. The thickness of the aortic wall when compressed within the graft will reduce the inside diameter of the aorta to restore the normal dimension, which is 15% less than the diameter of the aortic anulus. Using this short segment of graft is easier and more accurate than attempting to attach a longer graft directly to the sinutubular junction.

Aortic Anulus Normal or Enlarged, Aneurysm of Sinus of Valsalva, Sinutubular Junction Enlarged An enlarged aortic anulus with enlarged sinutubular junction is found in patients with anuloaortic ectasia, some of whom have Marfan syndrome. Less commonly, patients with aortic regurgitation and sinus of Valsalva aneurysm will have a normal aortic anulus. Both the remodeling and reimplantation procedures have been recommended for this condition. Both are described here.

Remodeling Procedure

In the remodeling procedure, the aortic sinuses are removed. The aortic anulus is reduced to a diameter appropriate for the patient’s body size (Fig. 12-22), generally 25 mm for the average adult male, 27 mm for a large male, and 23 mm for an adult female. A vascular graft 10% to 15% smaller than that is selected. Two 4- to 5-mm segments (rings) of the graft are prepared to adjust the anulus diameter. The remaining graft is tailored by making three incisions and trimming the flaps for sinus reconstruction and replacing the ascending aorta.

To achieve an LVOT 25 mm in diameter at the ventricular-aortic junction, the circumference of the aorta must be reduced to 78 mm (25 \cdot \pi = 78). This reduction is accomplished by anuloplasty, using the short segments of graft to size the anulus accurately and to support the repair. Anuloplasty mattress stitches are placed in the LVOT at a level plane.
**Figure 12-21** Repair of aortic valve regurgitation caused by dilatation or aneurysm of ascending aorta when aortic anulus is normal and sinutubular junction is enlarged without aneurysmal enlargement of sinuses of Valsalva and without displacement of coronary ostia. A 4- to 5-mm segment of graft the same diameter as anulus is placed as a band on outside of aorta at sinutubular junction to reduce inside diameter by 10%. Ascending aortic aneurysm is resected and replaced with graft of same size.

**Figure 12-22** Remodeling method for restoring aortic root dimensions in an aortic valve–sparing operation when aortic anulus and sinutubular junction are enlarged, as in anuloaortic ectasia with Marfan syndrome. A vascular graft 10% to 15% smaller than desired diameter of aortic anulus is used to provide 4- to 5-mm strips of fabric that will support a reduction anuloplasty of five-sixths of circumference of left ventricular outflow tract (avoiding conduction system) just below aortic valve. Graft adjusts diameter at sinutubular junction. Sinuses of Valsalva are reconstructed as described in text.
just below the hinge point of the aortic valve. The stitches are placed beginning below the nadir or midpoint of the right coronary cusp of the aortic valve and working counterclockwise to the commissure between the noncoronary and right coronary cusps. This places the stitches on five sixths of the circumference, avoiding stitches in the one sixth of the ventricular septum that contains the conduction system. A strip of fabric to cover five sixths of the circumference and achieve a diameter of 25 mm is 65 mm in length (78 · 𝜋 · % = 65). It is convenient that a 22-mm crimped tubular polyester graft provides a strip of fabric 75 mm in length when the 4- to 5-mm segment is cut, opened, and stretched to length. From the strip of the graft, 10 mm of length is removed. The annuloplasty stitches are placed through the fabric strip and passed through the LVOT to the outside. Thickness of tissue through which the needles pass is about 3 mm. Thus, the outside diameter to be supported will be about 28 mm in diameter. The length of fabric needed to support this diameter is, conveniently, about 75 mm (28 · 𝜋 · % = 73). The anuloplasty stitches are passed through the outside fabric strip. A 25-mm-diameter Hegar dilator is placed in the LVOT while the sutures are tied down. This narrows the LVOT to a calculated diameter while distributing the tension equally over five sixths of its circumference.

The sinus aorta is reconstructed to the flap graft. Diameter of the sinutubular junction is accurately restored by the diameter of the graft chosen for the repair. Relationships just described should hold for the various graft sizes that might be chosen for reconstructing the aortic root. Intraoperative TEE is performed with the heart contracting and ejecting at normal pressure to determine adequacy of the repair.

**Reimplantation Procedure**

The reimplantation technique involves excising all three sinuses, leaving a rim of 4 to 5 mm of aortic wall and buttons of aorta around the coronary ostia (Fig. 12-23, A). An appropriately sized polyester graft (see later text for sizing details) is selected and marks are made on one end of it corresponding to position of the commissures. Multiple interrupted pledgeted horizontal mattress sutures of 2-0 polyester are passed from inside the LVOT immediately below the nadir of the aortic valve following a horizontal plane except in the region of the left anterior fibrous trigone (dense adherence of fibrous trigone to pulmonary trunk) and near the conduction system at the commissure between right and noncoronary sinuses (Fig. 12-23, B). (In these two commissural areas, the sutures follow the hinge point line of the valve cusps). These horizontal mattress sutures are then placed through the base of the polyester graft (placed slightly higher in the two commissural areas noted). Position of the commissures within the graft is then determined (the orientation being critical to competence of the aortic valve), and the aortic wall above each commissure is sutured to the graft with 4-0 polypropylene mattress sutures. The remainder of the suturing of the native aortic valve to the inside of the graft is similar to a subcoronary allograft procedure, described earlier under “Allograft Aortic Valve.” The suture line starts at the lowest point of each scallop and is continued to the top of each commissure. The valve is inspected for adequate cusp coaptation. If the free edge of one or more cusps is elongated and tending to prolapse, the free margin can be shortened by using 6-0 PTFE suture to imbricate the central portion of the cusp (nodulus of Aranti).

The coronary artery reimplantation steps are the same as described for the total root replacement operation (Fig. 12-23, C). The distal aortic anastomoses can be performed either with the same graft or with a separate smaller graft (see text that follows on creating pseudosinuses).

Two important technical considerations in the reimplantation procedure deserve special comment: commissure resuspension height and graft sizing with the construction of pseudosinuses.

**Commissural Resuspension Height**  
*Placing commissures at the appropriate height within the graft is of critical importance for long-term valve competence. They should be placed at a height that mimics normal geometry and avoids abnormal cusp coaptation. Experimental studies suggest that an abnormally low commissural resuspension level may compromise optimal cusp coaptation.*

**Graft Sizing with Construction of Pseudosinuses**

Multiple algorithms have been suggested for selecting the appropriate graft size, particularly when attempting to create pseudosinuses. Although it remains unproven that creating neosinuses adds to long-term valve competence, experimental studies dating back to Leonardo da Vinci and subsequently by others suggest that presence of vortices in the sinuses facilitates cusp closure in early diastole and reduces cusp stress.

In a study by Katayama and colleagues in which a finite element simulation was used to model aortic valve–sparing root replacement with and without pseudosinuses, distinct differences were observed in the closing dynamics of the cusps. In the model without neosinuses the aortic valve was open longer and the cusps had a faster closing velocity. In the pseudosinus model, vortex formation occurred, which facilitated a more gradual and smoother closure of the valve cusps. Furthermore, in the model without pseudosinuses, cusp stress and bending deformation was greater in the middle of the cusps. Aybek and colleagues studied aortic valve cusp dynamics in patients undergoing aortic valve–sparing root replacement with and without incorporation of pseudosinuses. Patients who underwent the reimplantation procedure with a straight graft had an aortic valve opening velocity of 61 cm · s⁻¹ (normal opening velocity 29 cm · s⁻¹) vs. 46 cm · s⁻¹ in those with pseudosinuses. Aortic valve closing velocity mirrored opening velocity. Therefore, although it is true that the opening and closing velocities of the aortic valve were closer to normal in patients with pseudosinuses, they remain abnormally high. A finite element model simulating aortic valve–sparing root replacement found that in the straight graft simulation, the diastolic cusp stresses and strains were mostly on the cusp belly and attachment edge, which are the regions closest to the graft. These are areas of the cusp that normally have high bending and flexing stresses during valve opening. In the pseudosinus graft simulation the aortic cusp stresses were still abnormal at the attachment edge, but less than that seen in the straight graft simulation. This biomechanical information suggests that incorporating pseudosinuses into the aortic valve–sparing root replacement procedure may confer some benefit in terms of aortic valve opening and closing velocities and cusp stresses, although they remain abnormal.

Thus, although it remains uncertain whether these biomechanical benefits will translate into long-term improved cusp...
appropriately on the graft, they will crimp the proximal graft down to the appropriate size while simultaneously creating pseudosinuses. Reducing of the diameter at the sinutubular junction to about 15% less than the desired aortic anulus diameter can be achieved either by placing plication sutures in the graft above each commissure, or, alternatively, by using a second graft for the distal ascending aortic replacement that approximates the anulus size and is sewn end to end to the larger proximal graft, effecting a reduction in diameter at the level of the sinutubular junction (“Stanford modification”). A commercially prepared graft with pre-constructed pseudosinuses (Gelweave Valsalva) is available in sizes 24-34.

Reducing the size of a dilated aortic anulus to increase cusp coaptation is an essential component of the operation. A Hegar dilator can be used to measure the anulus, and Svensson has recommended placing the Hegar through the aortic valve when tying the subanular sutures to guide the anuloplasty effect of the proximal graft suture placement. A 19-mm Hegar is selected for BSA of about 1.5 m², 21-mm Hegar for BSA 2.0 m², and 23-mm Hegar for BSA 2.5 m².

A larger graft (selected for creating pseudosinuses) can be “necked down” to an appropriate size at the anular end by placing multiple plication stitches in it with the appropriate valve sizer inside the graft to aid in achieving a desired diameter (Demers 2004, Miller 2007). Another option is to place the pledgeted sutures within the aortic root below the valve level to create an anuloplasty effect; when spaced appropriately on the graft, they will crimp the proximal graft down to the appropriate size while simultaneously creating pseudosinuses.

Reduction of the diameter at the sinutubular junction to about 15% less than the desired aortic anulus diameter can be achieved either by placing plication sutures in the graft above each commissure, or, alternatively, by using a second graft for the distal ascending aortic replacement that approximates the anulus size and is sewn end to end to the larger proximal graft, effecting a reduction in diameter at the level of the sinutubular junction (“Stanford modification”). A commercially prepared graft with pre-constructed pseudosinuses (Gelweave Valsalva) is available in sizes 24-34.

Adequacy of aortic valve–sparing operations is confirmed by intraoperative TEE.

**Alternative Aortic Valve–Sparing Techniques**

Alternative techniques generally focus on simplifying the operation by retaining aortic tissue and providing an external wrap to prevent further aortic enlargement. The advantage is a simpler procedure with fewer suture lines to bleed, which must be weighed against the potential for dissection in the retained aorta. The *Florida sleeve repair*
is a valve-sparing operation in which the ventricular-arterial junction, sinuses of Valsalva, and sinutubular junction are supported by a polyester conduit as a sleeve. In a technique reported by Laks and colleagues,\textsuperscript{12} aortic root aneurysms associated with bicuspid aortic valve regurgitation are treated with a combination of pericardial cusp extension, lining the sinuses of Valsalva with autologous pericardium (with holes punched to accommodate the coronary orifices), and wrapping the ascending aorta with polyester.

**Aortic Valve Replacement and Coronary Artery Bypass Grafting**

Preparing and draping the patient, and simultaneous preparation of the coronary bypass conduits, are the same as in simple coronary artery bypass grafting (CABG) (see Technique of Operation in Chapter 7). Purse-string sutures for aortic cannulation are placed, with care taken that they are far enough distally (downstream) from the aortic valve to allow room for both the aortotomy and any proximal venous graft anastomoses.

CPB is established. The operative procedure begins exactly as for isolated aortic valve replacement through excision of the aortic valve and selection of replacement device. The distal graft-to-coronary artery anastomoses are performed. Then the valve is replaced and the aortotomy closed. If vein grafts are used, they are routed and sized, and the proximal anastomoses to the aorta are performed. After de-airing the heart, CPB is discontinued and the operation completed as usual.

**Redo Isolated Aortic Valve Replacement**

Not all redo operations after primary aortic valve replacement involve a second valve replacement. Acute thrombosis may be treated by thrombectomy, and periprosthetic leakage of a mechanical valve or stent-mounted bioprosthesis may be successfully treated by simple resection of the area of dehiscence. Prosthetic valve endocarditis, central leakages of all types, and extensive periprosthetic leakage typically require valve re-replacement. The technique of operation embodies general principles of all redo cardiac operations (see “Secondary Median Sternotomy”\textsuperscript{12} under Incision in Section III of Chapter 2).

When a freehand-inserted allograft or xenograft requires replacement, the entire graft should be removed, including remnants of its aortic wall. The graft tissues are dissected from the sinus aorta and anulus using a Freer septum elevator, cutting suture material as required. This approach leaves an aortic root of good quality for inserting either another allograft or other replacement device.

When a stent-mounted bioprosthesis or mechanical prosthesis has been used, the device is removed by pulling on the knots with a needle holder and using a #11 scalpel to cut individual sutures that were placed at initial operation. Then, using a Freer septum elevator, a dissection plane is established between the fabric of the prosthesis sewing ring and aortic root tissues. The prosthesis is thus removed intact and aortic root tissues remain in good condition to accept another prosthesis. Mechanical prostheses can also be removed by first separating the mechanical device from the sewing ring by sharply dividing the ring with a scalpel. Incision of the sewing ring is taken completely through the retaining thread that holds the ring to the mechanical device. Once these retaining threads are cut, the mechanical device comes away from the sewing ring. Fabric of the sewing ring is then more easily separated from tissues by cutting the sutures placed at initial operation.

**Redo Aortic Valve and Ascending Aorta Replacement, En Bloc**

In the setting of a prior cardiac operation with an aneurysmal ascending aorta or ascending aortic graft, proximity of the ascending aorta or aortic graft to the underside of the sternum can be evaluated with CT studies. When the situation is considered high risk for direct adherence of the graft or aorta to the sternum, the following approach can be considered. The technique of reoperation needs to be modified from the standard approach because of an important risk of massive hemorrhage from the polyester tube graft at sternal reentry if the graft has adhered to the back of the sternum. Reentry is further complicated if aortic regurgitation is present. Under such circumstances, CPB is commenced through groin cannulation of the common femoral artery and vein using vacuum-assisted venous return (see “Vacuum-Assisted Venous Return” in Section II of Chapter 2). Core cooling is instituted to lower the nasopharyngeal temperature to about 20°C. When there is important aortic regurgitation, a limited left anterolateral thoracotomy may be made through the fifth intercostal space and a vent placed into the LV apex, monitoring LV end-diastolic pressure to maintain it at normal levels and prevent overdistention, even in the event of ventricular fibrillation. Alternatively, a large catheter (12F) is inserted percutaneously into the LV and its position confirmed by echocardiography. Adequate hypothermia permits the sternum to be opened with a vibrating saw without risk of exsanguinating hemorrhage. If the polyester tube is cut, CPB is stopped; blood escaping from the aorta is returned to the circuit by suction device, and control of the aorta distal to the tear is obtained before CPB is resumed.

Alternatively, to reduce the major increase in diffuse coagulopathy and generalized bleeding associated with the approach just described, the femoral artery and vein are dissected out and purse strings placed on their anterior surface with 4-0 polypropylene sutures in preparation for percutaneous arterial and venous cannulation for CPB if needed emergently. Using surgical towel clips through bone and xiphoid at the lower end of the incision to elevate the sternum, the oscillating saw is used to partially divide the sternum, taking care not to penetrate the posterior table. The posterior table is divided with scissors while elevating the lower sternum, so most of the sternal division is carried out under nearly direct vision. As the aneurysm or graft is approached, a portion of the periosteum or posterior table is left with the aortic graft by the appropriate dissection plane. If bleeding is encountered, the patient is promptly heparinized and the incision rapidly closed with numerous sharp surgical towel clips (as many as 20 clips may be needed). As long as the pleural spaces have not been entered during sternotomy, the completely closed incision (sufficient to eliminate any bleeding between towel clips) creates a closed space, and no further internal bleeding occurs after the space is obliterated. Hemodynamics are usually maintained while CPB is established through the femoral artery and vein. A decision can then be made to initiate hypothermic perfusion and temporary circulatory arrest as described in previous text or to remove the towel clips, collect
the aortic blood with a cardiotomy sucker, and obtain digital control while completing sufficient dissection to repair the aortic graft tear. Transient low-flow perfusion and moderate hypothermia are used to avoid ventricular fibrillation in the presence of important aortic regurgitation.

When infection is present, the prosthetic material should be removed entirely and replaced with an allograft. In the absence of infection, prosthetic material can be used again if desired.

**SPECIAL FEATURES OF POSTOPERATIVE CARE**

Postoperative care after adult aortic valve surgery is generally the same as after other types of cardiac surgery (see Chapter 5). Patients receiving a mechanical prosthesis are begun on lifelong sodium warfarin anticoagulant therapy on the evening of the first postoperative day. Intensity of anticoagulation should be specific for both prosthesis and patient.

Modern mechanical prostheses are considered to have lower thrombogenicity than earlier devices. An international normalized ratio (INR) for prothrombin time of 2.5 is considered adequate to prevent valve thrombosis in the absence of abnormal intracardiac conditions. Atrial fibrillation alone does not raise the requirement for anticoagulation unless the left atrium is enlarged or LV function impaired. These additional risk factors dictate raising the intensity of anticoagulation to an INR of 3.0. Severe left atrial enlargement, greatly impaired LV function, or echocardiographic evidence of stasis in the left atrium require even higher levels of anticoagulation, with an INR of 3.5 to 4.0. Some evidence indicates that adding aspirin (81 mg daily) further reduces risk of thromboembolism. Aspirin at higher levels (200 mg daily) reduces total thromboembolic events but increases morbidity associated with bleeding. Newer platelet antagonists have not been completely evaluated as adjuncts to warfarin therapy.

Bioprostheses (human or xenograft) in the aortic position of stent-mounted or stentless design do not require anticoagulation with warfarin. It should be noted that optimal management protocols to prevent thromboembolism during the first several months after implantation of bioprosthetic aortic valves remain controversial. Recommendations from the 2006 ACC/AHA Guidelines include warfarin for the first 90 days. A study by El Bardissi and colleagues supported the use of warfarin only in the higher risk settings of small prosthesis size (19 mm) and New York Heart Association (NYHA) functional class III/IV symptoms preoperatively in patients in sinus rhythm. For most patients in sinus rhythm, it is judicious to use aspirin therapy (81 mg daily) for at least 1 month, when risk of thromboembolism is greatest.

Patients in atrial fibrillation for more than 48 hours after operation are anticoagulated with warfarin until sinus rhythm is restored.

The thick-walled hypertrophied LV secondary to aortic valve disease requires a higher-than-usual filling pressure to distend it. Thus, a mean left atrial pressure of 8 to 10 mmHg, considered appropriate under many circumstances, may be inadequate to develop optimal LV preload early after operation in patients with important LV hypertrophy (see “Cardiac Output and Its Determinants” in Section I of Chapter 5). Reduction in myocardial compliance that occurs during cardiac surgery further increases the disparity between the usual mean left atrial pressure (LV filling pressure) and optimal preload.

For these reasons, unless cardiac performance is already optimal, left atrial pressure should be maintained at 15 to 18 mmHg by appropriate fluid infusion during the early hours after adult aortic valve surgery, particularly for severe aortic stenosis. This need is often less critical when operation has been done for aortic regurgitation, when the sudden reduction in LV stroke volume by eliminating the aortic regurgitant flow improves left compared with RV performance (see Chapter 5). Therefore, mean left atrial pressure may not be as elevated early postoperatively as when operation has been done for aortic stenosis.

Sinus tachycardia is frequently observed after operations on the aortic valve. When heart rate exceeds 100 beats·min$^{-1}$ for several days and shows no signs of returning to normal, a β-blocker should be administered to reduce the rate. It may be necessary to continue this therapy for 2 to 3 months until heart rate control mechanisms are restored.

**RESULTS**

**Early (Hospital) Death**

The Society of Thoracic Surgeons (STS) National Database reports a 2.6% and 3.3% 30-day mortality for isolated aortic valve replacement for the years 2009 and 2011, respectively. Risk is higher for women than men (3.9% vs. 3.0%). When CABG is added to aortic valve replacement, the current risk of hospital death among STS National Database participants rises to 4.2%. Isolated reoperative aortic valve replacement does not appear to increase early mortality in the current era.

**Time-Related Survival**

Overall survival (including hospital deaths) after aortic valve replacement in heterogeneous groups of patients is about 75% at 5 years, 60% at 10 years, and 40% at 15 years (Fig. 12-24, A). These percentages are less than those in an age-gender-race–matched general population, except for elderly patients (see Fig. 12-25). Many factors likely contribute to this, including the possible palliative nature of the operation, incomplete regression of LV remodeling after valve replacement, poor control of chronic anticoagulation in patients receiving mechanical prostheses, reoperation for structural valve deterioration of bioprostheses, and other prostheses-related morbidity. Grunkemeier and colleagues report risk-unadjusted data suggesting that after adjusting for age differences, late survival is similar for mechanical and bioprosthetic valves.

The hazard function for death after aortic valve replacement is similar to that after other valve replacement operations in adults (Fig. 12-24, B). The early, rapidly declining hazard phase gives way to a late phase about 6 months after operation, which begins to rise as early as 5 years after operation.

**Modes of Death**

Of the few deaths early after aortic valve replacement, most are related to acute cardiac failure, neurologic complications, hemorrhage, and infection. Most late deaths are unrelated to
Device-related modes of death include thromboembolism, although the frequency may have decreased in recent years. Some patients, but its occurrence in patients with an allograft 20% of late deaths. It may result from thromboembolism in death occurs with surprising frequency, accounting for about cardiac infarction are the most common modes of death, as the specific replacement device used. *Risk factors classified based on experience and published reports, and not all obtained by multivariable analysis.

Key: CABG, Coronary artery bypass grafting; COPD, chronic obstructive pulmonary disease; NYHA, New York Heart Association.

Figure 12-26  Hazard functions for each mode of death after primary aortic valve replacement in a group of 1533 patients. (An age-gender-ethnicity-matched general population has an incidence of deaths - month⁻¹ of 0.001 across a 5-year period, similar to that for deaths in uncertain mode, marked K.) (From Blackstone and Kirklin.)
However, risk of premature death late postoperatively is meaning hemodynamic instability or cardiogenic shock. Ability is so advanced or acute that it is NYHA class V, which is often not highly correlated with functional status, as reflected in NYHA functional class III. Poor functional status, as reflected in NYHA functional class III, is a risk factor for death, usually in cardiac failure, primarily after isolated aortic valve replacement. Nomogram of multivariable logistic equation. Key: NYHA, New York Heart Association. (From UAB group, 1975 to July 1979; n = 842.)

Age 80 equivalent to that of the general population. Age is not so dominant a risk factor as to negate the effect of the other risk factors in elderly patients. Risk of operation for aortic valve replacement combined with CABG in patients over age 80 is 10% (95%; CL 6.9%-13%), compared with 7.9% (95%; CL 6.6%-9.2%) in patients under age 80. Death early after operation in elderly patients tends to be related to excessive bleeding (in part attributable to the poor quality of the tissues), pulmonary dysfunction (in part related to generalized weakness and consequent delay in weaning from intubation and ventilation), and susceptibility to infection. Precise surgical techniques and acceleration of convalescence, with departure from the intensive care unit as quickly as possible, are helpful in neutralizing these risks.

Older patients may be more subject to important neurologic complications. Levinson and colleagues reported neurologic sequelae in 9% of 64 patients age 80 to 89 years undergoing isolated or combined aortic valve replacement. Alexander and colleagues reported associated neurologic events (15% vs. 9.1%, P < .05) and renal failure (12% vs. 6.8%, P < .05) were higher in patients over age 80 than in younger patients. These data were compiled from results in 2035 patients having operations in 22 centers in the United States.

Race
African Americans appear to be at increased risk of death late after aortic valve operations. The reasons for this are unclear, but may include socioeconomic and genetic factors that predispose individuals to hypertension.

Functional Status
Poor functional status, as reflected in NYHA functional class, is a risk factor for death, usually in cardiac failure, primarily early after isolated aortic valve replacement. The effect on premature death late postoperatively is less, probably because later survival is related preoperatively more to LV function, which is often not highly correlated with functional status. Risk of death is particularly increased when the disability is so advanced or acute that it is NYHA class V, meaning hemodynamic instability or cardiogenic shock. However, risk of premature death late postoperatively is affected to some degree as well. Preoperative left atrial enlargement has been found to be one of the most powerful risk factors for premature death after aortic valve replacement for aortic stenosis.

Aortic Regurgitation
Aortic regurgitation is probably a risk factor for death early postoperatively under some circumstances. However, the interrelationship between aortic regurgitation and abnormalities of LV structure, size, and function indicates that these are likely the incremental risk factors.

Gender
Gender is a risk factor for late mortality after operation for aortic valve regurgitation. Klodas and colleagues reported increased late mortality after aortic valve operations for women with aortic regurgitation in a multivariable analysis that considered patient size, LV dimension, and concomitant replacement of the ascending aorta for aneurysm. McDaid and colleagues found that this late mortality was influenced by coexisting aortic pathology and subsequent rupture of the aorta. Female gender (and BSA < 1.8 m²) are risk factors for early mortality in patients older than 80.

Angina
Angina in patients with aortic valve disease increases the likelihood of coexisting coronary artery disease. Unless coronary artery disease is excluded or treated by concomitant CABG, angina becomes a risk factor for death after the operation.

Atrial Fibrillation
Using Cox regression analysis (univariable, multivariable, and age adjusted) to study 2359 patients with aortic valve replacement, Kvidal and colleagues found that atrial fibrillation was associated with a hazard ratio greater than 2 beyond 30 days of operation.

Coexisting Coronary Artery Disease
Coexisting coronary artery disease is a complex risk factor for premature death after operation. Among STS National Database participants, aortic valve replacement with concomitant CABG carried a higher early mortality (4.2%) during the early phase after operation than either aortic valve replacement alone (2.6%) or CABG alone (1.9%). However, patients with both diseases are generally older at operation and have more functional disability, more angina,
more previous myocardial infarctions, and a higher prevalence of hemodynamic instability than those with isolated aortic valve disease. These patients also usually require longer aortic occlusion time. Many of these factors have been found to increase risk of death after the combined operation. Some authors have not found concomitant CABG to be a risk factor for death during the early or intermediate period (up to 5 years) after aortic valve replacement operations, but others have observed a somewhat lower 5- to 10-year survival than after isolated aortic valve replacement (Fig. 12-28).

Most important, despite the variability in comparisons of outcome after isolated aortic valve replacement with that after operation combined with CABG, patients who have combined aortic valve and coronary artery disease who undergo only aortic valve replacement have a lower survival than patients who undergo concomitant CABG. Also, Czer and colleagues found sudden death late postoperatively to be more common in patients with combined aortic valve and coronary artery disease when concomitant CABG had not been performed than when it had.

**Acute Aortic Valve Endocarditis**

Surprisingly, native valve endocarditis at valve replacement is not a risk factor for long-term mortality. For replacement valve endocarditis, radical débridement of infected tissue and aortic root replacement with cryopreserved aortic allografts can be accomplished with low early risk.

**Coexisting Ascending Aortic Aneurysm**

Coexisting aneurysm of the ascending aorta has been associated with slightly decreased hospital and intermediate-term survival. However, it has not been shown to be a risk factor overall, and the decreased survival may be attributable to other factors, including longer periods of global myocardial ischemia and CPB required for ascending aorta plus aortic valve replacement than for simple aortic valve replacement. Overall survival in patients with this combination who undergo only valve replacement probably is considerably lower.

Survival after combined replacement of the aortic valve and ascending aorta is partly determined by the replacement device. When a composite valve conduit has been used, 1-month and 1-, 5-, 10-, and 15-year survival, as reported by Kouchoukos and colleagues, has been 95%, 88%, 74%, 57%, and 32%, respectively (Fig. 12-29). Survival was somewhat better in patients with anuloaortic ectasia than in those operated on for ascending aortic dissection. Early (hospital) death was 4.7% (CL 2.8%-7.5%), although it was less in patients with anuloaortic ectasia or chronic aortic dissection (Table 12-4), as also reported by Gott and colleagues.

With methods of myocardial management now in use, early...

Data from Kouchoukos and colleagues.\textsuperscript{531}  
*Includes syphilitic aortitis, replacement valve endocarditis, and extreme poststenotic aortic dilatation.

Key: CL, 70% confidence limits.

limited. Results presented by Okita and colleagues from the experience of Ross suggest poorer overall survival with allograft replacement, but this is related primarily to higher hospital mortality than that reported by Kouchoukos and colleagues.\textsuperscript{531} Also, the distribution of primary pathologies is quite different in the two series. However, Yacoub and colleagues reported 94% survival at 10 years in 74 patients having aortic root replacement with unprocessed viable (“homovital”) aortic allografts.\textsuperscript{51} They also reported a larger series of aortic root replacements with aortic allografts that included the homovital group plus a greater number of antibiotic-sterilized allografts.\textsuperscript{522} Survival at 20 years was 71%, excluding patients operated on for endocarditis or aneurysm of the ascending aorta or dissection, so this series does not provide the actual incremental risk for coexisting ascending aortic aneurysm.

Aortic root replacement with a stentless porcine bioprosthesis is also associated with low early mortality.\textsuperscript{526} In a multicenter trial (21 centers), 226 patients with mean age 70 ± 8.6 years received a Medtronic Freestyle porcine aortic root bioprosthesis.\textsuperscript{1,2} Two thirds were operated on for aortic valve regurgitation or mixed stenosis-regurgitation, and 24% required ascending aorta replacement. Operative mortality was 11% in the older age group of patients with a high proportion of aortic pathology. Hemodynamic performance has been excellent, and risk of thromboembolism leading to permanent neurologic deficit has been 1.0% per year over 6 years. The Freestyle bioprosthesis may be the device of choice for replacing the aortic root in patients over age 70 years.

Too few long-term follow-ups have been reported to define the intermediate-term results after use of an autograft pulmonary valve cylinder for replacement of the aortic valve and ascending aorta.

Era

Risk of hospital mortality has declined with each passing year since the beginning of operations to replace the aortic valve (Table 12-5). Even in the current era, risk of early death after aortic valve replacement continues to decrease.
Global Myocardial Ischemic Time

Global myocardial ischemic time remains a risk factor for death early after isolated or combined aortic valve replacement. Although most aortic valve operations are performed using cold cardioplegia, it is difficult to document that mortality after aortic valve replacement has been improved by abandoning continuous coronary perfusion or hypothermic ischemic arrest as the method of myocardial management. The duration of relatively safe global myocardial ischemia has increased considerably with widespread use of cold cardioplegia (see “Cold Cardioplegia [Multidose]” under Methods of Myocardial Management during Cardiac Surgery in Chapter 3). As is always the case, the incremental risk of duration of global myocardial ischemic time is additive to, and at times interactive with, the effects of other risk factors. Thus, the risk of 120 minutes of global myocardial ischemia using cold cardioplegia is relatively low in patients with aortic stenosis. Risk is also low in patients who are in NYHA class II (Fig. 12-32, A) preoperatively, but higher in preoperative class V patients with aortic valve regurgitation and hemodynamic instability (Fig. 12-32, B).

When the hemodynamic state is unstable before CPB, the period of relatively safe global myocardial ischemia seems longer with current techniques of antegrade plus retrograde infusion of the cold cardioplegic solution, controlled aortic root reperfusion, and warm induction of cardioplegia and substrate enhancement of the cardioplegic solution (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and When Needed Warm Cardioplegic Induction” in Chapter 3). These techniques should translate into increased survival.

Type of Replacement Device

Survival for at least 15 years is probably unrelated to the type of aortic valve replacement device used.\(^{31,15}\) This inference has been supported by two randomized trials.\(^{40,41,31,32}\) However, valve-related complications are more numerous in patients receiving mechanical valves, the result of considerably more nonfatal bleeding episodes in that group.\(^{31,11}\)

The literature is replete with nonrandomized studies comparing various cardiac valve replacement devices and claims of survival superiority of one over the other. Grunkemeier and colleagues presented data that, after correcting for age differences between groups, showed no survival advantage for use of either a mechanical or tissue valve.\(^{24}\) They suggested that important clinical differences, such as structural failures or bleeding, do not require randomized trials to demonstrate statistical differences in properly controlled clinical evaluations.\(^{23}\)

Stentless Valves

Increased rapidity and greater reverse remodeling of the LV after valve replacement are assumed to result in better survival. Statistical methods to prove this are still in the primitive stages of development, but in a study of 8905 postoperative echocardiograms after 3850 aortic valve replacements with a stented bioprosthesis, no influence of rapidity and completeness of reverse remodeling was found to correlate with time-related survival. A Framingham study showed that LV hypertrophy has important prognostic implications even for patients free of clinically apparent cardiovascular disease.\(^{13}\) Levy and colleagues followed 3220 subjects older than 40 for 4 years, correcting for age, diastolic blood pressure, pulse pressure, treatment of hypertension, cigarette smoking, diabetes, obesity, and lipid ratios.\(^{13}\) They found that for each 50 g · m\(^{-2}\) in LV mass corrected for height, the hazard ratio for death from all causes was 1.49 in men and 2.01 in women. However, inferences about the association of LV hypertrophy secondary to systemic hypertension may not be entirely transferable to that secondary to aortic valve disease. The former has complex systemic humoral, cellular, and vascular aspects not generally present in the latter.

Evidence supporting superiority of stentless aortic valve heterografts over stented heterograft prosthetic valves in reducing LV hypertrophy after valve replacement has been conflicting, but several recent randomized trials indicate similar survival and regression of LV hypertrophy with either
a stented bovine pericardial valve prosthesis or a stentless heterograft. In a randomized trial comparing the Toronto Stentless porcine valve (St. Jude Medical Inc., St. Paul, Minn.) with the PERIMOUNT stented bovine pericardial valve (Edwards Lifesciences, Irvine, Calif.), regression of LV hypertrophy and mortality out to 12 years were similar.\textsuperscript{28} These results are supported by other randomized trials.\textsuperscript{A4,C14,R9}

Studies comparing other stentless bioprostheses for aortic valve replacement are also inconclusive for differences in survival.\textsuperscript{22} Yacoub and colleagues showed promising results with almost no decline in survival for the first 10 years after aortic valve replacement with homovital aortic allografts.\textsuperscript{71} Cartier and colleagues compared stentless replacement devices for aortic valve replacement:\textsuperscript{16} survival at 5 years was 96% for pulmonary autografts (mean age 34 ± 16 years), 84% for aortic allografts (mean age 47 ± 19 years), and 84% for stentless porcine xenografts (mean age 68 ± 8 years), with major differences in the age of patients in each group. Aklog and Yacoub compared pulmonary autografts and aortic allografts (as an aortic root replacement) in a prospective randomized trial and found similar early risk and 5-year survival,\textsuperscript{A2} but at 10 years survival was 97% in the autograft group and 83% in the allograft group ($P = .006$).\textsuperscript{E3} Allograft aortic root replacement compares with aortic root replacement using a pulmonary autograft because of similarly exposed suture lines. After aortic valve replacement with a pulmonary autograft, death would be unusual, if not rare, as a result of bleeding from the pulmonary allograft used for RVOT reconstruction. Serious hemorrhage more typically results from the aortic root reconstruction. Risk of infection or heart failure after either procedure is similar. Follow-up is insufficient, however, to determine durability of the repair.

Use of an allograft replacement device sewn frechand (subcoronary technique) into the aortic position has had no adverse effect on early survival. This is evident from the previous discussions in this chapter, from the experience of O’Brien and colleagues\textsuperscript{44} (Fig. 12-33), and from the UAB experience (1981-1988) of no deaths (0%; CL 0%-2.5%) among 70 patients undergoing isolated aortic valve replacement and 7 undergoing concomitant.\textsuperscript{E20}

**Stent-Mounted Porcine Xenograft Valves** These valves have not been shown to affect survival adversely when further replacements can be performed.\textsuperscript{E20} However, Lytle and colleagues found that the combination of a stent-mounted bioprosthesis and chronic anticoagulation decreased 10-year survival.\textsuperscript{L28}

**Mechanical Valves** Mechanical replacement devices have not had an adverse effect on survival, but only because most bleeding complications from warfarin therapy are not fatal, although clinically important.\textsuperscript{126,127} Zellner and colleagues followed patients having aortic valve replacement with the St. Jude Medical prosthesis and analyzed competing risks of outcomes\textsuperscript{22} (Fig. 12-34). At 15 years, deaths related to the prosthesis reduced survival to 79%. Complications related to the valve (e.g., reoperation, endocarditis, thromboembolism, anticoagulant-related bleeding) that were not fatal occurred in 37% of patients, leaving only 42% free of death or complications related to the prosthetic valve. Non–valve-related deaths reduced the number of patients living and free of all complications to 23%.

Studies comparing different modern mechanical prostheses generally do not show clinical advantages among them.\textsuperscript{D23}

**Pulmonary Valve Autograft** The potential for adverse effects from a pulmonary valve autograft as a replacement for the aortic valve has not been evaluated completely. Earlier information suggested no adverse effect,\textsuperscript{G4,G11,R16} but more recent data suggest that 30-day mortality for this operation is 3.5% to 5.1% higher than for other replacement methods.\textsuperscript{E10,G34,539} (Table 12-6).

**Hospital Morbidity**

**Complete Heart Block**

Infrequently, replacement of severely calcific aortic valves leads to complete heart block. It usually results from trauma to the bundle of His after removal of calcium from the region of the membranous septum and right trigone beneath the noncoronary cusp–right coronary cusp commissure. Although this complication occasionally is unavoidable, care in removing calcium from these areas and rigorous avoidance of suture penetration of the membranous septum near its junction with the muscular septum should reduce its occurrence greatly. Heart block may be transient rather than permanent.

**Neurologic Deficits**

Neurologic complications after aortic valve replacement may mar an otherwise routine operation. The current risk of neurologic complications among STS National Database participants is 3.5%.\textsuperscript{G34} With known arteriosclerotic cardiovascular disease, the risk increases; when CABG is combined with aortic valve replacement, risk increases to 5.7%. Attention to the details of avoiding loss of calcific fragments during valve resection and to techniques for removing air from the heart after closing the aorta are the only methods available to reduce early risk of neurologic complications associated with aortic valve replacement. Late neurologic events appear to correlate more with degree of vasculopathy than with bioprosthetic aortic valve replacement itself.\textsuperscript{E329}
Symptomatic Improvement

The functional status of most surviving patients is good after aortic valve replacement. About 90% of patients traced 5 to 10 years are in NYHA functional class I or II.\(^{58}\) About 70% of preoperatively in NYHA class IV are in class I or II postoperatively, as are 80% of those preoperatively in class III and 90% of those preoperatively in class II. Hemodynamically efficient replacement devices appear to favor good functional results. After aortic valve replacement with aortic allografts in the subcoronary position, Prager and colleagues reported that at an average follow-up of 4.2 years, 100% and 97% of patients were in NYHA class I and II, respectively, when a root replacement technique was used.\(^{522}\) Doty and colleagues reported 94% of patients in functional class I and 4% in class II after aortic valve replacement with an allograft at an average follow-up of 4.6 years.\(^{146}\) The authors also reported 92% of an older group of patients (mean age 71 ± 8.4 years) in class I or II after aortic valve replacement with stentless porcine aortic bioprosthesis at an average follow-up of 2.3 years.\(^{143}\)

Exercise capacity tested objectively can approach normal after aortic valve replacement, as shown in patients with aortic stenosis, depressed preoperative exercise capacity, and near-normal resting LV end-diastolic pressure.\(^{11}\) In other situations, such as in many patients with aortic regurgitation and preoperatively increased LV end-diastolic pressure, exercise capacity is improved after operation but remains subnormal.\(^{511}\) Exercise capacity testing after aortic valve replacement with a pulmonary autograft has yielded impressive results. The Ross procedure provides excellent hemodynamic results at rest and exercise, with values indistinguishable from normal,\(^{521}\) including exercise capacity sufficient for athletic competition and ability to achieve extraordinarily high cardiac output with low pressure gradient across the LVOT.\(^{101}\)

Left Ventricular Structure and Function

The degree of improvement in LV structure and function, if any, after aortic valve replacement depends primarily on such factors as the type and extent of secondary cardiomyopathy at operation, coexisting disease, extent (if any) of permanent intraoperative LV damage, and energy loss and regurgitation across the valve replacement device.

Aortic Stenosis

Completeness of return of LV mass toward normal after normalization of LV systolic pressure by aortic valve replacement depends on extent of myocardial degenerative changes (and thus degree of LV hypertrophy) and related loss of LV reserve.\(^{823}\) When LV end-diastolic pressure is still low at operation, LV wall thickness and mass regress substantially, the latter from an average of 206 g · m\(^{-2}\) to 133 g · m\(^{-2}\) \((P < .05)\) in a study by Kennedy and colleagues.\(^{511}\) The regression continues for more than a year postoperatively,\(^{537}\) but completely normal LV mass is rarely relieved.

In addition to reduction in mass, reversal of LV remodeling gradually returns the LV to a more spheroidal shape.\(^{537}\) When LV end-diastolic pressure has become importantly elevated before aortic valve replacement, either because of afterload mismatch (see Natural History earlier in this chapter) or reduced contractility, LV mass may be importantly reduced after operation.\(^{58,511,516}\) However, at this stage many patients fail to show a reduction in LV mass, presumably because of irreversible myocardial degenerative changes. Krayenbuehl and colleagues showed that the preoperatively enlarged muscle fiber diameter shortens within 1 to 2 years after aortic valve replacement as part of this process, but with some increase in interstitial fibrosis.\(^{535}\) Interstitial fibrosis tended to decrease thereafter, but the myocardium did not return to normal, retaining some permanent fibrosis.

Rate and completeness of LV mass reduction after aortic valve replacement may be related to type of replacement device used and other factors at operation. LV function early after operation for aortic valve replacement with LV hypertrophy appears to be better when cold blood cardioplegia is
employed vs. other methods of myocardial management.\textsuperscript{111} Jin and colleagues showed more complete resolution of LV hypertrophy and greater improvement in LV function when an aortic allograft or stentless porcine bioprosthesis was used to replace the aortic valve than when a stent-mounted bioprosthesis or mechanical valve was employed.\textsuperscript{112} Walther and colleagues found regression of LV hypertrophy in all patients after aortic valve replacement in a randomized study comparing stentless and stent-mounted bioprostheses.\textsuperscript{113} but patients with stentless bioprostheses had greater regression at 6 months. Maselli and colleagues reported similar findings favoring aortic allografts and stentless bioprostheses, with the most rapid resolution of LV hypertrophy occurring when aortic allografts were used.\textsuperscript{114} Basarir and colleagues also found a greater decrease in LV hypertrophy with aortic allografts than with mechanical prostheses after aortic valve replacement.\textsuperscript{115}

Kleine and colleagues demonstrated that turbulence, and thus energy loss, caused by mechanical heart valves can be reduced simply by optimal orientation of the device relative to flow patterns created by LV ejection.\textsuperscript{116} They state that turbulence may be an important factor in reversing ventricular remodeling after implantation of a prosthetic heart valve, as well as in relief or reduction of pressure gradient across the LVOT. The premise is based on the observation that blood is ejected from the LV eccentrically at the level of the aortic valve. In humans (and pigs) the eccentric flow is toward the right posterior wall of the aorta, the location of the noncoronary sinus of Valsalva. Mechanical valves oriented to place the major flow orifice to take advantage of the eccentric flow pattern in the aorta have optimal performance in that orientation. Thus, a tilting-disc valve properly oriented can perform better than a bicuspid device, even though the latter is perceived as the better replacement device.

Functional response of the LV to sudden surgical normalization of systolic pressure can be anticipated from morphologic response.\textsuperscript{117} LV end-diastolic and end-systolic volume indices decrease and EF increases within 6 months after aortic valve replacement.\textsuperscript{118} However, Hwang and colleagues found that 66% (CL 54%-76%) of patients with preoperative LV dysfunction still had abnormal values 6 months postoperatively.\textsuperscript{119} When LV wall stress is essentially normal at operation because of appropriate LV hypertrophy and increased wall thickness, indices of LV systolic function (including EF) remain normal or become supra-normal postoperatively.\textsuperscript{120,121} By the time of operation, when LV hypertrophy is insufficient to prevent afterload mismatch, the reduced EF and elevated end-diastolic pressure still may return to normal.\textsuperscript{122,123} However, when these indices of LV function have deteriorated because of reduced contractility, usually associated with marked cardiomegaly, they often show little improvement after operation.

Hwang and colleagues developed a logistic risk factor equation for postoperative LV dysfunction after aortic valve replacement for aortic stenosis.\textsuperscript{124} Risk factors were lower preoperative EF, one or more myocardial infarctions preoperatively, low preoperative aortic valve gradient (low cardiac output), and unrevascularized coronary artery disease.

**Aortic Regurgitation**

The increase in LV mass that develops in patients with important aortic regurgitation can occur insidiously and in the absence of symptoms. Also, LV mass can become much greater in these patients than in those with aortic stenosis.\textsuperscript{125} At least experimentally, abolishing LV volume overload must be performed within 6 months of its inception to permit regression toward normal mass.\textsuperscript{126} This observation helps explain why reduction in LV mass after valve replacement for aortic regurgitation is often moderate in degree and unpredictable, even when indices of LV systolic and diastolic function improve after operation.\textsuperscript{127,128} When these indices do not improve, the often massive increase in LV mass fails to regress and may even worsen several years after operation.

Regression of muscle fiber diameter after aortic valve replacement described for patients with aortic stenosis also occurs after operation for aortic regurgitation.\textsuperscript{129} Decrease in interstitial fibrous content is greater after valve replacement for aortic regurgitation, however.

Thus, it is not surprising that when LV contractility and EF are good and LV end-diastolic pressure is only mildly elevated, LV mass becomes almost normal late after replacing a regurgitant aortic valve.\textsuperscript{130} When already severely diminished at valve replacement, LV systolic and diastolic function often remain compromised late postoperatively, and LV mass fails to regress.

When LV systolic function (estimated by resting and exercise EF, as well as end-systolic volume, LV fractional shortening, and velocity of circumferential shortening) is truly normal at aortic valve replacement (found in only about 10% of patients with symptomatic aortic regurgitation),\textsuperscript{131} LV diastolic function is usually normal and, with systolic function, remains normal postoperatively. When preoperative LV systolic function and diastolic function are mildly or moderately depressed at rest or with stress testing (usually associated with only moderate cardiomegaly and increased LV mass), regression (but not normalization) of impaired resting function usually characterizes the postoperative period, but response of systolic function to stress usually remains abnormal.\textsuperscript{132,133} Impaired preoperative exercise capacity adversely affects the probability of important recovery of LV systolic function after valve replacement.\textsuperscript{134} Also, even with other factors equal, the longer the duration of preoperative limitation of LV systolic function, the less likely the possibility of appreciable return toward normal.\textsuperscript{135} When systolic function improves within 6 months of valve replacement, however, it usually improves still further over the next several years,\textsuperscript{136} although about one third of patients show no additional improvement. Severe preoperative reduction of resting or stressed LV systolic function often indicates irreversible deterioration.\textsuperscript{137,138} Some patients may even show a progressive deterioration in LV systolic function and an increase in LV diastolic volumes leading to death with heart failure a few months to a few years after operation.

Although LV diastolic function is often not improved by aortic valve replacement for aortic regurgitation,\textsuperscript{139,140} the characteristically large LV end-diastolic volume is usually reduced toward normal within 10 days of ablation of regurgitation (and thus decrease in stroke volume).\textsuperscript{141} Further volume reduction occurs late postoperatively in many patients, with the greatest reduction in those with lesser degrees of abnormal LV structure and function preoperatively. Bonow and colleagues found that preoperative exercise capacity correlated well with postoperative reduction of LV end-diastolic dimensions.\textsuperscript{142} These fell strikingly and occasionally to near-normal values in patients with good preoperative exercise tolerance, whereas in patients with impaired exercise ability,
some hearts were larger postoperatively, and few regressed in size late postoperatively (Fig. 12-35).

Failure of LV end-diastolic volume to regress toward normal indicates irreversible morphologic and functional LV damage and portends poor long-term results. By the time exercise ability has become impaired, the diastolic properties of the LV may have even become irreversibly impaired, and fixed cardiomegaly may be present (Fig. 12-36). These relationships are particularly important because exercise capacity becomes limited earlier in the course of aortic regurgitation than in aortic stenosis.

These same considerations apply to patients with periprosthetic leakage late postoperatively. The hemodynamic and functional variables after operation for aortic regurgitation appear to be very sensitive to the LV volume overload of periprosthetic leakage. Thus, Schwarz and colleagues found that such patients had importantly reduced LV systolic function late postoperatively compared with patients who had no periprosthetic leakage.

In summary, patients overall experience considerable reduction of LV diastolic volume, decrease in end-systolic volume, and increase in EF after aortic valve replacement for aortic regurgitation. However, about 60% of patients with preoperative dysfunction have dysfunction postoperatively. Some of the variability among reports of postoperative LV function may relate to the variable interval between operation and postoperative testing; LV systolic performance at rest and particularly during exercise improves still further after 1 year. Borer and colleagues reported improvement between the second and third postoperative years and observed no subsequent deterioration in patients who improved.

LV systolic dysfunction preoperatively is the most predictive variable for postoperative LV dysfunction.

**Left Ventricular–Aortic Energy Loss**

All devices placed within the aortic root for replacement of the aortic valve are obstructive to some degree. This inherent obstruction may be minimized by complete replacement of the aortic root with an aortic allograft, stentless bioprosthesis, or pulmonary autograft. These operations are more complex than replacement of the aortic valve with a mechanical or stent-mounted prosthesis.

Gradients are minimal after freehand insertion of an aortic allograft or stentless aortic bioprosthesis, but are pronounced in patients receiving mechanical or stent-mounted
Chapter 12 Aortic Valve Disease

The magnitude of gradient varies greatly depending on characteristics of the prosthesis, size of the device relative to size of the patient, cardiac output (study done during rest, exercise, or pharmacologic stimulation), and abnormal conditions in or around the replacement device.

Fisher and colleagues evaluated mechanical and stent-mounted bioprosthetic valves in vitro with regard to pressure gradients generated at various flow rates. In vivo measurement of pressure gradient across mechanical or bioprosthetic cardiac valves by Doppler ultrasound has been complicated by complex blood flow velocity profiles associated with the prosthetic valve. Doppler ultrasound, although noninvasive, tends to overestimate energy loss resulting from pressure gradient across prosthetic valves. In addition, aortic curvature, arterial distensibility, arterial impedance, and unsteady flow appear to affect interpretation of pressure measurements.

Despite these limitations, reproducible estimates of pressure gradient are possible in vivo using Doppler ultrasound techniques. These values have been used to compare various prostheses and bioprostheses according to label size (Tables 12-7A and 12-7B). Resting gradient under 10 mmHg is desirable. Comparative figures are subject to interpretation, recognizing that most values are obtained during rest, and even then, cardiac output (flow) may vary considerably from patient to patient. In addition, label size among different types of device is associated with widely variable valve orifice size. Comparing studies is also complicated by what is reported: peak LV to aortic systolic gradient or mean systolic gradient, for example. After considering these confounding factors, however, hemodynamic performance characteristics clearly have improved with newer prosthetic valve designs. Also, most cardiac valve replacement devices function well at rest if greater than 23 mm in diameter. Some 21-mm devices are satisfactory, but 19-mm devices may have higher than desirable gradient even at rest.

Virtually all mechanical prostheses and bioprostheses larger than the 21-mm size can provide satisfactory performance in most adults. Some 21-mm mechanical prostheses and first-generation bioprostheses have high energy loss during periods of increased cardiac output. Among the 21-mm mechanical prostheses, the St. Jude Medical valve performs well in this regard. Other prostheses of either tilting-disc or bicuspid design also have good hemodynamic performance.

Because of the variability in the gradient usually present across the prostheses used for aortic valve replacement, unusual gradients may be difficult to identify. However, such abnormalities develop from fibrous ingrowth below or above the device, dense clot around the valve (thrombotic encasement), or leaflet calcification of a bioprosthesis. Gradients

![Figure 12-37](image-url) In vitro evaluation of mechanical and stent-mounted bioprosthetic valves. Bench testing of these devices for cardiac valve replacement compares root mean square (RMS) forward flow through device to pressure gradient generated. Mechanical and stent-mounted pericardial prostheses show a performance advantage compared with first-generation stent-mounted porcine bioprostheses. (From Fisher and colleagues.)

of 85 to 100 mmHg may be produced, but they can be much lower and more difficult to define as abnormal when cardiac output is reduced by these developments.

**Effective Orifice Area**

Acoustic anomalies caused by mechanical prosthetic valves after implantation make it difficult, if not impossible, to measure prosthetic valve area by ultrasound (echocardiography) using pressure half-time estimates. These methods are most applicable to bioprosthetic heart valves. Mechanical prostheses cause changes in the flow velocity patterns across the aorta, and in vivo measurements are often subject to question as to sampling sites. A modified Bernoulli equation appears to be the most reproducible and accurate method for calculating prosthetic valve area by ultrasound. The mathematical constants of these equations are loaded into modern echocardiographic equipment to facilitate estimating valve area.

**Hemolysis**

Patients with allograft valves sewn freehand into the aortic root do not have abnormal red blood cell hemolysis, even when there is periprosthetic or central leakage. Well-functioning stent-mounted xenografts generally do not produce hemolysis when central leakage develops, but they may do so with periprosthetic leakage. All well-functioning mechanical valves produce at least a small degree of hemolysis, with disc-type valves producing less than ball valves. Periprosthetic and intraprosthetic leakage produces increased amounts of hemolysis, the magnitude of which is related to the amount of regurgitation. Thrombotic narrowing of a prosthetic orifice also importantly increases hemolysis.

**Replacement Device Regurgitation**

**Periprosthetic Leakage**

Periprosthetic leakage may occur after replacing the aortic valve with an allograft or stentless porcine bioprosthesis placed as a freehand subcoronary implant. Elimination of the dead space between graft and the patient’s aorta by sutures is thought to reduce occurrence of leakage, although these sutures may actually cause periprosthetic leakage. Periprosthetic leakage in the presence of aortic allografts or freehand subcoronary-implanted bioprostheses is related to technical problems at the outflow or upper suture line. Buckling of the graft or dehiscence of sutures from the aortic wall results in dissection of blood along the patient’s aortic wall into the space between the graft and aorta. Eventually, a passageway is created to the inflow or lower suture line. Although placing sutures between the graft and aorta may reduce the space or may more securely approximate the graft and aorta at operation, it is virtually impossible to obliterate the space until healing has occurred. Sutures between the graft and aorta other than at the inflow and outflow suture line could actually open tracts to this space along the sutures and needle holes. The best preventive measure against periprosthetic leakage is a secure outflow suture line, as confirmed by intraoperative echocardiography and a strict policy to repair any leakage found at operation.

With use of mechanical prostheses or bioprostheses, important periprosthetic leakage is uncommon in the absence of infection, although minor leakage may occur. Periprosthetic leakage usually becomes evident during the early months after operation. Shean and colleagues reported a prevalence of minor periprosthetic leakage of 17% in the Massachusetts General Hospital series. In addition, 6% of patients (CL 5%-7%) had clinically recognizable hemolysis.

When periprosthetic leakage develops and no infection is present, the area of dehiscence is usually small and can be repaired with one or two pledgeted mattress sutures. The prosthesis does not have to be removed and replaced unless the area of dehiscence is large.

**Central Leakage**

**Allograft Aortic Valves**

Allograft valve central leakage has a variety of causes and a variable prevalence that relate to valve preparation, storage, and insertion techniques. For antibiotic-sterilized, wet-stored (at 4°C) valves, degeneration (cusp rupture with or without minor calcification) is the most common cause (Fig. 12-38), with a 10-year prevalence of up to 15% to 18%. The Stanford group reported a 30% 10-year prevalence of degenerative valve failure with antibiotic-treated valves. Differences in prevalence relate primarily to the definition of degenerative failure, which in the Stanford series was the appearance of a new regurgitant murmur, in the O’Brian series was reoperation, and in the Barrett-Boyes series was moderate or severe regurgitation. Patients with mild or trivial regurgitation are not considered examples of valve failure, because this may develop early after operation from imperfect cusp coaptation. Kirklin and colleagues reported an 85% freedom from valve failure (implantation for cusp failure or moderately severe or severe

![Figure 12-38](image-url)

*aRisk factors assembled based on experience and published reports, not obtained by multivariable analysis.

Although difficult to examine, imperfect freehand insertion of an allograft results in altered stress and strain on the cusps, storage, and implantation within a few days (homovital).71 These techniques reduce cusp degeneration and central leakage to a prevalence of 2% to 10% by 10 years after insertion.227,2048 Histologic findings in allograft cusps preserved by these techniques after implantation in animals,220 or retrieval after implantation in humans,204 indicates better preservation of cusp architecture and fibroblasts than when other methods are used. The allograft valve is antigenic,113 however, and both endothelial cells and fibroblasts are probably destroyed by an immunologic process. Antibiotic sterilization and cryopreservation are thought to reduce antigenicity of allograft valves,22 but low-grade rejection still may occur and promote graft degeneration. Tissue matching and immunosuppressive therapy fail to reduce degeneration.72

Donor age appears to be a continuous variable that affects the rate of cusp degeneration, but its effect is weak until after about donor age 50 years. The effect is probably produced by age-related structural changes in the cusps. Cusp calcification is also more common in valves from older donors, which presumably explains why most allograft valves that develop stenosis come from donors over age 60.116 The age effect is such that prevalence of valve degeneration by 10 years after insertion is 8%, 25%, and 40% when donor age is under 20 years, 20 to 50 years, and over 50 years, respectively.216 (Fig. 12-40).

Although aortic root diameter is also a continuously variable risk factor, its effect becomes strong only when it is greater than 30 mm (corresponding to an allograft inner diameter of greater than 28 mm). Thus, central leakage within 10 years is approximately 40% when the aortic root diameter is at least 30 mm and 10% when it is less than 30 mm.817,837 (Fig. 12-41).

The incremental risk of young age on cusp degeneration and central leakage is much weaker than with stent-mounted xenograft valves. However, an analysis by Kirklin and colleagues identified younger recipient age as the primary predictor of late cusp failure.220

A second, less common, cause of important central leakage after freehand insertions is technical error, with cusp distortion and prolapse or progressive host aortic root dilatation associated with bicuspid aortic valve or cystic medial necrosis of the aorta. The free edges of the cusps are overstretched and fail to meet centrally, but are otherwise intact. The latter mechanism can be prevented by avoiding freehand insertion in patients who have large aortic roots.

A third cause of central leakage is endocarditis (see “Replacement Device Endocarditis” later in this chapter).

Table 12-8 summarizes the incremental risk factors for central leakage caused by cusp degeneration. In allograft preparation and storage, integrity of cusp ground substance and fibroblasts is maintained either by short-duration, low-concentration antibiotic disinfection followed by cryopreservation204 and later insertion, or by sterile collection, wet

which in turn predispose to rupture in the cusp belly or even at the commissures where stresses are minimal in the native valve. Asymmetric location of the graft valve commissures at implantation or distortion of the commissural location during closure of an oblique aortotomy that extends into the noncoronary sinus of Valsalva may be an important cause of altered stress on the graft cusp tissues. Fig. 12-42 shows how a commissural positional abnormality results in lengthening and stretching of the right and left coronary cusps, compared with redundancy of the noncoronary cusp. Calcium deposits are greatest in the anulus and sinus of the redundant cusp, whereas the stretched cusps are subject to cusp tear or disruption. Septal myocardium left on the allograft is broken down and absorbed, because no myocardium is seen on the graft at explantation. This may explain why an aortic valve allograft inserted by the subcoronary freehand technique may show perfect function at operation but become regurgitant within a few weeks or months. In support of this, the prevalence of aortic regurgitation several months after operation is considerably greater with freehand aortic allografts than with aortic valve allografts or pulmonary autografts inserted as part of a full or “mini” root replacement.

Stent mounting of allograft aortic valves used as aortic valve replacements has resulted in a higher prevalence of cusp degeneration and valve regurgitation than has freehand insertion. Risk factors are incremental, so results appear to be best with cryopreserved or homovital valves when donor age is restricted to younger than age 50, recipient age is older than age 15, and aortic root diameter is less than 30 mm. These restrictions could reduce central leakage to 6% at 9 years, although the prevalence rises sharply thereafter.

Pulmonary Autograft. Cusp degeneration or central regurgitation of a pulmonary autograft implanted freehand into the aortic valve position (Ross procedure) may result from technical factors similar to those associated with freehand-inserted aortic valve allografts. It is important to note, however, that the majority of pulmonary autografts are now inserted by the full aortic root replacement technique.

When early regurgitation occurs in this situation, it is likely caused by technical problems with insertion, cusp shrinkage (which should be minimal or absent), and progressive changes of connective tissue related to genetic factors either in the native aortic root tissues that support the pulmonary autograft or in the autograft itself. Technical problems at operation relate primarily to matching diameter of the pulmonary autograft to the LVOT at the position of attachment. The LVOT should be sized up or down to a diameter within 2 or 3 mm of that of the autograft. The autograft should not be stretched over a larger LVOT, and the size of the autograft should not be “taken up” during implantation to a

\[\text{Figure 12-41} \text{ Freedom from important regurgitation according to aortic root diameter after allograft aortic valve insertion. Data set and format are as in Fig. 12-40. (From Barratt-Boyes and colleagues.}\]

\[\text{Figure 12-42} \text{ Effect of commissural position error in aortic valve replacement with an aortic allograft. A, Minor position error. Explanted aortic allograft is shown in surgeon's view, with diagram of major findings alongside. Distance (length of aorta) between commissures bordering noncoronary sinus of Valsalva is shorter than that between commissures bordering left coronary sinus and commissures bordering right coronary sinus. Presumably this is the result of closing an oblique incision in the noncoronary sinus with some aortic tissue loss. This commissural positional abnormality places stress on right and left coronary cusps. Calcium deposits appear greatest in noncoronary cusp. B, Major position error. Explanted aortic allograft is shown in surgeon's view with diagram alongside. Commissure between left and noncoronary sinuses is drawn far to the right above noncoronary sinus rather than following natural position posteriorly. Commissure between right and noncoronary sinuses is drawn far to the right, producing a similar deformity so that commissures nearly touch in noncoronary sinus. This is the result of closure of an oblique incision in noncoronary sinus of Valsalva with large tissue bites, which draws adjacent commissures toward each other, as well as simply not following anatomic contours of aortic valve. Stress on left and right coronary cusps resulted in leaflet tear; noncoronary cusp is redundant, prolapsed, and contains calcium deposits.}\]
substantially smaller aortic anulus. Use of an interrupted suture technique probably provides the most accurate method of suture placement for implanting the autograft and may result in near-perfect valve function later. Addition of a support or reinforcement ring to the LVOT suture line is associated with greater freedom from pulmonary autograft regurgitation (Fig. 12-43).

Connective tissue abnormalities, such as fibrillin deficiency associated with Marfan syndrome, are considered contraindications to aortic valve replacement with a pulmonary autograft because the pulmonary trunk will likely have the same tendency for dilatation as the aorta. Elkins and colleagues noted fibrillin or elastin abnormalities in the resected aorta in a high proportion of patients undergoing the Ross procedure for aneurysm or dilatation of the ascending aorta. Changes in pulmonary autograft dimensions did not correlate with the observed changes in fibrillin or elastin. Concern about potential dilatation of the pulmonary autograft, resulting in aortic valve regurgitation of a bicuspid aortic valve and dilatation of the aortic root and ascending aorta, appears to be overstated. Long-term series do not report this complication when the neoaortic anulus is supported and its diameter fixed.

Although aortic root dilatation is common late after autograft root replacement, it is probably not related to bicuspid aortic valve disease or preexisting degenerative changes in the pulmonary trunk. Histologic abnormalities of the pulmonary trunk are rare and equally prevalent in patients with bicuspid and tricuspid aortic valves. As noted in “Autograft Pulmonary Valve” under Isolated Aortic Valve Replacement earlier in this chapter, the pulmonary trunk may dilate up to 30% when subjected to systemic arterial pressure. Although the precise mechanism remains unclear, the tendency for late anular dilatation in some patients and its association with valve regurgitation has been well documented.

David and colleagues found a higher risk of late dilatation of the neo-aortic root with the root replacement technique than with the root inclusion method in which the autograft is implanted within the native aortic root. reported 10-year follow-up of 218 patients undergoing the Ross operation, 148 with root replacement and 70 with the intraaortic (inclusion) technique. Freedom from autograft reoperation at 10 years was 81% and 84%, respectively. Similar results were reported by Kouchoukos and colleagues.

Autograft dilatation is the main cause of failure following root replacement, and autograft valve prolapse is the main failure mode after the inclusion technique. Following root replacement, the rate of autograft dilatation has been reported to 0.5 mm · year$^{-1}$ in the adult population and 2 mm · year$^{-1}$ in a mixed pediatric and young adult population. Presence of preoperative aortic regurgitation is an independent predictor of autograft dilatation. Systemic hypertension may also play a role. Long autografts may be more prone to dilatation of the supracommissural segment, and some have recommended keeping the autograft as short as possible. Juthier and colleagues reported absence of neoaortic regurgitation at a mean follow-up of 4 years when the autograft was reinforced with a polyester tube.

Whether current methods to stabilize the neoaortic valve at the anular and sinutubular levels following root replacement, or wrapping the entire autograft with bovine pericardium or polyester, will affect late freedom from moderate or worse valve regurgitation has been incompletely studied. However, an analysis of the German-Dutch Ross registry (more than 1500 patients) identified preoperative aortic regurgitation and the nonreinforced full root technique as factors associated with late autograft failure (8-12 years). Elkins and colleagues reported an 83% freedom from autograft failure at 16 years, and also identified preoperative aortic regurgitation as a risk factor for late valve failure. Among patients undergoing valve implantation by the inclusion technique, late reoperation is normally associated with progression of early discrete aortic regurgitation, which likely results from a geometrically imperfect implant.

Increases in neoaortic anulus diameter over time in excess of that expected by somatic growth has also been observed in the pediatric population. Among pediatric patients, freedom from autograft valve-related reoperation is about 86% at 12 years following aortic root replacement. Shinkawa and colleagues reported a 95% freedom from autograft reoperation at 10 years, but only 64% by 15 years among neonates and infants. A meta-analysis of reports published between 2000 and 2008 indicates that durability limitations of the Ross procedure in children and young adults become apparent by the end of the first postoperative decade.

**Stent-Mounted Xenograft (Porcine) and Pericardial (Bovine) Glutaraldehyde-Treated Aortic Valves**

These valves, mounted on a cloth-covered stent, may develop central leakage because of cusp rupture either in the commissural region or in the cusp belly. Rupture is often associated with cusp calcification, in contrast to allograft valves inserted freehand. Also, calcification may produce stenosis rather than rupture. Although most ruptures in this type of bioprosthesis are precipitated by collagen fatigue and fracture and subsequent invasion of the cusp by macrophages, some may be caused by abrasion of the cusp against a stent. A few cases have resulted from cusp perforation by long, cut ends of rigid suture material projecting inward from the sewing ring toward the cusp base. Detachment of the valve’s aortic remnant from the stent pillar, in contrast to stent-mounted allograft valves and previously used formaldehyde-treated stent-mounted xenografts, is rare and associated with failure of host tissue overgrowth across the polyester bias strip onto the graft. Presumably the collagen cross-linkage from glutaraldehyde preservation of porcine aortic and bovine...
Figure 12-44 Nomogram of estimated risk-adjusted probability of bioprosthetic degeneration within 5 years of inserting first-generation stent-mounted porcine xenografts, according to patient’s gender and age at insertion. (From Blackstone and Kirklin.81)

pericardial valves strengthens the aortic tissue sufficiently to prevent tearing and detachment.

Among 478 patients who received a bovine pericardial prosthesis in the premarket approval stage, 70 experienced structural valve deterioration.518 Pathology was pure regurgitation in 23, pure stenosis in 18, and mixed in 20 (uncertain in 9). Modes of failure were calcification (39%), noncalcific degeneration (30%), fibrosis (7.1%), dehiscence (5.7%), and a combination of these (14%). Calcification and degeneration appeared to accelerate with time, and these modes of degeneration were particularly accelerated by younger age at implant.

Thus, risk factors for central leakage from degeneration (structural valve deterioration [SVD]) of the cusps of a stent-mounted glutaraldehyde-fixed xenograft include female gender and younger age of recipient (Fig. 12-44). This accelerated rate of degeneration of xenograft valves in the aortic position rapidly declines with advancing age. In patients older than about 65 years, failure at 10 years is less than 5%.837 Jamieson and colleagues showed that degeneration of first-generation porcine xenograft valves was related to younger age, decreasing after age 60 and almost imperceptible in patients over 70.36.39 A similar age-related effect on durability of bovine pericardial bioprostheses has been observed (Fig. 12-45); chance of valve explant for structural deterioration is less than 10% at 15 years in patients over age 65 years89 (Fig. 12-46). Statistical methodology also affects interpretation of the apparent frequency of degeneration625 (see “Computing Risks” in Section IV of Chapter 6). Kaplan-Meier analysis estimates accurately the biological frequency of SVD among living patients as an isolated event; competing risks analysis places SVD into the context of mortality before SVD occurs. Thus, in older patients, not only does the biological behavior of the xenograft contribute to a lower occurrence of SVD, but mortality decreases the probability that the patient will survive long enough to experience the event (Table 12-9).

Method of valve preservation is also probably a risk factor, because glutaraldehyde fixation at pressures above zero abolishes the normal collagen crimp and diminishes cusp pliability (distensibility). As a result, the cusp kinks rather than stretches on opening, leading to compression fracture of the collagen at sites of kinking.866,866 In contrast, zero-pressure fixation retains collagen crimp and produces a more pliable cusp with mechanical properties that closely approach those of fresh cusp tissue.3410 Second- and third-generation zero-pressure-fixed bioprostheses may perform better over time than first-generation pressure-fixed valves.35 Also, substances introduced into the fixation protocol may reduce risk of cusp calcification.

Accumulating data demonstrate that second- and third-generation bioprostheses last longer than first-generation devices.32,32 (Fig. 12-47). The Hancock II porcine aortic xenograft with improved stent and anticalcification treatment (T6) and the Edwards Lifesciences bovine pericardial valve with flexible stent and anticalcification treatment (T80) are showing less degeneration beyond 10 years than first-generation devices.38 Cryopreserved and homovital aortic allografts appear on the same curve as second-generation xenografts. Data are limited beyond 12 years with third-generation stentless porcine valves, but structural integrity appears good and on the same trajectory as aortic allografts.45
Stentless Xenograft (Porcine) Aortic Valves  Absence of a stent has the theoretic advantages of making the device less stenotic and decreasing perivalvar leakage. Also, by analogy with allografts, degeneration may occur more slowly in stentless than in first-generation stent-mounted xenografts. Experimental and short-term clinical results in a small number of patients are compatible with this hypothesis. Midterm data show that the prevalence of primary periprosthetic leak at 4 years is 2.2% and that virtually no central aortic valve regurgitation of I+ or greater occurs with the Medtronic Freestyle. Changes in the aorta, however, independent of degeneration of the valve may affect performance of the Toronto SPV bioprosthesis; dilatation of the sinutubular junction may result in aortic valve regurgitation and may be prevented by restricting the aorta above the valve with a circumferential band.

Mechanical Valve Replacement Devices  Mechanical replacements develop important central leakage only with mechanical failure (e.g., poppet escape, catastrophic structural failure or entrapment of a suture. Also, tissue or thrombosis may encroach into the seating area of the device, although the occurrence appears low.

Replacement Device Endocarditis  Endocarditis on the device used for aortic valve replacement is an uncommon but serious complication; overall, only about
PART III  Acquired Valvar Heart Disease

gram-negative cocci, or mixed organisms. The rare fungal infection is typically fatal. Replacement device endocarditis occurring late after operation is the result of a transient bacteremia, most often with streptococcal organisms.

Incremental Risk Factors

Incremental risk factors for developing endocarditis after primary aortic valve replacement (the same as after primary mitral valve replacement) (Table 12-10) are different from those after reoperation (Table 12-11). When the valve replacement operation is performed for endocarditis on either the native valve or a previously inserted replacement device, no risk factors for subsequent endocarditis other than the endocarditis have been identified, probably because of the dominant risk of infection already present.

Of particular therapeutic importance is the finding that a mechanical prosthesis is a risk factor for replacement device infection because of the higher early phase of hazard associated with its use (Fig. 12-50). The allograft aortic valve, inserted freehand into the aortic position, is unique in having no early hazard phase (Fig. 12-51), even when the operations are performed on already infected native valves or replacement devices. Bioprostheses seem less likely to develop prosthetic valve endocarditis than mechanical prostheses.

Presence of native valve endocarditis has some adverse effects on subsequent freedom from replacement device endocarditis. Replacement device endocarditis tends to develop after a redo operation more often than after an original valve operation (Fig. 12-52).

Data from Blackstone and Kirklin.837

30% of patients are long-term survivors.16 Infective endocarditis is discussed in detail in Chapter 15.

Prevalence and Incidence

The prevalence of endocarditis on an aortic valve replacement device is low, with 95% to 97% of patients free of this complication 5 years postoperatively (Fig. 12-48). Risk of endocarditis generally is greatest about 6 weeks after insertion of the replacement device, then gradually declines to a low constant hazard function by about 9 months837,838,16 (Fig. 12-49).

Etiology

Endocarditis early after valve replacement (early peaking hazard phase) is usually caused by organisms already present in the operative field or introduced at operation or within the next few days. The organisms are usually staphylococci, The rare fungal infection is typically fatal. Replacement device endocarditis occurring late after operation is the result of a transient bacteremia, most often with streptococcal organisms.16
This result, however, may reflect operations performed in patients with less extensive infections than those requiring aortic root replacement techniques for aortic root abscesses, as well as infectious processes extending beyond the aortic valve cusp tissues. In contrast, Sabik and colleagues reported that radical débridement and aortic root replacement with a cryopreserved aortic allograft resulted in 5- and 10-year survival of 73% and 56%, respectively.32

Table 12-12 lists the risk factors for death after valve replacement for native or prosthetic valve endocarditis.

### Thromboembolism

Risk of thromboembolism is approximately constant beyond the first month after operation. The authoritative report by Edmunds indicates that the overall linearized rate of thromboembolism in patients with aortic mechanical device replacement is 2 ± 1 per 100 patient-years and about half that value in patients with stent-mounted xenograft valves.34 The comprehensive study of Grunkemeier and colleagues showed considerable variance in rate of thromboembolism among published series of patients.32 Thromboembolism rate is about the same for the various mechanical devices; median rate for the St. Jude valve is 1.33% · year⁻¹; for the Medtronic-Hall, 1.20% · year⁻¹; and for the CarboMedics valve, 1.16% · year⁻¹. Rates for stent-mounted bioprostheses are also similar; median rate for the Hancock porcine is 0.78% · year⁻¹, for the Carpentier-Edwards porcine, 0.87% · year⁻¹; and for the Carpentier-Edwards bovine, 1.22% · year⁻¹. The rate is lower for allografts, with a median of 0.23% · year⁻¹. All these rates fall below the objective performance criteria required for U.S. Food and Drug Administration (FDA) approval of 3.0% · year⁻¹ for mechanical valves and 2.5% · year⁻¹ for bioprostheses. Adequacy of warfarin therapy is the key determinant of...
the rate in patients with mechanical aortic valves. Thromboembolism is rare in patients receiving aortic allografts or pulmonary autografts in the aortic position.

Thrombosis of the replacement device itself is uncommon. The linearized rate for mechanical prostheses is about 0.1% - year\(^{-1}\). Thrombosis occurs even less often in patients with stent-mounted xenograft valves.

**Complications of Anticoagulation**

Complications of chronic warfarin therapy in patients who have undergone aortic valve replacement are the same as in other patients (see “Complications of Long-Term Anticoagulation” under Results in Section I of Chapter 11). Excessive anticoagulation is accompanied by threat of bleeding. Antiocoagulant levels above therapeutic values but with INR less than 5 indicate need to withhold warfarin until INR returns to therapeutic range, then restart the medication at a lower dose. Warfarin is withheld in patients with INR of 5 to 9, and oral vitamin K (1.25-2.5 mg) is considered if the patient is at increased risk of bleeding. Vitamin K\(;\) (2.5-5 mg) is given orally to patients with INR greater than 9, and if the patient has serious bleeding, it is given intravenously (10 mg) accompanied by transfusion of fresh frozen plasma.

Frequent questions arise about managing potential bleeding in patients with mechanical heart valves taking warfarin who require cardiac catheterization, percutaneous catheter intervention, noncardiac surgery, or a dental procedure. Most dental procedures can be managed without interrupting anticoagulation. For patients with minimal risk of thromboembolism, warfarin should be stopped about 3 days before elective operation so that the procedure may be performed when INR is 1.5 or less. Warfarin is restarted as soon as risk for bleeding has ceased, usually 24 to 48 hours after completing the procedure. Where there is increased risk (atrial fibrillation with large atria, enlarged or poorly contractile LV), unfractionated heparin (enoxaparin) is administered when INR is less than 2. The short-acting anticoagulant is discontinued for the procedure, restarted along with warfarin after risk of bleeding has ceased, and continued for a 3- to 5-day overlap until INR is again therapeutic. Enoxaparin administered to patients prior to cardiac operations, however, increases risk of postoperative bleeding requiring re-entry. When emergency operation is required, operation proceeds immediately as indicated, with reversal of warfarin’s effect by transfusion of fresh frozen plasma as required to achieve adequate clotting.

More accurate control of level of anticoagulation by self-testing of prothrombin time has been associated with a reduction in major bleeding events. In a randomized trial of 325 patients, Byeth and Landefeld reported reduction of major bleeding events in the first 6 months of therapy with warfarin. Providing appropriate devices to allow patients to measure prothrombin time themselves and teaching them how to adjust the warfarin dose early after operation is effective in reducing complications related to anticoagulant therapy.

Aortic Root Complications

**Aneurysms**

At operation, a secure full-thickness closure must always be obtained to prevent not only acute postoperative bleeding but also late aneurysm formation. Three unexpected small aneurysms were found among 100 patients studied by aortography 6 to 9 months after aortic valve replacement by Bjork and colleagues. One was at the aortotomy suture line, and two seemed to originate from the left coronary sinus.

After composite graft reconstruction using the inclusion technique, there has been an important occurrence of aneurysm, most often arising from partial dehiscence of the anastomosis to the graft of the aorta around the coronary ostia and less often from the distal graft to aorta suture line. To overcome dehiscence, Cabrol and colleagues recommend routine use of a separate 8-mm polyester tube graft, the extremities of which are anastomosed to the aorta around the right and left coronary orifices. A large side-to-side anastomosis is then made between the center of this graft and the front of the 30-mm polyester tube. Alternatively, and probably preferably, an aortic button containing the coronary ostium is anastomosed directly to a window in the polyester graft (see Technique of Operation earlier in this chapter). Dehiscence at the distal graft suture line is avoided by using a prosthetic collar (cut from the primary graft) to cover the distal suture line.

False aneurysm at the proximal suture line has been observed when the full root replacement technique is employed for implanting an aortic allograft or pulmonary autograft (Ross procedure). This rare complication may be eliminated by routine use of a support collar at the proximal suture line and partial inversion of the graft while it is tied to the aortic anulus to ensure direct tissue approximation during implantation.

**Aortic Aneurysm Following Aortic Valve Replacement for Bicuspid Aortic Valve**

Progressive aortic enlargement in patients with a bicuspid aortic valve who undergo isolated aortic valve replacement requires special comment. Available data indicate that aortic valve replacement by itself does not ameliorate the adverse natural history of progressive aortic dilatation, suggesting that aortic dilatation results from inherent weakness of the aortic wall rather than hemodynamic factors. A study by Borger and colleagues concluded that among patients undergoing isolated aortic valve replacement, subsequent aortic complications and reoperation were more common when the aortic diameter was 4.5 cm or greater. This is consistent with current recommendations to replace the ascending aorta at the time of bicuspid aortic valve replacement if the aortic diameter is 4.5 cm or greater (see Special Situations and Controversies).

**Cessation of Gastrointestinal Bleeding**

In patients with aortic stenosis who have a history of gastrointestinal bleeding, an unusual but characteristic syndrome, nearly all (93% of 91 patients in one study) are free of bleeding after aortic valve replacement. In contrast, abdominal procedures for gastrointestinal bleeding are successful only occasionally.

**Reoperation**

Reoperation may be necessary early or late after aortic valve replacement. The nature of the reoperation varies with its
indication. When performed for acute thrombosis, thrombectomy can be an effective procedure, although valve replacement is often required. When performed for periprosthetic leakage, simple suture repair is often possible and effective. Valve replacement is required in a few patients when dehiscence of the valve from aortic root tissues is extensive. When the reoperation is for endocarditis, re-replacement is indicated when there is active infection. In unusual circumstances, when infection has been controlled and arrested for weeks or months and there is residual periprosthetic leakage, it may be possible to repair the leak and retain the valve.

Although hospital mortality can be low for a first-time aortic valve re-replacement (3.9%; CI 2.4%-6.0% in one study), replacement of an already replaced aortic valve has serious implications. Jones and colleagues have shown that operative mortality for repeat heart valve surgery has declined with each decade of experience. Mortality for aortic valve re-replacement was 6.4%. Risk increased with increasing age of the patient, presence of coronary artery bypass grafts, and indication for operation (particularly for valve thrombosis or endocarditis). Replacing a dysfunctional mechanical valve had 2.25 times the risk of replacing a bioprosthetic valve. Hasnat and colleagues reported an early mortality of 3.4% (CL 1.9%-5.8%) for replacing an aortic valve allograft with a second one. In their experience a second aortic valve allograft was associated with good long-term survival; accelerated degeneration did not occur. Byrne and colleagues reported 11% hospital mortality for aortic valve allograft re-replacement in 18 patients, 14 of whom (67%) received mechanical prostheses at reoperation. At least in the case of prosthetic and bioprosthetic valves, after each reoperation there is an increasing prevalence of still another reoperation (Fig. 12-53), of periprosthetic leakage (Fig. 12-54), and of prosthetic valve endocarditis (see Fig. 12-54). In addition, each reoperation increases the risk of death. Many factors contribute to the increasing prevalence of unfavorable outcome events as the reoperations accumulate, including increased fibrosis and decreasing local vascularity in the interior of the aortic root. This emphasizes the importance of making the first valve replacement operation the only one whenever possible.

The prevalence and incidence of a first reoperation vary to some extent with the circumstances. Thus, the shape of the hazard function for reoperation for mechanical devices differs from that for stent-mounted xenografts (Fig. 12-55). Mechanical replacement devices have an early peaking hazard phase and a constant hazard phase; in that for bioprostheses, there is an early peaking phase and a second rising late hazard phase. (From Blackstone and Kirklin.)
inserted, without the prevalence of early regurgitation attributable to technical error, there is no early hazard phase of reoperation, but rather a gradually increasing late postoperative phase (see Fig. 12-39).116,320,34

Late reoperation may be required after composite prosthetic graft reconstruction for graft or prosthetic valve infection, for prosthetic valve thrombosis or periprosthetic leakage, and for pseudoaneurysm. Freedom from reoperation was 81% at 7 years in one series.321

Reoperations after Valve-Sparing Aortic Root Replacement

The major reason to reoperate after valve-sparing aortic root replacement is progressive aortic regurgitation. In general, freedom from reoperation for both remodeling and reimplantation techniques has been good. In the absence of external fixation at the level of the aortic anulus, Yacoub and colleagues reported 85% freedom from reoperation at 15 years.34 David and colleagues310 suggest better late aortic valve preservation with the reimplantation technique than with the remodeling method (10-year freedom from moderate or severe aortic regurgitation of 94% with reimplantation vs. 75% with remodeling; \( P = .04 \)). The reimplantation technique appears particularly advantageous in Marfan syndrome and similar connective tissue disorders prone to progressive anular dilatation because of more secure anular fixation. However, others, such as Schaefers and colleagues, report excellent long-term valve function after the remodeling procedure.310 Whether the remodeling procedure will be enhanced by routine placement of an external aortic anuloplasty ring15 or prove superior in the setting of a bicuspid aortic valve (possibly enhanced early valve competency) will require long-term studies.

The situation in pediatric patients is even less clear. Late results of valve-sparing operations are confounded by aggressive connective tissue disorders often found in the pediatric phenotype of Marfan syndrome, Loeys-Dietz syndrome, and Ehlers-Danlos syndrome. Long-term follow-up is limited, but the reimplantation techniques appear to offer similar outcomes as in adults when an adult-sized conduit can be implanted.311

INDICATIONS FOR OPERATION, SELECTION OF TECHNIQUE, AND CHOICE OF DEVICE

Advances in diagnostic techniques, understanding of natural history, and operative procedures for aortic valve disease have resulted in enhanced diagnosis, more scientific selection of patients for surgery, and increased survival of patients with aortic valve disorders. The extensive literature on valvar heart disease, however, consists mostly of single-institution experiences in relatively small numbers of patients. ACC/AHA charged the Committee on Management of Patients with Valvular Heart Disease with the task of compiling an information base and making recommendations for diagnosis and treatment. The task force’s 2006 report, “ACC/AHA Guidelines for the Management of Patients with Valvular Heart Disease,” represents the most definitive treatise on this subject.850

**Aortic Stenosis**

**Symptomatic Patients**

Patients with symptoms of angina pectoris, dyspnea, or syncope caused by aortic valve stenosis have symptomatic improvement and increased survival after aortic valve replacement, even with LV dysfunction.829,121,332 Therefore, aortic valve replacement is indicated in virtually all symptomatic patients. Patients with severe symptomatic aortic valve stenosis associated with low transvalvular pressure gradient also have hemodynamic improvement and better functional results.564 Elderly patients over age 85 with severe heart failure and associated coronary artery disease may be exceptions and are candidates for transcatheter aortic valve replacement.530 Even severe concomitant noncardiac disease rarely contradicts aortic valve replacement, although advanced chronic obstructive pulmonary disease, widespread arteriosclerosis, and advanced neurologic disease may greatly increase the risk
of operation or render it inadvisable. Advanced age per se is not a contraindication for operation; improved quality of life has been reported in octogenarians 1 year after aortic valve replacement.

The urgency of operation in patients with important aortic stenosis and syncope (or near-syncope) as the only complaint has been debated. This presentation generally does not make operation urgent but does make it advisable.

**Asymptomatic Patients**

Controversy surrounds the approach to patients with absent or trivial symptoms. When stenosis is clearly severe (mean gradient > 40 mmHg, valve area < 1.0 cm², valve area indexed to BSA < 0.6 cm² · m⁻², jet velocity > 4.0 m · s⁻¹), operation is usually advisable even when patients are asymptomatic. Some clinicians, however, may be reluctant to proceed. Even though the perioperative risk of operation is low, long-term morbidity and mortality related to the replacement device may be appreciable. The combined risk of operation and late complications of the replacement device may exceed the 1% per year risk of sudden death in asymptomatic patients. Some asymptomatic patients may be at higher risk for sudden death without surgery, although supporting data are limited. Of clear importance, however, is the accurate identification of subtle symptoms of severe aortic stenosis and not denying such patients the opportunity for surgical therapy. Freed and colleagues noted a 14% mortality within 15 months in a patient cohort where symptoms were missed.

Patients with LV systolic dysfunction, abnormal response to exercise (hypotension), ventricular tachycardia, marked LV hypertrophy (≥15 mm), left atrial diameter over 4 cm, or valve area under 0.6 cm² are likely at higher risk with medical therapy and thus should be considered for surgical intervention. Such high-risk patients are usually symptomatic but if not will become so in a short time. Lancellotti and colleagues reported that the echocardiographic indices of peak aortic jet velocity 4.4 m · s⁻¹ or greater, valvar-arterial impedance (an estimate of LV afterload that is the sum of systolic arterial blood pressure and mean transvalvar pressure gradient divided by stroke volume index) 4.9 mmHg · mL⁻¹ · m⁻² or greater, and an indexed left atrial area 12.2 cm² · m⁻² or greater were predictive of subsequent cardiac events and could justify surgical intervention. An algorithm for managing patients with severe aortic stenosis as recommended in the 2006 ACC/AHA Guidelines is presented in Fig. 12-56.

**Patients with Ischemic Heart Disease**

Patients with severe aortic valve stenosis and important ischemic heart disease should have aortic valve replacement at the time of CABG. The approach is less clear if aortic valve stenosis is moderate or even mild, because it is difficult to predict when these patients will develop severe aortic stenosis after coronary revascularization. Some patients manifest rapid progression of aortic valve stenosis of up to 0.3 cm² · year⁻¹ and an increase in pressure gradient of up to 15 to 19 mmHg · year⁻¹. Most patients, however, show little or no change. The average rate of reduction in valve area seems to be about 0.12 cm² · year⁻¹. Mean time to reoperation for aortic valve replacement after CABG is 5 to 8 years. Experienced surgeons tend to be more aggressive in treating mild and moderate aortic valve stenosis in conjunction with coronary artery disease because of the unpredictable progression of the aortic valve disease. Patients over age 45, those over 35 with angina as a part of their symptomatology (which makes coexisting coronary artery disease more likely), and those with a strong family history of arteriosclerotic disease require coronary angiography before operation.

**Patients with Other Heart Valve or Thoracic Aorta Disease**

Patients with moderate (gradient 30 mmHg or greater) or severe aortic valve stenosis should have aortic valve
replacement in conjunction with operations on the aorta or other heart valves.

**Aortic Regurgitation**

Patients with pure, chronic aortic regurgitation should have aortic valve replacement only if the regurgitation is severe (see Box 12-1). Patients with symptoms and only mild or moderate aortic regurgitation may have other conditions, such as coronary artery disease, hypertension, or cardiomyopathy.

**Symptomatic Patients**

Aortic valve replacement is recommended for patients with normal systolic function (EF ≥ 50% at rest) and symptoms in NYHA functional class III or IV or angina pectoris in Canadian Heart Association class II to IV. Patients with new onset of mild symptoms require special attention and are usually considered for operation, even without reaching threshold values for LV size and function.

**Symptomatic Patients with Left Ventricular Dysfunction** Patients having symptoms of heart failure or angina pectoris and mild to moderate LV dysfunction (EF 25%-49%) should have aortic valve replacement. Postoperative survival and recovery of systolic function are reduced, however, compared with less symptomatic patients. Symptomatic patients with advanced LV dysfunction (EF < 25%, end-systolic dimension > 60 mm) present more difficult management problems; some recover LV function after aortic valve replacement, but many do not because of irreversible myocardial changes. Operative mortality in these patients approaches 10%. Chance of good results is better in patients with recent onset of symptoms in NYHA functional class II or III. Operation is usually recommended for patients with class II symptoms and normal EF who show evidence of progressive LV dilatation or declining EF at rest on serial echocardiographic or radionuclide studies. Even in the high-risk group with NYHA class IV symptoms, aortic valve replacement is usually a better alternative than the higher risks of long-term medical management.

**Asymptomatic Patients**

Aortic valve replacement in asymptomatic patients with aortic regurgitation is controversial, but most agree that operation is indicated in patients with LV systolic dysfunction. Aortic valve replacement is generally recommended for asymptomatic patients when EF is less than 50%. Severe LV dilatation (end-diastolic dimension greater than 75 mm, end-systolic dimension greater than 55 mm) is also an indication for operation, even if EF remains normal, because these patients have an increased risk of sudden death and postoperative results are good. Patients with systemic hypertension, coronary artery disease, concomitant mitral valve stenosis, or who are women deserve special attention and may be recommended for aortic valve replacement at reduced LV dimension thresholds. Reduced EF during exercise, mild decline in EF (but still within normal limits), or minor increases in LV dimensions less than those just detailed are not usually indications for operation in asymptomatic patients with aortic regurgitation. Improving methods of aortic valve replacement, however, may reduce objective thresholds for recommending operation.

**Patients with Ischemic Heart Disease, Other Heart Valve Disease, or Aortic Disease**

Coronary artery disease coexists with aortic regurgitation less frequently than with aortic stenosis. Patients having CABG or other heart valve replacement usually have aortic valve replacement for moderate or severe aortic regurgitation. Mild aortic valve regurgitation has a long natural history and is usually not an indication for aortic valve replacement in association with other cardiac operations.

Operations for primary disease of the aorta with associated aortic regurgitation require special attention and are discussed under Special Situations and Controversies.

**Native Aortic Valve Endocarditis**

Native aortic valve endocarditis in a hemodynamically stable patient should be treated in the hospital with appropriate antimicrobial therapy and serial echocardiographic examination of the aortic valve and root. If aortic regurgitation develops, if evidence of aortic root or mitral annular abscess appears, or if septic embolization or vegetation is observed, operation must be undertaken promptly, before hemodynamic deterioration increases the risks associated with operation.

An allograft valve is the replacement device of choice in these patients and may be used even when an aortic root abscess is present. A pulmonary autograft may also be used in patients with active endocarditis on aortic valve cusps, limited anular involvement with no associated medical comorbidity, and a life expectancy exceeding 20 years. Extensive aortic root destruction indicates aortic root replacement with an allograft aortic root. Rarely, the infected valve may be repaired rather than replaced. A detailed discussion of surgery for infective endocarditis is found in Chapter 15.

**Selection of Technique and Choice of Device**

After more than 50 years of experience with heart valve devices, it would seem reasonable that a single type of device should have emerged that is ideal for all circumstances when aortic valve replacement is necessary. This is not the case. The surgeon must choose from an ever-increasing number of replacement devices; new devices are constantly being designed, tested, and added to the market after short-term clinical trials. By the time midterm or long-term performance data are known, an equal number of valves are discarded in favor of new and unproven devices.

**Type of Replacement Device**

The type of operation performed on the aortic valve has changed over time as replacement devices have changed and improved. Current practice indicates a trend toward less frequent use of mechanical prostheses and more use of bioprosthetic devices (Table 12-13). Photographs of current mechanical and biological prosthetic valves for the mitral position are found in Chapter 11. Allograft aortic valve procedures are limited by donor availability to about 2% of aortic valve replacements.

Comparative information concerning performance specifications of the various valves is confusing. The body of literature on valve performance and outcome statistics is enormous; an individual surgeon cannot assimilate sufficient data to
The Starr-Edwards valve is a first-generation mechanical valve. Label size (mm) expresses prosthesis size (diameter) and is larger than the primary (geometric) orifice diameter.

Internal orifice area (measured geometric orifice in cm²) is larger than in vitro orifice area (measured in pulse duplicator).

In vitro orifice area is generally larger than the area measured in vivo by Doppler ultrasound after the valve is implanted (the exception is bioprostheses tested at low steady flow rates). The orifice area calculated either in vitro or in vivo is also called the effective orifice area (EOA, cm²), which may be indexed to body size by dividing by BSA (indexed EOA = EOA ÷ BSA). BSA is calculated from both height and weight, however, so obesity may distort this figure (however, see discussion under “Normal Pathways” in Chapter 1).

Devices for replacement of the aortic valve are divided into two groups: mechanical prostheses and bioprostheses, the latter commonly referred to as “tissue valves.” A complete listing of all available devices would serve little useful purpose. The focus here is on the devices that have been most widely used throughout the world. Generally, valves within these groups have similar performance characteristics, and choice is usually based on surgeon preference, handling characteristics of the device, availability, technical and service support, and cost.

### Mechanical Aortic Valve Replacement Devices

#### Ball-in-Cage Devices

Starr-Edwards Silastic Ball-Valve Prosthesis (Model 1260). The Starr-Edwards valve is a first-generation device of historical importance. The first device in this line was used in the first successful human orthotopic valve replacement operation. In small sizes in the aortic position, the model 1260 valve has somewhat more energy loss across it than other devices. It is no longer available in the United States.

**Omniscience, Omnicarbon Valve.**

The Omniscience valve (Medical CV Inc.) is an evolution of the discontinued Lillehei-Kaster pivoting disc valve. The Omnicarbon valve is an all-pyrolytic carbon design, a ceramic material that is extraordinarily hard.

### Bileaflet Devices

St. Jude Medical Valve. The St. Jude Medical bileaflet valve was introduced in 1977. The valve mechanism, unchanged since its first clinical use, consists of two semicircular leaflets with small ears that pivot in a butterfly-shaped recess in the housing of the device. It is manufactured from pyrolytic carbon and is durable, with leaflet fracture virtually nonexistent.

The St. Jude valve is available in a variety of models, all based on variations of the sewing ring; the basic mechanical device is the same in all models. It is available in rotatable and nonrotatable, standard, expanded, or reduced sewing ring; the basic mechanical device is the same in all models. It is available in rotatable and nonrotatable, standard, expanded, or reduced sewing rings and with silver impregnation to prevent infection (see “Silver-Coated Sewing Rings” under Special Situations and Controversies later in this chapter). Hemodynamic performance of even the 19-mm device is adequate, and sizes 21 mm and larger show good performance. Freedom from thromboembolism is good.
CarboMedics Valve. The CarboMedics valve is available in various designs of sewing cuff, but the basic mechanical valve is the same in all models. The bileaflet design has flat, pyrolytic carbon-coated leaflets in a pyrolytic carbon housing strengthened by a radiopaque titanium ring.

Edwards Tekna Valve. The Edwards Tekna device was originally called the Duramedics valve. Its unique design features are curved leaflets and a hinge mechanism below the inflow edge of the housing. After initial mechanical failures, minor modifications have apparently corrected the problems.

Sorin Bicarbon Valve. The Bicarbon device was introduced in 1990. It has a solid titanium housing and a bileaflet carbon mechanism. The sewing ring is carbon coated.

ATS (Advancing the Standard) Open Pivot Valve. The ATS valve, introduced in 1995, is unique in that the hinge socket is on the cusp, whereas the protrusion of the hinge mechanism is on the housing. The purpose is to reduce thromboembolism by better washing of the pivot mechanism.

MCRI (Medical Carbon Research Institute) On-X Valve. The On-X device is manufactured from an improved and more pure form of pyrolytic carbon for greater strength. It has an elongated housing and flared inlet to provide hemodynamic advantages.

Specifications for Mechanical Prostheses Table 12-14 lists manufacturers’ reported primary orifice area for the common mechanical cardiac valve prostheses. Compared with in vitro pulse duplicator studies, the effective orifice is smaller than measured geometric orifice (Table 12-15). In vivo performance studies of mechanical heart valves are often subject to error artifacts caused by turbulence and alterations of blood flow patterns by the prosthetic material in the LVOT. Also, some manufacturers’ labeled-size valves are mechanically equivalent, meaning that the same housing is used but the sewing rings are different, enabling the manufacturer to label the device differently. For the St. Jude prostheses, HP valves have label size 2 mm less than the standard valve sharing the same-size housing.

Mechanical cardiac valve prostheses produce sounds that are audible to patients. Occasionally the sound is disturbing. Sezai and colleagues interviewed patients 1 month and 1 year after aortic valve replacement with the St. Jude Medical or ATS prostheses. Many patients (52% St. Jude Medical, 8.3% ATS) reported that the valve was audible 1 year after implantation. The sound was sometimes disturbing in 9% of patients with the St. Jude Medical valve (0% ATS) and resulted in sleep disturbances in 9% and a desire for a less noisy valve in 9%. Reported loudness of the valve sound is the best measurement of a patient’s adverse reaction to the sound; this may be modified by hearing loss in patients. Erickson and colleagues studied mechanical heart valve sound loudness in vitro and found that the quietest valves were the St. Jude Medical and the CarboMedics. The Sorin Bicarbon valve was 10% louder. Loudness was doubled with the Edwards Tekna and Monostrut valves. The St. Jude Medical valve was confirmed as quiet in another study. Sezai and colleagues’ data, however, indicate that the ATS valve may be quieter.

Bioprosthetic Aortic Valve Replacement Devices

Stent-Mounted Xenografts The many stent-mounted bioprosthetic devices in clinical use include those with valve cusps made of xenograft aortic valves, pericardium, fascia lata, and dura mater. Theoretically, according to the physical characteristics of biological materials, only cusp tissue should be considered appropriate for this purpose, but pericardium has proved to be remarkably durable.

Carpentier-Edwards Glutaraldehyde-Preserved Porcine Xenograft (Edwards Lifesciences). The Carpentier-Edwards bioprosthetic model 2625 is used for aortic valve replacement. The EOA in smaller sizes of this device may be slightly smaller than equivalent mechanical prostheses, but EOA in bioprostheses, unlike mechanical prostheses, is flow dependent. Incidence of thromboembolism is low, so the device may be implanted without anticoagulating the patient. Durability is better in the aortic position than in the mitral position and is related to patient age. The device is more durable in patients over age 60 (see Table 12-9). The Hancock Glutaraldehyde-Preserved Porcine Xenograft (Medtronic). The original Hancock I valve (standard model) has an appreciable gradient across it in all sizes in the aortic position. This bioprosthesis is also available with a modified orifice. In the modified version, the right coronary cusp, with its muscular bar at the base, is replaced by a muscle-free noncoronary cusp from a second valve. This modification has not reduced the device’s long-term durability. The Hancock Modified Orifice bioprosthesis has been free of structural deterioration in 78% of patients over age 65 (7% cumulative incidence of SVD) and 84% of patients over 70 (3% cumulative incidence of SVD) at 19 years. It differs from the Hancock I in having a lower gradient across the valve.

Hancock II Glutaraldehyde-Preserved Porcine Xenograft (Medtronic). The Hancock II porcine xenograft is a second-generation device with a porcine aortic valve fixed at low pressure. The anticalcification agent sodium dodecyl sulfate surfactant (T6) is added to the fixative. A flexible,
high-strength stent is made of acetyl homopolymer with reduced implant height. Flow area is maximized. The stent is covered with polyester and is less bulky so that a larger valve can be implanted. The inflow edge and sewing ring are scalloped to allow supraaunlar implantation of a larger valve. Hemodynamic performance, reduced thromboembolic complications, and durability are improved compared with first-generation devices. Anticoagulation is not required.

**Intact Glutaraldehyde-Preserved Porcine Xenograft (Medtronic).** The Intact xenograft is a newer generation glutaraldehyde-treated porcine valve in which the fixation pressure is zero and toluidine blue is added to inhibit calcium deposition. Zero-pressure fixation preserves the collagen crimp of the porcine aortic valve so that it is more flexible and presumably more durable. This device has been used in large series of patients in New Zealand, Canada, and South Africa. Jamieson and colleagues report freedom from SVD at 12 years of 94% ± 3.3% for patients age 61 to 70 years and 98% ± 1.1% for those over age 70, and Corbineau and colleagues report similar results at 13 years.

**Biocor (St. Jude Medical).** The Biocor stent-mounted aortic valve bioprosthesis was developed in Brazil. This porcine aortic valve is fixed at zero pressure, and the stent has a supraannular configuration.

**Mosaic Glutaraldehyde-Preserved Porcine Xenograft (Medtronic).** The Mosaic xenograft is a third-generation stent-mounted bioprosthesis in which the porcine valve is subjected to physiologic aortic root fixation. Glutaraldehyde at 40 mmHg pressure is applied in the LVOT below the valve and also to the aorta above the valve. The effect is to apply zero net pressure to the valve cusps to preserve collagen crimp and flexibility while applying sufficient pressure to the aorta and sinuses of Valsalva to fix the aorta in anatomic relationships. Mechanical properties are such that they can withstand stress equivalent to normal valve cusps. α-Aminooleic acid, an anticalcification agent, is chemically bound to glutaraldehyde for permanence in the tissues. Jamieson and colleagues report freedom from reoperation for SVD at 12 years of 93% ± 2.6% for patients aged 60 years or older, and 76% ± 9.3% for those younger than 60.

**PERIMOUNT Glutaraldehyde-Preserved Bovine Pericardial Xenograft (Edwards Lifesciences).** The PERIMOUNT pericardial xenograft is a second-generation bioprosthesis. Bovine pericardium is fixed in glutaraldehyde at low pressure and applied to a flexible stent with distensible struts by intraaortic or subcoronary valve implantation. The anticalcification agent polysorbate (Tween 80) is added. The prosthesis has proved to be durable, with 80% freedom from SVD at 14 years in the aortic position. The postapproval Investigational Device Exemption Center (IDE) study showed 84% freedom from structural valve deterioration. The stent and method of tissue mounting provide for a very good EOA. Stent-mounted pericardial bioprostheses have superior hemodynamic performance compared with porcine aortic xenografts in sizes of 21 mm or less, which may translate into greater reduction in LV mass.

**Mitroflow.** The Mitroflow bioprosthesis is constructed from bovine pericardium mounted on a stent. It was introduced to clinical practice and received the CE mark of the European Community for the international market in 1997. A multicenter Italian study revealed reoperation for SVD at 18 years was 66%, but 78% in patients older than 70 at implant.

**Stentless Xenografts** Stentless xenografts are constructed from porcine aortic valves or bovine pericardium that use less cloth for stabilization and sewing than stented valves. The major advantages of stentless valves over stent-mounted xenografts are improved hemodynamic efficiency. They have a potential advantage in small aortic roots to avoid a root enlargement procedure, and flexibility of implantation as a subcoronary valve, intraaortic cylinder, or root replacement.

Although the larger EOA may translate into more complete regression of LV mass with stentless than with stented bioprosthetic valves, studies fail to demonstrate a consistent advantage. Observational data indicate a low risk of SVD at 8 to 10 years, but evidence for improved durability over stented xenograft valves is lacking. Some studies indicate an increasing hazard for structural valve failure after about 8 years. In addition to cusp calcification and cusp tear, rupture of the porcine aortic wall has been reported as a cause of valve failure. Their major disadvantage is increased complexity of implant (similar to allograft aortic valves) compared with stented valves. Reoperation for replacement also may be more difficult.

**Freestyle Glutaraldehyde-Preserved Porcine Aortic Root Bioprosthesis (Medtronic).** The Freestyle porcine bioprosthesis is a third-generation device presented as the complete porcine aortic root with a thin polyester covering of the septal myocardium. It has no support stent. The tissue is fixed in glutaraldehyde using the physiologic root pressure technique described for the Mosaic valve: there is zero net pressure applied to the valve cusps to preserve collagen crimp while the aorta is distended to normal configuration. The valve is designed to be implanted as a valve replacement in the subcoronary position, as an inclusion root cylinder, or as a full aortic root replacement. Thus, as the name Freestyle implies, the surgeon may choose the method of implantation. Hemodynamic performance of the device is excellent because without a stent, a large EOA valve may be implanted. Short-term durability has been excellent, with 97.7% freedom from SVD at 5 years. However, at 10 years, freedom from reoperation was 90% ± 5% in the Royal Brompton randomized trial comparing allograft and Freestyle aortic root replacement, an experience considerably less favorable than 97% ± 5% at 9 years reported by Ennker and colleagues.

α-Aminooleic acid is added to prevent or retard calcification. Effectiveness of anticalcification treatment is not known, but evidence suggests that it is beneficial. Electron beam CT shows a low amount of calcification in the aortic wall of the Freestyle bioprosthesis compared with homovital aortic allografts at 18 months. Calcium deposits have been noted in the aortic wall of the graft, but the cusps remain free of calcification up to 4 years. A Freestyle bioprosthesis removed at autopsy 68 months after implantation showed minimal calcification in the aortic tissue at the commissures and no calcium deposits in cusp tissue.

**Toronto SPV Glutaraldehyde-Preserved Porcine Xenograft (St. Jude Medical).** The Toronto SPV (stentless porcine valve) is a low-pressure glutaraldehyde-fixed porcine aortic valve. The aortic tissue is removed from all three sinuses, and the graft is covered with a thin coat of polyester. It can only be implanted as a subcoronary valve replacement. With no support stent, a large valve can be implanted with greater EOA compared with stented devices. Hemodynamic performance has been excellent and equivalent to the Medtronic
Freestyle device. Durability has been good, with freedom from structural valve deterioration of 85% at 9 years.399

Edward Prima. The Prima device is a low-pressure glutaraldehyde-fixed porcine aortic root similar to the Freestyle device. Markings on the outside of the aortic root guide the trimming of the aorta for subcoronary valve implantation. The hazard for structural valve failure rises after about 8 years.418

CryoLife-O’Brien. The CryoLife-O’Brien stentless porcine aortic valve is a manufactured composite of the noncoronary sinus and cusp from three porcine aortic roots. It is designed to be implanted below the coronary arteries in a supraannular position in the sinuses of Valsalva by a single suture line. Experience is limited to a few centers, and the technical aspects of implantation may be more difficult than with other stentless bioprostheses.

Pericarbon Freedom (Sorin Group). The Pericarbon Freedom stentless valve is composed of two sheets of bovine pericardium sewn together to produce a cylindrical shape and fixed with glutaraldehyde.825 The implant procedure requires two suture lines. A modification of this prosthesis, the Freedom Solo, can be implanted with a single continuous suture line in the subcoronary supraannular position. Five-year follow-up suggests hemodynamic benefit similar to other stentless xenografts.399

Cryopreserved Aortic Allograft. Human donor aortic valve allografts are presented as the complete aortic root, ascending aorta, and some or all of the aortic arch. The anterior leaflet of the mitral valve usually remains attached unless it has been removed for a mitral valve graft. The tissue is harvested under sterile conditions, the internal diameter at the ventricular-aortic junction measured, quality of the valve assured, and the graft packaged. The tissue is frozen using liquid nitrogen with the temperature drop controlled at 1°C per minute between +5°C and −40°C in tissue culture media containing 10% dimethyl sulfoxide (DMSO) to facilitate water transfer across cell membranes during the freezing process. The tissue is placed in liquid nitrogen for storage at −180°C. Cryopreserved aortic allografts are free of structural deterioration in 80% of patients at 15 years.45

Pulmonary autograft and cryopreserved pulmonary allograft. The patient’s own pulmonary trunk, including the pulmonary valve, may be used to replace the aortic valve, usually as a full aortic root replacement. The pulmonary trunk is then replaced with a cryopreserved pulmonary allograft as described earlier. This operation (Ross procedure) is hemodynamically superior to other procedures for replacing the aortic valve, because the patient’s own pulmonary valve is properly sized to accept cardiac output with little or no pressure gradient, even during the high cardiac output state of extreme exercise.415 In fact, the pulmonary valve is usually slightly larger than the aortic valve (see “Dimensions of Normal Cardiac and Great Artery Pathways” in Chapter 1). The pulmonary valve in the aortic position appears to function well over time (see Special Situations and Controversies).

Mechanical differences are minimal between aortic and pulmonary valve tissues, and the tensile strength of pulmonary valve cusps equals or exceeds that of aortic valve cusp tissues.412,422 Goffin and colleagues studied tissues removed at autopsy 17 months after the Ross procedure.49 Pulmonary autograft valve cusp tissues showed essentially normal histology, with preserved fibroblasts and some endothelial cells on the surfaces. Schoof and colleagues showed in growing pigs that developing pulmonary autograft wall in the aortic position becomes normally revascularized, remains viable without major degenerative phenomena, and retains morphologic features typical for pulmonary artery rather than remodeling to thickness similar to aorta.411 Smooth muscle rearrangement and increased collagen were observed in response to increased pressure on the vascular matrix, strengthening the vascular wall without increasing wall thickness. A meta-analysis based on current evidence calculated average reoperation-free life expectancy of the pulmonary autograft as 16 years after implantation.71

The cryopreserved pulmonary allograft is extensively devitalized, with valve cusps devoid of endothelial cells and few fibroblasts present.49 This phenomenon is likely immunologically mediated, as measured by presence of classes I and II anti-HLA antibodies after implanting cryopreserved allograft material in patients.418,420 Degree of histocompatibility, however, does not appear to be related to humoral response.434 Implanting decellularized human valve allografts does not provoke a panel reactive antibody (PRA) response nor encourage host recellularization.429 Stenosis of the pulmonary allograft (pressure gradients across the graft of 30 mmHg or more) occurs in 17% of patients after the Ross procedure, with a mean follow-up of 48 months; only 3% of patients, however, require reoperation.438 Cause of stenosis appears to be an inflammatory reaction to the pulmonary allograft leading to extrinsic compression or shrinkage. The reaction may be immunologically mediated, but could also be related to other as yet unexplained mechanisms.

Specifications for Bioprostheses. Manufacturer specifications for bioprostheses are more complicated than they are for mechanical cardiac valve prostheses. It is impractical to measure true internal orifice area because of the irregular shape presented by the biological tissues mounted within the stent. Therefore the manufacturers’ specifications refer to the inner diameter or the outside diameter of the mounting stent. The actual outside diameter including the sewing ring is always considerably larger than the diameter of the mounting stent, which is used for the label size (actually from midpoint to midpoint of the mounting stent).

Table 12-16 presents comparison data of widely used first- and second-generation stent-mounted bioprostheses. Stentless bioprostheses are labeled as the outside diameter of the device. In this respect, Medtronic Freestyle and St. Jude Medical Toronto SPV devices are equivalent. In vitro studies allow benchmarking of the EOA (cm²) of the various devices (Table 12-17). Second-generation stent-mounted bioprostheses (Hancock II, Carpentier-Edwards pericardial) have larger EOAs than first-generation devices because of improved mounting stents. Third-generation stentless bioprostheses (Medtronic Freestyle, St. Jude Toronto SPV) have even larger EOAs because the mounting stent has been eliminated, and generally a graft with a larger label size can be implanted.

Selection of Technique and Choice of Device for Isolated Aortic Valve Replacement

Mechanical Prostheses. Mechanical prostheses are useful because of their durability under all circumstances and because of their good performance, even in relatively small aortic roots.533 Although these prostheses carry the disadvantages of thrombogenicity requiring lifelong anticoagulation with its complications of thromboembolism and bleeding, they are

Chapter 12  Aortic Valve Disease

rarely contraindicated; exceptions include premenopausal women (because of risk to fetus and mother from warfarin) and those with unusual risk of hemorrhage, such as from severe peptic ulcer disease, ulcerative colitis, or hazardous occupation. Mechanical valves are particularly indicated for patients at any age who are willing to avoid undue physical hazards, who can follow a regimented medical protocol, and who prefer the low risks of chronic warfarin therapy to the lower potential risk, but greater anxiety and discomfort, of a second valve replacement operation.

Stent-Mounted Glutaraldehyde-Preserved Porcine Xenograft Valve  This type of valve is appropriate in patients over age 70, particularly those in sinus rhythm, because of its excellent hemodynamic performance and no requirement for warfarin anticoagulation. Long-term outcomes are unknown, but at midterm (5-10 years), performance and durability are good.

Cryopreserved Aortic Allograft Valve  Inserted freehand inside the aorta, the allograft valve has been chosen for aortic valve replacement because of excellent hemodynamic performance, lack of thromboembolism, no need for warfarin anticoagulation, and resistance to infection in patients requiring valve replacement for infective endocarditis of either native or prosthetic aortic valves. Allograft aortic valve replacement is primarily indicated in patients under age 55 and in selected older patients, generally for endocarditis. Primary contraindications include an aortic root with an LV-aortic junction or aorta at the level of the cusp commissures that is 30 mm or more in diameter, or an aortic root with dimensions that are 2 cm larger than those of the largest available allograft. Under these circumstances, the aortic root may be reduced in diameter (tailored) and an aortic root replacement used. The allograft aortic valve is less desirable than mechanical or biological prostheses when the ascending aorta is diffusely enlarged and thin walled and when severe and poorly controlled systemic hypertension is present.

Pulmonary Valve Autograft  A pulmonary valve autograft was considered by Ross and colleagues to be “an almost ideal means of aortic valve replacement in appropriate patients.” Hemodynamic performance of the pulmonary autograft in the aortic position is superior to any other replacement device. It is therefore possibly indicated in younger patients, usually younger than 50, when an active lifestyle or athletic performance requires superior hemodynamics. Warfarin anticoagulation is not required. The pulmonary autograft
Choice of Device for Replacing Aortic Valve and Ascending Aorta, En Bloc

The optimal device to replace the aortic valve and ascending aorta en bloc is controversial. Use of a composite mechanical prosthetic valve within a polyester cylinder probably offers the lowest early mortality (4.7%; CL 2.8%-7.5%) and the least risk of late postoperative complications, but it requires lifelong anticoagulation with warfarin and carries the usual risks of prosthetic valve thromboembolism.

Kouchoukos and colleagues reported early mortality of only 0.9% in patients with anuloaortic ectasia undergoing replacement of the aortic root and ascending aorta. This series was folded into a large multi-institutional study, and the results were reported by Gott and colleagues. Of the 675 patients studied, 604 had composite graft replacement, indicating that this was the treatment of choice from 1968 to 1996. Early mortality in this group was 1.5% (CL 1.0%-2.4%) among 455 patients having elective repair and 2.6% (CL 1.1%-5.1%) among 117 patients having operation performed urgently. Risk climbed to 12% (CL 8.3%-16%) among 103 patients having emergency operation.

Composite graft replacement is currently the procedure of choice in patients aged 55 to 70 who need replacement of the aortic valve because of demonstrated durability of the prosthetic valve. Operations that preserve the aortic valve are gaining more favor for these patients (see Special Situations and Controversies).

Use of an autograft pulmonary valve cylinder was once considered the ideal replacement device when the aortic valve and aortic root or ascending aorta are replaced en bloc, because the autograft is the patient’s own tissue. Even when the surgeon has specialized knowledge of the procedure, however, early mortality is 3.5% to 5.1% for this complex two-valve operation. With this initial risk and the high likelihood of late reoperation, the operation could be the procedure of choice in patients under about 30 years of age if the patient wishes to avoid anticoagulation and understands the likely need for reoperation. However, emerging data over the last decade have revealed an important risk of pulmonary artery dilatation and subsequent neoaortic valve regurgitation within the first 10 years following operation. In contrast to initial enthusiasm about the possibility that the pulmonary autograft may be a “permanent” normally functioning aortic valve, long-term follow-up indicates an actuarial freedom from autograft failure of 75% to 85% at 10 to 15 years in adults, with a progressively increasing probability of moderately severe or worse aortic regurgitation after 10 years (Fig. 12-58). Progressive aortic regurgitation can result from either dilation of the aortic anulus or aortic root (more common with the root replacement technique) or from SVD with progressive cusup prolapse (more common with the subcoronary technique). Longitudinal data from the German-Dutch Ross Registry indicate that both the root replacement technique with reinforcement of the autograft or the subcoronary technique are associated with greater freedom from autograft reoperation than is nonreinforced root replacement. Other reports support maintaining aortic diameter with reinforcement at least out to 6 years.

In pediatric patients, autograft reinforcement will likely impair autograft growth, which is a major disadvantage because autograft growth has been well documented in the nonreinforced root replacement technique. However, dilation of the aorta at the sinutubular junction in children is associated with progressive aortic regurgitation. Takkenberg and colleagues noted greater freedom from autograft reoperation in patients under age 16 years compared with older patients (93% at 10 years vs. 79%; P = .05). In infants undergoing the Ross procedure, late autograft failure appears to be low (≤5%), at least out to 10 years.

In both pediatric and adult patients, reoperations for replacement of the allograft in the pulmonary position are likely inevitable with sufficient follow-up. Among adults, freedom from conduit replacement is 85% to 95% at 10 to 15 years. Among pediatric patients, 10-year freedom from conduit replacement ranges from about 50% to 85%. Thus in pediatric patients, the Ross procedure seems to be the best option for aortic valve replacement. However, the family should be advised of the near certainty of reoperation and the real possibility of eventual autograft valve failure. For children with isolated valve replacement in whom a root enlargement procedure could allow an adult-sized mechanical prosthesis, the family would need to decide about the advantages of a single operation combined with lifelong anticoagulation (mechanical valve) vs. the absence of reoperation for the aortic valve.
of anticoagulation, but need for one or multiple additional operations over a lifetime (autograft).

Use of an allograft valve and ascending aortic cylinder is another option. The operation is less complex than when an autograft is used, but the replacement device is less durable, with a useful life of about 15 to 20 years. Early risk of the operation is low. O’Brien reported 30-day hospital mortality of 1.13% ± 1%.122 Yacoub and colleagues reported that of 67 patients who had complete aortic root replacement with an aortic allograft, 56% were free of tissue failure and 90% free of reoperation for valve replacement at 15 years.122 O’Brien reported only 7 valves removed for SVD over almost 15 years after full aortic root replacement in 350 patients using a cryopreserved allograft.122 The allograft is preferred when there is active native valve endocarditis with root abscess or infection from a previously placed prosthetic valve.122,214

SPECIAL SITUATIONS AND CONTROVERSIES

Low-Output, Low-Gradient Aortic Stenosis

In patients with low cardiac output, as in the presence of severe LV dysfunction, the calculated gradient and valve area may not reflect the severity of aortic stenosis, because the echo Doppler criteria are not sensitive to presence of low cardiac output (see Clinical Features and Diagnostic Criteria earlier in this section). In this circumstance, low-dose dobutamine may help distinguish true from “pseudo” aortic stenosis (Fig. 12-59). Although data support aortic valve replacement in patients with severe aortic stenosis and severe LV dysfunction,136,212 the major area of controversy relates to patients with a mean transvalvular gradient of 30 mmHg or less and an EF of 35% or less. Pai and colleagues reported a substantial survival benefit with aortic valve replacement in this group21 (Fig. 12-60).

Small Aortic Root and Small Prosthesis: Prosthesis/Patient Mismatch

Controversy surrounds whether a device used for aortic valve replacement can be too small for a patient and affect early, intermediate, and long-term outcomes. Foster and colleagues showed that prostheses as small as 17 mm in diameter can provide acceptable clinical results.29 Data from a multi-institutional meta-analysis of 13,258 patients having aortic valve replacement showed that small valve size increased operative mortality by less than 1% in the 10% of patients receiving a small valve relative to body size, and did not reduce midterm (6 months to 5 years) and late (5-15 years) survival.83 Similarly, Medalion and colleagues did not find that small aortic valve prostheses affected incidence of early or late mortality or cardiac events in patients, even when the prosthesis diameter was as much as four standard deviations below normal predicted for body size.220,221

Superior hemodynamics with a valve prosthesis, generally associated with a large orifice size and valve efficiency, should translate to a survival advantage. Such logic seems not to apply in this case, however, which may indicate that a marker other than survival should be analyzed when considering replacement of the aortic valve with a small aortic root. Although Izzat and colleagues argue that prosthesis/patient mismatch is not a problem of clinical significance,127 Pibarot and Dumesnil counter with a strong argument that when valve size and body size are used to calculate an indexed effective valve area, a strong relationship exists between small prosthetic valve size (19 or 21 mm) and pressure gradient across the valve during rest and exercise.116 This held for bileaflet mechanical and stent-mounted bioprosthetic valves. Del Rizzo and colleagues showed that indexed EOA less than 0.8 cm² · m⁻² affected the extent of LV mass regression after aortic valve replacement with stentless bioprostheses.127 Dumesnil and Yoganathan showed that indexed EOA predicts performance of prosthetic valves during exercise250 (Fig. 12-61). Indexed EOA greater than 0.85 cm² · m⁻² will keep pressure gradient from rising during exercise on the steep part of performance curves; indexed EOA less than that is considered to represent prosthesis/patient mismatch because of the

Hemodynamic performance of prosthetic heart valves during rest and exercise. Indexed effective orifice area is compared with mean pressure gradient across prosthesis at rest and during increasing levels of exercise. Prosthetic heart valves show a steep rise in pressure gradient when indexed effective orifice is less than 0.85 cm\(^2\) m\(^{-2}\). From Dumesnil and Yoganathan.

Managing the Small Aortic Root

Some adult patients have a smaller-than-usual LV-aortic junction or a narrow aortic waist at the level of the commissural attachment of the cusps (see discussion of true congenital subvalvar or supravalvar aortic narrowing in Sections II and III of Chapter 47).

The simplest technique in patients with a small aortic annulus is placing the device partly in a supraanular position (Fig. 12-63, A). This takes advantage of the bulging of the noncoronary sinus of Valsalva. A replacement device one size larger than the aortic annulus can be used by suturing it to the annulus along the left and right sinuses and in the supraanular position along the noncoronary sinus. In that area, pledged mattress sutures are placed from outside in or on the ventricular side of the aortic annulus.

The freehand (subcoronary) aortic allograft is the best device in the small aortic root. Appropriately sized allografts are available in graft banks and can be inserted within the aortic root, resulting in minimal gradient. Subcoronary valve replacement using a stentless porcine bioprosthesis is also effective for the small aortic root. These devices are designed to be implanted in the intraanular position in the LVOT (Fig. 12-63, B). Absence of a supporting stent allows insertion of a valve with an effective orifice large enough to provide good hemodynamic function even in the small aortic root. Sintek and colleagues implanted 19- and 21-mm Freestyle bioprostheses and found the average LV-aortic gradient was 13 mmHg for 19-mm valves and 8 mmHg for 21-mm devices. Doty and colleagues noted similar results.

When a mechanical prosthesis is used, a size smaller than 23 mm often results in considerable obstruction, depending on the device and the patient’s BSA. Replacement device mismatch is a serious iatrogenic disease that produces persistent or increasing LV dysfunction, hemolysis, and a very difficult reoperation. Reoperation is difficult because, at the initial operation, the largest possible prosthesis has been inserted in a small passageway, which often results in erosion of anular support. Coronary ostia are usually drawn close to the sewing ring, increasing the possibility of coronary obstruction. Reoperation often requires full root reconstruction. All these increase difficulty and risk.

A 19-mm device may be obstructive but could be used cautiously, thoughtfully, and infrequently in some circumstances in small and sedentary patients. Modern mechanical prostheses may be less obstructive than stent-mounted bioprostheses of the same label size. Second- and third-generation bioprostheses and mechanical prostheses may provide adequate hemodynamic performance in small and sedentary patients, provided a 21-mm device can be implanted. Otherwise, aortic root enlargement by one of several methods to allow use of a larger prosthesis will provide better hemodynamics and reduce the chance of residual LVOT obstruction. A stentless bioprosthesis (autograft, allograft, or xenograft) implanted in the subcoronary position or as a full root replacement may also accomplish the desired hemodynamic performance.
When the narrowing is only at the supraanular level at the top of the sinuses of Valsalva, supraanular enlargement with a patch graft into the noncoronary sinus of Valsalva is used.\textsuperscript{N4} A patch of pericardium has the advantage of ease of handling and insertion, and the suture line is easily made hemostatic (Fig. 12-64, \textit{A} and \textit{B}). Piehler and colleagues followed patients nearly 20 years and showed that a pericardial patch in this position does not become aneurysmal.\textsuperscript{P18} Alternatively, a knitted or woven polyester velour or felt patch with pericardium on the inner surface may be used.

When the anulus is also involved supraanular and anular enlargement by patch graft enlargement in the noncoronary sinus is carried across the anulus and into the aortic-mitral anulus below it. Nicks and colleagues described this method, with a slight modification by Blank and colleagues.\textsuperscript{B38,N4}

Enlargement of both supraanular and anular areas can also be achieved by extending the aortotomy through the left coronary–noncoronary commissural area and into the underlying aortic-mitral anulus, as originally described by Manouguian and colleagues.\textsuperscript{N4,R10,S21} The valve is excised and the need for aortic root enlargement determined. The aortotomy is extended posteroinferiorly directly through the left coronary–noncoronary commissural area (see Fig. 12-64, \textit{A}), across the anulus, and into the base of the aortic-mitral anulus, where it adheres to the left atrial wall. The incision does not reach the hinge point of the mitral leaflet. The left atrium is first dissected away and may or may not be opened as the incision is made. A broad teardrop-shaped patch, generally about 4 cm wide, is created. Beginning at the midpoint of the bottom of the incision, interrupted felt pledget-supported horizontal mattress sutures of 3-0 polyester are placed through the aorta and patch. Special care is used because it is difficult to see this area again after the stitches are tied and aortic clamp removed. The valve is sewn into place using interrupted horizontal mattress sutures in the region of the patch, bringing these in from the outside to secure the valve against the patch (see Fig. 12-64, \textit{B}). The remainder of the circumference of the prosthetic valve is attached to the anulus of the aortic valve as usual with continuous or interrupted mattress stitches. The valve is seated in the LVOT in the intraanular position. The prosthetic patch is used to close all or part of the aortotomy using continuous stitches of 4-0 or 3-0 polypropylene.

When more diameter enlargement is required, the aortic incision is extended across the anulus of the mitral valve and into the midportion of its anterior leaflet (Fig. 12-64, \textit{C-E}). Degree of enlargement is related to depth of incision into the anterior leaflet. Diameter increase of up to 4 to 5 mm may be possible with aggressive incision to the free edge of the mitral valve. The roof of the left atrium is entered as the incision crosses the mitral anulus, creating a defect in the atrium. The defect in the mitral valve anterior leaflet is repaired with a prosthetic patch, which is extended across the aortic-mitral anulus into the aorta. Interrupted stitches of 3-0 braided suture are used to attach the patch to the mitral leaflet tissues. Continuous stitches are probably less desirable than simple interrupted ones in terms of strength and accuracy of repair. Interrupted mattress stitches of 2-0 braided suture with PTFE felt pledgets are used to approximate an appropriately sized prosthetic valve to the prosthetic patch. These stitches may be started in the rim of the left atrial defect if the atrial tissues are sufficiently flexible to allow approximation to the prosthetic patch without tension. Otherwise, the atrial defect

\end{figure}
Figure 12-64  Aortic root enlargement.  

A, Incision is made through commissure between left and noncoronary sinuses and extended into intercusp triangle to level of mitral valve anulus. Loose connective tissues in triangle allow edges of aorta to separate. 

B, Teardrop-shaped patch of collagen-coated polyester is placed into defect in aortic wall. Pledget-reinforced mattress sutures placed from outside of patch through aorta and through sewing ring of a prosthesis create tight closure of widened left ventricular outflow tract (LVOT). 

C, Extending incision across mitral valve anulus into its anterior leaflet provides even greater separation of edges of aorta and further widens LVOT. Left atrium is also entered. A collagen-coated polyester patch is inserted to close defect in mitral valve and aorta. Interrupted stitches are used to attach patch to mitral valve leaflet tissues up to level of aortic valve anulus. 

D, Pledget-reinforced horizontal mattress sutures are placed through edge of defect in left atrium (if tissue is flexible and mobile), brought through polyester patch, then through sewing ring of prosthesis. A separate patch is used to close left atrium if there is any tension on closure. 

E, Patch is trimmed appropriately and used to fill defect in aorta.
is filled in with a separate patch of autologous pericardium. The prosthetic patch is tailored to a point and used to close all or part of the aortotomy.

An alternative to all these methods is replacing the aortic root and first part of the ascending aorta with a porcine aortic root bioprosthesis, an allograft aortic valve cylinder, or an autograft pulmonary valve cylinder. Excision of almost all the aortic root except for buttons of sinus aorta around the coronary arteries often opens up the narrow aortic anulus. Excision of the residual commissures to open into the intercusp triangles allows the more flexible tissues in the triangle to expand and enlarge the aortic root. The aortic root is then replaced with an appropriately sized porcine bioprosthesis, aortic allograft, or the patient’s own pulmonary trunk (autograft). In this technique, the conduit will represent an important “size up” compared with the original diameter of the aortic anulus and aortic root.

Associated subvalvar LVOT narrowing may be anatomic hypoplasia or acquired from excessive compensatory LV hypertrophy. In former practice, this was an indication for aortoventriculoplasty (Konno-Rastan operation; see Chapter 47). Clarke described a modification of this operation using an aortic allograft with its attached anterior mitral leaflet. An attractive alternative is the pulmonary autograft procedure in which the Konno-Rastan–type incision is less deep into the LV septum. The shallower incision virtually eliminates injury to the first septal branch of the left anterior descending coronary artery and resultant septal myocardial infarction and injury to the conduction system. The pulmonary autograft is implanted deeper into the LVOT below the aortic anulus for complete relief of the outflow tract obstruction.

Use of an LV apicoabdominal aortic valve conduit has nearly been abandoned. It should not be considered the primary approach to the problem of a small anulus or aortic root in patients requiring valve replacement. When the patient is facing a second or third replacement, however, and has no periprosthetic leakage, such a conduit might be considered as an alternative to aortic root enlargement.

Managing the Large Aortic Root

When the aortic root is large, it may be tailored to a size that will accommodate an allograft, pulmonary autograft, or stentless xenograft. Tailoring is accomplished by extending an incision in the noncoronary sinus across the base of the noncoronary cusp into the aortic-mitral anulus. The left atrium is dissected away as deeply as possible first, but whether this chamber is entered at the lowest point of the incision is not important. A second parallel incision is made posteriorly and tapered to remove an ellipse of aortic root with its widest point at anulus level. The amount of aortic wall to be removed to appropriately reduce the diameter can be calculated, but can also be judged visually, remembering that further reduction in circumference occurs when the sutures are placed several millimeters from the edge and tied down. The lowest part of the defect so created is closed using interrupted figure-of-eight or simple sutures through strong tissue, including the adjacent left atrial wall if it has been opened. This technique was used frequently in the past; residual aortic valve regurgitation afterward was common.

Current practice is full aortic root replacement in the presence of large dilated aortic root pathology. It may be necessary to reduce the diameter at the ventricular-aortic junction (anulus) so that an aortic root allograft or stentless porcine xenograft may fit perfectly into the LVOT. These methods are described earlier under “Repair of Aortic Valve Regurgitation due to Aortic Dilatation or Aneurysm.”

Repair of Aortic Valve Regurgitation

In the absence of dilatation of the aortic root at the anular or sinutubular level, the major causes of potentially repairable aortic regurgitation are forms of congenital aortic valve disease usually associated with a bicuspid aortic valve and floppy aortic valves resulting in cusp prolapse. Although use of reparative operations is not widespread, and the indications for and results of these procedures are not well defined, knowledge of reported techniques is useful for the cardiac surgeon’s armamentarium. Generally these procedures involve subcommissural anuloplasty, reefing up prolapsing tissue of one cusp at the commissural level using the Trussler technique (see Chapter 35), midcusp plication, (Fig. 12-65), partial cusp resection and pericardial cusp extension (Fig. 12-66), and free margin resuspension (Fig. 12-67). Applying these techniques in 122 patients with bicuspid aortic valve and isolated aortic valve regurgitation, Boodhwani and colleagues reported 83% freedom from aortic valve reoperation at 8 years.

Pettersson described a systematic morphology-directed repair of regurgitant bicuspid aortic valves, identifying repair at cusp, commissure, and root levels. A pliability and coaptation deficiency index was developed to evaluate reparable.

Aortic Regurgitation with Aneurysm of the Ascending Aorta

When aortic regurgitation is accompanied by aneurysms of the aortic root or ascending aorta, operation may be advisable for moderate or less aortic regurgitation when specific indications for operation are met regarding details of aortic enlargement. Prophylactic replacement of the ascending aorta to prevent rupture or (more likely) dissection is generally recommended when the aortic diameter exceeds about 5.5 cm. The precise diameter depends also on rate of enlargement and presence of other comorbidities that would increase operative risk.

In patients with Marfan syndrome, prophylactic aortic root replacement may have the greatest therapeutic benefit for patient survival. Elective aortic replacement is recommended in adults when the aortic root or ascending aortic diameter exceeds 5.0 cm or the aortic index (diameter of aorta-BSA) exceeds 4.25 cm · m⁻², or with slightly smaller aortic diameter if the progression of increase in aortic diameter exceeds 5 mm · year⁻¹. For women with Marfan syndrome who are contemplating pregnancy, prophylactic valve-sparing aortic root and ascending aorta replacement is generally advisable if the aortic diameter exceeds 4.0 cm by echocardiography. For shorter Marfan patients, dissection is likely at a smaller diameter, so operation may be considered if the maximal cross-sectional area in square centimeters of the ascending aorta or root divided by the patient’s height in meters exceeds a ratio of 10.
Other risk factors that push consideration for earlier operation include a family history of aortic dissection or rupture, and extension of dilatation beyond the sinuses of Valsalva. In pediatric patients, operation has been recommended when the aortic diameter increases by more than 10 mm · year⁻¹. In the absence of asymmetric cusp prolapse or multiple cusp perforations, valve-sparing root replacement is the preferred technique. The need for reoperation in Marfan patients appears to be lower with the reimplantation technique than with the remodeling operation. In patients with Loeys-Dietz syndrome or a confirmed TGFBR1 or TGFBR2 mutation, the threshold for aortic replacement should be lower than in Marfan syndrome patients because of the greater propensity for aortic dissection with an aortic diameter of less than 5.0 cm. Thus, surgical resection of the aortic root and ascending aorta with valve-sparing aortic root replacement is advisable with an aortic diameter of 4.2 cm or greater by TEE (internal diameter) or 4.4 to 4.6 cm or greater by CT scan or MRI (external diameter). Surgical procedures in this syndrome are not complicated by excessive tissue fragility.

In patients with Loeys-Dietz syndrome or a confirmed TGFBR1 or TGFBR2 mutation, the threshold for aortic replacement should be lower than in Marfan syndrome patients because of the greater propensity for aortic dissection with an aortic diameter of less than 5.0 cm. Thus, surgical resection of the aortic root and ascending aorta with valve-sparing aortic root replacement is advisable with an aortic diameter of 4.2 cm or greater by TEE (internal diameter) or 4.4 to 4.6 cm or greater by CT scan or MRI (external diameter). Surgical procedures in this syndrome are not complicated by excessive tissue fragility.

Reimplantation rather than remodeling appears preferable in the setting of adult connective tissue disorders such as Marfan, Loeys-Dietz, and Ehlers-Danlos syndromes, but each has its proponents for other forms of aortic root aneurysm and bicuspid or tricuspid aortic valves. The preferred procedure for infants and children has not been clarified.

**Bicuspid Aortic Valve and Ascending Aortic Aneurysm**

Because the natural history of ascending aortic aneurysm is more unfavorable in patients with a bicuspid aortic valve,
Figure 12-67  Leaflet prolapse resuspensions. A, Length differences between free margins can be easily appreciated by bringing together middle of free margins with a 7-0 polypropylene suture. B, A 7-0 polytetrafluoroethylene (PTFE) suture is passed twice in top of commissure. C, Successively, two running sutures are passed over and over around length of free margin. D, With gentle traction on each branch of PTFE sutures, applying opposite resistance with a forceps at the middle of free margin, first half of free margin is shortened by slightly wrinkling tissue until it reaches same length as adjacent normal free margin. E, Same maneuver is applied for second half of free margin. This two-step technique for free margin shortening allows symmetric and homogenous shortening. F, When appropriate shortening is achieved, the four suture ends are passed through aortic wall and tied externally.

Box 12-3  Bicuspid Aortic Valve with Dilated Ascending Aorta

1. Patients with bicuspid aortic valves and dilatation of the aortic root or ascending aorta (diameter > 4.0 cm) should undergo serial evaluation of aortic root/ascending aorta size and morphology by echocardiography, cardiac magnetic resonance imaging, or computed tomography on a yearly basis.

2. Surgery to repair the aortic root or replace the ascending aorta is indicated in patients with bicuspid aortic valves if the diameter of the aortic root or ascending aorta is greater than 5.0 cm or if the rate of increase in diameter is 0.5 cm per year or more.

3. In patients with bicuspid valves undergoing aortic valve replacement or repair because of severe aortic stenosis or aortic regurgitation, repair of the aortic root or replacement of the ascending aorta is indicated if the diameter of the aortic root or ascending aorta is greater than 4.5 cm.

*Consider lower threshold values for patients of small stature of either gender.

Percutaneous Balloon Aortic Valvotomy

Percutaneous balloon aortic valvotomy for aortic stenosis in adults was popularized in the late 1980s. One or more balloons are passed across the aortic valve and inflated. In elderly patients with calcific aortic stenosis, the balloon causes fracture of calcific deposits and separation of fused or calcified commissures. Reduction in gradient is usually moderate, but the resulting valve area rarely exceeds 1.0 cm². Embolization of calcific material and development of acute aortic regurgitation represent important risks. Furthermore, restenosis is common within 6 to 12 months. Despite these important limitations, percutaneous balloon valvotomy has an important role among patients who are elderly with multiple comorbidities and at high risk for surgical aortic valve replacement.

An additional important application is in patients with severe LV dysfunction who have likely severe aortic stenosis but without a high transvalvar gradient, and who are symptomatic with advanced heart failure. In this setting, especially with additional comorbidities, there may be uncertainty about whether the LV cardiomyopathy or aortic stenosis is the more important condition. If surgical risk is considered high, an initial balloon valvotomy may provide relief of the aortic stenosis and allow assessment of the patient’s heart failure symptoms and LV function. Improvement in one or both of these supports the role of aortic stenosis in the clinical setting, and aortic valve replacement can be undertaken with expectation of favorable outcome.

In addition, patients with refractory pulmonary edema or circulatory shock might be sufficiently improved and in stable...
condition for later operation to replace the aortic valve. Patients requiring urgent noncardiac surgery may also be considered candidates for balloon valvotomy, but they are usually successfully treated by other measures.07,113

Nonreplacement Valve Operations for Aortic Stenosis in Adults

Nonreplacement decalcification operations for aortic stenosis have given reasonably good results in selected patients.17,133 At a few centers, the procedure has been augmented by using ultrasonic decalcification. However, prevalence of immediate and delayed cusp rupture is sufficient to make the technique of doubtful value.28,113 In most patients, valve replacement operations yield better and more predictable overall results.

Silver-Coated Sewing Rings

Silver salts and colloids have a long history as antimicrobials. Silver has a broad spectrum of action against bacteria, although silver toxicity can be a problem if serum level is greater than 300 parts per billion (ppb).27 Ion beam–assisted deposition of silver as a coating on polyethylene terephthalate (polyester) fabric appears to be safe and is probably effective as an antimicrobial agent for use in the sewing cuffs of mechanical heart valves.116 Healing at the sewing rings in animal studies is not impaired, but pannus formation is thinner on the silver fiber.117

Silver coating (Silzone) was introduced onto the sewing rings of mechanical cardiac valves by St. Jude Medical to reduce infection on the device. More than 30,000 St. Jude Medical Silzone valves have been implanted. Some questions have been raised regarding reduced healing and increased thromboembolism. Ionescu and colleagues showed higher incidence of ischemic stroke and peripheral embolism when the Silzone sewing cuff was used (17.1% patient-year\(^{-1}\)) compared with the standard sewing cuff (0.85% patient-year\(^{-1}\)).11 The study groups were not randomized or even concurrent, but patient characteristics were similar.

A large randomized study comparing standard and silver-coated sewing rings (Artificial Valve Endocarditis Reduction Trial [AVERT]) enrolled patients to determine the effectiveness of preventing infective endocarditis. Enrollment in the study was suspended in January 2000 when audit of the data revealed 11 of 398 (2.8%) patients in the Silzone group had periprosthetic leakage, with 8 (2.01%) requiring reoperation for explant. Four of 394 (1.02%) patients in the conventional sewing cuff group had periprosthetic leakage, with one requiring explant (0.25%). The company voluntarily recalled all products with silver coating. Subsequent analysis of the data confirmed that the risk of explant for periprosthetic leakage was greater in the Silzone group (\(P < .02\)).22 Other studies independent of the AVERT trial, however, subsequently demonstrated no differences in prevalence of periprosthetic leakage between the silver-coated and standard St. Jude Medical prostheses.15,110,114 No differences were found in the incidence of thromboembolism or endocarditis. Continued follow-up of the patients may determine if there is any antimicrobial advantage of silver coating on the sewing ring of prosthetic cardiac valves.17

Aortic Valve Replacement Through Smaller Incisions

A number of reports have described a variety of incisions that are smaller than the standard median sternotomy for cardiac valve operations. Initial interest in performing cardiac valve operations through a minimal incision was stimulated by port access technology applied experimentally.13,114,120

The STS National Adult Cardiac Surgery Database has shown steady growth in the percentage of less invasive cardiac valve procedures, but they still represent a small fraction of all approaches.34 For isolated aortic valve replacement, 8.0% of operations were attempted by a minimally invasive approach. In the 2010 Cleveland Clinic experience, however, minimally invasive isolated aortic valve replacement reached 65%.114 The most popular incision for aortic valve procedures has evolved to a limited partial sternotomy. Reardon and colleagues studied the anatomy of partial sternotomy.86 Usually the incision is made vertically through the upper half or two thirds of the sternum for aortic valve operations, with a number of variations for the transverse section of the sternum, including T-, J-, C-, or even Z-shaped incisions.3,13,14,29,54

Parasternal and transverse sternal incisions have been tried and mostly abandoned because of limited exposure, injury to the internal thoracic arteries, and lung hernia.29,34,39 A lower-half sternotomy, however, provides a small incision that is so versatile that most if not all cardiac operations can be performed through this standard incision.14

To perform the partial lower half or lower two-thirds sternotomy, body habitus is studied after the patient is placed in supine position for operation. The angle of Louis (second rib) and the second and third intercostal spaces are located (Fig. 12-68). Length of the sternum is evaluated and shape of the thorax observed. It is desirable to make a large enough incision over the location of the cardiac valves to accommodate the surgeon’s hand, should direct palpation of the heart be required. When the sternum is long and the patient’s habitus slender, dividing the sternum in the third intercostal space is sufficient for most cardiac valve operations. When the patient’s sternum is short or body habitus

![Figure 12-68](image-url)
stocky or obese, a second intercostal transverse sternal incision will provide better access. Complex valve operations such as the Ross procedure are easier to perform through a second interspace incision. Third interspace incisions are shorter and cosmetically more appealing. The skin incision is made in the midline over the sternum, extending from the interspace selected to near the end of the sternum. The pectoralis major and intercostal muscles are dissected away from the sternum in the second or third intercostal space on each side of the sternum to free the internal thoracic vascular pedicle. The sternum is divided transversely at the second or third intercostal space and vertically from that point through the xiphoid process using an oscillating saw. The upper one third or half of the sternum, including the manubrium, remains intact.

CPB is established using a small (29F/37F) two-stage or three-stage (29F/29F) cannula for venous uptake, with oxygenated blood returned to a small (24F) cannula placed in the ascending aorta. Active venous uptake is used through a vacuum-assisted venous return system (see “Vacuum-Assisted Venous Return” in Section II of Chapter 2). The cannulae are brought through the primary incision. The aortic occlusion clamp is brought through a stab incision on the right side below the clavicle and passed through the open right pleural space into the pericardial sac to occlude the aorta. A small (12F) vent cannula is introduced through the right superior pulmonary vein. Cold blood cardioplegic solution is perfused into the coronary sinus through the usual cannula designed for this purpose. The aortic valve is exposed by dividing the aorta above the sinotubular junction. Retraction stitches are placed just above each of the commissures, which rotates the aortic root anteriorly and elevates it for optimum exposure.

Several reports suggest that smaller incisions lessen surgical morbidity as well as cost of the procedure. Aris and colleagues, however, found that reduced pulmonary function associated with aortic valve replacement was not prevented by a smaller incision. Szwercz and colleagues compared partial upper sternotomy with median sternotomy for aortic valve replacement and found similar results. They showed that partial sternotomy offered a cosmetic benefit but did not reduce pain, length of stay, or cost, although the Cleveland Clinic group has. They also noted that upper sternotomy does not provide access to the heart other than at the aorta and the base. This cardiac access problem is overcome by lower partial sternotomy, which centers the incision over the heart.

Arom and colleagues have compared port access to less invasive procedures in which a small incision is made, but the aorta and atria are cannulated directly. They found that port access procedures required more operating room time, longer operative and aortic clamp time, and more cost than the less invasive procedures. Their experience concurs with that of other surgeons. Therefore, the trend in cardiac valve operations is toward direct cannulation of the aorta and heart when small incisions are used. Byrne and colleagues have reported use of a partial upper hemisternotomy for reoperative aortic valve replacement. They found operative bleeding was reduced as well as operating time, compared with standard full sternotomy during reoperations.

In a diverse patient population, it seems that the approach at operation, age of the patient, and other comorbid factors are the major influences on outcomes, frequency of complications, and costs.

Percutaneous Transcatheter Aortic Valve Implantation

Despite the overall low mortality associated with aortic valve replacement, certain patient subsets carry a high risk of hospital mortality when exposed to a standard open aortic valve replacement using CPB. Such high-risk patients have been defined using the logistic EuroSCORE calculated risk of greater than 20%. Given the rather transient relief achieved with balloon valvuloplasty (see “Percutaneous Balloon Aortic Valvotomy” earlier in this chapter), major interest has developed in use of percutaneous or transapical valve implant systems for treating severe symptomatic aortic stenosis when both medical therapy alone and traditional aortic valve replacement carry a high expected mortality. As of 2011, two such devices have been approved for clinical use in Europe and are undergoing clinical trial in the United States: the SAPIEN valve (Edwards Lifesciences, Irvine, Calif.) and the CoreValve ReValving System (Medtronic Inc., Minneapolis, Minn.). The SAPIEN valve has been approved by the FDA for inoperable patients in the United States. Both systems can be delivered via transapical, femoral/iliac, or axillary/subclavian routes. In a recent review, Bande and colleagues noted that more than 4000 such implants occurred through early 2010. Thirty-day mortality is as low as 5% for a patient group considered surgically inoperable, with substantial survival advantage at 1 year over a similar group receiving medical therapy.

Relative advantages of one approach over another continue to be evaluated by multiple surgical and interventional multidisciplinary teams. Percutaneous approaches are less invasive but often limited by vascular access issues. Transapical approaches are more invasive but have no limitations with regard to access. The transapical approach is performed through a small left anterior thoracotomy centered over the LV apex in the fifth or sixth intercostal space. Apical deployment of transcatheter valves carries the additional advantages of avoiding the transverse aortic arch (a potential source of embolic strokes), and the short working distance may improve accuracy of valve deployment. Important LV apical bleeding and late pseudoaneurysms of the LV apical site have been reported in about 5% of patients. Intermediate and late outcomes of transcatheter valve implantation will be clarified in the coming years.

Functional Mitral Regurgitation Associated with Aortic Valve Disease

Important organic mitral regurgitation may coexist with severe aortic valve disease, and repair or replacement of both valves is the proper surgical procedure (see Chapter 13). However, mitral regurgitation of grade 1 or 2 (based on grades 1 to 4) may occur in the presence of aortic valve disease even when the mitral leaflets are normal, presumably because of annular dilatation. The mitral regurgitation is usually abolished or considerably reduced by aortic valve replacement.

When encountering this situation, the surgeon should evaluate the mitral valve by intraoperative TEE. If it seems structurally normal and regurgitation is no more than grade
2, the valve should not be repaired or replaced. In borderline cases, it is best to discontinue CPB after repair or replacement of the aortic valve and to reassess mitral valve function using TEE with the heart beating and ejecting. If mitral regurgitation continues to be important, CPB is recommenced, and the mitral valve is repaired with an anuloplasty band or ring.

Chapter 12 Aortic Valve Disease

Y

Z
**DEFINITION**

Acquired diseases of both the aortic and mitral valves severe enough to require simultaneous surgery (replacement, repair, or valvotomy) are considered in this chapter. Because tricuspid valve disease may form part of this spectrum and require simultaneous surgery, it is also considered, although discussed in more detail in Chapter 14.

**HISTORICAL NOTE**

Surgical treatment of combined aortic and mitral valve disease began during the early 1950s by closed methods. In 1955, Likoff and colleagues reported 74 patients who had undergone simultaneous closed repair of aortic and mitral stenosis by Bailey and Glover in Philadelphia. In 1958, Lillehei and colleagues were the first to report simultaneous repairs of both valves by open techniques using cardiopulmonary bypass (CPB). In 1963, soon after introduction of durable mechanical prostheses, Cartwright and colleagues first reported simultaneous aortic and mitral valve replacement. In 1964, Starr and colleagues reported 13 patients who had undergone multiple valve replacements, including one who received mechanical aortic, mitral, and tricuspid prostheses.

**MORPHOLOGY**

Morphology of diseases involving mitral, aortic, and tricuspid valves is described in Chapters 11, 12, and 14. In most patients, multivalvar disease is rheumatic in origin, but each valve may manifest a separate pathologic condition—for example, rheumatic aortic valve disease and mitral regurgitation from infective endocarditis, idiopathic chordal rupture, or ischemic papillary muscle dysfunction.

The effect of combined disease on morphology of the left ventricle (LV) is of great importance. Thus, at the extremes, combined aortic and mitral regurgitation imposes a large volume overload on the LV, and LV volume and wall thickness increase severely; combined aortic and mitral stenosis results in a small, thick-walled, noncompliant LV.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

In general, clinical criteria and noninvasive diagnostic tests are the same for mitral and aortic valve disease whether they are combined or isolated, but additional cardiac catheterization and angiography data are more frequently needed when they are combined. In patients older than 40 years of age, coronary angiography is indicated routinely, and the valve lesions are assessed at that time.

One lesion is usually dominant and may modify the clinical signs of the less dominant one. A frequent problem is assessing severity of the less dominant lesion; if it is mild or even mild to moderate, it may not require simultaneous correction. Historically, it was sometimes possible to obtain reliable information on the second lesion during operation by palpating an atrial chamber to detect systolic pulsation, by feeling the valve directly with the finger before beginning CPB, or by exposing the valve. Today, with two-dimensional (2D) and color Doppler echocardiography, the status of the aortic, mitral, and tricuspid valves is usually known before the patient enters the operating room. Intraoperative use of transesophageal echocardiography (TEE) verifies this status if necessary.

Dominant Aortic Stenosis

Dominant aortic stenosis is diagnosed by the same techniques used in isolated aortic stenosis (see Chapter 12). Dominant aortic stenosis may complicate diagnosing coexisting mitral stenosis by simple methods. The auscultatory signs of moderate mitral stenosis may be masked, and transmission of the aortic systolic murmur to the apex may confuse the assessment of mitral regurgitation. However, Doppler echocardiography can render as precise a diagnosis as in isolated mitral stenosis. Severity of pure mitral stenosis associated with aortic stenosis can be verified by pressure measurements (left atrium to LV) on the operating table, although varying cardiac output sometimes makes interpretation difficult. In questionable cases, the valve may be palpated on CPB or examined directly by opening the left atrium through the superior approach (see Chapter 11).

A convincing sign of important mitral regurgitation associated with aortic stenosis is a right parasternal systolic lift, especially if associated with an apical third heart sound when the venous and hepatic pulses do not indicate important tricuspid regurgitation. More than modest left atrial enlargement on the posteroanterior chest radiograph and also P mitrale in the electrocardiogram strongly suggest important associated mitral valve disease. Two-dimensional echocardiography with Doppler color flow interrogation is helpful in identifying mitral regurgitation, both preoperatively and intraoperatively.

Dominant Aortic Regurgitation

In dominant aortic regurgitation, as noted in Chapter 12, an Austin Flint murmur can mimic that of mitral stenosis, the absence of which can be confirmed by 2D echocardiography with Doppler color flow interrogation. If in addition to a mid-diastolic murmur there is an opening snap, left atrial enlargement above grade 2, and P mitrale, then important coexisting mitral stenosis is usually present.

With dominant aortic stenosis, severity of associated mitral regurgitation requires careful assessment by 2D echocardiography, particularly because it is frequently secondary to LV enlargement or dysfunction. If it is less than grade 2 in severity, it usually regresses after the aortic regurgitation is corrected. When the LV is severely enlarged, it is likely that both aortic and mitral regurgitation are severe.

Dominant Mitral Stenosis

Dominant mitral stenosis may minimize the usual signs and symptoms of coexisting aortic regurgitation. When aortic regurgitant flow is moderate or large, its presence and severity are readily assessed clinically by character of the arterial pulse and blood pressure. At times, however, what seems to be less than grade 2 aortic regurgitation becomes clearly moderate or severe after surgical relief of the mitral stenosis. Magnitude of aortic regurgitation cannot be assessed reliably at operation. Visual inspection of the aortic valve may provide information about extent of the rheumatic condition but not about magnitude of the leakage. Thus, evaluating the aortic valve preoperatively with 2D echocardiography Doppler color flow interrogation is important before undertaking mitral valve surgery. Intraoperative TEE can be of value as well. Size of the jet visualized by color Doppler echocardiography may not represent the degree of aortic regurgitation. It is possible to measure the vena contracta, which is the size of the regurgitant jet within the regurgitant aortic valve orifice. This measurement correlates well with effective regurgitant orifice. Width of the vena contracta is measured from the parasternal view long axis, just below the flow convergence. Vena contracta greater than or equal to 7 mm uniformly indicates severe aortic valve regurgitation, whereas measurements of 5 mm or less correspond to regurgitation that is moderate or less.

Moderate (grade 2) associated aortic stenosis can usually be identified clinically by characteristic physical findings (see Chapter 12), and LV-aortic gradient can be measured at operation, but flow may not be known. Therefore, an estimate of aortic valve orifice size by 2D echocardiography or cardiac catheterization (see Chapter 12) should be available when mitral valve surgery is undertaken.

Dominant Mitral Regurgitation

The same considerations discussed for dominant mitral stenosis apply to aortic valve disease associated with dominant mitral regurgitation.

Dominant Tricuspid Valve Disease

In uncommon cases of dominant tricuspid stenosis or regurgitation, accurate clinical assessment of downstream lesions in the mitral and aortic valves is seldom possible. Preoperative 2D echocardiographic study is required, and occasionally cardiac catheterization as well.

NATURAL HISTORY

The natural history of combined aortic and mitral valve disease is complicated by the same variability in dominance of one lesion over the other that makes diagnosis and decision making difficult. For example, in rheumatic aortic valve disease, the mitral valve is involved almost universally, although the lesions—either stenosis or regurgitation—may
be so mild that operation is not required until many years after replacement of the aortic valve. Double valve surgery in such patients is sequential. Patients with rheumatic mitral valve disease often have only mild rheumatic aortic valve disease at the time of their original mitral operation. The longer these patients survive, the more likely it is that a mild rheumatic aortic lesion will become important and require operation. Choudhary and colleagues followed 284 patients with rheumatic heart disease who had mild aortic valve involvement at the time of mitral valve surgery. After a mean interval of about 5 years, 35% of those with mild aortic valve stenosis had progressed to moderate or severe stenosis. Freedom from development of moderate or severe aortic valve stenosis was 75% ± 6%, 62% ± 9%, and 46% ± 11% at 5, 10, and 15 years, respectively. Mild aortic valve regurgitation at the time of mitral valve intervention, on the other hand, progressed slowly, with only 5% of patients developing moderate or severe aortic valve regurgitation after a mean interval of 12 years. Freedom from development of moderate or severe aortic valve regurgitation was 100%, 97% ± 2%, and 87% ± 5% at 5, 10, and 15 years, respectively.

Simultaneous development of important aortic and mitral valve disease usually results from a particularly severe and prolonged attack of rheumatic fever or from recurrent attacks, and there may be a florid myocarditis and pericarditis as well. Regurgitant combined valve lesions may mature particularly rapidly, requiring operation by the second decade of life.

When dominant aortic stenosis coexists with mitral steno-

sis, prognosis may be worse than that of isolated aortic stenosis. When dominant mitral stenosis coexists with important aortic stenosis, survival is shorter than for isolated mitral stenosis, with sudden death being a particular risk. When severe aortic and mitral regurgitation coexist, reduction of LV afterload by mitral regurgitation provides a protective effect (see Chapter 11), and patients with aortic regurgitation tend to remain asymptomatic despite advanced left ventricular dysfunction (see Chapter 12). Consequently, it is likely that patients with this combination will remain asymptomatic well beyond the stage when left ventricular dysfunction becomes irreversible.

**TECHNIQUE OF OPERATION**

After induction of general inhalation anesthesia and during appropriate preparation of the skin and draping of a sterile field, an echocardiography probe is inserted into the esophagus (see Chapter 4). Two-dimensional ultrasound imaging is used to evaluate valve morphology and color Doppler ultrasound to evaluate valvar hemodynamics. The plan for operation is then refined. The aortic valve is replaced in most circumstances, but it may be repaired if there is aortic valve regurgitation that is judged to be secondary to dilatation of the aortic root or to dilatation or aneurysm of the ascending aorta. The mitral valve may be repaired or replaced. The tricuspid valve may not need intervention or may be repaired. The crux of the operation usually involves the intervention judged necessary for the mitral valve; there are more options available for it than for the aortic valve, and the tricuspid valve is usually repairable.

A median sternotomy is performed. The cardiac valves lie in close proximity to each other, so an extensive incision is unnecessary. The pericardium is opened and suspended to provide optimal exposure of the heart. A systematic evaluation is made by assessing cardiac chamber size and palpating for thrills caused by turbulent blood flow. CPB is established using a single venous uptake cannula or two venous cannulae if the left atrium is small. Two venous cannulae and caval tapes with tourniquets are required for operations involving the tricuspid valve (see Chapter 2). Oxygenated blood is returned through a cannula placed in the ascending aorta. Multiple valve operations are enhanced by using small cannulae and vacuum-assisted venous return (see “Vacuum-Assisted Venous Return” in Chapter 2). The perfusate may be cooled to lower the body temperature to 28°C.

Operations involving more than one cardiac valve are most conveniently performed using intermittent retrograde administration of cardioplegic solution via the coronary sinus (see “Technique of Retrograde Infusion” in Chapter 3). A perfusion cannula is inserted into the coronary sinus through the right atrial wall for aortic and mitral valve operations, or directly after opening the right atrium for operations involving the tricuspid valve.

A vascular clamp occludes the ascending aorta. A vent catheter is inserted through the right superior pulmonary vein and advanced across the mitral valve into the LV. A transverse aortotomy is made and cold cardioplegia administered. For tricuspid valve operations, the right atrium is opened parallel to the atrioventricular groove, the coronary sinus cannula is inserted, and cold cardioplegia is administered.

The aortotomy is extended into the noncoronary sinus of Valsalva or extended to divide the aorta above the sinutubular junction. The aortic valve is inspected for the possibility of repair. If it is not reparable, it is excised. Calcific deposits are removed from the aortic anulus. Diameter of the LV outflow tract at the aortoventricular junction (aortic anulus) is measured.

The operation then focuses on the mitral valve. The left atrium is opened on the right side posterior to the interatrial groove at the junction of the right pulmonary vein, and the incision is extended superiorly behind the superior vena cava and inferiorly behind the inferior vena cava. Alternatively, the superior aspect of the left atrium is opened medial to the superior vena cava and behind the aortic anulus. This superior approach is particularly useful when the aorta has been divided. When operation on the tricuspid valve is required, a transeptal approach may be convenient, extending the right atrial incision superiorly medial to the superior vena cava and onto the superior aspect of the left atrium. The atrial septum is cut back inferiorly through the fossa ovalis to the inferior wall of the left atrium. A self-retaining retractor maintains exposure of the mitral valve.

The mitral valve is inspected for the possibility of repair. If repair is not feasible, the valve is usually replaced with a mechanical prosthesis, although second- or third-generation stent-mounted bioprostheses may be used in patients older than («)70 years of age. This influences the choice of replacement device for the aortic valve, because it is usually replaced with the same type of valve as the mitral valve (see “Choice of Device” in Chapter 12). The only exception to mixing rather than matching the type of prosthesis is in the case of a very small aortic root, when a stentless bioprosthesis (allograft or xenograft) may be chosen (see “Small Aortic Root and Small Prosthesis: Prosthesis-Patient Mismatch” in Chapter 12). If the mitral valve is reparable, more selection options are available for the aortic valve, with weight given to a bioprosthesis to avoid anticoagulation if the cardiac
rhythm is likely to be normal sinus after operation. The tricuspid valve is usually repaired regardless of choices made for the aortic and mitral positions. Occasionally the tricuspid valve is involved by rheumatic disease and requires replacement.

Coronary artery bypass grafting (CABG) may be required in combination with multiple valve procedures. It is usually performed after the valves are excised but before the prostheses are inserted, to reduce risk of atrioventricular groove disruption during cardiac retraction to expose the posterior wall of the LV. Proximal vein graft anastomoses to the aorta for left-sided grafts may be performed after completing distal anastomoses to the coronary arterics. For right-sided grafts, the proximal anastomosis is deferred until the atria and aorta are closed.

SPECIAL FEATURES OF POSTOPERATIVE CARE

Postoperative care of patients who have undergone combined aortic and mitral valve surgery is the same as that for other patients undergoing cardiac surgery with the aid of CPB (see Chapter 5). Anticoagulants are indicated in patients with atrial fibrillation or mechanical prostheses.

RESULTS

Survival

Early (Hospital) Death

Simultaneous aortic and mitral valve replacement is often accompanied by other procedures, so complexity of the operation partly explains higher hospital mortality after multiple valve operations than after single valve surgery. In the Society of Thoracic Surgeons National Adult Cardiac Surgery Database, operative mortality during the 1990s ranged from 6.9% to 9.9%. Hannan and colleagues reported hospital mortality of 9.6% in 1418 multiple valvuloplasty or replacement operations from 1995 to 1997 in the state of New York. John and colleagues reported 9.2% hospital mortality among 456 patients having aortic and mitral valve replacements, whereas Mueller and colleagues reported 5%. When CABG was added to the multiple valve operation, operative mortality doubled to 19% in the state of New York experience.

Time-Related Survival

Time-related survival of heterogeneous groups of patients undergoing simultaneous combined aortic and mitral valve replacement, including those undergoing concomitant tricuspid valve surgery and CABG, is lower than after single valve replacement. In the UAB group’s experience from an earlier era, it was 88%, 77%, 63%, 47%, and 23% at 1 month and 1, 5, 10, and 20 years after operation, respectively. The hazard function for death has a rapidly declining early phase of risk, giving way to a second slowly increasing hazard phase about 3 months postoperatively. The increasing phase of hazard may reflect an imperfect postoperative hemodynamic state dating from the time of operation.

Modes of Death

Most deaths early after primary combined aortic and mitral valve replacement are from acute or subacute cardiac failure. However, an unusually high prevalence of death with hemorrhage has occurred in this group of patients in the past. This is because of the ease with which left atrioventricular rupture can be produced at the time of double valve replacement. Currently, greater attention to this detail has considerably lessened the prevalence of this early postoperative complication.

Mode of death occurring after hospitalization discharge is most commonly due to chronic heart failure. Even when tricuspid valve regurgitation and right ventricular dysfunction have seemed to be absent before operation, a number of patients present late postoperatively with increasing evidence of tricuspid regurgitation, right atrial enlargement, and progressing hepatomegaly. The reason for the unusually high prevalence is not apparent. However, the primary feature appears to be right ventricular dysfunction, and tricuspid valve replacement at this stage generally does not improve the patient’s condition.

Incremental Risk Factors for Death

Double Valve Replacement

Double valve replacement itself is an incremental risk factor for death (9.4%) compared with isolated replacement of the mitral (5.7%) or aortic valve (3.5%). This is evident early after operation, and particularly in intermediate and long-term follow-up, when many deaths occur because of increasing tricuspid regurgitation progressing to right atrial enlargement, hepatomegaly, and finally cardiac cachexia. These types of death occur much less frequently after isolated mitral valve replacement and rarely after isolated aortic valve replacement. The relative roles of decreasing LV performance, increasing pulmonary vascular resistance, and decreasing right ventricular performance in this late deterioration after double valve replacement are uncertain.

Mitral Valve Replacement Rather than Repair

One-stage mitral and aortic valve operations may not involve replacement of both valves. When they do not, the early risks have generally been less, even when concomitant tricuspid valve surgery is performed, and the intermediate and long-term results are better. Gillinov and colleagues reported hospital mortality of 5.4% when the mitral valve was repaired and 7.0% when it was replaced. They also reported 15-year survival of 46% when the mitral valve was repaired compared with 34% when it was replaced (P < .01; Fig. 13-1).

The instantaneous risk of death was highest immediately postoperatively, decreased to its lowest level at 1 year, and increased slowly thereafter (Fig. 13-2). The late phase of hazard was consistently higher after mitral valve replacement than after repair.

Previous Operations

Approximately 15% of patients undergoing first-time simultaneous replacement of the aortic and mitral valves have had a previous valve operation. This has not, however, increased the risks of the double valve replacement.

Choice of Replacement Device

Choice of replacement device does not affect long-term survival. Caus and colleagues compared a matched population aged 60 ± 3 years having aortic and mitral valve replacement with either mechanical prostheses or bioprostheses. Survival at 5, 10, and 15 years was similar, although reoperation was
PART III Acquired Valvar Heart Disease

Left Ventricular Function and Preoperative Functional Status

The more advanced the heart failure, and thus the functional disability, the greater the early and late risks of death (Fig. 13-4). Patients whose condition necessitates an emergency operation can be expected to be particularly at risk early postoperatively. Even patients in New York Heart Association (NYHA) functional class II have reduced late survival. LV ejection fraction below 30% increased hospital mortality in multiple valve replacement in the New York State study to 13%, compared with 9.3% when it was higher. Mueller and colleagues found that LV ejection fraction below 50% increased risk of all deaths (P < .001). Moderate or severe LV dysfunction is a risk factor for death in the early and late hazard phases.

Age at Operation

Historically, age at operation has not been identified as an incremental risk factor for death during the first 30 days after operation (Table 13-1). However, more patients are now being operated on in their eighth and ninth decades of life, so older age is probably a risk factor for early postoperative death in the current era. It clearly is a risk factor for death late postoperatively, especially for patients older than 70 years at the time of operation (Fig. 13-3). Gillinov and colleagues demonstrated a 20% survival advantage for patients having operation at age 50 versus those having operation at age 65.

Left Ventricular Enlargement

Greater LV enlargement is a powerful risk factor for death late postoperatively. Because of the large volume overload, combined severe aortic and mitral regurgitation has a strong tendency to produce marked LV enlargement; the outcome after operation for patients with severe LV enlargement and this combination of valve lesions is particularly poor, with 5-, 10-, and 20-year survival of 64%, 37%, and 9%, respectively (Fig. 13-5).
Valve Pathology

Imperfect outcome after double valve replacement is well illustrated by survival of patients with the most favorable valve pathology—namely, important stenosis at one or both valves with only grade 2 LV enlargement (see Fig. 13-5). The combination of severe mitral regurgitation and severe aortic regurgitation has mildly increased the risk of death early after operation (see Fig. 13-5). Mueller and colleagues also found that aortic valve stenosis is a risk factor in the early hazard phase.

Patients having multiple valve operations for rheumatic valvar heart disease have greater survival benefit than those having operations for nonrheumatic disease. John and colleagues reported survival of 85% at 15 years and 82% at 24 years in patients with a mean age of 33 years having aortic and mitral valve replacement for rheumatic valve disease. Mueller and colleagues reported survival of 56% at 15 years and a linearized death rate of 2.3% per patient-year in a group of older patients (mean age 56 years) in whom 55% underwent operation for rheumatic disease. Gillinov and colleagues also reported that patients with rheumatic disease had greater predicted survival benefit than patients with nonrheumatic disease and that repair of the mitral valve further improved survival (Fig. 13-5). Nonrheumatic disease reduced survival in even the lowest-risk patients, and age at operation further reduced the chance of surviving for 16 years after aortic valve replacement and mitral valve repair or replacement (see Fig. 13-3, B).

Cardiac Comorbidity

Early mortality is increased by the presence of important tricuspid regurgitation, necessitating associated annuloplasty or, particularly, valve replacement, although this is not evident in all analyses. It is also increased by presence of ischemic heart disease requiring concomitant CABG, especially left main coronary artery stenosis. Pulmonary vascular resistance that is elevated before operation affects late survival. Mueller and colleagues also found that pulmonary systolic pressure of 60 mmHg or more is a risk factor for early death. Atrial fibrillation is a risk factor for death in the late
Noncardiac Comorbidity
Renal disease increases risk of death in the late hazard phase, and elevated blood urea nitrogen adds risk in the early phase after operation. Dialysis at the time of operation increases early relative risk ninefold. Diabetes mellitus also increases risk. Hepatic failure increased early risk of operation from 9.2% to 26% in the New York State series.

Functional Status
Most surviving patients are considerably improved by double valve replacement. However, by 10 years after operation, only 51% are in NYHA functional class I, and 34% are in class II (Fig. 13-7). The proportion of surviving patients who are in NYHA functional class I gradually declines as follow-up becomes longer, reaching only 35% by 20 years. Because only 47% of patients undergoing aortic and mitral valve replacement with or without concomitant procedures are alive 10 years after operation (see Fig. 13-1), only one fourth of patients operated on are alive and in NYHA functional class I 10 years after operation; at 20 years after operation, the percentage is only 8%. John and colleagues reported 72% in functional class I, 25% in class II, and 31% in class III at median 8.5 years of follow-up after aortic and mitral valve replacement for rheumatic disease. As noted earlier, this patient group was also young (mean age 33 years).

Freedom from Thromboembolism
Freedom from thromboembolism after primary combined aortic and mitral valve replacement (Fig. 13-8) is similar to that after isolated mitral valve replacement. The use of bioprostheses in both positions has not eliminated late postoperative thromboembolic episodes. Mueller and colleagues found similar results in a group of patients in which 82% had double valve replacement with bileaflet mechanical valves. Freedom from thromboembolism was 89% at 5 years, 74% at 10 years, and 66% at 15 years. Mitral valve repair did not reduce the risk compared with double valve replacement.

Just as after isolated mitral valve replacement or mitral commissurotomy, risk of a subsequent thromboembolic event is increased by more postoperative thromboembolic events (see Fig. 13-8) as well as those occurring prior to operation.

Complications of Anticoagulant Therapy
Prevalence of hemorrhage related to anticoagulant therapy is no different after double valve replacement than after single valve replacement (see “Complications of Long-Term Anticoagulation” under Mitral Valve Replacement in Section I of Chapter 11). In patients in whom mechanical prostheses were used (bileaflet in 82%), freedom from bleeding events was
89% at 5 years, 81% at 10 years, and 73% at 15 years. Linearized rates of valve-related thromboembolism and bleeding with bileaflet prostheses are listed in Table 13-2.

Hemolysis and Valve Thrombosis
With two mechanical prostheses, hemolysis and valve thrombosis are greater than with one. Both complications are rare.

Reoperation
As has been the experience with reoperations after valve replacement in general, the risk of yet another reoperation becomes greater after each (Fig. 13-9).

Need to reoperate is usually determined by the durability of the repair or replacement device applied in the mitral position (Fig. 13-10). Reoperation is done least frequently when mechanical prostheses are used. More than 90% of patients are free of reoperation at 15 years when a mechanical valve is used to replace the mitral valve in double valve operations; in contrast, that figure drops to 25% when a stented bioprosthesis is used.

The choice of replacement or repair of the mitral valve affects the procedure chosen for the aortic position. Patients requiring anticoagulant therapy for atrial fibrillation or recurrent deep vein thrombosis, for example, derive greatest benefit from the durability of mechanical prostheses. Extensive calcification of the mitral valve is usually best treated by mitral valve replacement. Severe mitral stenosis with thickening of the valve and subvalvar apparatus is usually treated by mitral valve replacement.

Repair of both the mitral and aortic valves can be accomplished with acceptable early and late mortality and valve-related morbidity. Unfortunately, the durability of both mitral and aortic valve repairs is limited. Freedom from reoperation for valve dysfunction was 94%, 82%, and 65% at 1, 5, and 10 years, respectively. However, results of repair of rheumatic-type mitral valves decrease between 10 and 15 years.

### INDICATIONS FOR OPERATION

Remarkably few data exist to objectively guide management of multiple valve disease. Each case must be considered individually, and management must be based on hemodynamics and ventricular function as well as on the probable benefit of medical vs. surgical intervention. The most logical approach is to operate when valvar disease produces more than mild symptoms, or, in the case of dominant aortic valve stenosis, when patients have only mild symptoms. In regurgitant dominant lesions, surgery can be delayed until symptoms of LV dysfunction develop in asymptomatic patients. Use of vasodilators to delay surgery in mixed valve disease is untested.

Aortic and mitral valve operation is required when the patient’s symptoms are important (NYHA functional class III or greater) despite an appropriate and intensive medical regimen. Such an approach—more conservative than that with isolated mitral or aortic valve replacement—is indicated by the higher early and late risks of double valve replacement and the probably increased late morbidity when there are two rather than one artificial devices in situ. Despite these early and late risks, outcome after double valve replacement is surely superior to what can be accomplished with nonsurgical means. Because of the markedly increased risks with advanced heart disease, it is unwise to insist on severe limitation (NYHA class IV) before recommending double or triple valve surgery.

It is particularly unwise to keep deferring operation until it suddenly becomes necessary to perform an emergency operation on a class V patient, because then the early and late risks become high.

Exceptions to these general indications are cases of combined aortic and mitral regurgitation. These patients are advised to undergo operation when LV enlargement is grade 2 or higher (based on grades 1 to 6), even though symptoms are absent or mild. Otherwise, there is a strong tendency to develop extreme LV enlargement before symptoms become important, considerably lowering long-term survival and increasing the probability of developing ventricular arrhythmias and sudden death.

Patients with active rheumatic carditis, severe aortic and mitral regurgitation, and critical heart failure must be operated on when it is clear that the acute episode is not subsiding. Patients with severe aortic and mitral regurgitation and active bacterial endocarditis in whom neither infection nor heart failure can be controlled medically must also undergo operation without delay (see Chapter 15).

### SPECIAL SITUATIONS AND CONTROVERSIES

**Multiple Valve Replacement Through Small Incisions**

It has become possible to perform almost all cardiac valve operations through incisions smaller than standard median sternotomy. Experience and familiarity with smaller incisions have shown that exposure of cardiac valves is not compromised, and even though the smaller incision provides more confined dimensions within which the surgeon must work, results have been equivalent. The frequency with which the minimally invasive approach to cardiac valves is used has increased, but it is still a small fraction of the total.

A lower half partial sternotomy approach may be considered for any cardiac valve operation. This approach allows the minimally invasive operation not only in isolated single valve replacement but also in complex cardiac valve operations. The incision is centered over the location of the cardiac valves. Cadaveric dissections performed by Reardon and colleagues affirm the lower half sternotomy exposure. They found the pulmonary valve behind the third left costal cartilage, the aortic valve behind the sternum opposite the third intercostal space, and the mitral and tricuspid valves related to the fourth costal cartilage and fourth interspace.

Operations on the aortic valve are facilitated by dividing the ascending aorta above the sinutubular junction. The aortic root may then be positioned for direct visualization, allowing precise examination. The mitral valve approach through standard left atriotomy posterior to the intraatrial groove on the right side is comfortable and familiar to the surgeon. When aortic and mitral valve operations are combined, the mitral valve is easily accessible through the superior aspect of the left atrium, especially with the aorta divided and aortic root retracted inferiorly. A transatrial septal approach is used (1) when the mitral valve is repaired or replaced in conjunction with operations on the tricuspid valve, or (2) for triple valve operations.

Complex operations are easier when the transverse section of the sternum is through the second intercostal space. The longer the sternal incision, the less the incision qualifies as minimally invasive. Nevertheless, it is unwise to compromise exposure or needlessly confine the incision to the point that

---

**Figure 13-10** Freedom from reoperation after mitral valve repair or replacement in combined aortic and mitral valve operations. Filled circles represent reoperation after replacement of the mitral valve with a mechanical prosthesis; triangles represent mitral valve replacement with a bioprosthesis; squares represent mitral valve repair in nonrheumatic etiologies; and circles represent mitral valve repair in rheumatic valve etiology. Parametric estimates are represented by solid lines; their confidence limits are suppressed for clarity. (From Gillinov and colleagues.)

---
the operation becomes tedious and prolonged. When either the third or second interspace is used, the entire manubrium remains intact, along with the clavicular attachment. This should be of substantial benefit to the patient in terms of chest wall stability after operation and should eliminate the possibility of dehiscence of the sternal repair at the manubrium.

Small-diameter cannulae as used in vacuum-assisted venous return considerably aid placement of aortic and venous cannulae through the primary incision. Vacuum-assisted venous return has also been helpful in providing more reserve and safety in the venous drainage system to the reservoir of the oxygenator (see “Vacuum-Assisted Venous Return” in Chapter 2). The right heart remains empty and collapsed more consistently than with gravity drainage, and air entrainment with air lock, frequently seen with gravity drainage, is eliminated. This and other advances in cardiopulmonary technology have made operating through a small incision easier, and the technology is transferable to full sternotomy operations.

Dotty and colleagues studied the partial sternotomy (lower half) approach in 16 patients undergoing double valve operations.\textsuperscript{12} One patient died (6.3%). Triple valve operations were performed in five patients, none of whom died. They concluded that this approach provides a smaller, less invasive incision through which essentially all cardiac valve operations may be performed. It provides standard exposure to the cardiac valves, and standard instruments and retraction devices are employed. Maintaining the integrity of the manubrium and upper sternum should be beneficial for patient mobilization and rehabilitation after operation, and the smaller incision is appreciated by patients of all ages. Atik and colleagues studied hospital outcomes of 114 patients undergoing less invasive (upper sternotomy) combined valve surgery compared with 381 patients undergoing full sternotomy combined valve operations during 1995 through 2003.\textsuperscript{14} Among propensity-matched patients, mediastinal drainage was less and early pulmonary function better after less invasive surgery, but otherwise, complications, mortality, pain scores, and length of hospital stay were similar.

### 13A Survival and Related Matters

This appendix discusses survival and related matters in patients undergoing simultaneous combined aortic and mitral valve replacement, with or without concomitant cardiac procedures, and excluding only those patients with a previous aortic or mitral valve replacement operation (UAB group, 1967-1981, \( n = 569 \)). Follow-up extended to 22 years.

#### Parameter Estimates

Shaping parameter estimates, the risk factors retained in the analysis, their coefficients, standard deviations, and (in parentheses) \( P \) values were as follows:

**Early phase:** \( \delta = 0, \eta = 7.989, \nu = 1, m = -2.519, \) intercept 7.134, body surface area 0.9023 ± 0.41 \( (P = .03) \), preoperative NYHA functional class 0.8177 ± 0.139 \( (P < .0001) \), aortic and mitral regurgitation 0.6092 ± 0.21 \( (P = .004) \), use of cardioplegia −1.054 ± 0.28 \( (P = .0002) \), global myocardial ischemic time (using cardioplegia) 0.02138 ± 0.0080 \( (P = .007) \), surgeon \( X \) 0.9934 ± 0.46 \( (P = .03) \)

**Late phase:** \( \tau = 1, \gamma = 1, \alpha = 1, \eta = 1.458, \) intercept −10.64, age at operation 0.02698 ± 0.0060 \( (P < .0001) \), African-American 0.7758 ± 0.20 \( (P = .0001) \), preoperative NYHA functional class 0.2528 ± 0.124 \( (P = .04) \), pulmonary resistance index 0.04011 ± 0.020 \( (P = .05) \), left ventricular (LV) enlargement grade 0.2654 ± 0.072 \( (P = .0002) \), concomitant coronary artery bypass grafting (CABG) 0.7388 ± 0.26 \( (P = .005) \), Bjork-Shiley prostheses used in aortic and mitral position −0.6490 ± 0.156 \( (P < .0001) \)

#### Specific Solutions of the Multivariable Equation

**Figure 13-4:** Age was entered as 65 years, African-American 15\%, body surface area as 1.7 \( \text{m}^2 \), pulmonary vascular resistance as 4.3 units · \( \text{m}^2 \), important aortic and mitral regurgitation = no, LV enlargement grade 3, CABG = no, and global myocardial ischemic time as 80 minutes, with cardioplegia.

**Figure 13-5:** The entries were similar, and NYHA was entered as class III.
13B

**Ordinal Logistic Equation for NYHA Functional Class**

The NYHA functional class on the date of latest follow-up (November-December 1988) in living patients was analyzed using the ordinal logistic model for an ordered categorical response variable. The intercepts and regression coefficient, its standard deviation, and $P$ value are as follows: intercept 1, $-0.7283$; intercept 2, $-2.417$; intercept 3, $-4.389$; interval (months) from operation to last follow-up $0.005665 \pm 0.0030$ ($P = 0.06$).

DEFINITION

This chapter discusses regurgitation and stenosis of the tricuspid valve in those uncommon situations in which it occurs as an isolated lesion, as well as tricuspid valve disease associated with mitral or combined mitral and aortic valve disease. Mitral valve surgery with coexisting tricuspid valve disease is also discussed in Chapter 11.

Tricuspid valve abnormalities or disease may be associated with various conditions discussed in other chapters, including atrioventricular septal defect (Chapter 34), ventricular septal defect with straddling tricuspid valve (Chapter 35), pulmonary atresia and intact ventricular septum (Chapter 40), Ebstein anomaly (Chapter 42), and right atrial myxoma (Chapter 18). Rarely, isolated tricuspid valve disease is secondary to chronic cor pulmonale, inferior myocardial infarction, administration of methysergide, scleroderma, lupus erythematosus, primary phospholipid syndrome, and hypercosinophilic syndrome.

MORPHOLOGY

Functional (Secondary) Tricuspid Regurgitation

The multitude of chordal attachments of the tricuspid valve, described in Chapter 1, may impair proper leaflet coaptation and promote tricuspid regurgitation (TR) in the presence of right ventricular (RV) dysfunction and dilatation. The tricuspid anulus shortens during systole when the tricuspid valve is competent. When right ventricular (RV) dilatation develops, usually as a consequence of important disease of the left-sided heart valves in association with pulmonary arterial hypertension, the tricuspid anulus also dilates (lengthens) and fails to shorten during systole. The leaflets and chordae remain normal in appearance.
Experimental work by Tsakiris and colleagues has shown that perfect systolic tricuspid leaflet closure depends on proper systolic shortening in the circumference of the tricuspid anulus. In support of this finding, Simon and colleagues have demonstrated a considerable increase in systolic shortening postoperatively in patients whose TR lessens after mitral valve surgery and no change in those in whom it persists or worsens. An increased diastolic diameter of the tricuspid anulus results in TR; diastolic diameter is increased by pulmonary artery hypertension, RV myocardial failure, and increased diastolic volume secondary to left-sided heart pathology.

The pathogenesis of functional TR in mitral valve disease is summarized in Fig. 14-3. The final common pathway is RV dysfunction and dilatation and tricuspid anular dilation. The process becomes self-propagating, because worsening TR exacerbates RV volume overload with further RV dysfunction and enlargement. In addition, because of ventricular interdependence, worsening RV dysfunction increases interventricular shift toward the left, causing restricted left ventricular filling, further elevation of left atrial pressure, pulmonary hypertension, and greater RV afterload, which further affects the RV.

It is these mechanisms that may produce TR late after isolated mitral valve operations or after combined aortic and mitral valve operations (see Chapters 11 and 13).

**Rheumatic Tricuspid Stenosis and Regurgitation**

Rheumatic tricuspid valve disease occurs in association with rheumatic involvement of the mitral valve, the mitral and aortic valves combined, or rarely, the aortic valve alone. It is not seen as an isolated lesion.

Experimental work by Tsakiris and colleagues has shown that perfect systolic tricuspid leaflet closure depends on proper systolic shortening in the circumference of the tricuspid anulus. In support of this finding, Simon and colleagues have demonstrated a considerable increase in systolic shortening postoperatively in patients whose TR lessens after mitral valve surgery and no change in those in whom it persists or worsens. An increased diastolic diameter of the tricuspid anulus results in TR; diastolic diameter is increased by pulmonary artery hypertension, RV myocardial failure, and increased diastolic volume secondary to left-sided heart pathology.

The pathogenesis of functional TR in mitral valve disease is summarized in Fig. 14-3. The final common pathway is RV dysfunction and dilatation and tricuspid anular dilation. The process becomes self-propagating, because worsening TR exacerbates RV volume overload with further RV dysfunction and enlargement. In addition, because of ventricular interdependence, worsening RV dysfunction increases interventricular shift toward the left, causing restricted left ventricular filling, further elevation of left atrial pressure, pulmonary hypertension, and greater RV afterload, which further affects the RV.

It is these mechanisms that may produce TR late after isolated mitral valve operations or after combined aortic and mitral valve operations (see Chapters 11 and 13).

**Rheumatic Tricuspid Stenosis and Regurgitation**

Rheumatic tricuspid valve disease occurs in association with rheumatic involvement of the mitral valve, the mitral and aortic valves combined, or rarely, the aortic valve alone. It is not seen as an isolated lesion.

Rheumatic tricuspid disease usually results in a regurgitant valve with variable amounts of stenosis, but in rare cases there

---

**Figure 14-1** Dilatation of the tricuspid valve anulus, indicated by a sequence of overlaid annulae. Tricuspid anular dilatation due to increased right ventricular and pulmonary artery pressures secondary to left-sided heart valve disease occurs predominantly in the septal-lateral direction, as indicated by arrows.

**Figure 14-2** Correlation between tricuspid anulus diameter (TAD) and tricuspid regurgitant volume ($V_{TR}$) in patients with valvar heart disease (open circles) and those with atrial septal defect (closed circles). Correlation with the former is .87 and with the latter, .88. Correlation lines cross the horizontal axis at a tricuspid anulus diameter of 33 to 34 mm, which is the threshold for tricuspid regurgitation in adult patients. Key: ASD, Atrial septal defect; VHD, valvar heart disease.

**Figure 14-3** Pathogenesis of tricuspid regurgitation in mitral valve disease. Key: DCM, Dilated cardiomyopathy; MR, mitral regurgitation; MS, mitral stenosis; RHD, rheumatic heart disease; RV, right ventricle; TV, tricuspid valve. (Redrawn from Shiran and Sagie.)
may be pure stenosis. In tricuspid stenosis, the orifice is larger than in mitral stenosis, even when hemodynamically there is severe obstruction. Therefore, the hemodynamic effects of anatomically moderate tricuspid stenosis are the equivalent of tight mitral stenosis. A mean diastolic gradient of even 4 to 5 mmHg across the tricuspid valve indicates important stenosis. Borders of the stenotic tricuspid orifice are usually fibrous and thickened, although peripheral portions of the leaflets remain thin.

The hallmark of organic tricuspid stenosis is commissural fusion. All commissures are usually equally fused, but occasionally fusion is limited to the anteroseptal commissure. Chordal thickening and fusion are usually mild, and calcification is usually absent.

Tricuspid Valve Endocarditis

Acute tricuspid valve endocarditis is rare and usually associated with habitual intravenous self-administration of drugs. The most common etiologic organism is Pseudomonas aeruginosa, followed by Staphylococcus aureus. A variety of gram-negative bacilli may be involved. Rarely, Candida albicans is the infective organism. The organisms may form masses on the valve leaflets, or simply erode and destroy large portions of leaflets and chordae (see Chapter 15).

Traumatic Injury of Tricuspid Valve

TR is an uncommon result of severe, nonpenetrating chest injury, and in this setting is due to rupture of one or more papillary muscles or chordae (see “Atrioventricular Valve Rupture” in Section II of Chapter 17). Usually it is the anterior tricuspid leaflet that becomes failed. Rarely, the ventricular septum may rupture. Occasionally a transvenous ventricular pacing lead is associated with important TR. This may be due to perforation, laceration, or scarring. Apical electric activation may also contribute. Rarely, pacemaker leads can cause tricuspid stenosis secondary to leaflet scarring and adhesions. Similar scarring of the septal and posterior leaflets following cryothermic or radiofrequency ablative procedures rarely can produce severe tricuspid regurgitation. Following cardiac transplantation, many years of repeated transvenous endomyocardial biopsies may induce severe TR secondary to inadvertent severing of chordae during biopsy.

Carcinoid Tricuspid Valve Disease

Carcinoid tumors originate from Kulchitsky cells in the gastrointestinal tract, which produce serotonin (5-hydroxytryptamine), a substance inactivated in the liver. However, carcinoid tumors that metastasize to the liver produce serotonin there, and this powerful substance passes into the pulmonary and, to a lesser extent, systemic circulation (because a good deal of it is inactivated in the lungs). Thereby, the carcinoid syndrome may be produced, with a good deal of it inactivated in the lungs. Thereby, the carcinoid syndrome may be produced, with a good deal of it inactivated in the lungs.

The chest radiograph shows right atrial enlargement, and the electrocardiogram shows a prominent P wave, followed by a sharp, deep y descent. The murmur maximal over the lower left sternal edge, which increases on inspiration; there may be a tricuspid opening snap. The jugular venous pulse shows a dominant a wave, followed by a sharp, deep y descent. The murmur, maximal over the lower left sternal edge, which increases on inspiration; there may be a tricuspid opening snap. The jugular venous pulse shows a dominant a wave, followed by a sharp, deep y descent. The murmur, maximal over the lower left sternal edge, which increases on inspiration; there may be a tricuspid opening snap.

Other signs include a mid-diastolic, often high-pitched murmur maximal over the lower left sternal edge, which increases on inspiration; there may be a tricuspid opening snap. The murmur can be confused with an aortic early diastolic murmur (because its timing may be relatively early) or with a mitral diastolic murmur. The liver is enlarged but not pulsatile (unless from forceful atrial contraction that produces a presystolic pulse).

The chest radiograph shows right atrial enlargement, and the electrocardiogram shows a prominent P wave unless atrial fibrillation is present. Two-dimensional (2D) echocardiography is helpful in establishing the presence of leaflet thickening. Cardiac catheterization with simultaneous measurement of right atrial and RV pressures identifies a diastolic gradient (>4 mm) across the valve.

Tricuspid Regurgitation

History and physical signs are sufficient to suggest diagnosis of important TR. The jugular venous pulse shows a dominant fused e and v wave, followed by a sharp, deep y descent. The murmur, maximal over the lower left sternal edge, is pansystolic, is often high pitched, and increases on inspiration. The enlarged liver shows systolic pulsation. However, when TR is severe, such as after excision of the tricuspid valve, a murmur may be absent. In advanced cases, there are other signs of right heart failure, including peripheral edema and ascites. Mitral or aortic valve disease signs can dominate the findings, and severe right heart failure may occur under such conditions without TR.

The symptomatic state of severe TR is generally manifested by progressive fatigue and weakness, related to reduction in cardiac output and the unpleasant sensation of ascites, congestive hepatosplenomegaly, and peripheral edema. The symptomatic state of right heart failure and volume overload can be palliated with aggressive diuretic therapy, but in the chronic stages, symptoms become refractory. In late stages, cachexia and jaundice may complicate the clinical complex.
Quantification of the degree of TR is important when surgical treatment of valvar heart disease is being considered, but preoperative assessment is often difficult because of the confounding effect of severe cardiac failure. In this regard, 2D echocardiography is particularly useful, because presence of the cardiac catheter across the tricuspid valve interferes with angiographic assessment. Both contrast and Doppler echocardiography have been useful, but the increasing precision of color flow mapping and Doppler color flow map-guided interrogation have made them the favored methods for estimating tricuspid regurgitant flow.\(^4\) The vena contracta, as determined by color flow Doppler, indirectly reflects effective regurgitant orifice area, which if greater than 0.7 cm indicates severe TR.\(^8\) Quantitative assessment of TR can also be accomplished with the proximal isovelocity surface area (PISA) method.\(^4\) Dilatation of the inferior vena cava and flow reversal in the inferior vena cava and hepatic veins provide supporting evidence. Echocardiography can also detect paradoxical ventricular septal motion and shift of the atrial septum toward the left atrium in isolated TR. Maximum circumference of the tricuspid anulus is larger in patients with TR than in normal adults (14 ± 0.7 cm and 11.9 ± 0.9 cm, respectively), and its reduction during systole is less (10% ± 2% vs. 19% ± 4%).\(^6\)\(^,\)\(^7\)

Despite these refinements in diagnosis, the presence and severity of TR need to be assessed in the operating room. The patient’s hemodynamic state must be optimized by the anesthesiologist for any form of assessment to have validity. The surgeon’s finger, inserted through the right atrial appendage, can appreciate a TR jet. Severe TR correlates reasonably well with a jet of greater intensity, greater width, and increased propagation from the valve orifice. If TR is severe, however, there may not be a jet with sufficient velocity to be identified in this manner.\(^3\) In the current era, rigorous assessment of TR and tricuspid anular circumference by transeosophageal echocardiography in the operating room has largely supplanted finger palpation.\(^6\)\(^,\)\(^13\),\(^3\)

In the special setting of tricuspid valve endocarditis in drug addicts, the valve is usually rapidly destroyed, and classic signs and symptoms of severe TR develop. The illness is usually only 1 to 3 weeks in duration before the patient presents for medical care. Frequently, pulmonary symptoms and signs secondary to septic pulmonary emboli are marked.\(^8\)\(^,\)\(^2\) The diagnosis can be strongly suspected from a history of drug abuse, evidence of pulmonary infection, elevated jugular venous pressure, pulsatile neck veins, and pulsatile liver. These features, combined with positive blood cultures (in samples withdrawn from the RV or pulmonary artery) and echocardiography, are usually sufficient to establish the diagnosis.\(^1\)^\(^4\)

Diagnosis of traumatic TR is usually easily established by signs of severe TR and a history of a blow to the chest (see Chapter 17). Occasionally, however, the relationship of these signs to a history of injury is not obvious. In patients with traumatic TR, right-to-left shunting may occur across a patent foramen ovale, which can lead to the mistaken diagnosis of Ebstein anomaly.

**NATURAL HISTORY**

The natural history of patients with dominantly stenotic tricuspid valve disease is usually determined primarily by the associated rheumatic mitral or aortic valve disease. No doubt, however, the increased systemic venous pressure, hepatomegaly, and peripheral edema accelerate deterioration of patients with rheumatic tricuspid stenosis.

Primary TR has an inherent tendency to progress, just as do other types of valvar regurgitation. However, the deleterious effects of ventricular volume overload on the right side of the heart are slower to develop than on the left. For example, in patients with traumatic TR who survive the initial trauma, regurgitation may be well tolerated for many months or years.\(^5\)\(^,\)\(^3\)\(^2\) Ultimately, however, symptoms develop as regurgitation increases; by 5 to 10 years after trauma, they are usually severe and incapacitating. In patients with acute tricuspid endocarditis caused by *S. aureus*, tricuspid vegetations greater than 1 cm in diameter (visualized by 2D echocardiography) worsen the natural history of TR.\(^5\) In a study of 60 patients with severe TR secondary to trauma, myxomatous change, or endocarditis, those who did not undergo operation had an increased risk of heart failure, atrial fibrillation, and death (Fig. 14-4). Functional (secondary) TR of severe degree is present in about 30% of patients with severe mitral regurgitation. If not surgically treated, the TR tends to progress, even after adequate treatment of the left-sided valvar lesion.\(^7\) The tendency for progression of TR related to anular size and other risk factors is also discussed in Chapter 11.

There is now increasing awareness of the potential deleterious effects of even moderate TR if left uncorrected at the first operation for mitral valve disease, especially if the tricuspid anulus is dilated. King and colleagues reported that 66% of patients returning for tricuspid valve procedures late after mitral valve replacement had only mild TR at the time of the initial valve operation.\(^3\)\(^7\) In this regard, preoperative echocardiography at initial operation is advisable to detect not only morphology and severity of TR, but also tricuspid anular size. Once the anulus dilates, its diameter does not spontaneously normalize. Typically, tricuspid anular dilatation is a progressive process that eventually leads to severe TR. The importance of a dilated tricuspid anulus in the genesis of severe TR is underscored by the study of Dreyfus and colleagues; they reported a dramatic reduction in late progression of TR by routinely performing tricuspid anuloplasty during surgery for...
left-sided valve lesions if the tricuspid anulus was greater than twice normal size. Thus, preoperative tricuspid anular dilatation is a predictor of late TR. Among patients with heart failure, approximately one third have moderate or severe TR, which is a predictor of reduced long-term survival (hazard ratio 1.3), and even more so when pulmonary hypertension is present.

### TECHNIQUE OF OPERATION

**Tricuspid Valve Anuloplasty**

**Anuloplasty Ring Technique**

Because isolated tricuspid valve disease is rare, the technique of operation is given for TR accompanying left-sided valve disease. When evaluation before cardiopulmonary bypass (CPB) indicates important TR, two venous cannulae are used. The tricuspid procedure may be performed in the beating, perfused heart during rewarming of the patient, with suction on the aortic vent needle after the left heart has been carefully de­aired, or during continuing antegrade/retrograde cold cardioplegia with addition of external cardiac cooling.

After the mitral procedure is completed, the right atrium is opened with the usual oblique incision (Fig. 14-5). When an anuloplasty is performed using a ring, length of the base of the tricuspid septal leaflet is measured with calipers, or area of the anterior leaflet with a sizer, and on this basis the proper­sized ring is selected. The Carpentier-Edwards anuloplasty ring, for example, is a modified oval corresponding to configuration of the tricuspid anulus, with a gap in the portion designed to overlie the atrioventricular (AV) node so that the conduction tissue is not compromised. It is unwise to select too small a ring in the belief that it will be more effective, because it distorts and narrows the orifice and may subsequently detach. Because tissues around the tricuspid valve are usually tenuous, sutures must take adequate bites, beginning in the atrial wall and passing into the deeper part of the anulus itself, carefully avoiding leaflet tissue. The surgeon must also be cognizant of the location and course of the right coronary artery, as its inadvertent suture ligation has been reported.

After discontinuing CPB and before decannulation, competence of the valve is assessed by 2D echocardiography, using either a handheld or esophageal probe. Presence of moderate or severe TR is an indication for valve replacement or repair. If the heart is beating and normothermic, a reasonable assessment of competence of the repair is possible as soon as it is completed. With the atrium still open, the RV is allowed to fill with blood, and the tricuspid leaflet apposition is assessed. If apposition is obviously inadequate, the valve is replaced or repaired. If it appears adequate, the right atrium is closed, air is aspirated from the RV and pulmonary artery, and the operation is completed in the usual manner (see “Completing Operation” in Section III of Chapter 2).

**Figure 14-5** Tricuspid ring anuloplasty. A, Exposure is through the usual oblique right atriotomy. Venous cannulae are inserted directly into superior and inferior venae cavae (for alternatives, see Chapter 2). B, Stay sutures provide excellent exposure (alternatively, a Cooley retractor may be used). The surgeon identifies anteroseptal tricuspid valve commissure, membranous part of atrioventricular septum, and coronary sinus orifice and can then mentally visualize location of the atrioventricular (AV) node and penetrating portion of the bundle of His. Using appropriate sizers, notched at points corresponding to the anteroseptal and posteroseptal commissures at both ends of the septal tricuspid leaflet, a proper­sized tricuspid anuloplasty ring is selected.
Chapter 14 Tricuspid Valve Disease

Figure 14-5, cont’d  C. The first stitch, of No. 2-0 or 3-0 polyester, is positioned exactly at the midpoint of the septal leaflet anulus, and only two further mattress stitches are needed for the septal portion of the ring. Small pledgets may be used on these mattress sutures. These and all other sutures are passed first through host tissue and then through the cloth of the undersurface of the ring, just as in suturing the ring for mitral anuloplasty (see Chapter 11). D, Five or six mattress stitches are needed in the portion of the anulus to be plicated, which is adjacent to the posterior leaflet, and these are passed through the cloth of the ring close together (marking stitches are present on the ring cloth to guide the surgeon). The remainder of the ring, corresponding to about half its circumference, is attached to the anulus at the base of the anterior cusp with, at most, four fairly widely spaced mattress sutures. The ring is lowered into position along the sutures and the sutures tied, with great care taken not to pull upward strongly on them, lest they tear out. In some cases the anuloplasty ring can be secured in place with three or four interrupted mattress sutures along the septal leaflet and then with continuous sutures for the remainder.

Bicuspidization Technique

An alternative technique is to shorten the circumference of the tricuspid anulus by simply excluding that part to which the posterior leaflet is attached. To accomplish this, a No. 2-0 or 3-0 polyester suture is passed through the anulus at the anteroposterior commissure, then at the center of the posterior leaflet, and then through the anulus at the posteroseptal commissure. The suture is tied snugly, and a second one is placed for reinforcement. Pledgeted mattress sutures also may be used. A further modification that incorporates a flexible strip into the posterior leaflet anuloplasty has been reported to be useful. The repaired tricuspid valve should have about a normal diameter (see “Dimensions of Normal Cardiac and Great Artery Pathways” in Chapter 1.)

De Vega Technique

The De Vega technique is used in patients with no more than moderate TR from anular dilatation, where it is anticipated that good long-term function is not dependent on integrity of the repair. This technique has the advantages of simplicity and low cost. A No. 2-0 polyester suture (not monofilament polypropylene) is passed in a counterclockwise direction as a circular stitch deeply into the junction of the anulus and right ventricular wall from 1 or 2 cm medial to the anteroseptal commissure to the base of the anterior leaflet 2 to 4 cm medial to the anteroseptal commissure (Fig. 14-6). The same suture is then reversed and passed in clockwise direction slightly peripherally to the first stitch back to the starting point. Separate pledgets of polyester felt are incorporated in the suture at each end to prevent its pulling through the tissues. The suture is tightened until the orifice will admit an appropriate sizer (24 to 30 mm) and is then tied.

Other Supplemental Techniques

Many of the techniques of mitral valve reconstruction have been applied to repair of TR, particularly in the setting of congenital heart disease. Partial or complete closure of accessory commissures, implanting artificial chordae, Alfieri edge-to-edge technique, and pericardial leaflet augmentation have all been described.

Tricuspid Valve Replacement

When tricuspid valve replacement is elected, the leaflets are excised, and a 2- to 3-mm fringe of leaflet tissue is left on the anulus (Fig. 14-7). Alternatively, the septal leaflet may be left in situ. Interrupted pledgeted mattress sutures are placed in the fringe of leaflet tissue along the area occupied by the
septal leaflet, to avoid damaging the AV node and bundle of His. Either a continuous polypropylene suture or interrupted pledgeted mattress sutures may be used for the remainder of the insertion. Alternatively, simple interrupted sutures may be used throughout. Infrequently, to avoid heart block, the suture line for valve insertion can be placed on the atrial aspect above the coronary sinus and base of the septal defect.

Tricuspid Valve Excision

In drug addicts with active tricuspid valve endocarditis, the three leaflets and their chordae tendineae can simply be excised, using the general techniques described earlier. However, postoperative convalescence and late cardiac performance are compromised by the resulting severe TR. In addition, later valve replacement is more difficult.

Stern and colleagues suggest that primary bioprosthetic valve replacement is preferable to valve excision and is not followed by recurrent endocarditis unless intravenous drug abuse continues.

Partial Tricuspid Valve Replacement with Cryopreserved Tricuspid Valve Allograft

Partial replacement of the tricuspid valve with a cryopreserved allograft is an attractive option for severe TR caused by endocarditis, because allografts are known to demonstrate greater freedom from reinfection compared with xenografts or mechanical valves in the aortic position (see Chapter 15). Shrestha and colleagues from Brisbane, Australia, reported favorable outcomes in 13 patients (three late reoperations) using tricuspid valve allografts for tricuspid endocarditis.

SPECIAL FEATURES OF POSTOPERATIVE CARE

Long-term anticoagulation is needed when a mechanical valve has been used or if there is an additional mechanical prosthesis in either the mitral or aortic position. Warfarin
Figure 14-7  Tricuspid valve replacement. A, Exposure is as for repair. All three leaflets of the tricuspid valve are excised, leaving a cuff at the base of the septal leaflet 5 to 8 mm wide. Alternatively, the septal leaflet may be left in situ. B, Starting at the midpoint of the septal leaflet cuff, interrupted horizontal mattress sutures buttressed with felt pledgets are placed first into remaining valve tissue and then through the sewing ring of the replacement device. C, After placing four to five interrupted mattress sutures, remainder of the insertion is completed using a continuous suture technique. Bites may be through the anulus, mindful that the right coronary artery lies deep to the anulus anteriorly. Alternatively, interrupted sutures can be used circumferentially. Key: AV, Atrioventricular.
administration is begun on the evening of postoperative day 1 (see “Special Features of Postoperative Care” in Chapter 11). If a bioprosthesis is used and has also been used for all other valves replaced, long-term anticoagulation is controversial.

Because of the risk of complete heart block in the latter part of the hospital stay, electrocardiographic monitoring should be continued until a stable rhythm is established at an adequate heart rate.

Fluid retention is prominent among patients with tricuspid valve disease. Characteristically, their postoperative care requires aggressive use of diuretic agents.

RESULTS
Tricuspid Valve Anuloplasty

Symptom Relief
Assessing the clinical benefit of tricuspid anuloplasty in the setting of concomitant mitral valve surgery is confounded by the favorable impact of relieving mitral valve stenosis or regurgitation. The symptomatic benefit can be more directly evaluated in patients undergoing isolated tricuspid valve surgery. In a study of 60 patients with flail tricuspid valve leaflets, symptomatic improvement occurred in 88% of those who underwent tricuspid valve repair or replacement.\(^{15}\)

Survival
Because tricuspid anuloplasty is rarely performed as an isolated procedure, its effect on early and late survival is difficult to assess directly. In patients with isolated TR from trauma or endocarditis, reported surgical mortality is low.\(^{15}\) In combined operations including tricuspid anuloplasty, early mortality can be similar to that of operations in which tricuspid anuloplasty was not required.\(^{15}\) However, end-organ damage from long-standing right heart failure increases the risk of operation. When right heart failure is severe enough to cause liver damage, the Model for End-Stage Liver Disease (MELD) score has been applied as a predictive model for operative mortality in combined procedures that include tricuspid anuloplasty.\(^{14}\) By multivariable analysis, a MELD score of 15 or greater was strongly predictive of increased mortality (hospital mortality of 19% with MELD score of \(\geq 15\) vs. 6% with score <15). Intermediate-term survival may be compromised by persistence of important RV dysfunction that often accompanies severe TR (see “Mitra Valve Surgery with Coexisting Tricuspid Valve Disease” in Chapter 11). An analysis by Singh and colleagues\(^{11,12}\) indicates that anuloplasty is an independent predictor of better 10-year survival compared with tricuspid valve replacement for organic disease.

Tricuspid Valve Competence
Anuloplasty of the tricuspid valve results in valvar competence in most patients. Freedom from moderate or severe recurrent TR in 98 patients receiving anuloplasty (mostly Carpentier rings) was 85% at 6 years.\(^{15}\) Carpentier and colleagues found that with use of the Carpentier ring, mild or less TR was present late postoperatively in more than 90% of patients with preoperative moderate or severe regurgitation.\(^{15}\) Long-term relief of TR by use of anuloplasty rings has been confirmed by postoperative 2D echocardiography with Doppler color flow mapping.\(^{13}\)

Kay and colleagues have also reported satisfactory results in a sizable group of patients after suture bicuspidization anuloplasty.\(^{14,15}\) Experience with the De Vega anuloplasty has also provided good results, confirmed in larger series by echocardiography.\(^{11,12,15}\)

However, there are established risk factors for persisting TR after repair. Recurrence is more likely when mitral disease progresses or severe pulmonary hypertension persists\(^{11}\) (see “Mitral Valve Surgery with Coexisting Tricuspid Valve Disease” in Chapter 11). Duran and colleagues found that when functional TR was repaired, 31 of 35 patients (89%; CL 80%-94%) with low late postoperative pulmonary vascular resistance (<6 units · m\(^{-2}\)) had no regurgitation, whereas this was true of only 6 of 14 patients (43%; CL 27%-60%) with high pulmonary vascular resistance \((P = .001).\(^{12}\)

Tethering of the tricuspid valve leaflets is a risk factor for early recurrent TR, and depressed right or left ventricular function predict later TR recurrence.\(^{12,13}\) Other factors increasing the risk of late TR recurrence include higher preoperative TR grade, depressed left ventricular function, and permanent pacing leads through the tricuspid valve. In a study of pacemaker leads remaining across the tricuspid valve following anuloplasty repair, 42% of patients had severe TR at 5 years, twice the prevalence of those without such leads.\(^{11,14}\) The relationship between anuloplasty technique and outcome is discussed in text that follows (see “Techniques of Operation, “Selection of Anuloplasty Technique and Choice of Device”).

Reoperation
Reoperation for tricuspid valve dysfunction is infrequent following Carpentier ring anuloplasty, with 97% of this group being free of reoperation 3 years postoperatively.\(^{15}\) Nakano and colleagues reported that after suture anuloplasty for important functional tricuspid regurgitation, 94% of patients were free of reoperation 10 years later, as were 70% 17 years later.\(^{15}\) Usually, redeveloped TR is associated with persisting or developed pulmonary hypertension. Because persisting severe TR appears to be a marker for underlying advanced myocardial and valvar heart disease, reoperations for recurrent TR are generally high-risk procedures, with hospital mortality of up to 35%.\(^{12}\)

Functional Status
Functional status as assessed by New York Heart Association (NYHA) functional class is usually improved by tricuspid anuloplasty.\(^{11}\)

Tricuspid Valve Replacement

Survival
Early mortality for tricuspid valve replacement with or without double or triple valve surgery is currently about 2% to 10%,\(^{13,20}\) less than in earlier years (see “Risk Factors for Premature Death after Tricuspid Valve Surgery” later in this chapter); however, mortality may exceed 25% in patients in NYHA class III or IV, those having repeat operations, or those with complex congenital heart disease.\(^{13}\) Of importance, a propensity analysis indicated no important differences in early and late survival among patients undergoing tricuspid valve repair versus replacement.\(^{11}\) Thus, the surgeon should not hesitate to consider valve replacement...
Mode of Premature Late Death
Following tricuspid valve surgery, most late deaths are related to advanced RV dysfunction or arrhythmias. Endocarditis and stroke are uncommon modes of death, as are recurrent moderate or severe tricuspid stenosis or regurgitation resulting from malfunction of the replacement devices or failed anuloplasty. Thus, among 284 patients followed over nearly 10 years (combined GLH-UAB), prevalence of these complications was similar after either tricuspid valve repair or replacement and accounted for 9 (11%; CL 8%-16%) of the late deaths, or 3.2% of the entire group (CL 2%-5%).

Complete Heart Block
Complete heart block occasionally develops late after tricuspid valve replacement, usually with associated mitral valve replacement. This association is undoubtedly related to the position of the AV node between the two replacement devices. In all, approximately 10% of patients undergoing both tricuspid and mitral valve replacement require insertion of a pacemaker late postoperatively because of heart block, and up to 10 years postoperatively the prevalence is 25%. Late heart block is rare among patients undergoing tricuspid valve replacement as an isolated procedure. Late development of complete heart block is also uncommon after tricuspid anuloplasty.

Thromboembolism
Pulmonary embolization is a rare complication of tricuspid valve surgery. Only 1 of 103 patients had probable large pulmonary emboli on follow-up (UAB), and the origin of that embolus was uncertain.

Thrombosis
After tricuspid valve replacement, thrombosis may occur, more often of mechanical devices than of bioprostheses. The older types of mechanical prostheses (Smelloff-Cutter, Bjork-Shiley) apparently had a greater risk than present bileaflet valves. The linearized thrombosis rate in Van Nooten’s series of 146 tricuspid replacements was approximately 1% per patient-year. In an Italian study of 43 patients undergoing tricuspid valve replacement with a variety of mechanical prostheses, actuarial freedom from valve thrombosis was greater than 80% at 10 years. Initial thrombolytic treatment using streptokinase may relieve obstruction in many cases. Hurrell and colleagues have reviewed the efficacy of thrombolytic therapy for all valve positions, and this approach seems particularly effective for prostheses in the tricuspid position (Table 14-1). Currently, thrombolysis is considered the first line of therapy for tricuspid valve thrombosis, in contrast to left-sided valve thrombosis, in which risk of systemic and cerebral emboli is increased.

Streptokinase is administered as in treatment of acute myocardial infarction: 1 million units over 45 to 60 minutes optionally followed by 150,000 units · h⁻¹ for 4 to 6 hours. Alternatively, urokinase may be infused intravenously at 50,000 to 150,000 units · h⁻¹ for up to 24 hours. Allergy to streptokinase is manifested by hypotension and fever. An unusual reaction to urokinase is severe rigor.

Functional Status
Late functional status of patients undergoing tricuspid valve surgery is influenced more by the multivalvar nature of most of the procedures than by the tricuspid repair or replacement itself. Nonetheless, most patients are considerably improved by the surgical procedure. Thus, in the GLH-UAB follow-up group, 42% of 103 patients were in NYHA class I late postoperatively. This is more impressive when it is realized that of these, 34 were preoperatively in class IV, 62 in class IV, and 6 in class III. In both series, less than 15% were in class IV late postoperatively.

Symptoms of Systemic Venous Hypertension
Most patients remain free of systemic venous hypertension late postoperatively. However, peripheral edema and hepatomegaly, with or without ascites, are common at follow-up. These symptoms could be the result of functional or organic obstruction of the tricuspid replacement device, residual left-sided cardiac failure with or without left-sided valvar disease, or important residual pulmonary hypertension (high pulmonary vascular resistance) or residual RV dysfunction. In this regard, Silver and colleagues reported higher right atrial pressures after tricuspid valve replacement than before in patients with Ebstein anomaly, but they also noted marked symptomatic improvement in cardiac function.

Overall success of thrombolytic therapy was 84%. Success for right-sided valves (88%) was similar to that for left-sided valves (83%; p = .4). From Hurrell and colleagues.

*bBased on patients (n) with reported follow-up.

When anatomic substrate is suboptimal for repair. No survival difference has been demonstrated between mechanical and bioprosthetic tricuspid valves. Survival at 10 years is approximately 55% to 60%, including hospital deaths. Most of these patients have multivalvar disease, and tricuspid valve failure is seldom the dominant factor in late death. Predictors of late mortality after tricuspid valve replacement include older age at operation, poor left or right ventricular function, endocarditis, preoperative stroke or renal failure, and concomitant mitral valve surgery.

*Class V is cardiogenic shock or hemodynamic instability requiring emergency operation. This class augments the usual NYHA class IV, based on the observation of the UAB group that this subgroup of class IV was generally at higher risk than patients simply confined to bed. The Society of Thoracic Surgeons National Cardiac Database classifies this as emergency salvage.
Performance of Replacement Devices

Both porcine and pericardial bioprostheses have performed well in the tricuspid position. Small gradients of 4 to 10 mmHg exist across stent-mounted xenografts in the tricuspid position (Table 14-2). In general, however, prostheses with an internal diameter of at least 27 mm do not exhibit clinically important gradients. Bioprosthetic valves seem to degenerate at about the same rate and with the same age-related occurrence in the tricuspid position as they do in the mitral and aortic positions (see “Reoperation” under Mitral Valve Replacement and Results in Section I of Chapter 11; see also “Central Leakage” under Replacement Device Regurgitation in Chapter 12), although studies by Cohen and colleagues and Ohata and colleagues suggest that freedom from degeneration may be somewhat greater in the tricuspid position than in the mitral position. Although Nakano reported 100% freedom from structural degeneration at 9 years, pannus formation on the ventricular side of the cusps was a frequent finding by echocardiographic analysis in patients with at least 5 years of follow-up.

The Starr-Edwards ball valve mechanical prosthesis and the Bjork-Shiley mechanical prosthesis have performed well in the tricuspid position. The St. Jude Medical valve (and other bileaflet valves) appears also to exhibit good hemodynamic performance in the tricuspid position; Singh and colleagues reported diastolic gradients of 2 mmHg or less in seven patients.

Reoperation

Most patients who have undergone tricuspid valve replacement are free of reoperation up to 10 years later. Of those receiving mechanical or xenograft valves at UAB, 96% were free from tricuspid reoperation at 5 years, and 89% at 9 years. In McGrath’s series of 530 patients having a procedure involving the tricuspid valve, freedom from reoperation was 26% at 15 years. However, because of the competing risk of 81 late deaths, cumulative incidence of reoperation was 59% at 15 years (see “Competing Risks” under Time-Related Events in Chapter 6).

Tricuspid Valve Excision

Survival

An early mortality of 12% was reported among drug addicts after excision without replacement of the tricuspid valve. Late survival in such patients exceeded 60% at 15 years, with death due to return to drug addiction and not to right-sided endocarditis.

Hemodynamic Status

After excision of the tricuspid valve, the expected hemodynamic state develops. Cardiac murmurs are usually absent, but hepatomegaly with systolic pulsation is often present. Jugular venous pulsations with prominent v waves are universal as a result of the dramatic increase in right atrial pressure during systole.

The volumes of the right atrium and RV are considerably increased within a few months of tricuspid valve removal. The atrial septum shifts to the left with each ventricular systole, and the left atrium is compressed. The deleterious effects of RV remodeling are generally progressive, but the point of irreversibility has not been defined. Tricuspid valve replacement has induced substantial reverse remodeling of the RV as long as 21 years after tricuspid valve excision.

Functional Status

Most young patients are in NYHA functional class II for at least several years. Ankle edema and mild exercise intolerance are noted in about half the patients. Hemodynamic and functional states begin to deteriorate progressively after about 5 years, often in association with troublesome substernal fullness, which is worse in the recumbent position.

Risk Factors for Premature Death after Tricuspid Valve Surgery

A general understanding of the results of tricuspid valve surgery per se, especially of the risk factors for surgical failure, is difficult to obtain because of the relative infrequency of these operations, variety of operations, numerous concomitant procedures, and heterogeneity of the patient population. It is possible to have low hospital mortality across all components of this heterogeneity, but this has not been the experience universally.

Tricuspid valve excision without replacement is clearly a risk factor for a poor early and long-term result. The need for tricuspid anuloplasty and replacement, particularly the latter, has been associated with an increased risk of early death in multivalvar disease (see “Mitrail Valve Surgery with Coexisting Tricuspid Valve Disease” in Chapter 11). However, early mortality after these combined procedures need not necessarily be determined by the tricuspid procedure.
Multivariable analysis of risk factors for both early and late deaths indicates that neither repair nor replacement is associated with a greater risk than the other; type of replacement device (allograft, mechanical, bioprosthetic) was not a risk factor.\textsuperscript{M7}

Older age has been a risk factor for death early and late after operation,\textsuperscript{B1} as has preoperative functional disability, as reflected in NYHA class, particularly when the disability was severe\textsuperscript{T5} and associated with cardiomegaly.\textsuperscript{B3,B4} Prior valve surgery was also a risk factor for premature late death.

**INDICATIONS FOR OPERATION**

Selection of Anuloplasty Technique and Choice of Device

*Tricuspid Regurgitation*

When isolated severe TR is present, operation is indicated. This should be anuloplasty rather than replacement unless competence cannot be achieved. In intravenous drug users with endocarditis, simple valve excision may suffice, but tricuspid valve replacement is preferred over total excision; partial valve excision and reconstruction can be considered for less extreme valvar destruction.\textsuperscript{N5} (Indications for operation in functional tricuspid regurgitation associated with mitral valve disease are discussed in detail under “Mitral Valve Surgery with Coexisting Tricuspid Valve Disease” in Chapter 11.) Because most tricuspid procedures are performed to accompany left-sided valve operations, the left-sided hemodynamics usually determines indications for operation. However, because NYHA class IV, severe heart failure, high mean pulmonary artery pressure, and icterus are incremental risks for mortality when a tricuspid procedure is done, intervention early rather than late in multiple valve disease is prudent.\textsuperscript{P4,V1} The general American College of Cardiology/American Heart Association Guidelines for surgical management of TR are listed in Box 14-1. In patients with severe TR secondary to pulmonary hypertension, the current standard treatment is vasodilator therapy and diuretics.

When important TR occurs late after mitral valve replacement, the outlook after tricuspid valve surgery is less optimistic. Five-year survival after subsequent operation is only 44%, and most patients who fail to survive have little or no symptomatic improvement from the tricuspid valve procedure.\textsuperscript{E7} Despite an early mortality of about 9% and important symptomatic improvement in most patients, Staab and colleagues reported event-free survival of only 42% at 5 years.\textsuperscript{S15} This suggests the frequent presence of severe and irreversible RV failure in such patients. Thus, TR after previously adequate mitral valve operation is an uncommon indication for tricuspid valve operation.

*Choice of Anuloplasty Technique*

Several longitudinal studies indicate that severe TR is more likely to return after the De Vega and suture plication techniques than after use of anuloplasty rings. The impact of anuloplasty technique on freedom from reoperation was analyzed by McCarthy and colleagues.\textsuperscript{M5} “Non-ring” anuloplasties (De Vega and Peri-Guard) were less effective than anuloplasty rings in preventing late TR after mitral valve repair for degenerative disease. The same advantage of prosthetic ring anuloplasty over non-ring techniques was demonstrated in rheumatic mitral and tricuspid valve surgery.\textsuperscript{B6}

Similar findings were reported by Tang and colleagues\textsuperscript{T3} and Navia and colleagues.\textsuperscript{N6} Although some surgeons have reported good results with bicuspidization or modified De Vega techniques,\textsuperscript{N5} a ring anuloplasty clearly provides more durable protection against recurrent or progressive TR. The durability of bands\textsuperscript{M6} or pericardial strips\textsuperscript{S5} is probably intermediate between these two techniques.

In a longitudinal study by Tang and colleagues, use of an anuloplasty ring (vs. a DeVega suture anuloplasty) was an independent predictor of better survival (hazard ratio 0.7) and event-free survival at 6 years.\textsuperscript{T2}

Thus, suture plication techniques should probably be reserved for mild anular reductions in the setting of moderate TR in which repair of the left-sided valve lesions is expected to favorably impact functional TR. Rigid or flexible rings or bands are preferable to bicuspidization or De Vega techniques if major anular reduction and durability are required.

In view of the high risk of recurrent TR if pacemaker leads are left across the tricuspid valve, consideration should be given to replacing such leads with an epicardial lead at the time of tricuspid valve repair.

*Choice of Replacement Device*

In no other valve position is the choice between durability of a mechanical prosthesis and lack of thrombogenicity of a xenograft more apparent. It can be argued that younger patients with a better prognosis should receive a low-profile mechanical device, and older patients a xenograft.\textsuperscript{V1} Nakano and colleagues report satisfactory valve performance using an inverted Carpentier-Edwards pericardial valve (Fig. 14-8).\textsuperscript{N1}
Others prefer porcine xenografts for all patients despite a 10% to 40% prevalence of structural deterioration within 7 to 10 years. In all cases a large device (27 mm or larger) should be implanted. There is no evidence favoring use of a xenograft in the tricuspid area when mechanical prostheses are implanted on the left side, and vice versa.

DEFINITION

Infective endocarditis includes conditions in which structures of the heart, most frequently the valves, harbor an infective process that leads to valvar dysfunction, localized or generalized sepsis, or sites for embolism (Box 15-1). The term infective endocarditis (IE) includes acute, subacute, and chronic processes; infection of bacterial, viral, rickettsial, or fungal etiology; and involvement of either native or prosthetic valves. As such, the term has no implication as to duration of the processes, infecting agent, or site of infection and thus supplants previously used terms such as “subacute bacterial endocarditis.”

HISTORICAL NOTE

In 1806, Corvisart described mitral valve vegetations found at autopsy in a 39-year-old man. In their 1824 book on heart disease, Bertin and Bouillaud discuss induration and vegetations on the valves of patients dying with endocarditis. The term endocarditis was introduced by Bouillard in 1841 when he described clinical and pathologic features of the disease. Earlier, Morgagni, Lancisi, and Sandifort had described hearts with probable endocardial vegetations. Weinstein and Bruschi reported that in 1886, Wyssokowitch and Orth designed an experimental model for endocarditis in which aortic valve cusps of animals were traumatized and the animals subsequently injected with bacterial suspensions from patients with endocarditis. The animals developed murmurs, embolic complications, and valve lesions at autopsy.

At the 1885 Gulstonian Lecture, Osler described the classic features of endocarditis. By 1909, he had refined his understanding of the pathologic anatomy (“proliferative vegetations”) and introduced the clinical finding of changing murmurs. Along with Horder, Osler emphasized the role of blood cultures for diagnosis.

Successful treatment of endocarditis lagged behind pathologic and clinical descriptions. In the 1940s, the era of sulfas, cure was achieved in about 5% of patients. By 1950, however, principles of antibiotic therapy had been established, including high-dose penicillin, long duration of treatment, and antibiotic suppression. It was also recognized at that time that delay in treatment, heart failure, advanced age, and preexisting rheumatic valvulitis were adverse prognostic factors. In 1940, Tauroff and Vessell successfully ligated a patent ductus arteriosus in treating a 2-year-old female with endocarditis. In 1957, Bahnon and colleagues reported occurrence of staphylococcal infection on silk sutures used for great vessel and intracardiac repairs.

Direct surgical treatment of IE began in 1961, when Kay and colleagues reported successful treatment of Candida endocarditis of the tricuspid valve. The native valve was debrided and an accompanying ventricular septal defect (VSD) closed. The first report of replacing a cardiac valve for native IE was published in 1965 by Wallace and colleagues. Their patient was a 45-year-old man who had severe aortic regurgitation with heavy Klebsiella vegetations on each cusp. He was treated intensively with antibiotics over 3 weeks, but there was resistant active infection and heart failure. Valve replacement was successful, eradicating the infection and restoring satisfactory hemodynamics.

In 1972, Merendino’s group from the University of Washington reported the collective results of cardiac operations for endocarditis in 139 patients, 24 of whom were treated by mitral valve repair, mechanical prosthetic mitral replacement, and replacement of the aortic valve with...
β-propiolactone–sterilized allografts; 17 of 24 patients survived. The report emphasized continuing sepsis and heart failure as indications for operation, compared native (“primary”) to prosthetic (“secondary”) valve endocarditis, and differentiated between active and healed lesions.

Most of the modern concepts of surgical treatment of IE were articulated by the late 1970s and reviewed in publications by Stinson and by Richardson and colleagues. 

### Pathogenesis and Morphology

#### Pathogenesis

The most common site of cardiac involvement is on the line of closure of a valve surface, typically on the atrial side of atrioventricular valves and on the ventricular surface of semilunar valves. Once bacteria become attached to the surface, the vegetation matures through bacterial proliferation and fibrin deposition. The preponderance of bacteria below the surface of the vegetation provides protection from phagocytes and high antibiotic concentration.

Several predisposing factors have been identified that may contribute to or be responsible for development of IE. Despite Osler’s initial observations, valvulitis of rheumatic fever was often confused histologically with IE. However, unlike rheumatic valvulitis, IE is not characterized in its early stages by global neovascularization or global inflammation of valve cusps. In most cases, the valvar endocardial surface must be altered to allow deposition of fibrin and platelets and subsequent attachment of bacteria. This injury may result from preexisting valvar lesions such as rheumatic valvulitis, anular or valvar calcification, or catheter trauma. Hemodynamic factors may contribute, such as the jet effect of blood flow through a patent ductus arteriosus or restrictive VSD, mitral valve prolapse, or bicuspid aortic valve. Bacteremia must occur in bacterial-based IE. Frequent transient bacteremias are found in 60% to 80% of normal individuals, but the number of organisms is small, and without the presence of one or more of the above factors, infection and vegetations do not result.

Several lines of evidence have demonstrated the importance of a compromised or altered immune system in the pathogenesis of IE. Histopathologic analysis of kidney tissue in patients with IE may reveal diffuse proliferative glomerulonephritis, with evidence of deposition of immunoglobulin (Ig)G and IgM. Circulating immune complexes (CICs) may be found in the glomerular basement membrane, retina, and peripheral lesions (Roth spots and Janeway lesions). Various manifestations of complement activation have been found in IE. Hooper and colleagues identified CICs in patients with prosthetic valve endocarditis (PVE). Kauffmann and colleagues found a positive correlation between CIC levels and duration of illness, and several investigators have noted a decline in CIC levels with successful treatment.

Staphylococcus aureus binds to porcine valvar endothelial cells by a mechanism that is specific and receptor mediated. This characteristic most likely represents a specific physicochemical interaction between microbial adhesins and a host-cell receptor that involves fibronectin lipoteichoic acid. IE involving a previously normal valve is often caused by S. aureus.

In several studies, one quarter of IE cases occurred on normal valves. Likely organisms are those that have increased adhesion molecules noted on dextran polymerization, namely Staphylococcus, Streptococcus viridans, and Enterococcus. Common risk factors are presence of overwhelming sepsis, resuscitation from shock, use of long-term indwelling catheters, intravenous (IV) drug abuse, and fungemia associated with prolonged antibiotic therapy. Only about 5% of patients with catheter sepsis are found to have IE, and this is generally due to staphylococcal organisms. Intravenous IE most often occurs in patients undergoing

### Definitions

**Endocarditis**: Exudative and proliferative inflammatory alterations of the endocardium, characterized by vegetations on the endocardial surface or within the endocardium. It may occur as a primary disorder (infective endocarditis) or as a complication of or in association with another disease (e.g., lupus erythematosus, rheumatic heart disease). **Infective endocarditis**: Invasion and multiplication of microorganisms on the endocardial surface, within the endocardium, within the myocardium, or on prosthetic materials within and around cardiac structures. It includes conditions in which structures of the heart, most frequently the valves, harbor an infective process that leads to valvar dysfunction, localized or generalized sepsis, or sites for embolism. The term covers:

- Acute, subacute, and chronic processes
- Infection of bacterial, viral, rickettsial, or fungal etiology
- Involvement of either native or prosthetic valves (or other prosthetic material)

**Acute endocarditis**: A severe form of infective endocarditis caused by virulent pyogenic microorganisms such as hemolytic streptococci or staphylococci. It can become life threatening within days.

**Subacute endocarditis**: A form of infective endocarditis that develops subtly over a period of weeks to several months. It may produce symptoms for months before heart valve damage or emboli make the diagnosis clear. It is usually caused by *Streptococcus viridans* or *Streptococcus fecalis*.

**Active endocarditis**: A surgical term indicating an operation carried out in the presence of obvious local cardiac infection manifested by inflammation, active vegetations, abscesses, burrowing sinuses, or fistulae. If such an operation is carried out while a patient is being treated with antibiotics for active infection, or has been treated within 2 weeks of operation, the disease is considered active.

**Healed endocarditis**: A surgical term indicating an operation carried out in the absence of obvious local cardiac infection and inflammation, generally following treatment and supposed eradication of microorganisms. It is characterized by lack of local inflammation; vegetations may be present but are generally endothelialized, and abscesses have resulted in well-defined and stable cavities, including sinuses and fistulae.

**Native valve endocarditis**: Infectious endocarditis involving a patient’s own (native) heart valve.

**Prosthetic valve endocarditis**: Infectious endocarditis involving a surgically implanted prosthetic heart valve. Prosthetic valve endocarditis and its abbreviation PVE are familiar, standard, and historical designations for infective endocarditis on any heart valve substitute, but “prosthetic” is at times a misnomer (e.g., infection of a pulmonary autograft). A more appropriate term is replacement device endocarditis, but in this chapter the historical term is maintained for the sake of familiarity.

**Iatrogenic IE**: Complications of, or in association with, another disease (e.g., overgrowth of indwelling catheters, intravenous [IV] drug abuse, and fungemia associated with prolonged antibiotic therapy).

**Enterococcus**: Common risk factors are presence of overwhelming sepsis, resuscitation from shock, use of long-term indwelling catheters, intravenous [IV] drug abuse, and fungemia associated with prolonged antibiotic therapy. Only about 5% of patients with catheter sepsis are found to have IE, and this is generally due to staphylococcal organisms.

**Intravenous IE**: Most often occurs in patients undergoing
chronic hemodialysis who have frequent staphylococcal bacteremias and also may have sclerotic aortic or mitral valves. It has long been acknowledged that usual bacterial vegetations of IE can result from seeding of a platelet-thrombin nidus after mechanical trauma. Garrison and Freedman produced endocarditis in rabbits by inserting a catheter into the endocardium and injecting bacterial isolates from humans with endocarditis. \(^{61}\) This model remains the principal experimental paradigm for the mechanical basis of IE.

Perhaps the most persuasive hypothesis for the pathogenesis of IE has been put forward by Rodbard.\(^{64}\) Basically, high-velocity jets of blood from a high-pressure source form at an orifice and enter a low-pressure sink. Venturi currents deposit bacteria immediately beyond the orifice to form vena contracta and result in mechanical erosion and deposition of platelets and thrombin (Fig. 15-1). These mechanical conditions exist beyond stenotic valves, on the pulmonary artery opposite a patent ductus arteriosus (Fig. 15-2), and on the left atrial aspect of a regurgitant mitral valve. Because most IE lesions of the aortic valve begin on the ventricular aspect, however, this suggests a role for valvar regurgitation in the pathogenesis of these lesions, and the Venturi effect would also apply (Table 15-1).

The abnormal endocardial and endothelial surfaces and increased turbulence imparted by numerous cardiac malformations create a substrate that is vulnerable to infection. The risk of infection associated with various cardiac abnormalities is reflected in the American Heart Association recommendations for prophylactic antibiotics in patients with such malformations.

**Morphology**

Usual sites for IE found at operation in patients with native valve endocarditis (NVE) not related to IV drug use are shown in Fig. 15-3. Vegetations and erosive cavities are on the ventricular aspect of the aortic valve cusps and at the base of the atrial aspect of the mitral valve leaflets, often resulting in separation or discontinuity at the ventriculoarterial or atrioventricular junction. Less often, discrete perforations caused by isolated vegetations are located on the aortic cusps themselves. Occasionally, “drop lesions” from the aortic valve occur on the anterior mitral leaflet or the tensor apparatus of the mitral valve.

In the vast majority of non–drug-related cases of NVE, valve deposits are left-sided. In IV drug–related IE, the tricuspid valve is involved in about half the cases and aortic or mitral valves in the remainder.\(^{64}\) Perianular pseudoaneurysms (abscesses) are more frequently associated with aortic than with mitral vena contracta endocarditis and occur in about one third of cases studied by transesophageal echocardiography (TEE); *S. aureus* is the predominant organism.\(^{79}\) Clinically, presence of pericarditis, rapid progression of symptoms, and a high degree of atrioventricular block are associated with perianular abscess.\(^{85}\)

In PVE, all or most vegetations are on the ventricular aspect of the prosthesis. Only a small area of sewing-ring detachment may be apparent and may appear sterile. At operation, therefore, a thorough search must be made beneath the prosthesis for the bulk of the pathologic process. As noted in some series, there may be important detachment without apparent vegetations; this may occur in either the presence or absence of positive blood cultures.\(^{11}\) This represents PVE and requires replacement of the prosthesis.

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

Infective endocarditis is present when defined in accordance with New York Heart Association (NYHA) criteria\(^{82}\): positive blood cultures associated with either new or changing murmurs or embolic phenomena; or new or changing murmurs in a patient with a congenital cardiac anomaly or prior valve damage, associated with either embolic phenomena or sustained fever, anemia, and splenomegaly. Most authorities accept a modification of that definition to include progressive heart failure in the presence of positive blood cultures. In an effort to improve specificity and sensitivity for the diagnosis of IE, investigators at Duke University have
The most common clinical manifestation of IE is fever, which is present in 95% to 100% of patients. This applies to both NVE and PVE. The fever may be low grade or spiking and generally follows peaks of bacteremia by about 2 hours. Patients at risk for IE who develop unexplained fever for more than 48 hours should have two or more sets of blood cultures drawn from different sites. Because of the importance of proper identification of the offending organism, administration of antibiotics should be delayed until blood cultures have been obtained.

Positive blood cultures are obtained in about 95% of patients even when right-sided endocarditis, endocarditis caused by fungus, endocarditis in addicts, and endocarditis caused by fastidious organisms are included.

In IE cases confirmed by echocardiographic, autopsy, or operation, positive blood cultures are obtained in 95% of cases with two blood specimens and in 98% with four specimens. However, occurrence of negative-culture endocarditis rises to about 10% in most surgical series, and PVE predominates in this group of patients.

Culture-negative IE is more likely with intracellular or fastidious organisms, or with previous antibiotic therapy. A history of antibiotic therapy or serologic evidence of Mycoplasma or Chlamydia species is likely responsible for negative-culture IE. Other causes include Candida, Aspergillus, and fastidious slow-growing organisms such as Q-fever (Coxiella burnetii) and Bartonella organisms.

A heart murmur is found in about 85% to 95% of IE patients. Changing murmurs occur much less frequently (≈15% to 20%). Although the concept of changing murmurs has been classically associated with IE since Osler’s Gulstonian Lecture in 1885, clinically changing murmurs are not often appreciated. Ten percent of IE patients lack murmurs, particularly those with tricuspid involvement. Infection involving the aortic valve and root is often characterized by a relatively short diastolic murmur. There may be a murmur only in early systole or mid-systole, although murmurs are often obscured by tachycardia. The murmur of mitral regurgitation caused by IE is similar to that of other mitral regurgitation murmurs and may exhibit a typical radiation posteriorly when the anterior leaflet is perforated. There also may be signs of mitral stenosis secondary to obstruction by large vegetations, in which case the murmur may be diastolic.

Pulse pressure may be normal or even narrowed in aortic regurgitation if IE is acute or important heart failure exists. Narrowed pulse pressure is caused by high left ventricular end-diastolic pressure with low cardiac output. There is frequently a gallop rhythm.

Infection of the mitral valve and its supporting structures is considered to be less frequent than aortic valve endocarditis, but may be more indolent in its course. The mitral valve is most commonly involved (~40% of cases), followed by the aortic valve in about 36%, when S. aureus is the infecting organism. Right-sided endocarditis is almost uniquely related to the tricuspid valve. Right-sided IE accounts for about 10% of IE cases and usually occurs in the setting of IV drug abuse. Affected patients tend to be younger and have fewer comorbidities and less structural heart disease than patients with left-sided IE. Right-sided lesions are associated with fever, but often a cardiac murmur is initially absent.

Anemia frequently occurs in IE patients and has multifactorial causes, but primarily it results from marrow suppression secondary to chronic disease. Arthritis and arthralgias are infrequently seen today, generally because endocarditis is diagnosed earlier. Myalgias are common and may be associated with bacteremia or occasionally may result from myocardial microabscesses, generally occurring in staphylococcal bacteremia.

Severity of heart failure in a hospitalized IE patient is not appropriately classified by NYHA functional class. In general, heart failure can be termed mild when only small doses of diuretic or digitalis are necessary; moderate when large doses

of diuretic, afterload-reducing medications and bed rest are necessary; and severe when cardiogenic shock is present and inotropic agents are needed.

Embolization is the presenting manifestation in about 10% to 15% of patients with left-sided IE, and about half of patients with IE have evidence of embolic phenomena on physical exam or via diagnostic imaging. These emboli seem about evenly distributed between cerebral and peripheral sites. Classic peripheral signs of endocarditis—Osler nodes, Janeway lesions, Roth spots, petechiae, and clubbing—are late manifestations and are infrequently seen in a surgical practice. The one exception may be Janeway lesions, and when noted, the infecting organism is almost always Staphylococcus.

In practice, diagnosis of IE is primarily based on two tests: blood cultures and echocardiography. The diagnosis is made most often by the presence of positive blood cultures and a cardiac lesion characterized by new stenosis, new regurgitation, or echocardiographic evidence for a vegetation. There are many more individuals with sepsis and positive blood cultures but without cardiac manifestations, and they are not considered to have IE.
An excellent microbiology laboratory is essential for accurate and prompt diagnosis. With current techniques, ability to culture fastidious organisms (e.g., Q-fever [Coxiella burnetii], Mycoplasma) is high. Thus, diagnosis of IE involving cardiac valves or congenital malformations is made on a constellation of findings, usually fever, positive blood cultures, and hemodynamic derangement within the cardiac structures that is best assessed and followed by echocardiography.

Echocardiography has become a standard modality for diagnosis and continuing observation of patients with IE. In all situations, TEE has greater sensitivity and specificity than transthoracic echocardiography (TTE). Specificity for TEE is approximately 90% and sensitivity 95%. For TTE, accuracy ranges from 40% to 80%. These figures apply equally to NVE and PVE. Perivalvar or perianular cavities associated with prosthetic valves are more easily delineated with TEE, and in the view of some authorities, these represent pseudoaneurysms rather than abscess cavities in most patients. Box 15-3 summarizes the echocardiographic and clinical findings in IE that indicate the potential need for operation.

An algorithm for diagnosis of IE begins with fever, requires positive blood cultures, includes some sign or symptom referable to the heart, and receives anatomic corroboration with TEE. From TEE, vegetation size, mobility, and position can be documented; degree of stenosis and regurgitation associated with the valve lesion can be assessed; and in PVE the presence of prosthetic leakage or perianular cavities can be determined.

The decision to use cardiac catheterization and angiography has varied over the years and continues to be made on a case-by-case basis. In few cases have vegetations been disturbed by intraarterial or venous catheters, and a reasonable policy is that if coronary artery disease or coronary embolization is suspected, coronary angiography should be undertaken before operation.

Neurologic abnormalities may have occurred in as many as 25% to 30% of IE patients at initial presentation. They are protean in nature and include stroke, transient ischemic attack, toxic encephalopathy, meningitis, brain abscess, loss of vision, seizures, headache, backache, and acute mononeuropathy. Funduscopic examination (Roth spots or flame hemorrhages), cerebrospinal fluid examination, and computed tomography (CT) scanning or magnetic resonance imaging are recommended in every case. 

### Box 15-2 Diagnostic Criteria for Infective Endocarditis

#### Major Criteria

**Positive Blood Culture**
- Typical microorganisms for infective endocarditis (IE) from two separate blood cultures (viridans streptococci, *Streptococcus bovis*, HACEK group, or community-acquired *Staphylococcus aureus* or enterococci) in absence of a primary focus, or
- Persistently positive blood culture, defined as recovery of a microorganism consistent with IE from:
  - Blood cultures drawn more than 12 hours apart, or
  - All of three or majority of four or more separate blood cultures, with first and last drawn at least 1 hour apart

**Evidence of Endocardial Involvement**
- Positive echocardiogram for infective endocarditis:
  - Oscillating intracardiac mass on valve or supporting structures, or in path of regurgitant jets, or on implanted material, in absence of an alternative anatomic explanation, or
  - Abscess, or
  - New partial dehiscence of prosthetic valve or new valvar regurgitation (increase or change in preexisting murmur not sufficient for diagnosis)

**Minor Criteria**

**Predisposition**
- Predisposing heart condition or IV drug use
- Fever ≥38°C

**Vascular Phenomena**
- Major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, Janeway lesions

**Immunologic Phenomena**
- Glomerulonephritis, Osler nodes, Roth spots, rheumatoid factor

**Microbiological Evidence**
- Positive blood culture but not meeting major criterion, or serologic evidence of active infection with organism consistent with infective endocarditis

**Echocardiogram**
- Consistent with infective endocarditis but not meeting major criterion

### Box 15-3 Echocardiographic and Clinical Features Suggesting Potential Need for Surgical Intervention in Patients with Infective Endocarditis

**Vegetation**
- Persistent vegetation after systemic embolization
- Anterior mitral valve leaflet vegetation, particularly with size ≥10 mm
- One or more embolic events during first 2 weeks of antimicrobial therapy
- Two or more embolic events during or after antimicrobial therapy
- Increase in vegetation size after 4 weeks of antimicrobial therapy

**Valvar Dysfunction**
- Acute aortic or mitral regurgitation with signs of ventricular dilatation
- Heart failure unresponsive to medical therapy
- Valve perforation or rupture

**Perivalvar Extension**
- Valvar dehiscence, rupture, or fistula
- New heart block
- Large abscess or extension of abscess despite appropriate antimicrobial therapy

---

*°Surgery may be required because of risk of embolization.
°Surgery may be required because of heart failure or failure of medical therapy.*
imaging (MRI) of the brain are performed as indicated, and results may alter timing of surgical therapy (see following discussion). MRI may be particularly effective in detecting cerebral embolic lesions in IE patients without neurologic symptoms.316

Embolic events are reported frequently in IE patients (24%-67%).46 Prevalence is probably higher in IV drug-related endocarditis and perhaps slightly lower in PVE. The brain is the most frequently identified site of emboli.54

**NATURAL HISTORY**

**Epidemiology**

The incidence of IE in the United States is reported to be 1.7 to as high as 11.6 episodes per 100,000 persons per year with variance due in great part to varying diagnostic and reporting criteria. Approximately 10,000 to 20,000 new cases of IE are diagnosed each year in the United States, accounting for about 1 in 1000 hospital admissions.31 The IE profile has changed over the past several decades; in the current era, IE is more frequently associated with invasive medical procedures and old age and less frequently associated with rheumatic heart disease and poor dentition.47 In the elderly, it is more often linked to a prosthetic valve and bacteria from the gastrointestinal tract.515

Terpenning and colleagues found that indwelling catheters were implicated as the source of bacteremia in half the cases of nosocomial IE.72

Prosthetic heart valves represent a strong risk factor for IE.56 In a large study of adult patients, occurrence of PVE was 4.1% at 48 months after valve replacement in 1465 consecutive hospital survivors, and 64% of these patients died.11 Occurrence of PVE after valve replacement appears to be much lower in the current era, with overall risk about 1% to 5% in the first year after valve replacement and about 1% per year thereafter.511 Other studies report an annual incidence of PVE ranging from 0.12% to 0.4% per patient-year.197 The hazard for developing PVE is greater in patients operated on for NVE than in those undergoing valve replacement for other reasons313,11 (Fig. 15-4). In addition to NVE as a risk factor for PVE, placement of a mechanical prosthesis (vs. a tissue valve), black race, male gender, and longer cardiopulmonary bypass time are incremental risk factors for subsequent development of PVE. Finally, prosthetic valve reoperation is a greater hazard for development of PVE than primary valve replacement (Fig. 15-5).

It is difficult to identify a precise causative factor for PVE. However, intraoperative surface contamination, introduction of contaminated blood or blood substitute, bacterial colonization of a member of the surgical team, bacterial aerosolization in ventilators, nasal colonization of the patient, and preexisting urosepsis have all been implicated. In contrast to prosthetic heart valves, implanted anuloplasty rings and indwelling pacemaker leads are infrequently disposed to IE.56,45

Among the pediatric population, IE most often occurs in patients with VSDs and valvar aortic stenosis. Incidence is low (14.5 per 10,000 person-years) but 35 times that of the normal population.43 Incidence of IE in patients with VSD is reduced by about 50% after surgical closure. Postoperative IE in children most often occurs after aortic valvotomy, valve replacement, or use of a right ventricular–pulmonary artery conduit.56 In both pediatric and adult populations, mitral valve prolapse has emerged as a frequent preexisting malformation in the spectrum of IE (29% of patients in McKinsey and colleagues’ series).38

**Causative Organisms**

Approximately 80% of endocarditis cases are caused by streptococcal or staphylococcal species. S. aureus predominates as the infecting organism in the majority of hospital-acquired and drug-related cases of IE. S. aureus involves the mitral valve more than the aortic valve and results in higher occurrence of embolism compared with other organisms.510 Streptococcal IE accounts for about 30% of IE cases, and viridans streptococci are the most common causative organisms. Enterococci are the third leading cause of IE, implicated in about 10% of cases.55 Enterococcal IE typically occurs in elderly males with multiple comorbidities, results less commonly in embolic events, and disproportionately affects the aortic valve. Gram-negative bacilli account for about 5% of
cases. Distribution of infecting organisms in the usual NVE population, however, may vary among institutions and temporally.\textsuperscript{26-30,32,34-36} In PVE occurring within 2 months of operation, \textit{Staphylococcus epidermidis} is the major offending organism. Late-onset PVE has the same general spectrum of causative organisms as NVE. Enterococcal PVE (usually caused by \textit{Enterococcus faecalis} or \textit{Enterococcus faecium}) is usually associated with manipulation of the gastrointestinal or genitourinary tract or with malignancy.

Complications

The most frequent cardiac complication of NVE is heart failure, primarily caused by valvar regurgitation. However, NVE occasionally results in mitral or tricuspid valve stenosis and infrequently in aortic valve stenosis. Perianular leakage and abscess and occasionally stenosis are the major causes of heart failure in PVE, with perianular extension occurring in over 50% of cases.\textsuperscript{36} It occurs in 10% to 40% of NVE cases and is more common with aortic valve involvement.\textsuperscript{38} This dangerous complication can lead to abscess formation, pseudoaneurysms, and aortocavitary fistula formation (which can develop from any aortic sinus).\textsuperscript{32} Myocardial abscesses (most commonly related to \textit{S. aureus} infection) complicate IE in 20% to 40% of cases and are particularly common with PVE and aortic valve involvement.\textsuperscript{39} Patients with a bicuspid aortic valve and IE carry a high risk of abscess formation.\textsuperscript{112} Development of conduction abnormalities should prompt further TEE evaluation for abscess formation or extension. If left untreated, abscess cavities may progress to fistula formation and intracardiac shunting from myocar-dial perforation. Once these complications develop, mortality may exceed 40% despite surgical intervention.\textsuperscript{32} If the rare patient with a small abscess cavity (≤1 cm), clinically controlled infection, and multiple comorbidities is treated medically, close follow-up with serial echocardiography during prolonged antibiotic therapy is mandatory.\textsuperscript{75} Pericarditis typically occurs in association with anular abscess or myocardial perforation.

Renal complications of IE take at least four forms: prerenal failure secondary to low cardiac output, microabscess formation caused by septic emboli, glomerular dysfunction resulting from circulating immune complexes, and renal failure caused by antibiotic toxicity.

Embolic events are common in IE patients (Fig. 15-6), with a reported prevalence of 43% in NVE, 67% in IV drug–associated IE, and 25% in PVE.\textsuperscript{34} Ting and colleagues report a 19% occurrence of splenic emboli in their series of patients with IV drug–related endocarditis.\textsuperscript{17} Occurrence is about 5% in the usual type of left-sided NVE. Metastatic infection of viscera is typically caused by \textit{Staphylococcus}. Other classic peripheral manifestations of IE (e.g., petechiae, Osler nodes, splinter hemorrhages) are infrequently seen now, probably because of earlier intervention in the disease process. Multiple coronary emboli may result in myocardial infarction and ventricular dysfunction; the highest risk of embolic complications occurs with \textit{S. aureus}, Candida, and HACEK (\textit{Haemophilus, Actinobacillus, Cardiobacterium, Eikenella, and Kingella}) species.\textsuperscript{75}

About half the embolic complications of IE are associated with neurologic manifestations, and one fourth to one third of patients with NVE or PVE at some time have neurologic complications, 90% of which are related to emboli in the distribution of the middle cerebral artery.\textsuperscript{14,32} Presence of \textit{S. aureus} increases risk of neurologic complications.\textsuperscript{36,74} Stroke is the most common neurologic event. Vegetations are seen on echocardiography in about 40% of patients with neurologic complications and in about 80% of patients without neurologic sequelae.\textsuperscript{32} Some characteristics of vegetations visualized on TTE or TEE (e.g., density, mobility) may not be helpful in defining emboli risk.\textsuperscript{126} Cerebral embolism generally occurs before the start of antibiotic therapy, with risk of stroke falling rapidly after initiation of effective antibiotics.\textsuperscript{110} A European multicenter study estimated the prevalence of acute ischemic stroke at 12% (CI 10%-14%) on hospital admission, but only 3.7% (2.7%-4.9%) after start of appropriate antibiotic therapy.\textsuperscript{113} Data from the International Collaboration on Endocarditis indicated a stroke incidence of 4.8 per 1000 patient-days during the first week of antibiotic therapy, which decreased to 1.7 per 1000 patient-days in the second week and fell further thereafter.\textsuperscript{112} After instituting antibiotic therapy, however, both absolute vegetation size and observed increase in vegetation size are associated with increased embolic risk\textsuperscript{74} (Fig. 15-7). Large vegetations are commonly caused by the HACEK group of organisms and fungi.

The most devastating neurologic complication is intra-cerebral hemorrhage, which complicates about 5% of IE cases.
and carries a mortality exceeding 50%. The pathophysiology may involve septic arteritis with erosion of the vessel wall during uncontrolled infection, hemorrhage following cerebral infarction, or rupture of a mycotic aneurysm. For patients on chronic anticoagulation who develop neurologic symptoms, anticoagulation should be discontinued (or maintained at low therapeutic levels in patients with a mechanical prosthetic valve) until intracranial hemorrhage can be excluded by CT scanning or MRI.

Medical treatment alone (vs. operative) increases risk of embolism. However, delaying repair of the cardiac lesion is usually advised in the presence of central nervous system (CNS) complications. Morbidity is less when repair is done in the presence of cerebral infarction versus cerebral hemorrhage (see Indications for Operation). Evidence indicates that cerebral mycotic emboli will regress after extirpation of the valvar septic lesion, so early cardiac operation in patients with mycotic aneurysm and cerebral abscess may be advisable.

Mortality

Mortality associated with IE is reported at 15% to 20% during the initial hospitalization and 20% to 30% during the first year. Early mortality is similar between NVE and PVE and between mitral and aortic valve IE. Gram-negative bacillus and fungal IE carry a mortality exceeding 50%. Development of heart failure, intracardiac abscess, embolism, a large mobile vegetation, hemodynamic instability, altered mental status, immunocompromise, and advanced age have also been identified as risk factors for mortality.

THERAPY

Antibiotics

Several blood cultures should routinely be obtained before initiating antibiotic therapy. Over half of cases can be managed solely with antibiotics. Because antibiotic penetration of vegetations is difficult, prolonged parenteral antibiotic administration is advisable. Once antibiotics are started, blood cultures should be drawn every 1 to 2 days until they become negative. Total duration of antibiotic therapy is counted from the time of the first negative culture.

Vancomycin and aminoglycoside therapy should be guided by blood levels to ensure adequate dosing while minimizing toxicity. Aminoglycosides are often used in combination with a cell wall–active agent (β-lactam or vancomycin) to effect synergy (by increasing aminoglycoside entry into bacteria) in treating staphylococci, streptococci, and enterococci. Standard antibiotic recommendations are listed in Table 15-2 for NVE and Table 15-3 for PVE. Detailed recommendations about antibiotic therapy for IE are available from the American Heart Association.

Surgery

About 40% to 45% of all patients with IE undergo surgical therapy. Goals of operative therapy are to (1) remove infected tissue and drain abscesses, (2) restore or reconstruct atrioventricular or ventriculoarterial continuity, and (3) reverse the hemodynamic abnormality. Drainage of abscesses, débridement of areas of necrosis, and improvement of mechanical function by repair or replacement of infected valves are done as required. Operation is also aimed at closing acquired defects (e.g., VSD, ring abscess, fistula, aneurysm) and in children may include repairing the underlying malformation.

All operations for IE are done through a partial or full median sternotomy. Presence of adhesive or suppurative pericarditis is strong evidence of previous perforation at the aortic or mitral ring or ring abscess. It is prudent to use bicaval cannulation to allow flexibility in the presence of burrowing abscesses, acquired septal perforation, unexpected right-sided valve involvement, and complex aortic root reconstruction. Intraoperative TEE is extremely useful to diagnose and plan treatment of the various manifestations of the infectious process. In left-sided IE, minimal manipulation of the heart

should be the rule to avoid dislodging infected thrombotic material or vegetations. As in other valvar procedures, myocardial management is accomplished with antegrade and retrograde cardioplegia supplemented with moderate systemic hypothermia (see “Methods of Myocardial Management during Cardiac Surgery” in Chapter 3). Thorough excision of infected tissue is performed with drainage of abscesses and closure of defects.

Operation for aortic IE should involve examining the anterior leaflet of the mitral valve and its chordae for drop lesions. It is sometimes necessary to open the left atrium to examine the posterior leaflet apparatus. Similarly, when mitral endocarditis is present, the possibility of concomitant aortic vegetations should be considered. However, absence of a murmur or thrill, presence of a competent aortic valve, and no echocardiographic evidence of vegetations at the aortic area argue against aortic involvement and preclude need for inspecting the valve.

Reparative procedures may be done on the mitral valve when the vegetation is healed, small, or discrete and does not involve a major portion of the tensor apparatus. It may include closing small perforations of the posterior or anterior leaflet using autologous or bovine pericardium or direct suturing (Fig. 15-8). Small vegetations may be stripped from chordae tendineae. Major destruction of the mitral leaflets by active infection presents a unique challenge if reconstruction is considered. Although one approach is valve replacement for all but small vegetations, the increased risk of early PVE in the setting of active infection (particularly in the setting of ongoing positive blood cultures) argues for concerted efforts at valve reconstruction. After débridement of infected tissue, a sliding anuloplasty technique (see Chapter 11) may be applicable to reconstruct commissural areas. Partial leaflet resection, pericardial patch replacement of mid-leaflet areas, or both may be needed. The remaining orifice size following reconstruction must be large enough (generally 25 mm in the average adult or a z value of −2 or greater in children) to prevent important mitral stenosis. Suture anuloplasty may be preferable to a prosthetic ring in an actively infected anulus, but a biodegradable anuloplasty ring has been suggested by Pektok and colleagues.³²

In the absence of active IE, as defined by positive blood cultures and overt inflammation at the site of vegetation, mitral repair of the classic type can be accomplished. Triangular resection of a portion of the anterior leaflet or quadrangular resection of a portion of the posterior leaflet may be performed, supplemented by inserting a partial or complete anular ring. Partial leaflet resection and anuloplasty procedures for tricuspid valve endocarditis can be applied on a more liberal basis (Fig. 15-9).

At the time of mitral valve resection, the posteroinferior portion of the mitral anulus should be inspected because the usual myocardial ring abscess occurs in this location. In infection of the aortic root, the abscess is usually found just posterior to the membranous portion of the ventricular septum or at the posterior portion of the septum just anterior to the orifice of the left coronary artery. When found, abscesses should be totally evacuated and surrounding tissue débrided. The concept of atrioventricular or ventriculoarterial discontinuity must be kept in mind. The infecting process often erodes those junctions, with potential or actual separation. In mitral valve IE with left atrioventricular discontinuity, the defect can be handled in several ways. Often a simple variation of the usual valve replacement technique is appropriate; interrupted horizontal mattress sutures anchored with felt or pericardial pledgets are placed on the ventricular aspect of the mitral anulus, brought up through the left atrial aspect, and then through the prosthetic sewing ring. Deep bites are necessary. This can be done only after thorough débridement of the infected tissue within the mitral ring (Fig. 15-10).

In more extensive ring abscess or often in PVE with abscess, a different type of reconstruction is necessary. The atrioventricular discontinuity is bridged by a patch fashioned from a sheet of autologous or bovine pericardium. The ventricular aspect is anchored to the endocardium and myocardium using deep bites of continuous 3-0 or 4-0 polypropylene suture. The superior aspect of this tissue reconstruction is anchored to the atrial endocardium with a similar suture.
The new prosthesis is anchored to the composite suture line on the ventricular aspect of the suture line using interrupted horizontal mattress sutures buttressed with felt pledgets. Various maneuvers have been suggested for seating valves in the aortic position in the presence of frank abscesses of the aortic root. The advantage of tissue valves over mechanical valves in preventing reinfection has not been conclusively demonstrated. In the aortic area, however, stentless tissue valves, either allografts or xenografts, have some advantage in that their pliability allows some flexibility in reconstructing continuity between the ventricle and aorta. When stent-mounted valves—either mechanical or tissue—are used, a technique using felt or bovine pericardial buttressed horizontal mattress sutures is advised. The mattress is placed on the ventricular aspect of the aortic anulus or from outside the aortic wall, dissecting the aortic root upstream in its noncoronary and posterior left coronary aspects and occasionally opening the right ventricular outflow tract to place pledged sutures from the infundibular septum through the aortic anulus.

When a simple small abscess lies under the left coronary ostium, evacuation, débridement, and patch closure of the defect can be accomplished. The stent-mounted or stentless tissue prosthesis is then placed in its usual orthotopic position using techniques similar to those required in noninfected cases (see Chapter 12). In many patients with important aortic valve IE, full root replacement offers the most satisfactory solution (Fig. 15-11). Infected tissue is first débrided, and formal root replacement is done in the usual way, with particular emphasis on locating the upstream (proximal) suture line within the left ventricular outflow tract, thus appropriately bridging the left ventricular–aortic discontinuity. All infected tissue is thus exteriorized.

Ancillary procedures during valve replacement may be helpful. Some authorities suggest soaking the prosthetic device in an appropriate antibiotic, and others have irrigated

**Figure 15-9** Repair of tricuspid valve infective endocarditis in which vegetation is localized to a portion of septal leaflet. A, Line of leaflet resection. B, Repair of defect using fine interrupted sutures. C, Completed repair supported by an anuloplasty ring.
Figure 15-10 Infective endocarditis producing a ring abscess involving base of posterior leaflet of mitral valve. A, Abscess is evacuated and débrided. B, Defect is covered by a pericardial patch anchored within left ventricle and extending up across base of portion of posterior leaflet, then sewn to left atrial wall. C, Prosthesis is sutured into place, siting posterior suture line either on patch (in this case) or occasionally below patch on ventricular wall.
or swabbed the local area with antiseptic solution such as povidone-iodine or antibiotics specific for the infecting organism. In fungal endocarditis, irrigation of the local area with amphotericin or other antifungal agents may be efficacious.

When both the aortic and mitral valves are involved but infection is limited to the cusps, usual sequencing of operation is followed: aortotomy, then aortic valve resection, followed by left atriotomy and mitral valve resection. The mitral anulus is then sized and an appropriate mechanical device or
bioprosthetic valve inserted. The aortic annulus is then sized and an appropriate mechanical or tissue prosthesis inserted. When infection is not limited to the leaflets, there may be destruction of aortomitral continuity with absence of the aortomitral curtain. In this case, seating of the mitral prosthesis is modified because much of the anterior lateral suture attachment of the sewing ring will be absent. As much of the mitral prosthesis as possible is inserted in the usual way. Attention is then redirected to the aortic exposure, and a new synthetic aortomitral curtain is formed with polyester or pericardium. Upstream or proximal anchoring is done with sutures to the sewing ring of the mitral prosthesis, and downstream aortoventricular continuity is established by suturing this curtain to the root of the aorta. Thereafter, the aortic prosthesis is inserted as usual, attaching the prosthesis in its right lateral aspect (noncoronary sinus aspect) to the reconstructed mitral curtain. Alternatively, the sewing ring of the aortic prosthesis can be attached where it interfaces directly to the sewing ring of the mitral prosthesis.124

Treatment of associated infection, particularly peripheral mycotic aneurysm; brain, spleen, or liver abscess; and renal parenchymal infection, usually takes second priority to the intracardiac operation. Use of cardiopulmonary bypass does not generally exacerbate associated neurologic deficits except in the specific case of cerebral hemorrhage (see Special Situations and Controversies). Persisting infection after valve replacement should alert the surgeon to splenic and liver abscesses. Similarly, continued renal decompensation suggests the presence of renal parenchymal disease.

SPECIAL FEATURES OF POSTOPERATIVE CARE

In general, patients undergoing operations for complications of IE are subject to the same early postoperative monitoring and intervention algorithms as non-IE patients undergoing similar operations for valve replacement or repair (see Chapter 5). Hemodynamic state is assessed by measuring or estimating cardiac output and measuring left atrial, right atrial, or pulmonary artery pressures, combined with assessing blood pressure and peripheral perfusion.

Occasionally, patients with an acute septic syndrome manifest decreased peripheral resistance with low, normal, or high cardiac output early postoperatively. Appropriate treatment may include use of phenylephrine, levarterenol, or arginine vasopressin to increase peripheral resistance. Mobilizing extravascular lung water may be important to facilitate extubation. Adequate diuretic therapy and positive end-expiratory pressure ventilation early postoperatively are then indicated.

In all patients, tissue should be obtained for Gram stain and subsequent culture and histologic analysis. Results of these studies are integrated into the postoperative care plan, with appropriate changes in antibiotic regimen. Because renal function often is compromised, antibiotic levels must be closely monitored during the initial stages of therapy to allow adjustment in dosing interval if renal function is changing.

Patients with compromised renal function often have increased blood urea nitrogen and creatinine levels early postoperatively, followed by a decline to near-normal levels over the next 3 to 7 days. Monitoring renal function is therefore important, and pharmacologic therapy with large doses of diuretics is often indicated. In some patients, temporary renal dialysis is necessary. Some surgeons may want to follow white blood cell counts or phase reactants over the postoperative period to monitor resolution of sepsis. If a septic picture continues, possible involvement of peripheral sites should be investigated.

Protocols for anticoagulation are the same in IE patients as in those having similar devices without IE.

Antibiotic treatment, most often administered IV, is continued for 4 to 6 weeks based on the type of organism and its sensitivity to antimicrobials. In the case of fungal endocarditis, oral treatment with ketoconazole or fluconazole may be appropriate for 3 to 6 months.

RESULTS

Early (Hospital) Death

Native Valve Endocarditis

Hospital mortality for valve operations (and associated procedures) in patients with IE varies between 4% and 30%.84,91,92,114,115,116,117,118,119,120,121 The variation can be ascribed to several factors, most notably the difference in risk between operation in the acute vs. healed stages of endocarditis (see Box 15-1 for definitions). In general, operations for healed IE are performed after a full course of antibiotic therapy.

Other factors affecting the variation in reported hospital mortality reflect the incremental risks for an operation, as discussed later.

Operative treatment of IE is in reality a combined medical-surgical treatment, and timing of the operation is an important factor in patient survival. However, it is convenient to compare strictly medical (nonoperative) treatment of IE with results of operative treatment. In general, the more urgent the surgical indication and the more severe the heart failure, the better the surgical results compared with medical therapy. However, no prospective or randomized studies have been done, so patients in the nonoperative medical group may not be strictly comparable with those in the surgical group. Richardson and colleagues reported that operative treatment in 81 patients with NVE resulted in 11 deaths (14%; CL 10%-19%), compared with 24 deaths (44%; CL 37%-52%) in 54 patients treated medically.82 Operative mortality was affected by urgency of operation. For elective operations (next convenient operative date), mortality was 5%, for urgent operations (next day) 16%, and for emergency operations in patients with severe heart failure and low cardiac output (immediate operation) 33%.

Operations in IE patients often demand complex procedures that may affect hospital mortality after valve repair or replacement.913,115 Complexity of the procedure is frequently dictated by duration of the illness and particularly by the infecting organism. Tissue destruction is characteristic of staphylococcal and some gram-negative organisms and is much less likely to occur in streptococcal or pneumococcal endocarditis. In reports from Bauernschmitt and Middlemost and their colleagues, however, early results of valve replacement did not seem to be adversely affected by excessive complexity of the procedure.94,131 Rather, preoperative complications and severity indices have a more profound influence on mortality.

Often, IE can be successfully treated without operative intervention in children. Nomura and colleagues reported on 98 patients seen over 13 years, 30 of whom were treated operatively, with a hospital mortality of 6.7%.124
remaining patients were treated medically, with a 10% hospital mortality. Tolan and colleagues reviewed 132 published reports in which children underwent operative intervention during active endocarditis.\textsuperscript{7,11} Hospital survival was 77%. Only 67% of patients had preoperative conditions thought to predispose them to IE, and about one quarter of those were operated on for infection associated with patent ductus arteriosus.

**Prosthetic Valve Endocarditis**

PVE is an incremental risk factor for operative mortality in the domain of all IE.\textsuperscript{2,52} Again, overall survival for patients with PVE is improved in those treated operatively compared with those treated medically. Although results may not be strictly comparable, most series report a difference in outcome when operative treatment of NVE is compared with PVE. In the Brigham and Women’s Hospital experience, mortality was 22% in 49 PVE patients vs. 6% in 109 NVE patients.\textsuperscript{1,3} Several factors more prevalent in the PVE group are likely responsible for this difference, including reoperation, prevalence of abscess, anular erosion and peri-anular aneurysm, insidious onset of infection, and fastidious or fungal organisms. However, Sabik and colleagues at the Cleveland Clinic report a 3.9% (CL 2%-7%) hospital mortality among 103 patients managed with radical débridement of infected tissue and aortic root replacement with a cryopreserved allograft.\textsuperscript{51}

**Time-Related Survival**

Late survival after valve replacement for NVE is good, but not as good as with similar operations done in the absence of endocarditis (Fig. 15-12). Death and other events late after operation often are not related to IE or recurrent IE but rather to other conditions associated with heart disease, such as the valve replacement device and associated complications, myocardial dysfunction, and coronary artery disease. Using mechanical valves exclusively, Bauernschmitt and colleagues reported 81% survival among 138 patients after 8 years.\textsuperscript{54}

There is an early, high-peaking hazard for death after operation, and then a constant later phase (Fig. 15-13). Survival is lower in patients who have PVE than in those with NVE (Fig. 15-14). Recurrent IE, nonstreptococcal organisms, and heart failure are associated with late death after valve replacement.

Data for long-term survival after heart valve replacement in IE patients are typified by those reported by d’Udekem and colleagues from Toronto; survival at 10 years was 61% ± 6%.\textsuperscript{D13} Aranki and colleagues, in two separate publications from Brigham and Women’s Hospital, reported 81% to 83% 5-year survival and 61% to 68% 10-year survival for both mitral and aortic valve replacement.\textsuperscript{A3, A4}

**Incremental Risk Factors**

Several factors portend higher mortality with operative treatment for IE. A strong risk is hemodynamic deterioration,\textsuperscript{B4, D3, H3} characterized as preoperative shock, advanced heart failure, or advanced NYHA functional class. Some have also found a relationship with low preoperative cardiac index.\textsuperscript{1,5} A second important risk factor is the infecting organism. Nonstreptococcal organisms, primarily staphylococci, increase operative risk. Staphylococcal infection is generally associated with abscesses, and abscesses independently may also increase risk.\textsuperscript{B4, D3, L3, A1, L3} Likewise, most studies report that PVE is associated with a lower early postoperative survival than NVE.\textsuperscript{B4, D3, M7} Additional incremental risk factors are older age, renal dysfunction, longer cardiopulmonary bypass time, acute vs. healed IE, insidious onset of infection, and associated procedures (Fig. 15-15). A 20-year analysis from Berlin identified preoperative ventilation, mitral valve abscess, and age older than 60 years as risk factors for early mortality following operation for mitral valve endocarditis.\textsuperscript{M21}

David and colleagues identified preoperative cardiogenic or septic shock and abscess formation in both mitral and aortic anuli as risk factors for hospital mortality in patients with periannular extension.\textsuperscript{B25} Anguera and colleagues found moderate or severe heart failure, PVE, and urgent or emergency operation to be major risk factors for mortality.\textsuperscript{A2}
Figure 15-14  Survival according to initial native valve endocarditis (NVE) or prosthetic valve endocarditis (PVE) in 108 patients undergoing aortic valve replacement ($P = .03$). (From Haydock and colleagues.$^{11}$)

**Figure 15-15**  Factors influencing operative mortality after surgical treatment of patients with infective endocarditis. Data are presented as relative risk (see Chapter 6 for definition) for each factor plus 95% confidence limits, as determined by meta-analysis of 30 major studies. Key: AV, Aortic valve; MV, mitral valve; NVE, native valve endocarditis; PVE, prosthetic valve endocarditis; Staph, Staphylococcus aureus or Staphylococcus epidermidis. (From Moon and colleagues.$^{13}$)

In-Hospital Morbidity

A few IE patients have continuing episodes of sepsis despite an apparently adequate cardiac operation. Almost uniformly, the source of this sepsis is not the heart; however, an overlooked valvar lesion must be sought, generally by repeat TEE. There is a high prevalence of splenic and other visceral infarcts, emboli, or abscesses,$^{13}$ but usually these do not cause continuing sepsis and are amenable to continued antibiotic therapy. Renal parenchymatous disease as a cause of sepsis is rare, as are cerebral mycotic aneurysms. Peripheral mycotic aneurysms are a potential source of continuing sepsis.

New or evolving conduction abnormalities preoperatively reflect evolution of the cardiac sepsis or may result from coronary emboli. Postoperatively, heart block occurs more often than in patients without endocarditis. In most situations, this is a predictable occurrence resulting from the radical débridement necessary to eradicate infections around the aortic root, mitral valve apparatus, and ventricular septum.

Most observers have noticed increased postoperative bleeding. Inflamed tissue, inflammatory pericarditis, complex reconstructions, renal dysfunction, and platelet dysfunction may play a role in excessive bleeding.

A devastating complication is a new or deepening neurologic deficit after valve replacement. Even with meticulous surgical technique, friable vegetations may dislodge to cause new CNS deficits. More frequently, however, an existing CNS finding is aggravated by operation. Ting and colleagues found evidence of cerebral septic emboli in 45 (42%) of 106 patients who underwent valve replacement for IE.$^{18}$ Neurologic complications after valve replacement included postoperative strokes in 6%, cerebral abscesses in 2%, and seizures in 1%. Presence of a hemorrhagic infarct preoperatively predisposes patients to perioperative stroke (see further discussion under Special Situations and Controversies).

Recurrent Infection

Some institutions report few cases of subsequent reinfection even when operation is done early in the course of NVE. Despite 20% of patients requiring valve replacement in the UAB series having uncontrolled infection at operation, no cases of subsequent PVE occurred.$^{82}$ This finding is similar to the experience of Utley and Mills and of Okies and colleagues, who reported that reinfections were rare in such patients and emphasized the importance of adequate débridement of infected areas.$^{32,11}$ In each of the studies, however, follow-up was short. Indeed, recurrent infection after valve replacement (or repair) does occur. In Larbalestier and colleagues’ report, 18 of 109 patients surviving surgery for NVE underwent reoperation.$^{13}$ Eight had developed recurrent endocarditis. Recurrent IE is more common when the initial organism is nonstreptococcal and when there has been major destruction of the anulus or surrounding valve structures. This finding is reflected in Aranki’s report, in which freedom from recurrent endocarditis in acute aortic IE surgical patients...
was 89% ± 3% at 5 years and 83% ± 4% at 10 years, vs. 96% ± 3% at 5 years and 86% ± 6% at 10 years in patients with healed aortic valve IE.\footnote{34}

Freedom from reoperation is higher when the mitral valve is involved (compared with the aortic valve), reflecting less anular destruction. In a series reporting results of operation for mitral valve IE at Brigham and Women’s Hospital, freedom from reoperation at 5 and 10 years was 92% ± 4% and 62% ± 13% for acute endocarditis and 94% ± 4% and 84% ± 10% for healed endocarditis (\(P = .7\)), respectively.\footnote{34} There was little difference in recurrent IE at 10 years for patients operated on for NVE (85%) vs. PVE (82%), although long-term survival was better for those with NVE. Reinfection with the same or different organism is common in drug abusers, and late mortality is greater in that group. In Hiramta’s experience, late mortality was 39% in drug abusers vs. 7% for non–drug users.\footnote{16}

There is some controversy as to whether a tissue valve, particularly a cryopreserved allograft, is preferable for use in aortic NVE. In 108 patients, Haydock and colleagues reported a small but statistically significant difference in incidence of recurrent IE in patients having allografts vs. prosthetic valves\footnote{13} (Fig. 15-16). Hazard functions were qualitatively different for allografts; there was a constant phase of hazard when an allograft was used, but an early peaking hazard phase and late rising phase when a prosthetic device was used (Fig. 15-17). In a similar study, McGiffin and colleagues noted that allografts in the aortic position had a higher freedom from \textit{recurrent endocarditis} than mechanical or xenograft valves\footnote{47} (Fig. 15-18). Thus, if there is an advantage among valve substitutes, it is conferred uniquely by allografts. In both Haydock’s and McGiffin’s series, where aortic valve replacement was done with allograft valves, freedom from recurrent endocarditis was about 80%.

Not all institutional experience supports this view, however.\footnote{11,13,14,15} In 138 patients who received only mechanical valves, \textit{reoperation-free survival} was similar (77%), suggesting that mechanical prostheses may perform as well as...
allografts when operation is done for aortic NVE. However, reoperation-free survival does not comparably address differences in early hazard for recurrent infection. Lytle and colleagues reoperated on 146 patients with PVE, with 19 (13%) in-hospital deaths. Subsequent reoperation was performed in 15% of hospital survivors, and in those who had aortic valve replacement, reoperation-free survival was similar among those who received biological, mechanical, or allograft valves (Fig. 15-19). Similar findings were reported by Nguyen and colleagues.

Thus, for aortic NVE, some evidence suggests that an allograft is the preferable replacement device. For all aortic PVE, mitral NVE, or mitral PVE operations, there is no evidence indicating the superiority of xenografts over mechanical devices.

INDICATIONS FOR OPERATION

In healed NVE, indications for operation are related primarily to hemodynamic severity of the valvar lesion or defect. It follows that, in general, results of operation in healed endocarditis are identical to those in patients with endocarditis having the same hemodynamic disturbance (see Indications for Operation in Chapters 11 to 14).

In the setting of active NVE, consensus is lacking about some of the specific indications for surgical intervention. Nevertheless, consensus has emerged from both the European and North American medical communities with regard to specific indications for operation (Box 15-4). Specific recommendations regarding timing of operation are listed in Box 15-5. Minor variations exist in the recommendations from the American College of Cardiology/American Heart Association Guidelines and European Society of Cardiology (Table 15-4).

Among the indications for operation for IE, surgery for acute heart failure provides the greatest survival benefit. Operation is best performed within about 1 week of presentation of heart failure symptoms, urgently in the presence of subtle deterioration, and emergently with rapid or marked hemodynamic compromise. Heart failure is usually secondary to valve regurgitation but occasionally results from valve obstruction or intracardiac shunting. Acute, severe aortic regurgitation is poorly tolerated and often requires emergency operation. Patients with reasonably compensated heart failure may benefit from several days of medical therapy with diuretics and afterload reduction prior to surgery. However, extended delay is not recommended because of the tendency for insidious progression with a marked increase in operative risk.

Early surgical treatment of staphylococcal NVE, regardless of hemodynamic compromise, is usually advocated. However, there are isolated cases of successful medical treatment. Development of new-onset atrioventricular block is highly predictive of abscess formation; after verification by TEE, prompt operation should be performed.

Because recidivism is common in drug abusers, surgical treatment of right-sided endocarditis is occasionally inappropriate despite or abandoned in favor of nonsurgical treatment. This approach may be particularly appropriate when replacement is more likely to be done than repair, because reinfection often follows tricuspid valve replacement. Tricuspid valve resection without replacement is an option, although hemodynamic sequelae are important limitations to this approach (see Chapter 14). Recurrent pulmonary emboli are not an indication for operation unless fever persists despite 3 weeks of antibiotic therapy in the absence of a pulmonary abscess.

Right-sided endocarditis in IV drug abusers is caused by Staphylococcus aureus in 80% of patients. Tricuspid valve replacement has been advocated in IE patients who have large vegetations and fever that persist for more than 3 weeks despite appropriate antibiotic therapy. Bayer and colleagues, however, correlating echocardiographic findings with clinical outcome in 53 patients with tricuspid NVE secondary to S. aureus, found that 50 patients were cured with antibiotics; only 3 required surgery. Of 38 vegetations detected, 21 were 10 mm or greater in diameter. Similarly, recurrent pulmonary emboli were not correlated with demonstrable vegetations or with size of the vegetation.

Surgical intervention in early PVE usually is recommended, particularly when the offending organism is Staphylococcus or a fastidious organism. In the complete absence of heart failure, emboli, or a large vegetation, however, nonsurgical treatment may suffice.

The clinical presentation and natural history of late PVE (>2 months after initial operation) are similar to those of active NVE. Therefore, inducations for valve replacement in late PVE—advanced degree of heart failure, emboli, continuing sepsis, and staphylococcal organism—are similar to those for NVE. Timing of operation for either NVE or PVE should be based on clinical considerations, not on duration of antibiotic treatment.

Echocardiography has become an integral part of the algorithm for diagnosing and treating endocarditis. Vegetation size as the sole indication for surgery remains controversial. However, the presence of mobile vegetations, vegetations larger than 10 mm, and obstructing vegetations warrant consideration for operative therapy. In left-sided NVE, Sanfilippo and colleagues found that vegetation size, extent, mobility, and consistency were univariable predictors of complications (Fig. 15-20). Patients with a vegetation greater than 10 mm in diameter on echocardiography have a substantially higher risk of embolic phenomena than those with small or no vegetations (47% vs. 19%). It must be stressed that...

**Modified from ACC/AHA 2006 Guidelines.**

*Surgery should be performed immediately, irrespective of antibiotic therapy, in patients with persistent pulmonary edema or cardiogenic shock. If congestive heart failure disappears with medical therapy and there are no other surgical indications, intervention can be postponed to allow a period of days or weeks of antibiotic treatment under careful clinical and echocardiographic observation. In patients with well-tolerated severe valvar regurgitation or prosthetic dehiscence and no other reasons for surgery, conservative therapy under careful clinical and echocardiographic observation is recommended, with consideration of deferred surgery after resolution of the infection, depending upon tolerance of the valve lesion.*

*In all cases, surgery for preventing embolism must be performed very early because embolic risk is highest during the first days of antibiotic therapy.*

*Surgery is contraindicated for at least 1 month after intracranial hemorrhage unless neurosurgical or endovascular intervention can be performed to reduce bleeding risk.*

vegetation size is only one of several criteria recognized as indications for surgical intervention. However, the combination of a recent nonhemorrhagic CNS event, a highly mobile (prolapsed vegetations crossing the plane of valve leaflet coaptation during the cardiac cycle) vegetation, and vegetation size greater than 10 mm while a patient is on effective antibiotic therapy should mandate serious consideration for operation.  

Indications for surgical intervention in children are much the same as those in adults: heart failure, continuing sepsis, and embolization. In children, however, large masses associated with chronic right-sided indwelling catheters are often indications for surgical extirpation. Small right-sided masses associated with indwelling catheters in both children and adults can be treated with antibiotics, heparinization, and nonsurgical removal of the catheter.

**SPECIAL SITUATIONS AND CONTROVERSIES**

Timing of Operation in Patients with Central Nervous System Events

The risk of urgent operation for IE complicated by stroke remains controversial. There is general agreement that if at all possible, operation should be delayed at least 4 weeks following an intracerebral hemorrhage, because the risk of deepening stroke or death resulting from a neurologic complication is particularly serious in patients with demonstrable cerebral hemorrhage (as opposed to infarction) as diagnosed with brain CT or MRI. On the other hand, a number of studies have shown that cardiopulmonary bypass is not particularly dangerous (risk of worsening neurologic event 3%-6%[36]) in patients with cerebral infarction without hemorrhage[31,32,33] or in those with cerebral mycotic aneurysm. In fact, mycotic aneurysms have been shown to regress in the presence of an adequate cardiac operation and continued antibiotic therapy.[34] Eishi and colleagues reviewed 2523 surgical cases of IE and found that 10% of patients had associated cerebral complications.[1] In-hospital mortality of those patients was 11%; cerebral infarction occurred in 65%, cerebral bleeding in 32%, and abscess in 3%. Exacerbation of cerebral complications (including death), according to interval from onset of cerebral infarction to cardiac operation, occurred in 46% of patients operated on within 24 hours, 44% of those operated on days 2 through 7, 17% of those operated on days 8 through 14, 10% of those operated on days 15 through 28, and just 2% of those operated on after 4 weeks (Figure 15-21). Thus, an important correlation existed between the interval from onset of cerebral complications to operation and exacerbation of cerebral complications (P = .008). Preoperative risk factors affecting exacerbation of cerebral complications were severity of cerebral complication, interval...

Figure 15-21 Exacerbation of cerebral damage, including death related to cerebral injury, according to interval from onset of cerebral infarction until cardiac operation. Key: CI, Cerebral infarction. (From Eishi and colleagues.)

between complication and surgery, and uncontrolled heart failure.

Postoperative exacerbation of cerebral complications is more likely in patients with more severe preoperative manifestation of brain infarction. In the Eishi study of 51 patients without exacerbation of their cerebral complication, operation occurred on average of 15 days after diagnosis, compared with 8 days among 17 patients having exacerbation (P = .01). Thus, exacerbation is inversely related to interval between diagnosis and operation. If cerebral infarction is not associated with hemorrhage, however, earlier operation is usually well tolerated.

In a large cohort of patients undergoing valve surgery after a neurologic complication of IE, Ruffman and colleagues found the risk of neurologic deterioration following brain infarction to be about 20% within 3 days, 20% to 50% between day 4 and 14, less than 10% after 14 days, and less than 1% after 4 weeks. On the basis of these data, Angstwurm and colleagues recommended valve surgery within 72 hours if a patient with brain infarction (but without hemorrhage) has severe heart failure, and after 4 weeks if the patient remains stable on antibiotic therapy. Urgent operation should be considered reasonably safe in patients with transient ischemic episodes or “silent” cerebral embolism.

Preferred Device for Operation

Choice of valve replacement device depends on several factors, including likelihood of PVE, durability, need for anticoagulation, availability, and ease of insertion. However, factors such as adequate eradication of foci of infection and “best fit” also apply. For that reason, a number of choices may be available for patients with aortic IE. Although good results have been reported with mechanical or stented bioprosthetic valves, the preponderance of data suggests better outcome with an aortic allograft. When abscess cavities can be excluded by a pliable allograft, this device is preferable. On the other hand, when aortic root replacement is necessary, insufficient evidence exists to indicate that a tissue valve is superior to a mechanical valved conduit (although indirect evidence would support the use of an allograft root).

Because tricuspid valve endocarditis frequently accompanies IV drug abuse, repair is preferred over replacement. If replacement is necessary, choice of device depends on the usual factors associated with tricuspid valve replacement (see Chapter 14). Tricuspid valve allografts have provided encouraging outcomes (see Chapter 14).

Repair is occasionally successful in mitral valve endocarditis, but most repairs are done when IE is healed rather than acute. In the acute stage, a mechanical valve is a suitable option if satisfactory reconstruction is not possible following effective débridement.

In cases of extreme recurrent PVE despite multiple reoperations, cardiac transplantation may be considered if systemic foci of infection are absent.

Guidelines for Antibiotic Prophylaxis

The important morbidity and mortality of IE despite its relative rarity has prompted development of national and international guidelines for prophylactic antibiotics, beginning in 1955. Periodic revision of existing guidelines has been driven by emerging information about shifting patterns of disease. A rise in the prevalence of staphylococcal skin flora has been noted as the causative organism for community-acquired as well as iatrogenic nosocomial IE. Treatment of IE has been complicated by emergence of multidrug resistance for streptococci, staphylococci, and enterococci. Lack of complete concordance among various guidelines stems from the preponderance of case-control studies, animal data, and expert opinion in guiding the recommendations.

Patients considered at high or moderate risk have an increased risk of contracting IE from a transient bacteremia. High-risk groups include patients with a previous history of IE, prosthetic heart valves, surgically created conduits, and complex cyanotic congenital anomalies. Moderate-risk groups include persons with acquired valvar heart disease, noncyanotic congenital heart disease, hypertrophic cardiomyopathy, and mitral valve prolapse with regurgitation or severe valve thickening. The risk of IE in patients with mitral valve prolapse and important mitral regurgitation is estimated to be five times that of the normal adult population. Use of antibiotic prophylaxis for anyone with a systolic murmur has been deemed cost-effective in the British guidelines. IE has been reported following colonoscopy, but transient bacteremia is not associated with CT colonography.

The regimens indicated here can be used for invasive respiratory procedures and gastrointestinal and genitourinary procedures in which prophylaxis is indicated.

Key: IM, Intramuscular; IV, intravenous.

Box 15-7  Procedures to Possibly Consider for Antibiotic Prophylaxis Because of Associated Bacteremias

- Transesophageal echocardiography
- Percutaneous transluminal coronary angioplasty with or without stenting
- Occlusive device implantation
- Balloon valvuloplasty
- Upper gastrointestinal endoscopy with or without biopsy
- Circumcision
- Cervical smears
- Acupuncture, body piercing, and tattooing

Adapted from Delahaye and colleagues.⁶²

Recommendations regarding specific procedures differ somewhat between U.S. and European guidelines. Procedures common to all guidelines are listed in Box 15-6, and additional procedures to consider from the 2004 British guidelines are listed in Box 15-7. Specific antibiotic recommendations are summarized in Table 15-5.

Bradycardia

DEFINITION

Abnormal bradycardia is a slow cardiac rate that results chronically or episodically in inadequate cardiac output or life-threatening ventricular arrhythmias.

HISTORICAL NOTE

During the early 1700s, peripheral pulsations of the circulation began to be timed, and in 1717 Gerbezius recognized bradycardia as a deviation from the usual pulse rate. Morgagni is believed to have surmised the relationship between bradycardia and syncope in 1761, but he attributed both to melancholy. In 1827, Adams accurately described Adams-Stokes syndrome and proposed that it had a cardiac origin. This idea was not well accepted until Stokes, in 1846, collected reports of seven patients with the condition and agreed with Adams’ concepts. The phrase maladie de Adams-Stokes was originated in 1899 by Huchard.

Understanding the morphologic basis of Adams-Stokes syndrome began after Harvey’s description of the cardiac cycle. Cardiac conduction tissues were first described by Purkinje in 1845, which he mistook as cartilage tissue. The atrioventricular (AV) conduction bundle was described by His in 1893, and in 1896, Aschoff and Tawara described the AV node and its connection to the His bundle.

It has long been known that the heart responds to external electrical stimulation. As long ago as 1804, Aldini successfully stimulated systole in the hearts of decapitated criminals. Apparently it was known during the late 1800s that direct heart puncture with or without injecting drugs would occasionally produce effective cardiac contractions. Mond reported in 1929, Lidwill in Australia successfully paced the heart of a stillborn infant for a time by direct ventricular puncture. In 1932, Hyman atrially paced several patients with what he termed an artificial pacemaker, and Bigelow and colleagues in Toronto paced canine hearts by esophageal and precordial electrodes in 1950.

In 1952 in Boston, Zoll reported successfully pacing hearts of patients with complete heart block with external cutaneous electrodes and a large and relatively nonmobile pulse generator. This method was the only one available when intracardiac surgery came into existence during the mid-1950s, and although stimulation of each heartbeat was accompanied by skeletal muscle contractions, and skin under the electrodes quickly became excoriated, this method kept some cardiac surgical patients alive until sinus rhythm returned. However, for patients in whom sinus rhythm did not return, the agony of skeletal muscle contractions and skin excoriations increased as the days passed. Sheer terror developed with approach of the surgeon who would each day provoke an Adams-Stokes episode by turning off the pacer to see whether an adequate idioventricular rhythm, let alone sinus rhythm, would replace the electrocardiographic image of P waves without any QRS complex.

Change began when Lillehei, in Minneapolis, enlisted the help of Earl Bakken, a television engineer and later founder of Medtronic Corporation, in developing a small portable pacemaker. More importantly, he devised the technique of...
leaving a wire attached to the ventricular epicardium at operation and bringing it out externally. The external electrode was used to pace the heart with minimal patient discomfort.\textsuperscript{96} Later, Thevenet, Hodges, and Lillehei devised a method of inserting the wire into the ventricle through a needle passed through the skin over the precordium without an operation.\textsuperscript{72} These systems used a portable pacemaker system devised by Bakken.

In 1959, Elmquist and Senning in Stockholm reported placing the first totally implantable pacemaker system using epicardial electrodes.\textsuperscript{87} This advance was made possible by invention of transistors during the 1950s. In 1960, Chardack, Gage, and Greatbatch described a self-contained, implantable pulse generator driven by a mercury cell battery for use with implanted epicardial leads.\textsuperscript{65}

During the previous year, Furman and Robinson had reported the use of endocardial electrodes introduced transvenously rather than epicardially.\textsuperscript{14} Their data supported the idea that endocardial and epicardial electrodes perform similarly. This led to widespread availability by 1961 of both endocardial electrodes inserted transvenously and epicardial electrodes inserted by thoracotomy. These early pacemakers paced at a set rate and did not sense spontaneous cardiac activity. They were crude by present standards but allowed 85% of patients having Adams-Stokes episodes to survive for at least 1 year, in contrast to less than 50% before their introduction.

Rapid developments followed, and pulse generators that sensed the QRS and fired only when no spontaneous QRS occurred within a specified time became available during the mid-1960s. Much work led by Greatbatch during the late 1960s and early 1970s to improve the cells (batteries) resulted in commercial availability of lithium cell–powered pulse generators during the early 1970s. The lithium cells were much more reliable and, with hydrogen gas no longer being liberated in the pulse generator, hermetic sealing of the entire device became possible. More complicated electronic circuits were developed to permit programming of rate and stimulus duration as well as better QRS sensing as transistorized circuits with a few components evolved into hybrid circuits with more components, into integrated circuits, and finally into implantable pulse generators containing microprocessors.

Further improvements permitted atrial sensing and pacing as well as ventricular sensing and pacing (universal pacing) and ventricular pacing synchronized with the patient’s atrial contractions, and sequential AV pacing.\textsuperscript{1,11} Currently available pacemakers provide sensing of either body motion or increase in respirations and use the information to alter pacing rate appropriate for patient activity. Finally, the combination of multiprogrammability with diagnostic radio and telephonic transmission has permitted accurate evaluation of pacemaker function and noninvasive adjustment of pacemaker variables for optimal treatment of the patient.

Improvements in pacing electrodes have been made through the years in the form of better wire alloys, antifracture characteristics, electrode pacing threshold properties, and lead insulation. These improvements have diminished the occurrence of high pacing thresholds and lead fracture.

**MORPHOLOGY**

Abnormal bradycardia may be the result of complete heart block, a condition in which P waves (atrial depolarization) occur at a constant interval but are unrelated to the less frequently occurring or absent and often broad QRS complexes (ventricular depolarization).

**Heart Block**

Complete heart block may be present at birth or develop later in life.

**Congenital Complete Heart Block**

Musculature of the atrial septum may be congenitally deficient near the AV valves, such that there is a diminished or absent connection between the atria and the AV node. Lev described morphologic discontinuity between AV node and bundle of His as another basis for congenital complete heart block in otherwise normal hearts.\textsuperscript{1,3} In hearts with AV discordant connections, complete heart block may be present at birth, presumably related to these same mechanisms.

**Spontaneously Developing Complete Heart Block**

Some congenital anomalies of the bundle of His may predispose patients to developing complete heart block. Thus, in hearts with AV discordant connection, unusually long length of the bundle of His is believed to predispose it to fibrosis and loss of function.

Certain disease processes may damage the conduction system. Calcification of the aortic valve may extend into the underlying ventricular septum and damage the bundle of His by a shearing effect during certain phases of the cardiac cycle. Mitral calcification does the same less commonly. Acute coronary occlusions resulting in posteroinferior myocardial infarctions may be associated with temporary AV node ischemia and heart block.

An increase in fibrous tissue of the bundle of His and its branches, accompanied by a decrease in number of conduction fibers, seems to be part of the aging process. Progressive fibrosis and fiber loss in left and right bundle branches and resultant heart block (Lev disease, Lenegre disease) may represent acceleration of this process. Anteroseptal myocardial infarctions produce ischemic necrosis in and around right and left bundle branches and may result in permanent heart block. Chronic ischemic heart disease can gradually result in septal fibrosis, with loss of function in both bundle branches. Dilated cardiomyopathy (see “Dilated Cardiomyopathy” in Section II of Chapter 20) may be associated with long-standing left ventricular fibrosis that may involve the bundle branches and produce complete heart block.

**Surgically Induced Complete Heart Block**

During surgical procedures for repair of ventricular septal defects (isolated or as part of tetralogy of Fallot and other complexes; see Chapters 35, 38, and 52 through 56) or AV septal defects (see Chapter 34), resection of discrete subvalvar aortic stenosis (see Chapter 47), and replacement of the mitral, aortic, or tricuspid valves (see Chapters 11 through 14), the bundle of His or contiguous AV node may be severed or sutured. In the absence of such direct injuries, the conduction bundle or AV node may be functionally damaged by hemorrhage, with resultant complete heart block. Although fibrosis must develop in these surgical areas late postoperatively, it is interesting that complete heart block is rare late after operation.
Other Bradyarrhythmias

Sinus Node Dysfunction

Important sinus node dysfunction may develop without identifiable morphologic changes in the node. Loss of sinus node cells normally associated with aging may accelerate and cause dysfunction, especially in patients with a subnormal nodal cell population at birth. Amyloid deposition may occur within the sinus node and produce dysfunction. Direct damage to the sinus node by surgical procedures occurs but is uncommon. Damage to the sinus node can result in a junctional rhythm that becomes slower as time passes. In the absence of direct injury, surgical procedures in the region of the sinus node, such as the atrial switch operation (see “Atrial Switch Operation” under Technique of Operation in Chapter 52) and Fontan operation (see “Technique of Operation” in Section IV of Chapter 41), may result in late perinodal fibrosis, with consequent loss of sinus node function. This process may be due to damage to the sinus node artery. This transeptal approach to the left atrium, which often involves an incision in the roof of the right atrium and division of the sinus node artery, can also result in temporary or permanent sinus node dysfunction.

Dysfunction of Pathways between Sinus and Atrioventricular Nodes

Preferential conduction pathways between the sinus and AV nodes may be interrupted by congenital absence of electrical continuity in these areas. Surgical procedures, especially atrial switch and Fontan operations, may rarely damage preferential conduction pathways immediately. More commonly, late postoperative fibrosis develops and interferes with conduction along these pathways, and a slow junctional rhythm results.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Pathophysiology

Hemodynamic Effects

Although blood flow into the aorta and large arteries is intermittent (pulsatile), the combined effects of the aortic valve, elasticity of the aorta and great arteries, and characteristics of the arterial distributing system make flow rate relatively constant in capillaries. Thus, cells of the brain and other organs receive continuous nutrient flow. The magnitude of this flow is related to, among other things, net forward flow across the aortic valve with each ventricular systole and heart rate. When the stroke volume is large and heart rate slow, as in trained athletes at rest, elasticity of the aorta and its filling during systole are sufficient to maintain an adequate volume of runoff during a long diastolic period, and thus an adequate nutrient flow to cells of the brain and other organs. When stroke volume is not large, runoff during the late part of chronically long diastolic periods may be inadequate to maintain the proper internal milieu of cells of the brain and other organs. Because the brain is particularly sensitive to hypoxia, cerebral symptoms usually develop before those from dysfunction of other organs.

Cardiac Electrophysiologic Effects

The longer the intervals between periodic depolarizations of ventricular myocardium, the greater the degree of QT prolongation and the higher the likelihood of developing ventricular extrasystoles or tachycardia or both, especially of the torsades de pointes variety (long QT syndrome). Thus, bradycardia predisposes the patient to life-threatening ventricular arrhythmias. Furthermore, with complete heart block, there is the possibility of prolonged ventricular asystole.

Symptoms

Clinical manifestations of first-degree heart block (PR interval > 0.2 second in adults) are rare. Second-degree heart block (intermittent lack of AV conduction) may be manifested by bradycardia and symptoms. In third-degree (complete) heart block (all atrial impulses fail to be conducted to the ventricle), bradycardia is present, and symptoms are frequent.

Approximately a quarter of patients with sinus node dysfunction have ischemic heart disease.

Diagnostic Criteria

Bradycardias are diagnosed largely by electrocardiographic (ECG) criteria.

Atrioventricular Block

Complete AV block and symptomatic incomplete AV block (such as 2:1 second-degree AV block) are diagnosed by standard ECG. When paroxysmal AV block is suspected as the cause of symptoms, prolonged ambulatory ECG monitoring may provide confirmation of the diagnosis (see “Indications for Intervention” later in this section).

Sick Sinus Syndrome

Symptomatic arrhythmias in sick sinus syndrome include profound sinus bradycardia, junctional bradycardia, sinus arrest, sinus node exit block, and the so-called tachycardia-bradycardia syndrome in which paroxysmal atrial tachycardia, flutter, or fibrillation is followed by symptomatic pauses caused by overdrive suppression of the sinus node and subsidiary pacemakers. In most of these patients, the resting ECG may not be diagnostic, and prolonged ambulatory ECG monitoring is required to document the abnormal rhythm. Electrophysiologic study is of limited help because abnormal sinus node recovery times or sinoatrial conduction times are demonstrable in only a small minority of symptomatic patients.

Carotid Sinus Syndrome

A hyperactive carotid sinus reflex is said to be present when digital stimulation of the carotid sinus results in cardiac asystole lasting 3 or more seconds. Carotid sinus syndrome is diagnosed when, in addition to the presence of a hyperactive reflex, the patient’s spontaneous symptom complex can be reproduced by stimulation of one or both

---

1The two types of second-degree heart block are Mobitz I, in which AV conduction time is progressively prolonged (Wenckebach period) until one atrial impulse is not conducted to the ventricle, and Mobitz II, in which AV conduction times are constant, but episodically an atrial impulse is not conducted to the ventricles.
(not simultaneously) carotid sinuses. Pacemaker therapy may completely relieve symptoms in patients with only a cardio-inhibitory response. However, the presence of a simultaneous vasodepressor response should also be sought by repetition of massage after intravenous atropine and measurements of the blood pressure. Preservation of the heart rate may not prevent symptoms caused by hypotension in such patients.

**NATURAL HISTORY**

Bradyarrhythmia from both spontaneous heart block and spontaneous sinus node dysfunction tends to occur in elderly patients. The mean age of patients at the time of diagnosis of spontaneously occurring heart block is 70 years. The proportion of patients who have complete heart block developing spontaneously who remain asymptomatic is not known. The most common clinical manifestation is an Adams-Stokes episode. This syndrome is part of the history in 60% to 70% of patients. Symptoms probably eventually develop in most patients. The exact proportion of symptomatic patients is in part determined by functional status of the heart as a whole. Likewise, the tendency toward premature death is related to functional status of the myocardium along with other risk factors.

Patients with Adams-Stokes episodes as a manifestation of complete heart block and who are not paced have a 1-year survival of 50% to 75%, much less than that of an age-sex-race–matched general population. One-year survival is said to be 70% to 80% in patients with complete heart block but without a history of syncope. These differences persist with follow-up to 15 years and appear to be related to the considerably higher prevalence of sudden death in the patients who have syncopal attacks. Syncopal attacks, as well as sudden death, in patients with idioventricular or bundle of His rhythm usually result from sudden ventricular asystole. Syncopal attacks also may be precipitated by a sudden reduction in stroke volume or increased metabolic demands.

**Congenital Complete Heart Block**

Infants born with congenital complete heart block and hearts that are otherwise normal have a prognosis that may be somewhat better than that for patients with spontaneously developing complete heart block. Ten-year survival for congenital complete heart block is about 85%, with most deaths occurring in the first month of life. Deaths occurring after this time are related to Adams-Stokes episodes.

**Surgically Induced Complete Heart Block**

In the early years of cardiac surgery when epicardial and transvenous pacing was not possible, hospital mortality was greatly increased in patients in whom complete heart block developed perioperatively. Unpaced hospital survivors had a 1-year survival of about 40%.

**Sinus Node Dysfunction**

The natural history of patients with this type of bradycardia has not been clearly described.

**TECHNIQUE OF INTERVENTION**

Development of techniques and devices for cardiac pacing has involved surgeons, physicians, interventional cardiologists, and industry, and advances continue to be made. Methods of insertion and the devices implanted are constantly being improved. Whereas in the 1960s pacemakers were usually inserted by cardiothoracic surgeons, currently in many parts of the world they are inserted, managed, and followed by cardiologists, and often by cardiologists with specialized knowledge of cardiac electrophysiology. Because of these developments, it is no longer practical to include detailed descriptions in a textbook of cardiac surgery. Instead, only general information regarding cardiac pacemaking and basic device insertion procedures are discussed.

**Pacing Modes**

There are a number of pacing modes. In addition to the basic characteristics described here, many pacemakers have special tachyarrhythmia functions and other programmable functions. Also, some pacemakers sense some surrogates of increased metabolic activity (e.g., body motion, increased rate or volume of respiration) and increase pacing rate accordingly.

**VVI**

In VVI mode, the ventricle is paced (V), sensing is from the ventricle (V), and response to a sensed spontaneous ventricular depolarization is inhibition (I) of delivering the next electrical stimulus by the pulse generator. The disadvantage of this pacing mode is lack of atrial contributions to ventricular filling. The advantage is simplicity of electrode placement and a relatively long life of the pulse generator.

**AAI**

In AAI mode, the atrium (A, usually the right) is paced, sensing is from the atrium (A), and sensed atrial depolarization inhibits (I) the next programmed electrical impulse. The AAI mode requires normal AV conduction and functioning atrial pathways to the AV node. This type of pacing mode was anticipated and pioneered by Lillehei and colleagues as early as 1963.

The AAI mode is seldom used (<5%), primarily because many patients with sinus node dysfunction ultimately require ventricular pacing. Its advantage is preservation of atrial contribution to ventricular filling.

**VDD**

VDD mode, as well as DVI and DDD modes described subsequently, requires both atrial and ventricular electrodes. It also requires relatively normal sinus node function. In VDD mode, the ventricle is paced (V), both the atrium and ventricle are sensed (D denotes dual chamber or dual function), and the response of the pulse generator may be either the triggering or inhibiting (D) of the next electrical pulse. Generally, sensed atrial depolarization triggers a stimulating pulse to the ventricular electrode at a preset or variable PR interval. Ventricular stimulus is inhibited when spontaneous ventricular depolarization follows atrial depolarization within the set PR interval of the pulse generator. The pulse generator is programmed so that when the PP interval becomes excessively long, the pulse generator functions in VVI mode.
Advantages of the VDD mode are preserved atrial contribution to ventricular filling and ventricular rate that follows the patient’s own atrial rate, thereby responding appropriately to stress and exercise. Disadvantages are need for both atrial and ventricular electrodes and the possibility of producing a reciprocating (loop) tachycardia by retrograde conduction.

**DVI**
Both atrium and ventricle (D) are paced in DVI mode, with an appropriate interval between the stimuli to each. Ventricular (V) but not atrial depolarization is sensed. A sensed ventricular depolarization inhibits (I) the next dual pacing stimulus in noncommitted DVI mode; it does not do so in committed DVI mode.

The advantage is maintaining atrial contribution to ventricular filling even when sinus node function fails. Raza and colleagues, Raichlen and colleagues, and others have documented the hemodynamic advantages of this arrangement. The disadvantage is that AV synchronization is lost when the atrial rate increases during exercise or stress.

**DDD**
DDD mode, or universal pacing mode, can pace both atrium and ventricle (D), sense both atrial and ventricular depolarization (D), and either trigger or inhibit (D) an electrical pacing pulse. Its advantage is universality of application. Disadvantages are that dual stimulation reduces battery lifetime, and loop tachycardia can occur with variations in retrograde conduction from ventricles to atria. These disadvantages can be eliminated or reduced by programming the pacemaker pulse generator characteristics according to changes in the patient’s AV and ventriculoatrial conduction characteristics.

**Electrode Testing**
Each electrode placed is tested at the time of insertion. The **pacing threshold**, or the lowest delivered voltage at which myocardial depolarization occurs, is tested first. For ventricular electrodes, a threshold of 0.3 V or less (usually at 0.5-ms pulse duration) is optimal. A threshold of 0.3 to 0.5 V is frequently observed, and a threshold as high as 1.0 V is acceptable. Higher thresholds are undesirable because they reduce pulse generator life. For atrial electrodes, a stimulating threshold of 1.0 V or less is acceptable. In open chest insertion, use of the electrocautery tends to increase the stimulating threshold.

The electrode is then tested for its **sensing capabilities**. For both endocardial and epicardial ventricular electrodes, a QRS complex in the electrogram of 5 mV or more is desirable. For atrial electrodes, a P wave with peak-to-peak amplitude of 2 mV or more is acceptable.

Other important testing for a transvenously placed electrode includes determining that (1) it does not provoke ventricular tachycardia by its position, (2) its position is mechanically stable, and (3) it does not pace the diaphragm or skeletal muscle. Bipolar electrodes are generally used; they are less subject to interference by skeletal muscle contraction than unipolar electrodes. The latter are sometimes used when the pulse generator surface serves as the indifferent electrode.

**Transvenous Electrode Insertion and Pulse Generator Placement**
After the patient is positioned on the operating table, temporary pacing wires, if present, are secured with their tips outside the operative field and attached to an external pulse generator. The operative field is prepared and draped, including the lower neck and anterior chest wall. Wires are passed from the surgical field for emergency pacing, obtaining endocardial electrograms, pulse generator testing, and lead threshold measurement. An adjustable constant-current, dual-channel, external pulse generator is used to determine atrial capture when simultaneous atrial and ventricular pacing are necessary.

Local anesthesia is administered to achieve a field block. An oblique or transverse incision is made below the clavicle, generally on the left side (on the right for left-handed individuals). A subcutaneous pocket is created over the pectoralis major fascia. The pocket should be appropriate for size of the pulse generator. If no permanent pacing electrodes are in place, electrocautery may be used for the dissection and to achieve hemostasis.

Edges of the incision are retracted to expose the space between first rib and clavicle for access to the subclavian vein. A needle with a syringe attached is used to locate and penetrate the vein. A flexible J-tip guidewire is passed through the needle into the subclavian vein and advanced into the superior vena cava. Position of the guidewire is confirmed by fluoroscopy, and the needle is withdrawn and replaced with a peel-away sheath catheter. The distal 5 cm of the stylet for the ventricular electrode is bent into a small curve and inserted into the electrode. The electrode and stylet are placed into the sheath catheter and advanced into the right atrium, after which the sheath catheter is peeled away and removed. Under fluoroscopic control, the electrode is advanced through the tricuspid valve into the right ventricle and further advanced into the pulmonary trunk to ensure that the coronary sinus has not been entered. The curved stylet is replaced with a straight one that is not fully inserted, leaving the electrode flexible in its distal 5 to 10 cm. The electrode is withdrawn along the ventricular septum until an appropriate anatomic position has been found among the trabeculations near the ventricular apex. The stylet is advanced to the tip of the electrode to stiffen the electrode. It is advanced gently among the trabeculations and “seated.” It is secured passively by the tines on the electrode or by extruding its attachment coil. The stylet is removed.

The electrode is then tested (see “Electrode Testing” earlier in this section). Testing with deep breathing is done to judge and set the final length of catheter within the ventricle when the diaphragm is in its most inferior position. Once a suitable anatomic and functional position has been located, the lead is secured with a small plastic sleeve to the pectoral fascia to prevent inadvertent displacement.

Placing the atrial electrode, if one is to be used, is done after inserting the ventricular electrode. Penetrating the subclavian vein for inserting the atrial electrode is preferentially performed at the beginning of the procedure. After the guidewire for the ventricular electrode is inserted, a second guidewire is inserted into the subclavian vein. Separate penetration of the subclavian vein is desirable to prevent dislodging the ventricular electrode while manipulating the atrial electrode. Alternatively, the guidewire used for ventricular
electrode insertion may be withdrawn and used subsequently for atrial electrode insertion. Bleeding from the subclavian vein puncture site, however, may be a problem.

A second peel-away sheath catheter is inserted into the subclavian vein over the guidewire and the atrial electrode inserted through it over the guidewire. The electrode is advanced into the right atrium with stylet in place. The stylet is withdrawn, permitting the pre-formed J-curve to appear in the electrode. Manipulation of the stylet and gentle rotation of the electrode permit positioning of its tip into the atrial appendage. This position is verified by the lateral to-and-fro motion of the tip and may be confirmed by lateral fluoroscopy. The electrode tip is secured to atrial endocardium by extruding the screw-in coil. The electrode is then tested (see “Electrode Testing” earlier in this section). After a satisfactory position is achieved, the electrode is secured to the pectoralis fascia by a suture.

The appropriate pulse generator is selected, inspected, and checked by the pacemaker system analyzer. The ends of the pacing leads are cleaned to remove blood or tissue and are inserted into the pulse generator. Satisfactory function of the pacing system is verified by ECG before wound closure. The wound is inspected for hemostasis and irrigated with antibiotic solution. The pacing system is cleaned with an antibiotic solution, placed in the pocket, and secured with nonabsorbable sutures. The pacing leads are kept away from the anterior surface of the pulse generator to prevent injury during subsequent pulse generator replacement. The wound is closed in layers, with the first layer isolating the pulse generator pocket from the remainder of the incision.

Electrode Insertion by Thoracotomy and Pulse Generator Placement

When an open technique is necessary, the patient is positioned on the operating table for a sternotomy, left anterior thoracotomy, or epigastric incision. For single-chamber (ventricular pacing) insertion, anterior thoracotomy or epigastric incisions are adequate. When dual-chamber pacing is contemplated or when pacing is required early after a cardiac operation, a median sternotomy is used. Procedures regarding temporary pacing wires, skin preparation, and draping are the same as for the transvenous approach.

In adults, a separate transverse left upper quadrant abdominal or infraclavicular incision is made and a pocket developed in the prefascial space. In infants and usually in children, the pocket is created behind the rectus abdominis muscle. A site for electrode attachment to the right or left ventricle is identified in a region of myocardium uncovered by fat, away from any coronary arteries and from the phrenic nerve, and if possible, not directly under the sternum. If there is uncertainty about the site, an electrode probe can be used to locate an appropriate site for placing the electrode. Screw-in electrodes are commonly used for ventricular pacing because of ease of insertion. They are secured by clockwise rotation of the cork-screw electrode with gentle pressure on the myocardium. Electrodes that lie on the epicardial surface, held in place with fine sutures, are preferable for atrial pacing even though they are more difficult to insert. If space permits, two electrodes are placed in each location. The electrodes are tested as previously described.

A tunnel is created from the pericardial cavity to the previously formed subcutaneous pocket. An appropriate pulse generator is selected, tested, and connected to the electrodes.

Wounds are closed in layers, and one chest tube is left for closed drainage.

Permanent Pacing after Intracardiac Surgery

Complete heart block occurring during cardiac operation is managed by placing temporary pacing electrodes on the right ventricle and right atrium so that AV sequential pacing can be performed using an external pulse generator. The pacing threshold of the temporary electrodes should be tested daily. When it appears that complete heart block or profound bradycardia is likely to be permanent, an implantable pacing system is inserted by the transvenous or open route.

The notable exception to this strategy is when there is a high probability of complete heart block developing at operation or when heart block may develop later and access to the right ventricle by the transvenous route is not possible. This includes patients who have replacement of the tricuspid valve with a mechanical prosthesis. These patients should have permanent epicardial electrodes placed at the time of the cardiac operation. Bioprosthetic valves in the tricuspid position may be crossed by a transvenous electrode without important impairment of prosthetic valve function.

Before discontinuing cardiopulmonary bypass (CPB), cardiac action is established by AV sequential pacing through two temporary right atrial and two temporary ventricular wires attached to an external pulse generator. Single bipolar temporary wires may also be used. Preferably, permanent ventricular electrodes are placed after discontinuing CPB and completing hemostasis, because electrocautery tends to increase the pacing threshold of already implanted leads. Permanent atrial electrodes should also be placed if dual chamber pacing is desired. The ends of the permanent leads are capped and placed subcutaneously in the left upper quadrant of the abdomen or brought through the anterior chest wall to a subcutaneous position below the left clavicle. A loop of lead is left within the pericardial cavity.

If heart block persists, the patient is returned to the operating room. With the patient under local anesthesia and conscious sedation, the surgical field is prepared. A transverse incision is made over the left upper quadrant of the abdomen (or below the clavicle), and the electrode ends are retrieved. The electrodes are tested and attached to the pulse generator, a pocket is created for it, and the incision is closed. The temporary wires are withdrawn.

Alternatively, the pulse generator can be attached to the electrodes and implanted at the time of cardiac repair. The disadvantage is that sinus rhythm may return in a few days, and the pulse generator may no longer be essential. There is also risk of bleeding into the pulse generator pocket, with formation of a hematoma.

SPECIAL FEATURES OF POSTOPERATIVE CARE

Usual care for cardiac surgical patients is given early postoperatively (see Chapter 5). In addition, a chest radiograph is obtained to ascertain position of the leads. Pacing threshold is usually not determined by noninvasive testing prior to hospital discharge, because thresholds obtained at this time are always higher than those obtained 6 weeks to 3 months
later. Reprogramming of the pulse generator at an appropriate voltage is best done later, leaving the relatively higher and safer pacing voltage until that time.

The electrodes are considered to have become stable by about 6 months after implantation.\(^{113}\) Around that time they are rechecked, and the pulse generator is set at the lowest output considered to be safe.

### RESULTS

#### Survival

It is generally agreed that survival of patients with bradycardia is improved by permanent pacing.\(^{35}\) Death early after pacemaker insertion is unusual, and when it occurs it is usually due to coexisting cardiac problems.\(^{85,324}\) This is true for children as well as adults.\(^{318}\) Ten-day mortality is 1.6%, and 30-day mortality is 2.7% (Fig. 16-1).

Survival late after pacemaker insertion is satisfactory, with 5- and 10-year survival of 59% and 39%, respectively\(^{212,111}\) (see Fig. 16-1). Survival is similar in those whose bradycardia is from heart block and those in whom it is related to sinus node dysfunction.\(^{111,324}\) Advanced age decreases late survival (Table 16-1), as does chronic heart failure and presence of ischemic heart disease.\(^{49,10,11,10,2,324}\)

### Infection and Pulse Generator Erosion

Infection and pulse generator erosion are not always identified separately as complications of pacemaking, and they must therefore be considered together.

Even with meticulous surgical technique and prophylactic antibiotic therapy, infection in the wound and around the pulse generator and leads occurs in 0.5% to 2% of cases.\(^{311,321}\) Treatment consists of inserting an entirely new pacemaker system at a different site and complete removal of the old system.\(^{83}\)

Excessive pressure of the pulse generator or wire against the overlying skin or subcutaneous tissue can cause necrosis and permit their exposure.\(^{321}\) The true prevalence of this condition is unknown because it is often considered infection. Insertion of pulse generators in small pockets with skin closure under tension increases the chance of skin necrosis. When the pulse generator and leads become exposed as a result of pressure necrosis, treatment is the same as for an infected pacemaker. Preventing this problem is best achieved by forming the pulse generator pocket in the immediate prefascial space to permit as much tissue as possible to come between pulse generator and skin.

### Lead and Electrode Malfunction

#### Time-Related Variability of Pacing Thresholds

The lowest possible initial pacing and sensing thresholds are sought at the time of placing the electrodes, because thresholds frequently rise later.\(^{110}\) One or more months after insertion, more than half the leads have a threshold pacing level greater than any level measured initially or during the first month of use.\(^{520}\) Forty-five percent of epicardial electrode leads have either a grossly unstable threshold pacing level or a gradually increasing level (Fig. 16-2) for as long as 10 years after insertion (Fig. 16-3).\(^{520}\) These “spikes” in the threshold pacing level may be associated with episodes of intercurrent infection. Such changes probably account for at least some of the sudden deaths that occur late after initiating pacing for complete heart block after repair of congenital heart disease.

![Figure 16-1](image-url) Survival of 1068 patients with permanently implanted pulse generators. Time zero is time of pacemaker implantation. Vertical lines encompass ±1 standard error. Numbers in parentheses indicate patients remaining at risk. (UAB group, 1961 to 1984; Shepard RB: personal communication; 1985.)

![Figure 16-2](image-url) Variation in pacing threshold after development of complete heart block following repair of “single” ventricle. Note episodic and unpredictable sudden increases in threshold, which could have led to sudden death if output from the pulse generator had been insufficient to overcome them. (From Shepard and colleagues.\(^{529}\))
these symptoms may not be the result of pacing per-
ding either ventricular or atrial endocardial leads. Dislodgment
occurs in less than 2% of cases.\textsuperscript{F10,V4}

Undersensing
Undersensing, or lack of recognition of the heart’s depo-
larization, is related most commonly to inadequate placement
of the electrode. At times it can result from fibrosis at the
electrode-myocardial junction. This complication leads to
competitive pacing. Undersensing can generally be treated by
noninvasive programming to increase sensitivity of the pulse
generator.

Electrode Dislodgment
Electrode dislodgment, with or without right ventricular or
atrial perforation, is the most common complication of insert-
ing either ventricular or atrial endocardial leads. Dislodgment
occurs in less than 2% of cases.\textsuperscript{F10,V4}

Lead Fracture
Lead fracture, with consequent loss of pacing, is an infre-
tant early complication of pacemaking but is not uncom-
mon years after implantation.

New Symptoms from Pacing in VVI Mode
Syncope or near-syncope is one of the most important symp-
toms resulting from pacing. Syncope as a manifestation of
pacemaker syndrome occurs in less than 10% of patients being
paced in VVI mode. Arterial hypotension may also develop.
These symptoms usually occur when ventriculoatrial conduc-
tion is intact and the indication for pacing has been sinus
node dysfunction.\textsuperscript{N6} The exact etiology of symptoms is uncer-
tain, but they may be due to lack of atrial contribution to
ventricular filling secondary to AV asynchrony, with or
without atrial contraction against a closed AV valve. Also, AV
valve regurgitation may be caused by asynchronous contrac-
tion of atria and ventricles.\textsuperscript{M10} Diagnosis is suspected when
those symptoms and signs are present and can sometimes be
verified by an increase in blood pressure when pacing is
stopped and a decrease when it is restarted. Treatment is
VDD or DDD pacing.

Dizziness occurs in about one third of patients. Because
both dizziness and syncope are common in elderly patients,
these symptoms may not be the result of pacing per-

\textbf{INDICATIONS FOR INTERVENTION}

The most common indication for permanent cardiac pacing
is symptomatic bradycardia.\textsuperscript{F12} It may be intermittent or per-
manent and due to complete heart block, second-degree AV
block, or sinus node dysfunction. Symptoms must be directly
attributable to the bradycardia and may include syncope, diz-
ziness, exercise intolerance, and heart failure. When ambula-
tory ECG monitoring is negative for abnormal bradycardia,
electrophysiologic study is indicated in patients with unex-
plained transient neurologic symptoms. The finding of pro-
longation of the HV interval (time from onset of activation of
the bundle of His to the earliest onset of ventricular depo-
larization) of at least 70 milliseconds supports a diagnosis
of paroxysmal AV block as the cause of the symptoms and
justifies elective pacemaker implantation.\textsuperscript{N8} In the absence of
neurologic symptoms, however, the finding of such HV pro-
longation rarely if ever warrants prophylactic pacemaker
implantation.\textsuperscript{D8}

Another indication is surgically induced complete heart
block, because of the risk of an Adams-Stokes episode. Patients
in sinus rhythm after repair of congenital malforma-
tions, but in whom complete heart block follows repair and
persists for a number of days before reversion to sinus rhythm,
are at increased risk for developing late symptomatic heart
block. These patients should be considered for prophylactic
pacemaker implantation before hospital discharge, particu-
larly when subsidiary escape pacemakers have been absent or
unreliable.

In some situations, permanent pacing may be indicated in
asymptomatic patients because of risk of an Adams-Stokes
episode.\textsuperscript{F11} These situations include profound bradycardia
(ventricular rate < 40 beats \textperiodcentered min\textsuperscript{-1}), second-degree AV block
at the infra-His level, advanced second-degree AV or com-
plete heart block after myocardial infarction, and congenital
heart block with a wide QRS escape rhythm. Other rhythms
may be an indication for pacing in asymptomatic patients.
These include new bundle-branch block with transient
second-degree AV block postmyocardial infarction, bifascicu-
lar bundle-branch block with intermittent type II second-
degree AV block, sinus node dysfunction, and transient
post-surgical AV block that reverts to bifascicular block in
children.\textsuperscript{F11,H16} In sinus node dysfunction, for example, when
symptoms are relatively infrequent, the decision to advise
permanent pacing may rest on the demonstration of asym-
ptomatic sinus pauses, sinoatrial exit block, or both.

A special situation is extensive intraatrial operations such
as the Senning or Mustard operation (see “Senning Tech-
nique” and “Mustard Technique” under Technique of Oper-
ation in Chapter 52) or the Fontan operation (see Chapter
41). Junctional rhythm often develops late postoperatively
with the potential of tachybradycardia and sudden death. This
situation is an indication for atrial pacing (AAI).\textsuperscript{M10}

In response to publication of studies advancing the knowl-
edge of the natural history of cardiac arrhythmia optimally
-treated by cardiac pacing and important advances in pacing
Box 16-1  Indications for Permanent Pacemaker Insertion Based on ACC/AHA/HRS Guidelines: Acquired Atrioventricular Block in Adults

**Class I**
1. Third-degree and advanced second-degree atrioventricular (AV) block at any anatomic level associated with:
   a. Bradyarrhythmias with symptoms or ventricular arrhythmias presumed to be due to AV block
   b. Arrhythmias and other medical conditions requiring drug therapy that result in symptomatic bradycardia
   c. No symptoms, but with documented periods of asystole ≥ 3 seconds or any escape rhythm < 40 beats \( \cdot \) min\(^{-1} \) or with an escape rhythm below the AV node
   d. No symptoms but with atrial fibrillation and bradycardia with 1 or more pauses of at least 5 seconds
   e. Catheter ablation of the AV junction
   f. Postoperative AV block that is not expected to resolve after cardiac surgery
   g. Neuromuscular diseases with AV block (myotonic muscular dystrophy, Kearns-Sayre syndrome, Erb dystrophy, peroneal muscular dystrophy)
   h. Exercise in the absence of myocardial ischemia
2. Second-degree AV block with associated symptomatic bradycardia
3. Asymptomatic persistent third-degree AV block with average awake ventricular rates of 40 beats \( \cdot \) min\(^{-1} \) or faster if cardiomegaly or left ventricular dysfunction is present, or if site of block is below the AV node

**Class IIa**
1. Third-degree AV block with escape rate ≥ 40 beats \( \cdot \) min\(^{-1} \) in asymptomatic patients without cardiomegaly
2. Asymptomatic second-degree AV block at intra- or infra-His levels at electrophysiologic study
3. First- or second-degree AV block with symptoms similar to those of pacemaker syndrome or hemodynamic compromise
4. Asymptomatic type II second-degree AV block with narrow QRS

**Class IIb**
1. May be considered for neuromuscular diseases (see above) with any degree of AV block with or without symptoms

**Class III (Pacemaker Not Indicated)**
1. Asymptomatic first-degree AV block
2. Asymptomatic type I second-degree AV block at the supra-His (AV node) level or that level not known to be intra- or infra-Hisian
3. AV block that is expected to resolve and unlikely to recur

Modified from Epstein and colleagues.\(^{19} \)

Box 16-2  Indications for Permanent Pacemaker Insertion Based on ACC/AHA/HRS Guidelines: Chronic Bifascicular Block\(^{a} \)

**Class I**
1. Advanced second-degree atrioventricular (AV) block or intermittent third-degree AV block
2. Type II second-degree AV block
3. Alternating bundle-branch block (Level of evidence: C)

**Class IIa**
1. Reasonable for syncope not demonstrated to be due to AV block when other likely causes have been excluded, specifically ventricular tachycardia
2. Reasonable for an incidental finding at electrophysiologic study of a markedly prolonged HV interval (≥100 ms) in asymptomatic patients
3. Reasonable for an incidental finding at electrophysiologic study of pacing-induced infra-His block that is not physiologic

**Class IIb**
1. May be considered in the setting of neuromuscular diseases such as myotonic muscular dystrophy, Erb dystrophy (limb-girdle muscular dystrophy), and peroneal muscular atrophy with bifascicular block or any fascicular block, with or without symptoms
2. Permanent pacemaker implantation is not indicated for fascicular block with first-degree AV block without symptoms.

Modified from Epstein and colleagues.\(^{19} \)

\(^{a}\)Bifascicular block refers to electrocardiographic evidence of impaired conduction below the AV node in two or three fascicles of the right and left bundles; it is commonly associated with syncope and precedes third-degree AV block associated with increased incidence of sudden death.

\(^{b}\)Class I = Conditions for which there is evidence and/or general agreement that treatment is beneficial, useful, and effective. Class II = Conditions for which there is conflicting evidence and/or divergence of opinion about benefit, usefulness, and/or efficacy of treatment. Class III = Conditions for which the procedure is not useful and/or effective or is harmful.

Section II  Tachycardia

**DEFINITION**

Abnormal tachycardia is a rapid heartbeat out of proportion to metabolic demands on the circulation.
HISTORICAL NOTE

Surgical procedures that successfully controlled many abnormal tachycardias resistant to drug treatment were developed during the 1970s and 1980s. Electrophysiologic studies accomplished by cardiac catheterization were necessary for precise diagnosis of many abnormal tachycardias, and cardiac electrophysiology rapidly became a field of special interest and competence among a small group of cardiologists. With the advent of interventional cardiology, methods for highly selective catheter ablation of areas identified by electrophysiologic studies have become successful and are replacing more invasive and somewhat cumbersome techniques of intraoperative mapping and cryoablation.

TACHYCARDIA FROM ATRIOVENTRICULAR NODAL REENTRY

Atrioventricular (AV) nodal reentrant tachycardia is the most common cause of paroxysmal tachycardia. One of its characteristics is the electrophysiologic phenomenon of dual AV nodal pathways. The fast pathway (with a normal AV conduction rate) is believed to be located within or near the AV node, and the slow one adjacent to and usually inferior to the node, lying closer to the coronary sinus.

A successful surgical approach to this problem, using cryosurgical ablation, was developed and used by Sealy, Cox, Holman, and colleagues. Results of this type of surgical therapy have been good, with no deaths among 23 patients (CL 0%-8%) who underwent surgical correction without the production of heart block. Currently, however, catheter ablation techniques are used for this purpose, and they are directed at selective ablation of the slow or fast pathway, usually the slow one, to eliminate the reentry circuit (and thus the tachycardia) while avoiding the need for implanting a permanent pacemaker. This can be successful in up to 90% of patients. Occasionally, open cryosurgical ablation is performed in symptomatic patients who require open cardiac surgery for other indications.

ECTOPIC ATRIAL TACHYCARDIA

Ectopic foci of activation in either right or left atrium can provoke paroxysms of atrial tachycardia. When localized by electrophysiologic studies, they can be treated successfully by catheter ablation. However, most ectopic atrial tachycardias, particularly those originating in the right atrium, have multiple sites of origin and are best treated pharmacologically.

INDICATIONS FOR INTERVENTION

Development of modern devices for cardiac pacemaking and for implantable cardioverter-defibrillators (ICD) has made sophisticated understanding of cardiac electrophysiology and electrical engineering necessary for proper care of patients with these conditions. Currently these requirements are met by few cardiac surgeons. Furthermore, most interventional therapies for these abnormal atrial tachycardias can now be performed using percutaneous techniques.

Section III Wolff-Parkinson-White Syndrome

DEFINITION

Wolff-Parkinson-White (WPW) syndrome as originally described is a condition in which episodes of rapid heart rate (paroxysmal tachycardia) occur in otherwise healthy young people in combination with an ECG demonstrating delta waves and a broad QRS complex (bundle branch block with
short PR interval).\textsuperscript{710} WPW is one of the preexcitation syndromes, a term that implies activation of a cardiac chamber partially or wholly by an impulse arising in another chamber and arriving earlier than would be expected if the impulse had proceeded over the normal conduction system pathway.

WPW syndrome characteristically allows paroxysmal atrial tachycardia (PAT) by atrioventricular (AV) conduction occurs over an accessory AV conduction pathway, or bypass tract, a concept first proposed in 1932 by Holtzmann and Scherf.\textsuperscript{162} This was confirmed in the same year by Burchell and colleagues, who also showed that ventricular preexcitation could be temporarily abolished by injecting procaine into the AV groove at the site of earliest ventricular activation.\textsuperscript{16}

In 1893, Kent described muscular bridges connecting right atrium to right ventricle in several mammalian species, and Wood and colleagues supported those observations in 1943.\textsuperscript{56,919} Truex and colleagues in 1958 and 1960 demonstrated the presence of muscular accessory pathways in human hearts, and Lev and colleagues added further information on accessory pathway morphology in the early 1960s.\textsuperscript{14,15,57,77} Further proof of the morphologic basis of WPW syndrome came in 1968, when Cobb, Sealy, and colleagues reported dividing the accessory pathway; PR interval and QRS complex became normal, the delta wave disappeared, and ventricular preexcitation and recurrent supraventricular tachycardia were eliminated.\textsuperscript{78} In that operation, an epicardial approach was used and a transmural ventricular incision made below the AV groove. Iwa and colleagues published a confirmatory report in 1970 and introduced the endocardial approach.\textsuperscript{19} Sealy and colleagues then also adopted an endocardial approach from within the atria, which consisted of separating atrium from anulus after dissecting away the AV fat pad.\textsuperscript{317} Sealy, Gallagher, and their colleagues also pioneered a successful surgical approach for patients whose accessory pathways were in the septal area and introduced cryosurgical ablation.\textsuperscript{54,511} This method was combined with the epicardial approach using CPB by Guiraudon and colleagues.\textsuperscript{523,525,512}

These surgical developments provided much of the information that made catheter ablation of the accessory pathways possible beginning in the early 1980s.\textsuperscript{317,199,88} Early experiences in patients used direct current (DC) as the energy source, but limitations were imposed by this method. Catheter ablation became reproducible and safe when radiofrequency (RF) energy was introduced.\textsuperscript{31,88,87} Different effects can be achieved by varying the RF output mode, frequency, waveform, and power output. Currently, catheter ablation techniques have replaced surgical techniques for interventional therapy of supraventricular tachycardia of all types and at all ages, except for occasional patients being operated on for other cardiac conditions.

MORPHOLOGY

Accessory AV conduction pathways (Kent bundles) mediating WPW syndrome may occur at any point around the anulus of either AV valve, except along the junction of the mitral anulus and aortic valve.\textsuperscript{32} However, they are most commonly located:

- Along the strong, well-formed mitral anulus, adjacent to the free wall of the left ventricle laterally or posteriorly (WPW type A)
- At the less well-developed tricuspid valve anulus anterosuperiorly, adjacent to the right ventricular free wall (WPW type B)
- Along the tricuspid anulus, adjacent to the anterior aspect of the ventricular septum
- Along the tricuspid or mitral anulus, adjacent to the posterior aspect of the ventricular septum, near the crux cordis

Accessory pathways adjacent to the posterior aspect of the ventricular septum lie in the potential space overlying the inlet portion of the septum and may be on either its right or left ventricular aspects.\textsuperscript{311} Kent bundles are said to have an average width of 1.8 mm.\textsuperscript{314} Multiple functioning bundles are present in 10% to 20% of cases.\textsuperscript{15,512,512}

From the standpoint of cardiac surgeons and interventional cardiologists, location of accessory AV pathways is important, as are the normal location of the AV node and bundle of His (see “Conduction System” in Chapter 1) and details of the structures and spaces around the AV valve anuli and fibrous skeleton of the heart. The central fibrous body, where mitral, tricuspid, and aortic valves meet, is the most prominent part of the fibrous skeleton. The area of fibrous continuity between aortic and mitral valves, the aortic-mitral anulus, contributes to the fibrous skeleton. The leftward extension of this anulus is the left fibrous trigone. The right fibrous trigone is at the right-sided extremity of the mitral-aortic anulus and is part of the central fibrous body. It lies adjacent to the AV portion of the membranous septum at the point where tricuspid, mitral, and aortic anuli come together. Atrial muscle is not in juxtaposition with ventricular muscle in the area between left and right fibrous trigones (along the aortic-mitral anulus), and thus accessory AV connections are not found in this area. As the surgeon views the mitral valve through the opened left atrium, the right fibrous trigone is just anterior to the medial commissure, and the left fibrous trigone is just lateral to the lateral commissure. As the surgeon views the tricuspid valve, the central fibrous body is in the region of the muscular portion of the AV septum (see “Cardiac Valves” in Chapter 1).

Normal anatomy in the region of the crux cordis and contiguous posterior septal area is of critical importance in therapy to ablate accessory AV conduction pathways in the region of the posterior aspect of the ventricular septum. This anatomy was described by Sealy and Gallagher as a “toppled pyramid enclosing a fat-filled space.”\textsuperscript{511} The apex of the pyramid is the right fibrous trigone, and its base is the
His bundle electrogram is recorded at the time of the P wave in the standard ECG, a His bundle electrogram 60 to 100 milliseconds later, and ventricular electrical activity at the onset of the QRS complex (Fig. 16-5, A).

In WPW syndrome, with the Kent bundle offering an AV bypass tract, the electrical impulse travels antegrade down the normal pathway but also antegrade down the Kent bundle, where delay normally imposed by the AV node is absent. This results in ventricular preexcitation at the insertion of the Kent bundle and short PR interval, delta wave, and wide QRS complex characteristic of WPW syndrome (Fig. 16-5, B).

The normal AV conduction pathway and the accessory pathway constitute the basis for the reciprocating tachycardia (circus movement) sometimes seen in patients with WPW syndrome. Most commonly, the circus movement uses the normal AV conduction system as the antegrade limb and bypass tract as the retrograde limb of the reentrant circuit (orthodromic circus movement tachycardia). Less commonly, the accessory pathway is used in an antegrade manner, and the normal AV conduction system in a retrograde manner (antidromic circus movement tachycardia).220

When atrial fibrillation develops, rapid conduction via the accessory pathway may result in life-threatening ventricular responses, sometimes degenerating into ventricular fibrillation.

**Symptoms**

Patients usually present because of palpitations, with or without symptoms of acute cardiac failure. Palpitations and documented episodic tachycardias have often been present for 10 to 15 years and repeated hospitalizations may have been required.212 More than half of patients with paroxysmal tachycardia and WPW syndrome give a history of syncope or near-syncpe.212 Rarely, they present after resuscitation from an episode of sudden death.

**Signs**

Diagnosis is made from the characteristic ECG (see Fig. 16-5). Atrial fibrillation or flutter may coexist. Preexcitation and presence of accessory AV conduction pathways are

---

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

**Pathophysiology**

Electrical impulses originate in the sinoatrial (SA) node and travel to the AV node through preferential pathways (see “Conduction System” in Chapter 1). Normally, fibrous anuli of mitral and tricuspid valves prevent direct transmission of electrical impulses from atrium to ventricle (fibrous tissue, in contrast to muscle and specialized cells, does not conduct), and conduction occurs only via the AV node and bundle of His. At the AV node, a delay in AV conduction normally occurs before the impulse passes to the bundle of His and ultimately to the Purkinje cells. This delay is reflected in the normal His bundle electrogram, in which an atrial
confirmed by electrophysiologic testing in a specially equipped cardiac electrophysiology laboratory.

**NATURAL HISTORY**

Electrocardiographic diagnosis of preexcitation WPW syndrome is made in about 0.25% of healthy young people, with documented tachyarrhythmias occurring in about 2% of those with preexcitation. However, in other patient subsets of WPW, prevalence of tachyarrhythmias is as high as 80%. Half the infants and children with supraventricular tachycardia difficult to control medically have WPW or concealed accessory muscle bundles (see Section IV later in this chapter).

Patients with WPW may present at any age, including the early months of life. The syndrome is more common in males. Most adults with WPW have otherwise normal hearts, although it may complicate a variety of acquired and congenital cardiac defects, including Ebstein anomaly. Patients with Ebstein anomaly often have multiple right-sided accessory pathways, and preexcitation is said to be limited to the atrialized portion of the ventricle. Rossi and Thiene have shown in patients having arrhythmogenic death that a few of them have accessory conduction pathways combined with very mild downward displacement of the tricuspid septal leaflet.

Among patients with WPW and tachyarrhythmias, 80% have paroxysmal supraventricular tachycardias of a reciprocating type, 15% have atrial fibrillation, and 5% have atrial flutter. Sinus node dysfunction is said to be more common in patients with WPW than in those without it.

Patients with WPW, otherwise normal hearts, and no tachycardia have normal cardiac function and life expectancy. Morbidity is considerable in those with recurrent tachycardia, and sudden death occurs in a small proportion. These sudden deaths are most likely the result of combined paroxysmal atrial fibrillation and fast antegrade conduction across the accessory AV pathways.

Some children and young adults with WPW and recurrent tachycardia lose the tendency toward developing tachyarrhythmias as they grow older. Also, preexcitation may be intermittent with loss of the delta wave, a situation suggesting a benign prognosis.

**TECHNIQUE OF INTERVENTION**

The object of catheter ablation (or operation) is electrical isolation of the ventricles from the atria except for the normal AV nodal pathway. Patients are brought to a cardiac electrophysiology laboratory. The study is performed under sedation with fentanyl and midazolam and accessory pathways are localized. An electrode catheter is appropriately positioned and RF current delivered. Repeat ablations at subsequent procedures are required in a few patients.

**RESULTS**

Surgical procedures for termination of WPW syndrome were successful in 80% to 90% of patients. Interruption of the accessory pathways prevents both reentrant AV arrhythmias and those due to atrial tachycardia, flutter, or fibrillation associated with rapid antegrade conduction across the accessory pathways.

RF catheter ablation is highly successful. Accessory pathway conduction was eliminated in 164 (99%) of 166 patients in one study, without mortality. Preexcitation or AV reentrant tachycardia occurred in only 15 (9%; CL 7%-12%), all of whom underwent a second successful catheter ablation.

**INDICATIONS FOR INTERVENTION**

Symptomatic tachyarrhythmias associated with one or more accessory AV pathways are an indication for catheter ablation.

When cardiac operation is indicated in an asymptomatic patient with WPW, accessory pathways should probably be interrupted by catheter ablation techniques before operation, because serious postoperative tachycardias and life-threatening atrial fibrillation can result from their presence. When catheter ablation is not available, a surgical procedure is indicated for interruption of the accessory pathways by either the endocardial or epicardial approach. The well-tested endocardial approach was described in the first edition of this text and has been clearly illustrated by others.

---

Section IV  Atrial Fibrillation and Flutter

**DEFINITION**

Atrial fibrillation is a disorder of cardiac rhythm characterized by rapid (350-500/min), irregular disorganized atrial impulses and ineffective atrial contractions. P waves are absent from the ECG, and the bipolar electrogram reveals beat-to-beat polarity, morphology, amplitude, and cycle length that vary. The QRS complex is irregularly irregular. Atrial flutter is a disorder of cardiac rhythm characterized by rapid (250-350/min) regular atrial impulses. QRS complexes are uniform in morphology, and P waves may have sawtoothed configuration.

**HISTORICAL NOTE**

The first clear description of atrial fibrillation is attributed to Herring in 1903 (pulsus irregularis perpetuus), although this was before the era of electrocardiography. Withering, in his studies on digitalis, was probably also aware of atrial fibrillation, because he noted that digitalis was a “moderator and regulator of rhythm.” The beneficial effect of digitalis in atrial fibrillation was clearly noted in 1836 by Bouillaud in his classic textbook, quoted by Meijler. By 1914, MacKenzie and Sir Thomas Lewis had framed the controversy on the mechanism of action of digitalis, presaging continuing discussions as to the etiology of atrial fibrillation and electrophysiologic state of the atria during atrial fibrillation.

Pharmacologic interventions, notably digitalis (to slow the rate) and quinidine (to convert the rhythm), were the mainstays of treatment. There are obvious advantages of sinus rhythm, and in 1962, Lown and colleagues and in 1963, Oram and colleagues published their landmark studies of electrical cardioversion as treatment for atrial fibrillation. Perhaps only 15% of patients with persistent or permanent atrial fibrillation respond to these interventions. Therefore,
there has been a continuing interest in finding an interventional solution to the problem of atrial fibrillation.

Catheter-induced His bundle ablation introduced by Scheinman and colleagues, and Gallager and colleagues in 1982 controlled the tachycardia of established atrial fibrillation but required implanting a pacemaker. In 1990, Guiraudon and colleagues reported seven of nine patients free of atrial fibrillation after an operation designed to isolate a corridor of atrial tissue connecting the sinus and AV nodes. Creating a maze by multiple atrial incisions was developed by Cox and colleagues in 1991. The left atrial isolation procedure was described in 1980. This operation confined atrial fibrillation to the left atrium and obviated the need for a permanent pacemaker while restoring cardiac hemodynamics. Vulnerability to systemic thromboembolism remained unchanged. In 1982, Scheinman and colleagues, as noted previously, described catheter ablation of the His bundle with insertion of a permanent pacemaker to restore regular rhythm as a means of controlling ventricular rate. Risk of thromboembolism was unaffected. Guiraudon and colleagues described the corridor procedure in 1985. This procedure isolated a strip of atrial septum (the “corridor”) containing both the sinoatrial node and the AV node so that the sinoatrial node could once again pace the ventricles, even though the atria continued to fibrillate. AV synchrony was not restored, and risk of thromboembolism persisted. Understanding the electrophysiology of atrial fibrillation based on work of Boineau and colleagues and Alessie and colleagues led to development of the atrial transaction procedure. Initial success in a patient was followed by recurrence of atrial fibrillation. Further advances in the understanding of atrial fibrillation using more sophisticated means of atrial mapping led to the concept that interruption of the multiple macro-reentrant circuits responsible for the arrhythmia would be possible. The surgical procedure was based on the concept of a maze and was named the maze procedure.

As cited by Cox and colleagues, following dialogues between Mackenzie and Lewis, there evolved three theories regarding the electrophysiologic mechanism of atrial fibrillation. Rotherberger believed there was a single automatic atrial focus, the inference being that its resection or isolation might cure atrial fibrillation. Engleman suggested the presence of multiple small automatic foci. Garrey experimentally disproved both hypotheses by isolating smaller and smaller segments of fibrillating atrial tissue. His observations suggested that (1) some critical atrial mass was necessary to sustain atrial fibrillation and (2) the underlying mechanism was reentry, not automaticity. Based on experiments using programmed electrical stimulation, Moe hypothesized the existence of multiple wavelets with different refractory periods within the atrial mass. Inhomogeneous tissue refractoriness lends itself to reentry, not automatic mechanisms. Moe’s theories were later confirmed by Alessie’s group using multiplexed computerized recordings in rabbit atria. Boineau and colleagues mapped circus motion around the superior vena cava orifice in a dog with naturally occurring atrial flutter. They concluded that in addition to functional factors (nonuniform repolarization), anatomic factors also contribute to atrial dysrhythmias. Cox and colleagues then created atrial fibrillation in experimental animals and mapped the electrophysiologic events. In their 1991 publication they concluded, “The presence of macro-reentrant circuits and the absence of either micro-reentrant circuits or evidence of atrial automaticity suggests that atrial fibrillation should be amenable to surgical ablation.” They subsequently demonstrated the ability to terminate atrial fibrillation in humans by performing the classic maze procedure. In 1994, Haissaguerre and colleagues reported successful ablation procedures for atrial fibrillation using a catheter-based technique. Since the publication of these two landmark studies, many modifications of the initial ablation techniques to terminate atrial fibrillation have been introduced.

PATHOPHYSIOLOGY

Theories of the mechanism of atrial fibrillation involve two processes: focal triggers of enhanced automaticity and multiple wavelets of macro-reentry activation migrating across the atria. Rapidly firing foci, located mostly in pulmonary veins and also but less frequently in the right atrium, superior vena cava, or coronary sinus, can initiate atrial fibrillation in susceptible patients. Fractionation of multiple wave fronts as they spread across the atria results in self-perpetuating “daughter wavelets” that cause complete absence of coordinated atrial systole. The reentry circuits follow different pathways each time after initiation and have been thought in the past to be random.

Recent evidence suggests that there may be more organization than previously thought. Three patterns of atrial fibrillation have been identified by Allessie and colleagues:

- Single wave fronts
- One or two wave fronts
- Multiple activation wave fronts propagating in different directions across the atria

Focal triggers as the only mechanism of atrial fibrillation probably apply to patients with normal atria; triggers plus macroreentry (substrate) mechanisms apply to enlarged or diseased atria.

Risk factors for developing atrial fibrillation include inflammation, oxidative stress, and atrial morphology. In addition, genetic susceptibility factors related to several ion channels have been implicated in its pathogenesis. Missense mutations of the gap junction protein connexin-40 (encoded by the GJA5 gene), which plays a critical role in electrical intercellular coupling, has been implicated in a small number of cases of atrial fibrillation. Lu and colleagues have found that microRNA-328 contributes to adverse atrial electrical remodeling in atrial fibrillation by targeting L-type calcium channel genes.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Classification

Classification of atrial fibrillation begins with the first detected episode. If two or more episodes occur, atrial fibrillation is considered recurrent. Recurrent atrial fibrillation is designated as paroxysmal, persistent, or permanent as described in Box 16-5. These categories are not mutually exclusive. An individual patient may have several episodes of paroxysmal atrial fibrillation and occasional persistent atrial fibrillation or
the reverse. It is practical to categorize a given patient by the most frequent presentation. The definition of permanent atrial fibrillation is often arbitrary. This terminology applies to episodes lasting more than 30 seconds without a reversible cause.

Secondary atrial fibrillation in the setting of acute myocardial infarction, cardiac surgery, pericarditis, myocarditis, hyperthyroidism, or acute pulmonary disease is considered separately, and treatment of the underlying disorder usually terminates the arrhythmia. The term lone atrial fibrillation refers to individuals younger than 60 years of age without clinical or echocardiographic evidence of cardiopulmonary disease, including hypertension. The term nonvalvar atrial fibrillation refers to patients without rheumatic mitral valve disease, prosthetic heart valve replacement, or valve repair.

Diagnosis, Symptoms, and Signs

Shortness of breath is a common presenting symptom. Cardiac conditions associated with atrial fibrillation include hypertension, ischemic or valvar heart disease, cardiomyopathy, cardiac tumors, and pericarditis, and presenting symptoms and signs are often those associated with these conditions. Noncardiac conditions associated with atrial fibrillation are chronic obstructive pulmonary disease, thyroid disease, electrolyte imbalance, and alcohol abuse. Vagally mediated atrial fibrillation resulting from high vagal tone occurring after meals or exercise and during sleep or rest can be exacerbated with digitalis. The ECG shows very short atrial intervals at a rate faster than the ventricular rate. An irregular ventricular rate is usually present. Spontaneous conversion of atrial fibrillation is common, with up to 70% of patients with first-time atrial fibrillation reverting to normal sinus rhythm. Frequency of spontaneous conversion decreases with each subsequent episode.

NATURAL HISTORY

Atrial fibrillation is not a benign arrhythmia and presents a difficult clinical challenge. It is the most common cardiac arrhythmia, accounting for about one third of arrhythmia diagnoses. It is estimated that 2.2 million people in the United States and more than 5 million people worldwide have atrial fibrillation. It is present in approximately 1% of the general population and 6% of those older than age 65 years. There are about 360,000 new patients diagnosed annually in the United States. According to the Centers for Medicare and Medicaid Services, atrial fibrillation resulted annually (up until 1990) in 227,000 hospitalizations (50% as emergencies) at a cost of $6.6 billion.

Atrial fibrillation is associated with thromboembolism, including stroke or pulmonary embolism, and results from slow and stagnant blood flow in the atria. Risk of stroke associated with atrial fibrillation is 5% to 12% per year. Prospective studies on the treatment of atrial fibrillation place the risk of stroke at 5% to 8% in patients receiving placebo treatment. Risk of stroke may be reduced by 37% to 86% by anticoagulation with warfarin, but at a cost of bleeding risk in 0.5% to 2.8% of patients per year.

Factors that increase the risk of stroke in patients with atrial fibrillation include older age, diabetes, heart failure, previous myocardial infarction, and previous embolism. Chronic atrial fibrillation is associated with cellular changes that progress to atrial myocardial fibrosis. The progressive nature of the condition leads to enlargement of the atria and eventual loss of function of the atrial myocardium. Tachycardia-induced cardiomyopathy is an end-stage complication of atrial fibrillation.

TECHNIQUE OF INTERVENTION

Two treatment approaches are used to manage patients with atrial fibrillation: (1) control of ventricular rate and anticoagulation and (2) restoration and maintenance of sinus rhythm.

Ventricular Rate Control

Ventricular rate control can be accomplished with a variety of drugs, including digoxin, β-blockers, and calcium channel blockers. Adequacy of ventricular rate control is usually assessed with the patient at rest. However, assessment of ventricular rate should also be done during exercise, because activity may result in an excessively high ventricular rate. Persistently elevated ventricular rate may induce tachycardia-mediated cardiomyopathy. Risk of thromboembolism increases 48 hours after the onset of atrial fibrillation. If sinus rhythm is not restored during this time, anticoagulant therapy should be initiated. Random trials evaluating oral anticoagulation in patients with atrial fibrillation and subjected to meta-analysis demonstrated a 61% reduction in stroke compared with placebo. Risk stratification models have been introduced to identify patients with atrial fibrillation who benefit from oral anticoagulation. The ACC/AHA/European Society of Cardiology (ESC) guidelines for managing patients with atrial fibrillation have developed such a model using risk factors that predict an increased risk of thromboembolism (Table 16-2). Aspirin is the agent of choice for patients with no risk factor, and warfarin for those with one or more risk factors.

### Clinical Classification of Atrial Fibrillation

The joint American College of Cardiology/American Heart Association/European Society of Cardiology task force has recommended the following nomenclature for classifying atrial fibrillation. Classification begins with the first detected episode of atrial fibrillation. If a patient has two or more episodes, atrial fibrillation is considered recurrent. Recurrent atrial fibrillation is designated as paroxysmal, persistent, or permanent.

**Paroxysmal**
Atrial fibrillation lasting 7 or fewer (most <24 hours) days and terminating spontaneously

**Persistent**
Atrial fibrillation lasting more than 7 days that does not terminate spontaneously, but requires electrical or pharmacologic cardioversion to restore normal sinus rhythm; if the first detected episode of atrial fibrillation does not terminate spontaneously, it is also designated persistent

**Permanent**
Atrial fibrillation in which sinus rhythm cannot be sustained after cardioversion or the patient and physician have decided against further efforts to restore sinus rhythm

*Both paroxysmal and persistent atrial fibrillation may be recurrent.*
with one severe or more than one moderate risk factor. Either can be used with one moderate risk factor.

Warfarin and other vitamin K antagonists are cumbersome to use and require frequent laboratory monitoring. This has led to the search for other drugs that do not require laboratory monitoring. Several have been evaluated in clinical trials, including clopidogrel, idraparinux, and dabigatran. In a large randomized clinical trial of 18,113 patients, dabigatran (a potent direct inhibitor of thrombin) at a dose of 110 mg twice daily was associated with rates of stroke and systemic embolism that were similar to those associated with warfarin, as well as lower rates of hemorrhage. In separate trials, clopidogrel plus aspirin or idraparinux were found to be less effective than warfarin.

### Restoring and Maintaining Sinus Rhythm

Restoring and maintaining normal sinus rhythm is desirable because symptoms of discomfort and anxiety related to the arrhythmia are eliminated, hemodynamics are improved, cardiac rate is controlled physiologically, and the risk of thromboembolism may be reduced.

### Cardioverison

Pharmacologic cardioversion involves use of a variety of agents from various classes (Vaughan-Williams) of antiarrhythmic drugs (Tables 16-3 and 16-4). Ibutilide is a class III agent used intravenously for converting atrial flutter and atrial fibrillation to sinus rhythm. It also lowers atrial defibrillation energy requirements and facilitates transthoracic electrical cardioversion. Ventricular tachyarrhythmia has been associated with the use of this drug in patients with low left ventricular ejection fraction, so it should only be used if QT interval is less than 480 milliseconds. Other drugs employed are class IA (quinidine, procainamide, disopyramide), class IC (flecainide, propafenone), or class III (amiodarone, sotalol) agents. Each has potentially serious proarrhythmic and other side effects and is effective in only 40% to 60% of cases.

Electrical cardioversion is often combined with drug therapy.

### Ablation to Block Atrioventricular Conduction

When medical therapy is ineffective in controlling episodes of rapid ventricular rate, catheter ablation of the AV junction to induce complete heart block and implantation of a permanent pacemaker will control it, although atrial flutter or fibrillation persist. Intracoronary ethanol ablation of the AV conduction system is an alternative to radiofrequency (RF) ablation.

### Interruption of Macro-Reentrant Circuits

A series of operative techniques based on contemporary electrophysiologic understanding has led to useful methods of operative or catheter-based intervention for treating atrial fibrillation.
**Cox-Maze III Procedure**

Multiple incisions are made in the atria that not only interrupt conduction routes of the most common reentrant circuits but also direct the sinus node impulse to the AV node along a specified route. The entire atrial myocardium (except for the atrial appendages and the pulmonary veins) is electrically activated by providing multiple blind alleys about 2 to 3 cm wide off the main conduction route between the sinoatrial node and the AV node, thus preserving atrial transport function. A modification of the technique as described by Cox and colleagues, called the maze III procedure with minor changes, is described here.

Bicaval cannulation is required (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2). A cannula is inserted directly into the superior vena cava, and the inferior vena cava is cannulated through the right atrium as close as possible to the diaphragm. Small venous cannulae (24F) may be used if active venous uptake is provided by vacuum suction applied to the reservoir of the oxygenator (see “Vacuum-Assisted Venous Return” in Section II of Chapter 2). Perfusion is normothermic to maintain the heartbeat during initial phases of the operation on the right atrium.

The right atrial appendage is excised, removing all trabeculations attached to the appendage. Alternatively and preferably, an incision (see Fig. 16-6, A) is made through the tip of the right atrial appendage, extending to the base of the appendage medially and laterally to preserve natriuretic receptors. This incision is extended toward the midpoint of the right atrium. A longitudinal incision is made in the lateral wall of the right atrium along the crista terminalis. This incision extends onto the superior and inferior vena cava. The lower end of the incision is immediately closed to a point about 2 cm cephalad to the inferior vena cava cannula by a continuous suture of 4-0 polypropylene to prevent tearing during retraction. At this point, a vertical incision is made extending anteriorly. The inside of the right atrium is exposed (Fig. 16-6, B) so that the intraatrial incision may be extended to the tricuspid valve anulus at about the midpoint of the posterior leaflet. A 3-mm cryolesion is placed at approximately the 2-o’clock position on the tricuspid anulus for 2 minutes at −70°C. All muscle fibers of the right atrial wall are divided, exposing the fat of the AV groove and occasionally the right coronary artery. The atrial incision is closed from the anulus of the tricuspid valve to the free wall of the right atrium by a continuous 4-0 polypropylene suture. An incision is made on the medial aspect of the remnant of the appendage (Fig. 16-6, C). This incision extends to the tricuspid valve anulus at the midpoint of the anterior leaflet or approximately at the 10-o’clock position. Another 3-mm cryolesion is placed at the tricuspid anulus for 2 minutes at −70°C.

Systemic cooling is then initiated. The aorta is occluded preparatory to the left atrial portions of the operation. Cold blood cardioplegic solution is administered to the heart via the coronary sinus through an appropriate cannula (see “Methods of Myocardial Management during Cardiac Surgery” in Chapter 3). The left atrium is opened by incision just posterior to the interatrial groove near the orifices of the right pulmonary veins. The incision is extended superiorly and inferiorly onto the left atrium around the right pulmonary veins. The atrial septum is incised above the fossa ovalis. The incision is curved across the limbus of the fossa ovalis and across the membrane of the fossa to the inferior margin of the fossa near, but not into, the tendon of Todaro (Fig. 16-6, E). The left atrial incision is continued across the left atrium toward the left pulmonary veins to isolate and encircle them. The heart is retracted to the right to expose the left atrial appendage (Fig. 16-6, F), which is excised at its base. It is incised in a cephalad direction near the AV groove across its base and back into the left atrium. The incision in the left atrial appendage is joined to the pulmonary vein incising incision at a point near the left superior pulmonary vein. The incision in the base of the left atrial appendage is closed back to the encircling incision, and the portion of the encircling incision below the left atrial appendage is closed with continuous sutures of 3-0 polypropylene (Fig. 16-6, G). These sutures are passed from the outside into the left atrium and retrieved from within the atrium (Fig. 16-6, H). The encircling incision closure is continued cephalad and around the superior aspect to the midpoint of the encircling incision. The encircling incision is closed inferiorly to the midpoint. An incision is made across the floor of the left atrium to the midpoint of the anulus of the posterior leaflet of the mitral valve. This incision is carefully opened by sharp dissection.

The coronary sinus is exposed by incision into the fat of the AV groove. The circumflex coronary artery may also be visualized in the incision. A 15-mm cryoprobe is placed posteriorly on the coronary sinus, and a cryolesion is created at −60°C for 3 minutes. After 1 minute, a 3-mm cryoprobe is placed at the mitral valve anulus at −70°C for 2 minutes. Timing of freezing with the two probes is coordinated so thawing can occur simultaneously. Mitral valve repair or replacement is performed at this point if required. The incision in the floor of the left atrium is closed by a continuous suture of 4-0 polypropylene, beginning at the mitral anulus and continuing to the encircling incision (Fig. 16-6, I). The sutures are joined and continued to close the encircling incision over to the right pulmonary veins.

The atrial septum is a thin membrane within the fossa ovalis. The limbus is muscular and thicker. There are discrete layers of the right and left atria that represent the infolding of the atria at the interatrial groove rather than true septum. These layers should be closed separately (Fig. 16-6, J). The septal closure begins at the inferior border of the fossa ovalis using continuous sutures of 4-0 polypropylene. Suturing continues across the limbus and along the left atrial fold to the free margin. A second layer of closure is started at the limbus and continued along the right atrial fold to the junction, with the longitudinal incision in the right atrium. The remainder of the pulmonary vein encircling incision is closed and joined to the left atrial septal closure (see Fig. 16-6, J).

A venting catheter is inserted via the left superior pulmonary vein through a separate purse-string suture. Air is evacuated from the left cardiac chambers and aorta, and the aortic occlusion clamp is removed (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2). The heart is reperfused and defibrillated if necessary. The longitudinal incision in the right atrium is closed beginning at the superior vena cava and working inferiorly (Fig. 16-6, K). The suture is joined to the right atrial septal closure, then continued to the vertical right atrial incision. The vertical incision is closed.
Figure 16-6 Maze III procedure. A, Operation is performed via median sternotomy. Cannulae for venous uptake are placed in superior vena cava and through the low right atrium into inferior vena cava. Small venous cannulae (24F) and vacuum-assisted venous return are employed. Cardiopulmonary bypass is established, and tourniquets are tightened around venae cavae. First incision divides right atrial appendage and extends obliquely to midpoint of right atrial free wall. Medially, incision extends to atrioventricular groove. Longitudinal incision is made from superior to inferior vena cava along crista terminalis. Lower 2 cm of incision is closed with a continuous suture of 4-0 polypropylene to prevent tearing during retraction. Vertical incision is made from point of closure to atrioventricular groove. B, Vertical incision is extended to tricuspid valve anulus in area of posterior leaflet (2-o’clock position, surgeon’s view), working on endocardial surface of atrium cutting through the entire atrial wall. Residual myocardial fibers are ablated by applying a 3-mm cryolesion (~70°C for 2 minutes) at tricuspid anulus. This portion of incision is closed with 4-0 polypropylene suture. C, Incision of medial aspect of right atrial appendage is continued into atrial groove to tricuspid valve anulus (10-o’clock position, surgeon’s view) by dissecting on endocardial surface. A cryolesion is placed at anulus of tricuspid valve to ablate residual myocardial fibers. This portion of incision is closed with 4-0 polypropylene suture.

Continued
Operation is completed by closing the right atrial appendage opening, beginning at the midpoint of the right atrium and continuing through the appendage incision.

The maze procedure has been performed experimentally and clinically as a closed heart procedure. Radial incisions in the atria have been proposed as a modification of the maze III procedure by Nitta and colleagues. Atrial incisions radiate from the sinoatrial node toward the AV anular margins to allow a more physiologic atrial activation sequence that may improve atrial transport function. These operations have not substantially reduced the time or complexity required to complete the standard maze III operation.

Modified Maze Procedure
The maze III procedure is an effective means of relieving atrial fibrillation, but it is a complex and sometimes prolonged procedure. Consequently, it is performed infrequently. A number of modifications of the operation and use of various
energy sources to ablate atrial myocardium have been introduced to simplify the operation and reduce operative time.

Modified operations include those applied to only one atrium, the unilateral maze procedure. The right-side maze operation creates the usual incisions for the maze procedure on the right atrium only. The left-side Maze procedure is usually a pulmonary vein-encircling incision, with or without extension to the mitral anulus and excision of the left atrial appendage.

Ablation modalities that have been used to obviate the need for incision and closure of atrial tissues include cryoablation or controlled freezing, microwave, RF, and laser energies. Of prime consideration with the use of any energy source is consistent creation of transmural lesions that ensure conduction block. Cryoablation has been a widely used modality and is an integral part of the standard maze III procedure to produce tissue ablation at the AV valve anuli and on the coronary sinus. Cryoablation is somewhat cumbersome to apply to atrial tissues and requires specially modified instrumentation. Microwave has been the least employed energy source, and a device to deliver microwave energy has been removed from the market. Laser energy applications are in clinical trial.

RF energy has been the most frequently used energy source; it heats and shrinks myocardial cells to destroy them. The energy may be applied to produce a focal or linear lesion as alternatives to incisions in conventional maze operations. It can be applied through a unipolar electrode to the endocardial surface of the atria, but may also be applied on the outside of the heart. The objective is to create full-thickness destruction of the wall of the atrium, resulting in scar tissue that blocks reentry pathways that sustain atrial fibrillation. When the energy is applied through an electrode placed directly on the endocardium, surface heating limits depth of...
penetration because once the tissue is destroyed or charred, impedance to energy flow by the injured tissue inhibits further tissue destruction. Cooling the electrode tip and contact surface with saline solution (irrigated RF-Cardioblate, Medtronic Inc., Minneapolis, Minn.) allows heating to be directed several millimeters below the surface, resulting in a lesion about 4 mm deep. RF energy applied through bipolar electrodes has the potential of assuring a full-thickness lesion. Electrodes placed along the jaws of clamps are placed on the endocardial and epicardial surfaces, with the atrial wall trapped in between. Energy flows until all myocardial tissue capable of conducting the energy is destroyed. Impedance then rises, and a steady state of energy flow is established. Bipolar devices should solve the problem of irregular
thickness due to trabeculation of the atrial wall, provided uniform electrode contact is assured with atrial tissues. Although thin areas will be destroyed early in the energy flow cycle, thick areas will continue to conduct energy until heating and destruction of tissue is complete. Gillinov and McCarthy showed conduction block in 7 of 10 patients with one application of bipolar RF energy using the Atricure clamp device (Atricure Inc., West Chester, Ohio). Repeat application of the energy achieved block in the remaining three patients. Bipolar probes have been developed that provide access to areas inaccessible to bipolar clamps, such as the valve anuli, vena cavae, and tissue overlying the coronary sinus. However, these probes, as well as cryoprobes, may not create completely transmural lesions.

RF ablation maze procedures performed on both right and left atria appear to achieve about 80% success in restoring sinus rhythm. The number and length of surgically created incisions are reduced compared with the standard maze III procedure by using RF ablation lines as alternatives to or extensions of incisions. The set of surgical incisions for the modified RF maze procedure is shown in Fig. 16-7, A. After establishing cardiopulmonary bypass, an incision is
Figure 16-7  Modified radiofrequency (RF) maze III procedure.  

A, Incisions are depicted. Incision is made through right atrial appendage. Curved incision is made in right atrium extending from atrioventricular groove toward right superior vena cava, crossing crista terminalis. Note relation of this incision posterior and caudal to site of sinoatrial node. Left atrial appendage is amputated at the base. Left atrium is incised on right side posterior to interatrial groove. Left-sided incisions are made later in procedure. B, Primary incision is extended laterally and posteriorly into superior vena cava by RF ablation lesion. It is extended similarly into inferior vena cava. Ablation of inferior isthmus is performed by extending a linear lesion from posterior aspect of inferior vena cava across inferior isthmus to anulus of tricuspid valve at its posterior leaflet. Right atrial appendage incision is extended to tricuspid valve anulus by radiofrequency ablation. Aorta is occluded and cold cardioplegia infused through coronary sinus.
C, Left atrial appendage is amputated at the base. Working through base of appendage, RF ablation lesion is created anterior to left pulmonary veins. This lesion is connected to base of appendage by RF ablation lesion. Appendage is closed by suture. Working through the primary incision, left pulmonary vein RF ablation lesion is extended posterior to veins to completely encircle them. Encircling lesion is extended to anulus of mitral valve across coronary sinus. Right pulmonary vein encircling lesion is completed by extending RF ablation lesion from primary incision posterior to veins. The two pulmonary vein isolation lesions are joined across posterior and superior aspect of left atrium. D, Atrial septum is ablated on left side from fossa ovalis to primary left atrial incision (inset), and on right side from fossa ovalis across limbus to primary incision in right atrium.
Completed repair. Figure 16-7, cont’d E, Completed repair showing closure of all incisions.

made through the right atrial appendage. An incision is made in the right atrial lateral wall that curves from the fat over the AV groove toward the right superior pulmonary vein, crossing the crista terminalis. The left-sided surgical incisions to amputate the left atrial appendage and to enter the left atrium posterior to the interatrial groove are also shown, but these incisions are actually made later. Working through the primary incision in the lateral wall of the right atrium (Fig. 16-7, B), linear RF ablation lesions are created with a bipolar clamp or probe to extend the primary incision laterally and then posteriorly into the superior vena cava to the level of the caval tourniquet. An inferior isthmus ablation is performed to control atrial flutter by extending the inferior vena cava ablation line across the inferior isthmus to the tricuspid valve. The appendage incision is extended to the tricuspid valve anulus by ablation.

A clamp is placed on the ascending aorta, and cold cardiopugic solution is infused by cannula into the coronary sinus (see “Technique of Retrograde Infusion” in Chapter 3). The left atrial appendage is amputated at its base. Working through the base of the appendage, an ablation line is created anterior to the left pulmonary veins and joined to the base of the appendage. The appendage is closed by suture. Working through the primary incision posterior to the interatrial groove into the left atrium (Fig. 16-7, C), the left pulmonary vein encircling ablation lesion is completed. This encircling ablation lesion is extended to the anulus of the mitral valve. The right pulmonary vein isolation is completed by extending the primary incision (which is anterior to the veins) posterior to the veins with a RF ablation lesion. The pulmonary vein encircling ablation lesions are connected by RF tissue ablation in one or two locations. A coronary sinus ablation lesion may be added, extending from the mitral anulus along the course of the coronary sinus. Thickness of the septal tissues makes full-thickness ablation by RF energy somewhat unreliable. In other areas where RF is employed, such as around the AV valves, in the vena cavae, around the pulmonary veins, and over the coronary sinus, the atrial tissues are thin and smooth, making full-thickness tissue penetration by ablation energy easier and more reliable. The atrial septum, therefore, is ablated on both the left atrial endocardial surface from the fossa ovalis to the primary left atrial incision, and on the right atrial endocardium from the fossa ovalis over the limbus to the primary incision in the right atrium (Fig. 16-7, D). Surgical incisions are closed in the usual fashion (Fig. 16-7, E).

Modified radiofrequency maze III procedures that combine unipolar and bipolar ablation lesions offer the promise of even smaller surgical incisions, as well as assurance of complete-thickness wall lesions. Bipolar ablation is performed for long linear lines crossing thick or irregular atrial wall. Unipolar ablation is performed to extend the bipolar lesions to areas where the tissues are more delicate, such as around the AV valves, in the cavae, or across the coronary sinus. These lesions can also be created with a cryoprobe, but as noted earlier, the lesions created with unipolar RF probes or cryoprobes may not be consistently transmural. Fig. 16-8 shows a lesion set that combines unipolar and bipolar modalities and allows the operation to be performed through four surgical incisions 1 or 2 cm in length, in addition to the incision to amputate the left atrial appendage.

Anatomic studies in human hearts by Castellá and colleagues have shown that bipolar clamps cannot be used safely to create lesions in the left atrium at the mitral anulus because of possible injury to the coronary sinus and circumflex coronary artery. In the right atrium, clamp placement toward the tricuspid anulus that excluded the right coronary artery left 8 to 18 mm of atrial muscle free from the bipolar electrodes. These authors suggested that lines to the AV anuli should be completed with the cut-and-sew technique.
Figure 16-8  Modified radiofrequency (RF) maze III procedure using bipolar and unipolar ablation. A, Small incision is made at tip of right atrial appendage. Bipolar full-thickness RF ablation (lines) of lateral wall toward midportion of atrium are depicted. Small incision is made in lateral wall of right atrium anterior to crista terminalis, corresponding to middle of atrial septum. Bipolar RF lesions are made on lateral wall of right atrium directed to atrioventricular groove and toward superior vena cava posterior to site of sinoatrial node. Latter lesion is extended by unipolar RF ablation (stippled) posteriorly onto thin part of superior vena cava. Small incision is made at inferior vena cava–right atrial junction. The two surgical incisions are joined by bipolar ablation. Left atrial appendage is excised and oversewn. Left atrium is opened by incision behind interatrial groove on right side. B, Bipolar full-thickness RF ablation is made through right atrial appendage medially to atrioventricular groove and extended to the tricuspid anulus, using unipolar energy. Working through cavoatrial incision, a bipolar ablation lesion is made across inferior isthmus toward midportion of posterior leaflet of tricuspid valve. This lesion is extended to anulus by unipolar ablation. Unipolar ablation is used to extend from surgical incision into inferior vena cava. Bipolar ablation of atrial septum is performed.

Continued
Less Invasive Surgical Procedures
During the last decade, a primary objective of most new surgical procedures has been to make them less invasive. Off-pump and minimally invasive techniques incorporating video-assisted thorascopy have been developed. These techniques have used differing energy sources and lesion sets and have principally involved pulmonary vein isolation and amputation of the left atrial appendage.

Catheter-Based Interventions
A number of catheter-based endocardial techniques have been devised to treat atrial fibrillation, based on the assumption that trigger sites for initiation of atrial fibrillation are found principally within the orifices of the pulmonary veins. These techniques are often not as successful in controlling atrial fibrillation as the maze III procedure. Nevertheless, it is likely more patients will be treated with these techniques in the future because of their less invasive nature.

RESULTS
Ventricular Rate Control
The AFFIRM clinical trial of 4040 patients with atrial fibrillation persisting for more than 6 months has shown at 5-year follow-up that cardiac rate control and anticoagulation results in 40% of patients in normal sinus rhythm and comparable outcomes compared with more aggressive treatment to control the cardiac rhythm. There was no difference in survival, stroke, functional status, or quality of life. Combined rates of death, stroke, major bleeding, and cardiac arrest were 29% in the rate control group vs. 28% in the rhythm control group. Other randomized trials have failed to demonstrate a benefit of rhythm control over rate control, including trials in patients with heart failure and an ejection fraction of 35% or less.

Cardioversion
Drug and electrical cardioversions are nearly always successful for the first episode of atrial fibrillation or flutter. Failure to achieve sinus rhythm increases with subsequent episodes. Recurrence during the first year after cardioversion is at least 50%. The rhythm control arm of the AFFIRM study employed amiodarone, sotalol, propafenone, or procainamide for aggressive medical treatment of atrial fibrillation. At 5-year follow-up, 60% of patients were in normal sinus rhythm, although they required more hospitalizations than the rate control group.

Ablation of Atrioventricular Conduction
Quality of life has been considerably improved by catheter ablation of the AV junction. Other than abolishing rapid ventricular rate, it does not protect against thromboembolism or other consequences of atrial flutter or fibrillation.

Rhythm Control by Surgical Intervention
Maze III Procedure
Cox and colleagues reviewed outcomes in 346 patients who underwent the maze procedure, 299 of whom underwent the maze III modification. Operative mortality was 2%
(CL 1.3%-3.1%). Overall success in curing atrial fibrillation was 99%. There was no permanent damage to the sinoatrial node. Left atrial contractile function after operation occurred in 93% of patients, and right atrial function in 99%.

Schaff and colleagues performed 221 maze procedures in which 75% of patients underwent concomitant operations for associated cardiac disease. Early mortality was 1.4% (CL 0.6%-2.7%), and 85% to 90% of patients were free of atrial fibrillation. In addition to restoring sinus rhythm, mean ejection fraction increased in these patients from 31% to 53%, but 26% had reduced left ventricular ejection fraction.

Arcidi and colleagues reported overall cure of atrial fibrillation in 97% of 99 patients having the maze III procedure, 78 of whom underwent another cardiac operation, usually on cardiac valves.

The effect of the maze procedure on stroke was studied in 306 patients followed for up to 12 years. Fifty-eight of these patients had stroke before operation, and there were two perioperative strokes. After operation, only one patient experienced stroke. Warfarin anticoagulation was used in only 45 of the patients who received mechanical or mitral valve prostheses.

**Modified Maze Procedures**

The left side unilateral maze procedure is commonly performed by creating either a pulmonary vein–encircling incision or lesion, with or without extension to the mitral valve anulus, or with a cryolesion on the mitral valve anulus, and excision of the left atrial appendage. When energy sources rather than surgical incisions are used to interrupt the macroreentrant circuits, and when fewer lesions are created in the atria, results have been less optimal. Left atrium–only modified maze procedures using RF ablation for creating lesions encircling the pulmonary veins and a lesion extending from this to the mitral anulus were described by Melo and colleagues. Sinus rhythm was restored in 44% of patients. Others have reported greater success (77%-82%) using left atrial RF lesions applied either endocardially or epicardially. Pasic and colleagues created encircling RF ablation lines around right and left pulmonary veins separately, joining the left pulmonary vein ablation line to the mitral valve anulus across the coronary sinus, and joining the separate pulmonary vein lines with another lesion on the roof of the atrium. The left atrial appendage was not excised. Freedom from atrial fibrillation was 92% at 6 months. Mohr and colleagues reported that 81% of 234 patients were in normal sinus rhythm 6 months after having left-side-only atrial ablation using RF energy.

The longest clinical experience with radiofrequency ablation of both atria is that of Sie and colleagues. Two hundred patients were treated with the biaxial modified maze procedure using irrigated RF ablation. Follow-up extended to 80 months, with mean follow-up of 41 months. Normal sinus rhythm or atrial rhythm was present in 73% of patients; 20% remained in atrial fibrillation or flutter, and 6.3% required a permanent pacemaker.

Clinical series have compared left-side-only RF ablation vs. ablation of both atria. In a meta-analysis of 5885 patients undergoing surgical ablation, Barnett and Ad reported that bilateral procedures demonstrated better freedom from atrial fibrillation at all time points (up to 3 years) than left atrial procedures. In a study of 575 patients with permanent atrial fibrillation (duration > 6 months) by Gillinov and colleagues, the Cox-maze procedure and lesion sets resembling it resulted in a similarly low prevalence of late postoperative atrial fibrillation. Pulmonary vein isolation and lesion sets that did not include a lesion to the mitral anulus were less effective. Older age, larger left atrium, and longer duration of atrial fibrillation preoperatively were risk factors for increased prevalence of postoperative atrial fibrillation.

**INDICATIONS FOR OPERATION**

Patients should be considered for operation when maximal medical therapy has failed to relieve symptoms associated with atrial fibrillation. Symptoms that interfere with lifestyle or ability to work include dyspnea on exertion, easy fatigue, lethargy, malaise, and anxiety or sense of doom during periods of atrial fibrillation. Separation of symptoms due to atrial fibrillation from associated cardiac conditions, primarily valvar heart disease, may be difficult. Operation is not recommended when there is severe left ventricular dysfunction not directly attributable to atrial fibrillation, or when there is associated cardiac or noncardiac disease that would increase the risk of operation. Performing a maze procedure is advisable for patients who are undergoing mitral valve surgery and have documented evidence of atrial fibrillation. Epicardial pulmonary vein isolation can be performed in selected symptomatic patients with aortic valve or coronary artery disease.

**SPECIAL SITUATIONS AND CONTROVERSIES**

**Maze Procedures for Paroxysmal Atrial Fibrillation**

Patients with paroxysmal atrial fibrillation are often symptomatic with palpitations, irregular heart rhythm, and breathlessness due to intermittent episodes of rapid ventricular rate. They may be refractory to medical treatment. Isolated paroxysmal atrial fibrillation is not a common indication for maze procedures, because satisfactory results can be obtained with catheter ablation, but symptomatic patients may benefit from this therapy. Forty-two patients with paroxysmal atrial fibrillation were treated with a maze III procedure by Lonnerholm and colleagues. A subgroup of 17 patients who had normal sinus rhythm prior to operation and no associated cardiac operation was carefully studied to determine outcomes and atrial function. Sixteen of 17 were in normal sinus rhythm after operation; one was atrially paced. Two years after operation, 10 of 12 patients had normal sinus rhythm (83%; CL 65%-94%), one was paced, and one had nodal rhythm. Left and right atrial size decreased at 2 months, but there was a gradual decrease of left atrial transport function during 2-year follow-up. Fifteen patients (88%; CL 74%-96%) had signs of left atrial contraction.

In patients with paroxysmal atrial fibrillation who are undergoing mitral valve surgery, pulmonary vein isolation may be adequate therapy, particularly when atrial fibrillation is of short duration. If it is of longer duration, a bilateral maze III procedure would be performed. For patients with coronary artery disease or aortic valve disease where a left atriotomy is not otherwise indicated, epicardial pulmonary vein isolation is reasonable.

Pulmonary vein isolation as the sole lesion set can be arrhythmogenic, especially in patients with enlarged or
diseased left atria. In this setting, atrial flutter is a frequent postoperative event.\textsuperscript{c16} Atrial flutter and other arrhythmias also occur after more extensive ablation procedures.\textsuperscript{c38} Ablation of ganglionated plexi that enter the heart along the pulmonary veins has been proposed as a mechanism to reduce the frequency of atrial fibrillation following pulmonary vein isolation procedures. Several clinical trials of catheter ablation of paroxysmal atrial fibrillation by pulmonary vein isolation in which obliteration of these ganglionic plexi was also performed have demonstrated clinical benefit in terms of lower frequency of recurrence of atrial fibrillation.\textsuperscript{c11,p14,s5} Experimental studies, however, have demonstrated early reinnervation and vagal activity.\textsuperscript{o2,s1} Thus, the role of ablation of ganglionic plexi during surgical pulmonary vein isolation procedures for paroxysmal atrial fibrillation has not been clearly established.

Standards for Assessing Success or Failure

Uniform standards for assessing success or failure of the various surgical procedures for treatment of atrial fibrillation have not been consistently employed. According to Cox, all occurrences of postoperative atrial fibrillation, atypical left atrial flutter, and classic right atrial flutter should be classified as failures.\textsuperscript{c16} The methods by which these arrhythmias can be detected postoperatively are variable and controversial. Ad and colleagues evaluated three modalities to determine success of the Cox-maze III procedure: electrocardiography, 24-hour Holter monitoring, and long-term monitoring (5 days).\textsuperscript{s1} Mean time to monitoring was 9.8 months postoperatively. Electrocardiographic monitoring underestimated success by 12% compared with long-term monitoring. Nearly 50% of the events detected were shorter than 5 minutes for the entire 5-day period. They have suggested that use of a specific algorithm-driven clinical protocol postoperatively, including longitudinal follow-up and long-term monitoring, will increase the success of the various surgical procedures.\textsuperscript{o2}

The central challenge in defining success of ablation procedures for atrial fibrillation is its episodic nature (Fig. 16-9). Frequency of detecting return of atrial fibrillation will therefore depend on frequency and duration of “snapshots” of rhythm (Fig. 16-10).\textsuperscript{a12} The U.S. Food and Drug Administration has approved use of an implantable loop recorder for continuous monitoring of heart rhythm (Fig. 16-11) using a detection algorithm based on regularity of R-R intervals.\textsuperscript{c16,m6} Data from this device, as well as from pacemakers and implantable cardioverter-defibrillators, will be required to ascertain the true success of these procedures.

Atrial Fibrillation and Flutter Occurring after Cardiac Surgery

Atrial flutter or fibrillation occurs in 20% to 40% of patients after coronary artery bypass grafting.\textsuperscript{e1,g18} Daubert and Mabo, in a review of five controlled trials, reported a prevalence of 27% to 39%.\textsuperscript{d3} Occurrence after cardiac valve operations is even greater.\textsuperscript{b7} Improved operative techniques, anesthesia, and myocardial management have not decreased prevalence. The arrhythmia usually occurs within the first 3 days after operation, although it may occur later. It occurs spontaneously, usually follows a self-limiting course, and becomes chronic in only a small percentage (<5%) of patients.\textsuperscript{b7,o4} More than 90% of patients have no prior history of atrial arrhythmia and are in normal sinus rhythm within 6 to 8 weeks after operation. Tachycardia can produce symptoms of anxiety and light-headedness. When heart rate is very high for a prolonged period, it may result in hemodynamic compromise, particularly in patients with left ventricular dysfunction. There is an increased risk of thromboembolism associated with atrial fibrillation, with the incidence of stroke approximately three times higher than in patients without postoperative atrial fibrillation.\textsuperscript{c30,e1,m7} Hospital and late mortality are also increased.\textsuperscript{a8,e1,s5}

The cause of atrial fibrillation after cardiac surgery is not known and is likely related to a number of factors, most of which are uncontrollable. These include increased catecholamine release, pericardial inflammation, alterations in balance of other neurohormonal agents or electrolytes (hypokalemia), and cellular electrical properties. Age, with its accompanying degenerative changes in atrial myocardium, and systemic arterial hypertension are important risk factors.\textsuperscript{b7,d3} Other risk factors include decreased left ventricular function, chronic obstructive pulmonary disease, chronic renal failure, and diabetes. Withdrawal of β-blockers has also been implicated.\textsuperscript{d3}

Preventing atrial arrhythmias in the postoperative period would be optimal. A number of medications have been administered before and after cardiac operations as prophylaxis against atrial fibrillation. Bharucha and Kowey\textsuperscript{b7} reviewed management and prevention of atrial fibrillation after cardiac operations and suggested that the only
medications with proven benefit are β-blockers. Medications with possible benefit include digitalis, propranolol, sotalol, amiodarone, corticosteroids, and statins. Meta-analysis indicates that β-blockers, sotalol, and amiodarone reduce the frequency of postoperative atrial fibrillation compared with placebo groups, although the magnitude of reduction is variable. These studies include non-blinded trials. Atrial pacing may be beneficial when combined with medical prophylaxis. Calcium channel blockers have not proven to be effective.

Because postoperative atrial fibrillation has a self-limited course in most patients with no history of prior atrial arrhythmia, treatment strategy is directed toward control of ventricular response. First-line drugs of choice are β-blockers. Digoxin is sometimes administered via rapid intravenous administration, partly because of tradition and because it may be helpful in slowing the ventricular response and restoring sinus rhythm, but scientific data are not supportive. Calcium channel blockers (verapamil, diltiazem), which affect the AV node, also control ventricular rate, but the effect is transient unless given as a continuous intravenous infusion. They are no more effective than β-blockers in controlling ventricular rate. Intravenous amiodarone may be beneficial in controlling ventricular rate or restoring sinus rhythm. Pharmacologic cardioversion is desirable, but there is no drug that is uniformly successful. Ibutilide given intravenously has been most effective in patients with atrial flutter, but it is proarrhythmic and may cause sustained ventricular tachycardia (torsades de pointes) in about 2% to 4% of patients.

Anticoagulation is initiated if sinus rhythm is not restored within 48 hours after the onset of atrial fibrillation, because the risk of thromboembolism increases at that point. This is especially important if electrical cardioversion is anticipated. Conventional recommendations for anticoagulation are followed. Intravenous heparin or one of its analogs is administered with warfarin and continued until a therapeutic level of anticoagulation is established.

Electrical cardioversion may be performed. Ordinary transthoracic cardioversion is usually successful. Cardioversion may be applied urgently for patients with rapid ventricular response and hemodynamic instability. Antiarrhythmic drugs are continued for at least 3 weeks following successful electrical cardioversion.

Guidelines for prevention and management of postoperative atrial fibrillation have been published jointly by the ACC, AHA, and ESC and are summarized in Box 16-6.

Pacing and Other Methods of Atrial Electrical Cardioversion

Temporary epicardial wire pacing electrodes placed during cardiac operations and used for diagnostic or therapeutic purposes have been part of standard postoperative cardiac care for many years. Ideally, two electrodes are placed...
on the right atrium and the right ventricle. An atrial electrode may be used to diagnose atrial arrhythmia simply by attaching the wire to the chest lead of the ECG. This magnifies the atrial electrical activity and permits identification of large P waves of sinus rhythm, rapid spikes of atrial flutter, or the disorganized atrial electrical activity of atrial fibrillation. Attaching atrial electrodes to a rapid-rate external pacemaker with rate set at 400 to 800 beats · min⁻¹ overdrives the atrial arrhythmia rate. Gradual reduction of the pacing rate may capture the atrium at a lower rate and convert atrial rhythm to normal sinus. Experience has shown that success in conversion to sinus rhythm occurs in about one of four patients. Success is higher when atrial overdrive pacing is done for atrial flutter (65% of patients converted) and when the patient is pretreated with an intravenous β-blocker (metoprolol 2.5 to 5 mg intravenously).²⁹

Temporary defibrillation electrodes may also be placed on the atria at the time of cardiac operation and used to deliver low-energy direct current cardioversion of atrial fibrillation. Liebold and colleagues reported use of epicardial defibrillation wire electrodes placed on the left and right atria during cardiac operations in 100 consecutive patients.¹¹⁶ Atrial fibrillation occurred in 23 patients (23%). The atrial electrodes were used to deliver synchronous monophasic shocks with low energies ranging from 2 to 10 J. Defibrillation was successful in 16 of 20 patients (80%). Sedation was required during defibrillation in 30% of patients. Electrode wires and a device to reduce the output of a standard defibrillator to 9 J has been developed (Syncerus, Guidant, Santa Clara, Calif.). Patel and colleagues²⁶ used this device in 45 patients; 16 (35%) developed atrial fibrillation. Fifteen patients were successfully cardioverted at initial treatment, one 6 hours later, and 4 after atrial fibrillation recurred. This technique was based on experimental defibrillation in experimental models.²⁷,²⁸ Waldo suggested that this technique of low-energy atrial defibrillation with temporary epicardial wire electrodes should become standard in treatment of atrial fibrillation after open heart surgery.²⁹ More important, he proposed that use and success of temporary electrodes opened the way for implantable atrial defibrillators to provide automatic atrial defibrillation. Wells and colleagues reported implanting a defibrillator (Attrioverter) connected to electrodes placed in the right atrium and coronary sinus in 81 patients with recurrent atrial fibrillation who did not respond to antiarrhythmic drugs.³⁰ Successful defibrillation of the atrium was accomplished in 96% of 227 episodes of atrial fibrillation in 41 patients without inducing ventricular arrhythmia. Devices are available that can detect and treat atrial tachyarrhythmias with pacing and high-energy defibrillation.³⁵

Section V Ventricular Tachycardia and Ventricular Fibrillation in Ischemic Heart Disease

HISTORICAL NOTE

In 1938, Parkinson and colleagues apparently first noticed the association between ventricular aneurysm and intractable ventricular tachycardia.³² However, the problem seemed to be known to Sir Thomas Lewis, who stated in 1909 the need for studying and understanding the condition by a controlled method of inducing tachycardia.³³ This need was met in 1967 when Durrer and colleagues in Holland, and Coumel and colleagues in France, introduced the technique of programmed electrical stimulation of the human heart.³⁴³⁵

The first surgical approach to treating life-threatening ventricular tachycardia in patients with ischemic heart disease was reported in 1959 by Couch using simple aneurysmectomy.³⁶ Fontaine, Frank, and Guiraudon reported surgical epicardial mapping as an adjunct to this kind of surgery in 1974, and Gallagher and colleagues reported successful use of ventricular aneurysm resection guided by electrophysiologic mapping in 1975.³⁷,³⁸ In 1978, Guiraudon and colleagues introduced encircling endocardial ventriculotomy as a method of directly treating life-threatening ventricular tachycardia in patients with ischemic heart disease.³⁹ Harken and colleagues reported electrophysiologically directed endocardial resection as a method of treatment in 1980.⁴⁰

An entirely new concept of interventional management was introduced in 1980 when Mirowski and colleagues reported implanting a cardioverter-defibrillator in humans.⁴¹ This important event was preceded by more than 10 years of work directed at this endpoint and nearly 100 years of experimental and clinical studies of increasing sophistication.⁴²,⁴³,⁴⁴,⁴⁵

MORPHOLOGY

Sustained ventricular tachycardia is an uncommon complication of ischemic heart disease in the absence of a previous
myocardial infarction. It occurs most commonly in patients in whom a large area of infarction has developed, and particularly in those with a left ventricular aneurysm. These patients have, as a group, more left ventricular impairment than patients without this life-threatening complication. Thus, Kirklin and colleagues reported that patients undergoing operations for ventricular tachycardia had a mean ejection fraction of 30%, similar to that of patients undergoing surgical treatment for left ventricular aneurysm, whereas those undergoing isolated coronary artery bypass grafting had a mean ejection fraction of 51% (P = .0001). However, life-threatening ventricular tachycardia develops in only a minority of patients with ischemic heart disease and left ventricular aneurysm with impaired left ventricular function. Although all the determinants of which patients are affected by ventricular tachycardia are not clear, septal involvement in the scarring seems to be one of them. The morphologic substrate for ventricular tachycardia in ischemic heart disease resides for the most part in the subendocardium of the left ventricle and left ventricular aspect of the ventricular septum. This substrate is most commonly near the border of an aneurysm or infarct. Virtually all hearts with a myocardial infarction have a mixture of myocardial cells and fibrous tissue in at least some areas of the left ventricle; such areas provide a basis for slow conduction and conduction block, two conditions necessary for ventricular reentry to occur. Thus, in areas of the subendocardium where ventricular tachycardia may begin, bundles of viable myocardial cells are embedded in dense connective tissue. These bundles may consist of Purkinje fibers or ventricular muscle fibers or both. These generally parallel muscle bundles do not appear to connect to fibers within the ventricular wall, and in regions where ventricular tachycardia seems to originate, there may be no surviving myocardial cells above the subendocardium. Thus, the surviving subendocardial muscle bundles are generally connected to the rest of the ventricle across the borders of subendocardial portions of the scar.

This arrangement of parallel bundles of myocardial fibers separated by fibrous or connective tissue forms a nonuniform anisotropic (conducting in one direction) structure that is considered an ideal substrate for reentrant circuits. Conduction between muscle bundles is probably slow, whereas conduction along the length of the muscle bundles is probably rapid. The fractionated character of electrograms recorded from such regions is also probably related to the nonuniform anisotropic anatomy. It is hypothesized that the larger the proportion of left ventricle involved with these morphologic characteristics, the greater the possibility that reentrant circuits develop, activate contiguous subendocardium, and provoke ventricular tachycardia or ventricular fibrillation. Actual time and place of development of the electrical phenomenon responsible for ventricular tachyarrhythmia (VT) appears to be determined by chance.

Even among individuals with life-threatening ventricular arrhythmias but without any other evidence of cardiac disease, a morphologic substrate likely to be responsible for the arrhythmia is usually found. Sugrue and colleagues report several different types of histopathologic abnormalities in such patients coming to autopsy, including myocardial cellular hypertrophy, interstitial fibrosis, myocardial degenerative changes, and acute myocarditis.

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

**Pathophysiology**

Most life-threatening ventricular arrhythmias in patients with ischemic heart disease arise as a result of macro- or micro-reentry circuits, but some result from normal or abnormal automaticity or triggered activity. In many patients, the abnormal impulse breaks through onto the endocardial surface near its origin, resulting in the earliest ventricular electrical activation at this point. Its breakthrough onto the epicardial surface may be some distance away.

**Symptoms**

In some patients, sudden death is the first manifestation of important ventricular tachyarrhythmia. In others, premature ventricular contractions, ventricular tachycardia, or ventricular fibrillation causes the first symptoms during recovery from a myocardial infarction. In still others, frequent palpitations, sometimes accompanied by faintness or syncope, are the presenting complaint.

**Signs**

The diagnostic finding is a verified history of life-threatening ventricular tachycardia or fibrillation, or sustained ventricular tachycardia induced during electrophysiologic study.

**NATURAL HISTORY**

Sustained ventricular tachycardias and fibrillation may occur within the first 48 hours after an acute myocardial infarction but do not worsen prognosis; they are presumably ischemic in origin. Such arrhythmias occurring later in the course of recovery are less common but worsen prognosis. Episodes are often multiple, and when they occur, in-hospital mortality is as high as 60%. Such patients generally have inducible ventricular tachycardia when studied by programmed electrical stimulation, and a poor long-term prognosis even with intense medical therapy. Marchlinski and colleagues reported only 20 (50%; CI 41%-59%) of 40 such patients alive after a mean follow-up period of 20 months, with more than half the deaths occurring suddenly. As is the case in other patients with ischemic heart disease, prognosis of medically treated patients with life-threatening ventricular tachyarrhythmias is adversely affected by presence of severe proximal anterior descending coronary artery stenosis.

Some patients present after resuscitation from sudden death. The most important risk factors for sudden death in patients are advanced functional disability, as indicated by New York Heart Association functional class; lack of response to therapy, as judged by programmed electrical stimulation; and depressed left ventricular function. The natural history of individuals resuscitated from sudden death is highly variable, but in general is not favorable. Seward and colleagues found that 34% of resuscitated patients died suddenly within 3 years of their first episode.

Ability of medical treatment to improve natural history is limited because an effective antiarrhythmic drug can be identified by electrophysiologic testing in less than 35% of cases. Empirical therapy with high-dose amiodarone has been favorable in several large series. However, in an...
appreciable number of patients, severe adverse drug reactions or aggravation of arrhythmic symptoms develop.\textsuperscript{2,3,5}

**TECHNIQUE OF INTERVENTION**

Because even type of intervention remains arguable, techniques for intervention continue to be modified.

A direct surgical approach, usually at the time of ventricular aneurysmectomy and coronary artery bypass grafting, consists of electrophysiologic mapping at surgery and procedures designed to isolate the presumed arrhythmogenic focus from the rest of the ventricular mass. Mapping has been done sequentially or with special arrays of electrodes and computer-based electrophysiologic analyses that allow all the information to be obtained during a few heartbeats.\textsuperscript{19,21,34,48}

Cryoablation techniques have been used to electrically isolate the arrhythmogenic focus. When the ventricular tachycardia is monomorphic, catheter ablation techniques in the cardiac electrophysiologic laboratory can also be effective. This, however, has been the case in a minority of patients.

The implantable cardioverter-defibrillator (ICD) has come to be the most appropriate method of treating most patients with life-threatening ventricular tachyarrhythmias resulting from ischemic heart disease. Implantation methods have improved over time such that it has become possible to insert an ICD using techniques similar to pacemaker insertion. Two electrodes are required and, although larger in diameter than those employed for pacemaking, may be inserted by needle and guidewire technique using direct puncture of the subclavian vein. ICD pulse generators are larger than those of a pacemaker. A larger subcutaneous pocket is required, but the device can be placed in a prepectoral position below the clavicle. Operation for inserting and testing the device is performed under local anesthesia with intravenous conscious sedation, although general anesthesia is sometimes required.

**RESULTS**

**Direct Surgical Approach**

Most patients with ischemic heart disease undergoing interventional therapy for life-threatening ventricular tachyarrhythmias die in cardiac failure, not suddenly or with an intractable arrhythmia.\textsuperscript{39,48} This fact, plus its considerable early and late risks approach, accounts for lack of enthusiastic acceptance by cardiologists of direct surgical treatment of life-threatening ventricular tachycardia in patients with ischemic heart disease. Improved early mortalities have been reported by others, but a highly favorable effect on long-term survival has not been demonstrated.\textsuperscript{19,21,34,48,50} Again, this is largely related to the fact that left ventricular structure and function tend to be poor in this subset of patients.

**Implantable Cardioverter-Defibrillator**

Increasing evidence as to the efficacy of ICD devices, coupled with low hospital mortality after their insertion, has made them virtually the therapy of choice in patients with ischemic heart disease in whom life-threatening intractable ventricular tachyarrhythmias develop.\textsuperscript{2,5,44,47,54} Operative mortality associated with transvenous ICD implantation is 0.5% to 0.8%.\textsuperscript{52,71} Even with this device in place, poor left ventricular function adversely affects prognosis.\textsuperscript{58} Recurrence of life-threatening ventricular arrhythmias is observed in 30% to 50% of patients after ICD implantation, yet only 1% to 2% of patients die of sudden cardiac death.\textsuperscript{51}

ICDs successfully terminate ventricular fibrillation in 98% of cases. Ventricular tachycardia is successfully converted by overdrive pacing in 89% to 91% of cases, and when not successful, defibrillation shock terminates the arrhythmia in 98% of cases. Antiarrhythmia pacing features add 5% to 10% to the cost of ICDs, but it has been shown that antiarrhythmia pacing is activated frequently (68% of patients) and will terminate the arrhythmia in as high as 96% of arrhythmia episodes.\textsuperscript{20} Inappropriate pacing or shocks are delivered typically for atrial fibrillation, with rapid ventricular response in 5% to 11% of patients. Dual-chamber sensing and pacing ICDs should largely eliminate inappropriate pacing or shocks in patients with associated atrial arrhythmias.

Prospective randomized trials have shown improved patient survival for patients treated with an ICD compared with those receiving drug therapy, including those receiving class III antiarrhythmic drugs, with estimated risk reduction of 39% at 1 year and 31% at 3 years.\textsuperscript{51}

**INDICATIONS FOR INTERVENTIONAL THERAPY**

Results of drug therapy for managing patients with ischemic heart disease and recurring ventricular tachyarrhythmias have been disappointing.\textsuperscript{93} Some patients requiring surgical therapy for a left ventricular aneurysm with otherwise excellent ventricular function and important coronary stenoses only in the anterior descending coronary artery may be treated by bypass grafting to the anterior descending coronary artery, resection of the left ventricular aneurysm, and electrophysiologically directed cryoablation for the control of the tachyarrhythmia. Patients whose tachycardia is monomorphic should be considered for catheter ablation, which is successful in about half of patients.\textsuperscript{23}

Most patients with life-threatening ventricular arrhythmias, however, are best treated by insertion of an ICD. In response to publication of numerous studies showing that ICD insertion can alter the natural history of cardiac arrhythmia and major advances in the technology of automatic cardioversion by pacing therapy or defibrillation by shock therapy, the ACC, AHA, NASPE, and HRS appointed a committee of physicians to develop guidelines for implantation of ICDs.\textsuperscript{51} An updated summary of these indications is listed in Box 16-7.\textsuperscript{19} This comprehensive document is a definitive statement on indications for cardiac pacing. Because device development continues to advance rapidly, these indications may be subject to frequent revision.

**Section VI**

**Intractable Ventricular Tachycardias**

**ARRHYTHMOGENIC RIGHT VENTRICULAR DYSPLASIA**

Right ventricular dysplasia is an uncommon and somewhat poorly defined entity. Uhl anomaly, a condition in which the free wall of the right ventricle is “like parchment,” with only
a few myocardial fibers between epicardium and endocardium, is often included within this group of patients. In other patients, the right ventricular free wall has both thick and thin areas of pathologic development. The basic pathologic process is believed to be progressive replacement of myocardial fibers in the subepicardium and mid-myocardium by fatty tissue. Characteristically, the right ventricle is enlarged and deformed by bulging areas over the infundibulum, apex, and basal portion of the inferior wall. Involvement of the right ventricle is initially regional and may progress to global involvement of the right ventricle. The left ventricle may eventually be involved, but the septum is spared. The disease is often familial, with autosomal dominant inheritance but incomplete penetrance.

Intractable ventricular tachycardia may develop in childhood or in adult life in patients with arrhythmogenic right ventricular dysplasia. Strands of partially degenerated myofibrillar fascicles, which connect with normal myocardium, are believed to provide a basis for slow conduction and reentry. Electrophysiologic studies are indicated. Rarely, a site of monomorphic inducible sustained ventricular tachycardia can be identified, and catheter ablation is then the treatment of choice (Epstein A: personal communication; 1991). More often it is polymorphic and multifocal and resistant to drug therapy. Right ventricular isolation is then an effective therapy. This extensive procedure does not change regional right ventricular systolic or diastolic performance. In some patients, a properly oriented simple ventriculotomy, cutting across the arrhythmogenic focus, is recommended, although at times a localized resection has been done.

### ARRHYTHMOGENIC LEFT VENTRICULAR DYSPLASIA

In arrhythmogenic left ventricular dysplasia, a rare cause of intractable ventricular tachycardia, the histopathologic substrate is the same as in arrhythmogenic right ventricular dysplasia but with more fibrosis. Preoperative and intraoperative electrophysiologic studies are said to identify the condition, and encircling endocardial ventriculotomy is performed to stop the arrhythmia.

### IDIOPATHIC INTRACTABLE VENTRICULAR TACHYCARDIA

Idiopathic intractable ventricular tachycardia has also occasionally been treated surgically. In one report, the tachycardia...
seemed to originate in the left ventricular free wall in one of three cases and in the ventricular septum in the other two cases. Most commonly, idiopathic intractable ventricular tachycardias are treated with calcium channel blocking agents and other drugs. In a small subset of patients, this tachycardia arises in the right ventricular outflow tract and is amenable to catheter ablation.\textsuperscript{15}

*Cardiac trauma* is damage done to the heart by penetrating or nonpenetrating injuries.

---

**Section I  Penetrating Cardiac Trauma**

**Historical Note**

The first suggestion that wounds of the heart and great vessels could be sutured may have been by Roberts in 1881. In 1882 and 1895, studies of experimental closure of cardiac wounds in animals were reported. On September 9, 1896, Rehn in Germany successfully repaired a penetrating cardiac wound. Mead reported that Williams first successfully performed a heart operation in the United States when, in 1889 at Provident Hospital in Chicago, he repaired a stab wound. The first published report of a successful heart operation in the United States was by Hill, who repaired a stab wound in Montgomery, Alabama, in 1902. In his report, Hill not only described successfully suturing the wound, but also summarized 37 other cases reported by that time.

---

**Morphology**

When a sharp, long-bladed instrument is violently driven into the midportion of the thorax and penetrates the pericardium, a laceration of the heart or great vessels commonly results. The right ventricle alone is involved in 35% of patients reaching a hospital after their traumatic episode. Occasionally, however, a missile may produce a tangential laceration of a ventricle or penetrate a cardiac chamber and come to rest within it.

**Clinical Features, Diagnostic Criteria, and Natural History**

**Pathophysiology**

Most stab wounds of the heart result in acute pericardial tamponade, although occasionally, rapidly exsanguinating hemorrhage may result. The patient thus usually presents
with symptoms and signs of acute cardiac tamponade complicated by acute blood loss. (For a discussion of cardiac tamponade, see “Acute Cardiac Tamponade” under Clinical Features and Diagnostic Criteria in Section I of Chapter 23.)

Missile wounds usually result in acute hemorrhagic shock, which may be rapidly fatal. If not, the patient enters the hospital profoundly hypotensive, with tachycardia and collapsed veins.

Penetrating cardiac wounds are frequently accompanied by wounds involving the pleural space, the intrapericardial thoracic vessels, the lung, and occasionally by wounds of the liver and other abdominal viscera.

Symptoms and Signs

External evidence of a penetrating wound is usually apparent, although in the case of injury with a stiletto, the external wound may initially escape discovery. The external wound and evidence for either hemorrhagic shock or acute pericardial tamponade dominate the clinical presentation.

Special Studies

If the patient’s condition permits, a chest radiograph is made. In the rare situation of an initially stable patient, or in a patient recovering from repair of a penetrating wound in another organ and now suspected of having also suffered a cardiac laceration, usual techniques of cardiac investigation are used. Two-dimensional echocardiography, particularly transesophageal echocardiography (TEE), is the technique best adapted to these situations. Its use minimizes, in nonemergency situations, subxiphoid exploratory pericardiotomy.\textsuperscript{8,52,54}

**TECHNIQUE OF OPERATION**

When a patient presents with a penetrating wound of the chest in a location and direction that could involve the heart, the assumption is made that a penetrating wound of the heart exists. Resuscitative measures, including endotracheal intubation, volume replacement, and insertion of chest tubes, are performed promptly on admission to the emergency department, except in stable patients without shock or respiratory distress.

All centers properly prepared for treating patients with cardiac wounds have well-developed protocols.\textsuperscript{36} Only general methods of management are described here.

**Stab Wounds**

Patients with stab wounds of the heart and great vessels usually survive when treatment is adequate, except for those in extremis on admission (most of whom have suffered immediate and massive hemorrhage from laceration of a great vessel).

If the stabbing device is still in place when the patient is admitted to the emergency department, it is not removed until the incision is made and ideally not until the pericardium is opened.

When the patient arrives in the emergency department unconscious and without vital signs or semiconscious with gasping respirations, a thready pulse, and no blood pressure, and all evidence points to a cardiac or great vessel wound as the cause, prognosis is poor; immediate thoracotomy (see discussion under “Missile Wounds” later in this chapter) is indicated if the emergency department is prepared for this type of major surgery.\textsuperscript{45,11,56} If not, a large-bore needle (13F) is inserted into the pericardial space through the subxiphoid route, and the patient is transported rapidly to an operating room. Because of the pathophysiology of acute cardiac tamponade (see Chapter 23), removal of even 40 to 50 mL of blood usually improves the hemodynamic state, at least temporarily. When the patient is in shock but has vital signs, a pericardiocentesis is performed as described, followed by rapid transfer to the operating room. When the patient’s condition is stable and a cardiac stab wound is only suspected, investigation can be accomplished in the emergency department or in the operating room if a noncardiac procedure is indicated. This evaluation is best performed by TEE.

Once in the operating room, the patient is rapidly anesthetized, prepared, and draped for operation. A large-bore needle is placed in an easily accessible large vein as these preparations are being made. Surgical draping should be wide, with the chest and abdomen fully exposed. Median sternotomy is made and the pericardium opened. (In institutions in which cardiac surgery is not frequently performed, an anterolateral incision, usually left-sided, is made, because this incision can be made rapidly and is the most generally useful.)

Blood is rapidly aspirated from the pericardial space with high-vacuum suckers. Ventricular wounds are best controlled initially by digital compression. Atrial and caval wounds are generally not well controlled in this manner, and wide Allis (Allis-Adair) clamps serve ideally to establish hemostasis by apposing the wound edges. If this is not possible or if the wound edges tear after application of clamps, a Foley catheter with a large balloon volume can be inserted into the cardiac chamber or vein and inflated. Only after digital or instrumental control of active bleeding has been accomplished should attention be turned to suturing the wounds. At this time, physiologic resuscitation should be completed. Blood volume is reconstituted with donor-specific matched or unmatched type O-negative blood to augment previously infused crystalloid or colloid, and blood pH is restored toward normal with bicarbonate. Supplementation calcium is usually given.

Ventricular wounds are best sutured with interrupted pledgeted mattress sutures of No. 2-0 or 3-0 polyester or polypropylene. A great danger in myocardial lacerations is their enlargement by the act of passing sutures in a fully filled and beating ventricle. It is often appropriate to induce inflow occlusion to empty the heart and provide a quieter field. After an interval of hyperventilation, the vena cavae are occluded using vascular clamps, followed by clamp occlusion of the ascending aorta after the heart has emptied a few beats later. The cardiac wound is sutured over the next 2 to 3 minutes; thereafter, the caval and aortic clamps are released. The heart will have continued to beat slowly during the occlusion period. Occasionally, a ventricular laceration is so extensive that it requires cardiopulmonary bypass (CPB) and patch-grafting of the ventricular free wall. Wounds near a major coronary artery are similarly sutured, with pledges on both sides of the artery and the sutures passing beneath it. If the left anterior descending coronary artery has been damaged, a coronary artery bypass graft should be placed (see Chapter 7). Atrial or caval wounds are closed by continuous No. 4-0 or 5-0 polypropylene sutures. Suturing is done beneath the clamp or carefully over the top of the inflated balloon of a
Foley catheter, and the clamp is removed (or balloon deflated) only after the suture line is largely in place.

Unless there is near certainty that the pleural spaces have not been violated, both are opened widely through the median sternotomy. The internal thoracic arteries, a potential source of hemorrhage, are examined and, if damaged, are suture-ligated. Damaged areas of lung are oversewn or stapled. The hilum of each lung is examined for injury to the pulmonary vessels.

Drainage catheters are placed in each pleural space (see “Positioning Chest Tubes” under Completing Cardiopulmonary Bypass in Section III of Chapter 2), and one may be placed in the pericardial space as well. If hemostasis within the pericardium has been satisfactory, the pericardium is loosely closed with widely spaced interrupted sutures. The sternotomy is closed in the usual manner (see Section III of Chapter 2).

Missile Wounds

Patients with missile wounds of the heart are far less likely to survive than those with stab wounds. Patients who are unconscious or without vital signs, or who are semiconscious but without a measurable blood pressure, should receive immediate thoracotomy if the emergency room is properly prepared. A left anterolateral incision is made, curving beneath the breast, and the thorax is entered through the fifth or sixth interspace. An assistant spreads the wound with two handheld retractors, or a self-retaining thoracotomy retractor is inserted, and digital control of the hemorrhage is obtained. If trained surgeons are in attendance and the repair appears to be a simple one, repair is then performed. Otherwise, the patient is transferred to a prepared operating room while digital control of the hemorrhage is maintained. If digital control of the hemorrhage is not possible, survival is unlikely and any further intervention inadvisable.

Patients not meeting these criteria for operation in the emergency department are transported immediately to the operating room. Principles of management are the same as described for penetrating wounds, but the result is less often successful.

SPECIAL FEATURES OF POSTOPERATIVE CARE

If a central venous catheter was not inserted in the operating room, it is placed postoperatively. Principles of care are the same as those used for patients after other forms of cardiac surgery (see Chapter 5).

A special consideration is the possibility that a major coronary artery has been damaged by the trauma or at operation. Thus, during the first few postoperative hours, if the hemodynamic state is unexpectedly unsatisfactory despite appropriate ventilator filling pressures—and particularly if the electrocardiogram suggests coronary injury—emergency coronary arteriography is performed. If a major vessel is interrupted or importantly narrowed, emergency coronary artery bypass grafting is performed.

During the early postoperative period, it must be kept in mind that penetrating wounds may have perforated a cardiac septum or damaged an atroventricular or, rarely, a semilunar valve. Should any evidence suggest such an injury, appropriate studies are indicated. TEE is particularly informative. If the findings are positive, in unstable patients, immediate repair should be considered. If the hemodynamic state remains satisfactory, however, delay for 8 to 12 weeks permits a more secure repair.

RESULTS

Prompt and effective therapy allows good results in most patients with stab wounds of the heart. Overall, about 80% of patients survive. Results for missile wounds are less satisfactory and depend upon extentiveness of the wound, condition of the patient on admission, and associated injuries. Overall survival is about 40%. The functional result in surviving patients is usually excellent, even when patch-grafting of the left ventricular free wall has been necessary.

INDICATIONS FOR OPERATION

Presence of a penetrating wound to the heart is an indication for immediate operation. A stab wound over the heart without bleeding or hypotension may indicate that no penetration has occurred, and is therefore not an indication for operation. TEE is helpful in this situation.

Occasionally, patients convalesce apparently satisfactorily and without special treatment (usually a stab wound rather than injury by a missile), only to come to medical attention weeks to years later because of a murmur or heart failure. Special studies usually demonstrate a ventricular septal defect (VSD), laceration of a cardiac valve, or aorta-to–pulmonary artery or aorta-to–brachiocephalic vein fistula. Operation is indicated, and a good result can usually be obtained.

Section II  Nonpenetrating Cardiac Trauma

HISTORICAL NOTE

In earlier times, cardiac rupture was the only sequela of nonpenetrating (closed or blunt) cardiac trauma to receive attention. Apparently, this catastrophic event was originally observed by Senac in 1778. Although rupture of the ventricular septum was described in 1847 by Hewett, not until 1959 did Campbell and colleagues at the University of Minnesota first successfully repair a VSD produced by nonpenetrating trauma. More recently, surgical attention has focused on rupture of cardiac valves as a consequence of nonpenetrating cardiac injuries, although in 1927 Adam described such injuries as well as the natural history of patients with valvar rupture secondary to trauma. Cardiac contusion has more recently been recognized as one of the complications of nonpenetrating cardiac trauma.

MORPHOLOGY

When the heart is compressed between two objects, such as the sternum and the vertebral column, intracardiac—and particularly intraventricular—pressure suddenly becomes elevated, and the free atrial or ventricular walls, ventricular septum, tensor apparatus of the atroventricular valves, or
aortic valve cusps may rupture. The same holds true when there is sudden deceleration of the chest with the heart thrust forward against the sternum. Rarely, a coronary artery fistula to a cardiac chamber develops after nonpenetrating chest trauma.

Less violent nonpenetrating injury may result simply in contusion of the myocardium. Such contusions may vary from small areas of subepicardial or subendocardial petechiae to full-thickness injury of the cardiac wall. Radionuclide angiography has shown that the anteriorly situated right ventricle is particularly susceptible to contusion.\textsuperscript{51,13}

Commotio cordis is a syndrome of sudden death seen infrequently after low-energy trauma to the anterior chest wall. Experimentally, Link and colleagues found this to occur within a narrow window during the repolarization phase of the cardiac cycle, 30 to 15 ms before the peak of the T wave.\textsuperscript{1,2} Clinically, this has been reported in children struck in the chest with a baseball.\textsuperscript{51}

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

**Cardiac Contusion**

Patients with cardiac contusion may exhibit no symptoms, precordial pain, or symptoms indistinguishable from those of angina. Dysrhythmias of different types may develop. Electrocardiographic abnormalities may be present shortly after injury or can be delayed 12 to 24 hours. Abnormalities may be transient or longer lasting, depending on extent of myocardial damage.\textsuperscript{52,12} Q waves may develop similar to those seen in acute myocardial infarction. Myocardial enzymes may become elevated after injury and, if so, provide a near-positive diagnosis of cardiac contusion.\textsuperscript{52} However, the electrocardiographic and enzymatic criteria are relatively insensitive and nonspecific indicators of cardiac contusion.\textsuperscript{51}

A more sensitive indicator is radionuclide angiography. Demonstration of decreased right or left ventricular ejection fraction in a previously healthy person and abnormalities of left ventricular segmental wall motion suggest myocardial contusion.\textsuperscript{12} This diagnostic study also permits sequential examination and indicates that considerable myocardial dysfunction can fail to impair the hemodynamic state; in other cases, if myocardial dysfunction does impair the hemodynamic state, it can revert to normal within a few weeks.\textsuperscript{51}

**Cardiac Rupture**

When rupture of the heart occurs, the most common site is the right atrium. In most cases, immediate and severe acute cardiac tamponade develops. An exception is when there has been concomitant rupture of the pericardium, and then there is exsanguinating hemorrhage. Cardiac rupture may occur immediately upon injury or several days later; in the interim, there may be no suggestion of impending catastrophe. Rupture occasionally may be localized, involving primarily a branch of a coronary artery.\textsuperscript{51}

**Ventricular Septal Rupture**

When the ventricular septum ruptures, it usually occurs at the time of injury. The characteristic murmur of a VSD appears. When the rupture is small, the hemodynamic state remains good. When it is large, the patient exhibits signs and symptoms of pulmonary venous hypertension, and cardiac output is likely to be low.

**Atrioventricular Valve Rupture**

When rupture of the tensor apparatus or leaflet of an atrioventricular valve is a complication of closed trauma, its occurrence is usually immediate. Most commonly, the tricuspid valve is ruptured, and this may be accompanied by rupture of a branch of the right coronary artery into the right ventricle.\textsuperscript{51} Thus, initial clinical manifestations are minimal, and the diagnosis is not suggested until a number of weeks have passed, by which time the characteristic signs and symptoms are present\textsuperscript{59} (see “Tricuspid Regurgitation” under Clinical Features and Diagnostic Criteria in Chapter 14).

Less frequently, the tensor apparatus of the mitral valve is ruptured.\textsuperscript{51} Patients usually exhibit sudden pulmonary venous hypertension and rapidly developing symptoms including frank pulmonary edema.\textsuperscript{51} Occasionally, mitral regurgitation may slowly worsen, and operation is required several weeks to several months after injury.\textsuperscript{1,3,11}

**Aortic Cusp Rupture**

Rarely, an aortic valve cusp is ruptured by nonpenetrating cardiac trauma. Acute pulmonary edema can be precipitated by rupture of two cusps, but symptoms may become evident only after an apparently symptom-free interval.\textsuperscript{51}

**NATURAL HISTORY**

**Cardiac Contusion**

Only fragmentary information is available concerning the natural history of patients with myocardial contusion, because this condition often goes undiagnosed. The natural history is probably similar to that of acute myocardial infarction. When the area involved is small, premature death is uncommon. When it is of moderate size, and particularly when there is associated damage to the left anterior descending coronary artery, a typical large left ventricular aneurysm may develop.\textsuperscript{51,10} The natural history then is that of other large left ventricular aneurysms (see Chapter 8). When the area involved is extensive, death may occur relatively early after injury in the same modes as after acute myocardial infarction. Pericarditis and hemopericardium may develop as complications of cardiac contusion.\textsuperscript{51,32,35} The natural history then becomes that of these conditions (see Chapter 23), with possible late development of cardiac tamponade and chronic constrictive pericarditis.

**Cardiac Rupture**

Cardiac rupture is generally rapidly fatal without operation. However, if the rupture is small, and particularly if it involves the right atrium or right ventricle and the pericardium is intact, the hemopericardium that develops may tamponade the bleeding, and the hemodynamic state may remain reasonably good. Some patients survive such an episode, as evidenced by the very old finding of Cabriolanus (in 1604) of healed cardiac wounds in persons who had been thought to be well.\textsuperscript{51}
Ventricular Septal Rupture

As in congenital VSDs, the natural history of ventricular septal rupture depends on the size of the defect (see Chapter 35). When it is small, the early posttraumatic hemodynamic state is good, as is the long-term outlook. When it is large, the hemodynamic state may not be good early after the injury, and chronic heart failure may ensue.

Atrioventricular Valve Rupture

In the same way that excision of the tricuspid valve is well tolerated (see Chapter 14), so is acute traumatic rupture of the tricuspid valve. Often the diagnosis is not made at the time of injury. Usually, within 2 to 3 months the patient exhibits decreased exercise tolerance, and signs of tricuspid valve regurgitation become evident.

In mitral valve rupture, as in spontaneous rupture of chordae tendineae or postinfarction mitral regurgitation, the patient often becomes acutely ill within a few hours of injury. Perhaps because traumatic mitral valve rupture is associated with a variable amount of cardiac contusion and myocardial dysfunction, this condition often results in deterioration and death within 24 hours.

Aortic Cusp Rupture

Natural history of acute aortic cusp rupture may be similar to that of acute aortic regurgitation occurring with infective endocarditis and cusp perforation (see Chapters 12 and 15), although there may be a symptom-free interval.

TECHNIQUE OF OPERATION

When diagnosis is rupture of a cardiac free wall, immediate operation is undertaken, but preparations must be made for CPB. If the patient’s condition permits, the femoral artery is exposed and cannulated (after heparinization) before median sternotomy. After median sternotomy, it may be seen that the rupture involves only a small area. In that case, digital control and placement of pledgeted mattress sutures suffice. If digital control cannot be obtained, CPB is established; blood is aspirated from the pericardium for venous return, and a reduced systemic blood flow rate is used. As soon as a single venous cannula can be inserted into the right atrium, CPB is converted to usual techniques and flow rates. Repair of the free wall rupture is improvised but, in the case of the ventricle, is generally similar to repair of a myocardial rupture complicating acute myocardial infarction (see Chapter 8).

Posttraumatic VSDs and traumatic injuries of the tricuspid valve are managed in a manner similar to that for congenital and postinfarction VSDs and other types of tricuspid valve regurgitation (see Chapters 9, 14, and 35). In tricuspid valve rupture the tensor apparatus is usually involved. An attempt should be made to reconstruct the leaflets using pericardium, and the tensor apparatus using artificial chordae of polytetrafluoroethylene (PTFE) suture. For trauma to the mitral valve, repair, if possible, is advised (see “Repair of Mitral Regurgitation” under Technique of Operation in Chapter 11). Occasionally, mitral valve replacement is necessary. In the rare case of rupture of a single aortic valve cusp, repair is possible; when two cusps are involved, valve replacement is usually necessary.

SPECIAL FEATURES OF POSTOPERATIVE CARE

Care usually given to patients after cardiac surgery is used (see Chapter 5).

RESULTS

Except in massive traumatic cardiac ruptures, results of repair in young and otherwise healthy persons are good. Aggressive therapy can salvage a number of patients if carried out in an institution in which cardiac surgery is frequently performed.

INDICATIONS FOR OPERATION

Cardiac Contusion

There is no indication for surgical treatment of patients with cardiac contusions. Close follow-up is indicated, however, in case delayed ventricular arrhythmia, cardiac rupture, or constrictive pericarditis develops.

Cardiac Rupture

When a patient survives the acute rupture long enough to reach a hospital, immediate operation is indicated.

Ventricular Septal Rupture

Unless the patient is asymptomatic and the ventricular septal rupture small, surgical closure is indicated. However, the possibility of preoperative improvement by use of percutaneous techniques should be considered (see “Percutaneous Closure of Defect” under Special Situations and Controversies in Chapter 9). If the hemodynamic state remains good during the early posttraumatic period, repair is deferred to 8 to 12 weeks after injury so that a more secure closure can be made.

Atrioventricular and Aortic Valve Rupture

Because important valvar regurgitation usually develops after atrioventricular or aortic valve rupture, operation is advisable. When the tricuspid valve has ruptured, operation is rarely urgently necessary and is often best delayed 8 to 12 weeks after the injury. In mitral or aortic valve rupture, operative repair is often urgently indicated.

**DEFINITION**

Cardiac tumors include benign and malignant neoplasms arising within the cardiac chambers or in the myocardium. Metastatic neoplasms to the heart are not included.

**HISTORICAL NOTE**

First recognition of a heart tumor is attributed to Columbus in 1559, followed by Malpighi, who in 1666 wrote a dissertation entitled “De polypo cordis.” Morgagni wrote of heart tumors in 1762. By 1931, Yater was able to publish an extensive dissertation and tabulation of primary cardiac tumors using a classification similar to that used today. Clinical diagnosis of a primary tumor—a sarcoma—was first recorded in 1934. The first antemortem diagnosis of a myxoma was made in 1951 using angiography. A major diagnostic landmark was echocardiographic diagnosis of a left atrial myxoma in 1968, which was confirmed at operation and successfully treated. In 1934, Beck partly removed an intrapericardial teratoma, and in 1951 Maurer successfully excised an intrapericardial lipoma. Among the earliest surgical approaches to myxomas was that of Bahnson and Newman, who in 1952 removed a myxoma from the right atrium via a right anterior thoracotomy using a short period of caval occlusion at normothermia. The patient died 24 days later of complications related to transfusion and electrolyte imbalance. Using cardiopulmonary bypass (CPB), Crafoord in 1954 successfully excised a myxoma from the left atrium, as did Bigelow in 1955, using hypothermia and inflow occlusion. Successful excision of a right atrial myxoma was reported in 1957 and in 1958. A left ventricular myxoma was excised in 1959 by Kay. The first successful excision of a right ventricular myxoma was reported in 1960. By 1964, 60 intracardiac myxomas had been successfully removed. Biatrial myxomas were first removed in 1967. In 1967, Gerbode and colleagues described recurrence of a left atrial myxoma 4 years after initial excision.

**TYPES OF CARDIAC TUMORS**

In a study from the Armed Forces Institute of Pathology, approximately 70% of cardiac tumors were benign and 30% malignant and potentially capable of invasion or metastasis (Table 18-1). In a more recent study of 533 primary tumors removed surgically, 10% were malignant.

Data from McAllister and Fenoglio. Key: AV, Atrioventricular.
Section I  Myxoma

DEFINITION
Cardiac myxomas are primary cardiac tumors that are generally pedunculated but may have a broad base. Cells are uniform, small, and polygonal, with round or oval nuclei and a moderate amount of cytoplasm. They lie in a myxomatous stroma in which other elements may be seen. One feature that distinguishes them from thrombi is that they are covered by endothelium and have endothelium-lined crevices and clefts. The notion that myxomas are derived from thrombi has been thoroughly dispelled.

MORPHOLOGY
Myxomas are intracavitary tumors occurring within any of the cardiac chambers, but they have a predilection for the atria, particularly the left. They are usually 5 to 6 cm in diameter, with a range of 1 to 15 cm. Characteristically, they are polypoid and pedunculated, projecting into a cardiac chamber. They can be gelatinous or mucoid, often with areas of hemorrhage. Generally, they are not sessile but have a short, broad-based attachment. The external surface of papillary forms of the neoplasm consists of a frondlike mass that is friable and likely to produce emboli.

Histology
Myxomas are composed of cells, primitive capillaries, and foci of extramedullary hematopoiesis within a myxoid matrix of acid mucopolysaccharide. The stroma contains variable numbers of reticulocytes and elastin fibers, smooth muscle cells, and collagen deposits. The matrix also contains polygonal cells with scant eosinophilic cytoplasm, either single and stellate or multinuclear and in small nests. At the periphery of the tumor, the cells form a monolayer with clustering in the crevices, thereby simulating primitive capillaries. The stalk has abundant large arteries and veins that communicate with the subendocardium, and at this interface, lymphocytes and plasma cells are prominent. Microscopic foci of calcium and areas of metaplastic bone are found in 10% of myxomas. The nucleus of the polygonal cells is typically irregular and slightly hyperchromatic, but mitoses are not seen. The cells contain fine parallel filaments similar to those seen in glomangioma and fibromyxosarcoma. These filaments are believed to be the contractile components of smooth muscle cells. Immunologically identifiable smooth muscle–type filaments are recognized in endocardial cells, which are more abundant in the left atrium, especially in the region of the fossa ovalis, than in other chambers.

Tumor Biology
The notion that myxomas are derived from thrombi has been thoroughly dispelled. Ferrans and Roberts believe the organelle content of myxoma cells does not provide sufficient information to determine the cell of origin. Although myxoma cells have a “vasoformative” tendency, in their view the cytoarchitectural features of the variously differentiated blood vessel–like structures differ from those of normal blood vessels. Thus, myxomas are considered to arise from pluripotential mesenchymal cells capable of differentiating into various types of cells, a view supported by the finding of bone and bone marrow tissue in myxomas. Histologic examination of the atrial septum in 11 autopsied patients younger than age 4 months revealed myxomatous or myxofibrous tissue in the endocardium near the fossa ovalis, further supporting the concept that myxomas are derived from embryonal undifferentiated mesenchymal cells, perhaps during endothelial-mesenchymal transformation, leading to cardiac septation and valve formation.

Based on immunohistochemical identification of three neuroendocrine markers in 24 excised atrial myxomas, Krikler and colleagues have suggested that these tumors originate from endocardial sensory nerve tissue. Occasional association of cardiac myxomas with cutaneous leiomyomatosis and systemic findings such as fever, hypergammaglobulinemia, and weight loss resemble manifestations of other tumors of neural origin. Increasing numbers of reports document the malignant potential of myxomas. Extensive local invasion has been noted. Death attributable to metastatic spread of an atrial myxoma was once reported as a result of fatal brainstem compression from an expanding cerebellar mass with histologic features identical to those of a large, pedunculated left atrial myxoma also found at autopsy. There have been many reports of local recurrence and of distant metastases with invasion of vessel walls, aneurysmal change, and independent growth.

Atrial Myxoma
Most atrial myxomas, whether left or right, arise from the atrial septum, usually from the region of the limbus of the fossa ovalis. About 10% have other sites of origin, particularly the posterior and anterior atrial walls and the appendage (in order of frequency). Importantly, atrial masses thought to be myxomas but not originating from the intraatrial septum may have more complex pathology. On the left atrial side, they may be extensions of hilar lung tumors such as mesothelioma, sarcoma, or carcinoma. On the right side, they may be intracaval extensions of renal or uterine tumors. Most myxomas—80% to 90%—are in the left atrium. Right atrial myxomas tend to be more solid and sessile than left atrial myxomas, with a wider attachment to the atrial wall or septum. In one reported case, an atrial myxoma presenting in the right atrium arose from the inferior vena cava.

Atrial myxomas may be multicentric (within a single chamber) or biatral. The most common arrangement (75%) of biatrual tumors involves attachment of two stalks to opposite sides of the same area of the septum. Of 312 cases of right and left atrial myxomas reviewed by Newman and colleagues, only two were complicated by presence of an atrial septal defect; Natarajan and colleagues reported four cases. Such cases may have right-to-left shunts.

Ventricular Myxoma
Found commonly on the right ventricular free wall or ventricular septum, ventricular myxomas are sometimes described as infiltrating the ventricular myocardium. In about 15% of reported cases, right ventricular myxomas are associated with other cardiac myxomas. Left ventricular myxomas are rare. Both right and left ventricular myxomas can
extend into the outflow tract and cause partial outflow tract obstruction.\textsuperscript{82}

Valvar Myxoma

Myxomas arising from the mitral, tricuspid, or pulmonary valves have been reported.\textsuperscript{6,81,82,72}

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

**Pathophysiology**

Myxomas may produce (1) symptoms of hemodynamic derangement from obstruction of flow within the cardiac chambers or deformation of a cardiac valve, (2) symptoms associated with embolization, and (3) constitutional symptoms, the least common manifestation.\textsuperscript{31,32} In rare circumstances, atrial myxomas may become infected; only 2 of 12 reported cases were diagnosed before death.\textsuperscript{31,33} Central nervous system embolism has been a constant association.

**Hemodynamic Derangement**

Myxomas may obstruct pulmonary or systemic venous drainage or may impair flow across the atroioventricular valves, the likelihood of these events being greater with larger tumors. The obstruction is characteristically progressive.\textsuperscript{83} When obstruction is intermittent, syncope, often related to postural change, or sudden death may occur. This happens in less than one fourth of patients with left atrial myxomas, about one third of those with right atrial or right ventricular myxomas, and about half of those with left ventricular myxomas.\textsuperscript{4,84,85,86,87} Impairment of valve closure, either by obstruction or leaflet damage, may cause regurgitation.\textsuperscript{87} Valves may be structurally damaged by frequent tumor impingement, a sequence that also causes regurgitation. Although regurgitation is the dominant abnormality, obstruction predominates in a few patients.\textsuperscript{88} Symptoms are commonly of short duration, are episodic, and may be associated with syncope.\textsuperscript{89}

**Embolism**

A major feature of cardiac myxomas is embolization. Emboli may arise from tumor fragmentation or detachment of the entire tumor, or from thrombi or infected foci on the surface of the neoplasm.\textsuperscript{82,90} Systemic emboli occur in 30% to 45% of patients with left atrial myxomas.\textsuperscript{91} They have been reported in every organ and may occlude coronary arteries.\textsuperscript{81,82,83,92,93} About 50% of emboli involve intracranial or extracranial arteries to the central nervous system.\textsuperscript{82,83,85,87,88,94} Cerebral emboli characteristically cause major permanent neurologic deficits. On rare occasions, they are amenable to excision.\textsuperscript{88,89,90,91,92,93} Large emboli may obstruct the aortic bifurcation.\textsuperscript{83} Although left ventricular myxomas are rare, prevalence of embolism from them is high (64%), apparently unrelated to tumor size, and greater to the brain than elsewhere.\textsuperscript{91} Left atrial myxomas that come to attention because of embolization tend to be small when examined after that event.\textsuperscript{95} Embolism from right-sided tumors occurs in about 10% of cases and may cause massive fatal pulmonary obstruction.\textsuperscript{88} However, pulmonary arterial obstruction from this mechanism is much less common than true thromboembolism to the pulmonary arteries in patients who have sustained systemic tumor emboli from a left atrial myxoma.\textsuperscript{10,16} Multiple emboli from right-sided tumors may be a cause of pulmonary hypertension.\textsuperscript{97} Paradoxical embolism is rare.\textsuperscript{94,97,101}

**Constitutional Manifestations**

In about 30% of patients, the only manifestation of a cardiac myxoma is a plethora of constitutional symptoms and certain laboratory findings. Large left atrial myxomas are particularly apt to produce constitutional symptoms.\textsuperscript{99} Symptoms include fever, weight loss, clubbing of the fingers and toes, Raynaud phenomenon, and myalgia and arthralgia.\textsuperscript{83,92} By themselves, these findings are not pathognomonic. Because the presence of antibodies to fresh heart muscle has been demonstrated preoperatively in some patients, with appropriate postoperative diminution, it is speculated that an immune reaction to the neoplasm or to heart muscle mediated by presence of the neoplasm may cause the constitutional symptoms.\textsuperscript{C22} Total globulin levels are often elevated, and the electrophoretic patterns may reveal prominent $\alpha_2$, $\beta_1$, or $\gamma$ heterogeneous globulin peaks. Immunoelectrophoresis localizes the elevated globulins in either the immunoglobulin (Ig)M or IgA fractions. Elevated globulin levels are associated with an increased erythrocyte sedimentation rate and C-reactive protein levels.\textsuperscript{100} Further nonspecific symptoms may be related to seeding of multiple small emboli in muscle and joints, and hemorrhage or degeneration within the tumor. Other unusual manifestations of cardiac myxomas include polycythemia with or without associated arterial hypoxia, and clubbing (with both left and right atrial myxomas) associated with a right-to-left shunt at the atrial level through a patent foramen ovale or atrial septal defect.\textsuperscript{10,17,88,94} Hemolytic anemia occurs in about one third of cases, particularly in association with a calcified myxoma; this and the thrombocytopenia that sometimes occurs are probably due to mechanical destruction of formed blood elements. These features are reversible with tumor removal.\textsuperscript{11,92,94}

**Familial versus Nonfamilial Myxoma**

Nearly all solitary myxomas have a normal DNA ploidy, and nearly all are nonfamilial. Nonfamilial (“sporadic”) cardiac myxomas are disorders primarily of middle-aged women. The tumors are usually single (94%) and in the left atrium (about 75%); they uncommonly have associated conditions, they rarely recur, and only about 20% have abnormal DNA ploidy.\textsuperscript{112}

Myxomas have a familial occurrence in about 5% of patients.\textsuperscript{112} They have a pattern of Mendelian dominant inheritance\textsuperscript{113} and are primarily disorders of young men. They are less common in the left atrium (62%), are more often multiple (33%), and in about 20% of patients are associated with unusual conditions. These conditions include Sertoli cell tumors of the testes, Cushing syndrome as a result of primary adrenocortical nodular dysplasia, pituitary tumors, centrofacial and labial lentiginosis (brown macules with regular edges, sometimes termed spotty pigmentation), cutaneous myxomas, and multiple myxoid mammary fibroadenomas.\textsuperscript{111,14,15,16} Familial myxomas have the same histologic appearance as nonfamilial myxomas and produce the same symptoms. However, they have a strong tendency to recur.\textsuperscript{112} Some patients with these complex findings have no identifiable cardiac myxoma; in a few others the myxoma has been found unexpectedly at autopsy.\textsuperscript{3,83,111} Familial cardiac myxomas are aneuploid in
virtually all cases, supporting the concept that they are neoplasms.

Symptoms

*Left atrial myxomas* produce symptoms similar to those of mitral stenosis (see Chapter 11) in most patients, with dyspnea and hemoptysis predominating. Symptoms are commonly of short duration, episodic, and associated with syncope. They may rapidly become severe and intractable and are associated with heart failure. *Right atrial myxomas* may also produce episodic symptoms, and these may progress rapidly. Abdominal proptuberance from hepatomegaly and ascites and peripheral edema are frequent presenting complaints. In the review by Morrisey and colleagues, all 18 patients had right heart failure, with a prominent *a* wave, raised venous pressure, hepatomegaly, ascites, and peripheral edema; absence of orthopnea and paroxysmal nocturnal dyspnea was notable. Symptoms that result from embolization include neurologic deficits, coldness and pain in an extremity, angina or infarction from coronary embolization, and dyspnea from pulmonary embolization. Constitutional symptoms may be subtle or absent when the tumor is small, but occasionally constitute the entire symptomatology.

**Signs**

Diagnosis of atrial myxoma is sometimes made immediately after hospital admission by histologic examination of an embolus removed from a peripheral artery. However, absence of myxoma cells in the embolus does not rule out myxoma, because thrombus forming on the neoplasm may be the cause of the embolism. Before the advent of echocardiography, interpretation of auscultatory findings for *left atrial myxomas* was aided by a combination of phonocardiographic and hemodynamic studies. A loud first heart sound is prolonged by vibrations coinciding with the *c* wave of the left atrial pressure tracing and also with a characteristic notch in the left ventricular pressure curve; these vibrations occur after mitral valve closure when the tumor momentarily comes to rest in the left atrium. For mobile tumors moving from the left ventricle to the left atrium in early systole, a notch in the ascending limb of the left ventricular pressure tracing is attributed to a sudden increase in left atrial volume, which itself is manifested in the left atrial pressure pulse by a prominent *c* wave and subsequent dominant *v* wave. Accordingly, the first heart sound may be preceded by a loud ejection sound resulting from forceful ejection of the tumor from the left ventricle back into the left atrium. When the tumor stays in the left atrium during the entire cardiac cycle, the diastolic murmur and pressure tracings may be indistinguishable from those of mitral stenosis (i.e., there is no notch in the ventricular pressure wave, and the *y* descent is relatively slow). The second heart sound is normally split, of low intensity, and followed by a third heart sound described as either an opening snap or a ventricular gallop. The opening snap occurs after the mitral valve opens and is thought to be due either to the tumor striking the heart wall or to the diastolic sound of mitral regurgitation caused by increased blood flow. Systolic murmurs have also been recorded and have been attributed to associated mitral regurgitation.

With *right atrial myxomas*, a loud early systolic sound is heard, usually regarded as a widely split first heart sound, corresponding to expulsion of the tumor from the right ventricle. This sound is likely to correspond to a notch in the upstroke of the right ventricular pressure curve. A pulmonary ejection murmur with a delayed and accentuated pulmonic second sound and an early, late, or prolonged tricuspid diastolic murmur or rumble is heard. A systolic murmur is due to tricuspid regurgitation.

**Ventricular myxomas** are sufficiently rare that their auscultatory features are not fully known, but murmur may suggest aortic or pulmonary stenosis. Occasionally, friction rubs are heard, presumably a result of physical contact of the tumor with the endocardium of one of the cardiac chambers. Rarely, patients presenting with constitutional manifestations exhibit cyanosis and clubbing of the fingers and toes, or a gallop rhythm and sinus tachycardia.

**Laboratory Studies**

Results of laboratory studies are usually normal. In rare instances of presentation with constitutional manifestations, some findings may be characteristic but not pathognomonic. Among them are anemia, thrombocytopenia, and findings associated with an immune response (see “Constitutional Manifestations” earlier in this section).

**Electrocardiography**

Electrocardiographic findings associated with myxomas are not specific, but include arrhythmias and conduction disturbances, particularly atrial fibrillation and bundle branch block, and abnormal P waves.

**Chest Radiography**

Features on a plain chest radiograph are not specific. Generalized cardiomegaly or specific chamber enlargement may be evident, particularly in the case of large left atrial myxomas causing obstruction. Septal lines, especially at the base and in the mid-zone of the lung, are fairly common findings because of coexisting pulmonary venous hypertension.

**Echocardiography**

Transthoracic echocardiography (TTE) supplemented by transesophageal echocardiography (TEE) has become the most appropriate screening and diagnostic imaging modality for myxomas (and most other cardiac tumors). Mitral valve stenosis can be excluded, and tumor prolapse through the atrioventricular valve may be demonstrated. Tumor prolapse is characteristic evident if echoes are seen behind the anterior leaflet, particularly if they move into the left ventricle during diaстole. Echocardiography is invaluable in identifying the precise origin of the myxoma (Figs. 18-1, 18-2).

**Computed Tomographic and Magnetic Resonance Imaging**

Atrial myxomas and other cardiac tumors can also be identified with computed tomography (CT) or magnetic resonance imaging (MRI), either alone or in combination with echocardiography. Asymptomatic tumors are occasionally identified when CT or MRI scans are performed for other indications.
Cardiac Catheterization and Angiography

Unless other types of cardiac or coronary artery disease require assessment, catheterization and angiography no longer constitute the investigative method of choice. If invasive study is required for suspected left atrial tumors, a selective right heart study is performed by injecting radiopaque media into the pulmonary artery and filming as the dye passes through the left atrium. This method usually gives a clear demonstration of the tumor, whereas selective left ventricular cineangiography often fails to delineate it. For right atrial myxomas, catheter placement into the right atrium is contraindicated, and injection is made into one of the venae cavae.

NATURAL HISTORY

Myxomas occur in older adults and are two to three times more common in women than in men. They are rare in children and have not been described in infants. MacGowan and colleagues estimate the incidence of atrial myxoma to be 0.5 per million population per year. The older literature contains reports of familial myxoma (three restricted to siblings and three with a parent-child relationship). Current knowledge indicates that the natural history of patients with familial myxomas is different from that of patients with nonfamilial, sporadically occurring myxomas (see “Familial versus Nonfamilial Myxoma” under Clinical Features and Diagnostic Criteria earlier in this section).

Myxomas are usually benign, but rarely the tumor metastasizes. Metastases have been reported in brain arteries, sternum, vertebral column, pelvis, scapula, and soft tissues of the back. Metastasis can occur despite benign gross and microscopic appearances, but it is rare. The course of surgically untreated patients with cardiac myxomas is highly variable and cannot be clearly defined. However, once symptoms of dyspnea and hemoptysis develop in the case of left atrial myxomas, or symptoms of abdominal protuberance from ascites or hepatomegaly develop in the case of right atrial myxomas, death usually follows within 1 to 2 years. Little information is available about the frequency of embolization in patients with myxomas, the tendency to repeated embolization if the tumor is not removed, or the course without treatment of patients presenting with constitutional symptoms only.

TECHNIQUE OF OPERATION

Single, nonfamilial left atrial myxomas in patients older than about age 50 can simply be excised. Familial myxomas in younger patients should be treated more aggressively. Preparations for operation, median sternotomy, CPB, and myocardial management are the usual ones for adult cardiac surgery (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2 and “Methods of Myocardial Management during Cardiac Surgery” in Chapter 3). Direct caval cannulation is routinely practiced for removal of atrial myxomas. A left atrial vent is not used.
Left Atrial Myxoma

The approach is bilateral. For initial exploration and orientation, the usual incision is made in the left atrium posterior to the interatrial groove (Fig. 18-3, A). Blood is removed from the left atrium, and the point of attachment of the tumor to the atrium is determined by inspection (Fig. 18-3, B). Assuming it is attached to the atrial septum, which is usually the case, the tumor is not removed from the left atrium. Instead, an oblique right atriotomy is made and the interior of the right atrium examined in case a second tumor is present (Fig. 18-3, C). As much as possible of the interior of the right ventricle is also inspected through the tricuspid valve. The atrial septum is then opened with a knife near the center of the fossa ovalis, and a sufficient amount of atrial septum is excised to include the tumor attachment and, if possible, uninvolved tissue 5 mm beyond it. The superior half of the fossa ovalis and adjacent limbus are, if possible, included in the excision, because cells thought to be the precursor of myxoma are more abundant in this area. The tumor is then removed from the heart through the left or right atriotomy, whichever is larger (Fig. 18-3, D). Very large tumors may have to be removed piecemeal, although every attempt is made to keep the tumor intact and to avoid tumor embolization. After the tumor is removed, the interior of the left atrium is copiously irrigated with saline solution to evacuate any residual tumor fragments. The defect in the atrial septum is closed either by direct suture or, if too large for this, with a pericardial or synthetic patch (Fig. 18-3, E).

Figure 18-3  Resection of left atrial myxoma. A, Two atrial incisions are used. Tumor is explored via left atrial incision (dashed line). Later, tumor will be removed from right atrial approach. B, As for exposure of mitral valve, left atrium is opened and explored and attachment of myxoma to atrial septum identified. (Tumor may be isolated from pulmonary vein orifices at this point by small packing sponges.) C, From opened right atrium, tumor attachment to atrial septum is usually apparent. A circular septal incision is made to surround the tumor origin (seen as a dimple). Key: Ao, Aorta; IVC, inferior vena cava; PT, pulmonary trunk; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

Continued
If the tumor is attached to the left atrial wall rather than the septum, the zone of attachment is excised, preferably with the full thickness of the adjacent wall, but if this is impractical, with endocardium and some underlying muscle. The wall defect created can be closed by direct suture or with a patch of autologous or bovine pericardium. The atria are closed and usual precautions against air embolization taken (see “De-airing the Heart” in Section III of Chapter 2). The rest of the procedure is completed in standard fashion.

**Right Atrial Myxoma**

Separate left and right atriotomies are not necessary unless there is preoperative evidence of an associated left atrial myxoma. Instead, the right atrium only is opened by the usual oblique incision (see Chapter 30, Fig. 30-14), and after attachments of the tumor are defined, it is excised with the adjacent portion of atrial septum in the manner described in the preceding text. The left atrium is then carefully inspected via the surgically created atrial septal defect. Only if a tumor is seen in the left atrium is that chamber opened by a separate incision. The atrial septal defect is closed as described in the preceding text, and the remainder of the procedure is completed as described.

**Other Myxomas**

Removal of ventricular myxomas does not require excision of full-thickness ventricular wall, because such a procedure would increase risk and no recurrences have been recorded.
following less radical removal. Tumors in the left ventricular outflow tract can sometimes be removed via an aortic approach. Otherwise, the approach is through the right atrium for right ventricular tumors and left atrium for left ventricular tumors. The ventricle is opened directly only when the atrial approach is inadequate for tumor removal. The procedure should include careful inspection of the interior of both right and left atria to exclude the presence of additional atrial tumors, which have been found in 15% of patients with right ventricular myxomas.

SPECIAL FEATURES OF POSTOPERATIVE CARE

Postoperative management is conducted in the usual fashion (see Chapter 5).

RESULTS

Survival

Early (Hospital) Death

Hospital mortality after removal of atrial myxomas is less than 5% (Table 18-2). Virtually all deaths are in patients with advanced disability or old age, the mode of death being generally related not to the atrial myxoma but to coexisting cardiac or degenerative disease. Early risks seem somewhat higher after removal of myxomas from the ventricular cavities. Among 32 patients who underwent removal of right ventricular myxoma, there were three hospital deaths (9%; CL 4%-18%), and among 14 patients in whom a left ventricular myxoma was removed, there were three hospital deaths (21%; CL 10%-38%).

Time-Related Survival

Death after hospital discharge is uncommon, but recurrence of the myxoma (see “Recurrence” later in this section) can lead to fatal complications. Most other late deaths are from causes other than the cardiac tumor. Excellent long-term results have been reported in a number of studies (Fig. 18-4). Presumably, these contained only patients with nonfamilial myxomas. Too few patients with familial myxomas have been reported for adequate assessment of long-term survival. Presumably, their survival is considerably worse than that of those with nonfamilial myxomas. Premature late death may occur more commonly when prosthetic valve replacement is necessary at time of myxoma removal because of complications from the prosthesis.

Recurrence

What has been classified as recurrence can be due to (1) tumor implantation (seeding at the time of removal), (2) incomplete removal, or (3) growth from a new focus (multicentric origin). Recurrence of a “sporadic” myxoma is unusual, occurring in only about 1% to 3% of patients, and myxomas with a normal ploidy rarely recur. In contrast, 30% to 75% of patients with familial myxomas experience
Papillary fibroelastomas usually develop on a valve leaflet, most commonly an aortic cusp or mitral leaflet. Less commonly, they appear on the tricuspid valve and ventricular septum, or rarely, on the aortic wall.\textsuperscript{F6,F8,O2,Y2}

**Clinical Features and Diagnostic Criteria**

This uncommon tumor rarely appears to cause trouble at its site of origin.\textsuperscript{I2,Y2} More often, it is responsible for embolization, either by detachment and embolization of one or more of its fronds or by inciting thrombus formation on its surface, with subsequent thromboembolism. Reported sites of embolism include primarily the brain and coronary arteries.\textsuperscript{G12,M8,M13,T5} They have also been observed in the lungs and retinal arteries.\textsuperscript{W2,Z1} Diagnosis in all living patients has been made by echocardiography and most accurately by TTE and TEE with Doppler color flow interrogation.\textsuperscript{D2,F8,G12,O2,S7,S12,S25,T5} Characteristically, by echocardiographic interrogation the tumor is small (about 1 cm\textsuperscript{2}), usually pedunculated and mobile, with a homogenous speckled pattern and stippling along its edges\textsuperscript{K6} (Fig. 18-6).

**Natural History**

Little is known about the natural history of papillary fibroelastomas of the heart, except that they tend to produce emboli. Embolization is the presumed mechanism of sudden death in some patients.

**Indications for Operation**

Surgical removal is indicated whenever diagnosis of cardiac myxoma is made. Historically, it was considered an urgent procedure, particularly if the patient had a history of embolism or syncpe, because it had been noted that 8\% to 10\% of patients died of embolic complications while awaiting operation.\textsuperscript{N7,S28,T3} However, more recent experience suggests that elective operation (as opposed to urgent) has resulted in no greater mortality or morbidity.

**Special Situations and Controversies**

Yu and colleagues in China have reported totally thorascopic surgical resection, often left atrial and two right atrial myxomas, using peripheral cannulation for CPB.\textsuperscript{Y4}

---

**Section II Papillary Fibroelastoma**

**Definition**

Papillary fibroelastomas are benign tumors representing less than 10\% of all cardiac tumors, and they are important because, like myxomas, they are a curable and identifiable cause of strokes and other embolic events.

**Morphology**

Papillary fibroelastomas are usually small tumors but may extensively involve structures such as the mitral valve.\textsuperscript{G12} They have characteristic papillary fronds, which can be recognized grossly (Fig. 18-5). At times they have been thought to be myxomas, but their histologic appearance is diagnostic. The fronds have a central core of dense connective tissue sometimes lined by hyperplastic endocardial tissue. They have been said to resemble normal chordae tendineae.\textsuperscript{M6}

---

**Figure 18-5** Papillary fibroelastoma removed from left ventricular outflow tract. (From Vivacqua and colleagues.\textsuperscript{V9})

Papillary fibroelastomas usually develop on a valve leaflet, most commonly an aortic cusp or mitral leaflet. Less commonly, they appear on the tricuspid valve and ventricular septum, or rarely, on the aortic wall.\textsuperscript{F6,F8,O2,Y2}

**Clinical Features and Diagnostic Criteria**

This uncommon tumor rarely appears to cause trouble at its site of origin.\textsuperscript{I2,Y2} More often, it is responsible for embolization, either by detachment and embolization of one or more of its fronds or by inciting thrombus formation on its surface, with subsequent thromboembolism. Reported sites of embolism include primarily the brain and coronary arteries.\textsuperscript{G12,M8,M13,T5} They have also been observed in the lungs and retinal arteries.\textsuperscript{W2,Z1} Diagnosis in all living patients has been made by echocardiography and most accurately by TTE and TEE with Doppler color flow interrogation.\textsuperscript{D2,F8,G12,O2,S7,S12,S25,T5} Characteristically, by echocardiographic interrogation the tumor is small (about 1 cm\textsuperscript{2}), usually pedunculated and mobile, with a homogenous speckled pattern and stippling along its edges\textsuperscript{K6} (Fig. 18-6).

**Natural History**

Little is known about the natural history of papillary fibroelastomas of the heart, except that they tend to produce emboli. Embolization is the presumed mechanism of sudden death in some patients.

**Indications for Operation**

Surgical removal is indicated whenever diagnosis of cardiac myxoma is made. Historically, it was considered an urgent procedure, particularly if the patient had a history of embolism or syncpe, because it had been noted that 8\% to 10\% of patients died of embolic complications while awaiting operation.\textsuperscript{N7,S28,T3} However, more recent experience suggests that elective operation (as opposed to urgent) has resulted in no greater mortality or morbidity.

**Special Situations and Controversies**

Yu and colleagues in China have reported totally thorascopic surgical resection, often left atrial and two right atrial myxomas, using peripheral cannulation for CPB.\textsuperscript{Y4}
RESULTS

Tumor recurrences have not been reported.

INDICATIONS FOR OPERATION

When a cardiac papillary fibroelastoma is discovered in a patient who has experienced an embolic event, removal is indicated. Whether the incidental finding of such a tumor is an indication for removal is arguable; when the tumor is on the mitral or aortic valve or the left ventricular endocardium, removal is advisable in patients at low risk for operative intervention.

Section III  Rhabdomyoma

DEFINITION

Cardiac rhabdomyomas are histologically specific cardiac tumors that tend to occur in patients with tuberous sclerosis. They are probably the same entity termed by some as cardiac hamartomas, Purkinje cell tumors, and histiocytoid cardiomyopathy.\(^{G1, N8}\)

MORPHOLOGY

Cardiac rhabdomyomas are benign, yellow-gray tumors, the microscopic characteristic of which is the so-called spider cell containing a central cytoplasmic mass suspended by fine, fibrillar processes radiating to the periphery. The cells are considered altered myocytes.\(^{G1}\) They are about twice the size of normal myocytes and are round or polygonal, with large hyperchromatic nuclei and eosinophilic granules in the cytoplasm. At times, there is no discrete myocardial tumor but only a gray-white area in the ventricular endocardium.\(^{G1}\) Rhabdomyomas occur almost invariably in the ventricles, with both sides equally involved and commonly in multiple locations. Whether rhabdomyomas are true neoplasms or myocardial hamartomas is controversial, but the latter is generally considered more likely.\(^{B24, F4}\) Consistent with this view is that at least half the patients have tuberous sclerosis, with multiple hamartomatous lesions in the brain. Cardiac rhabdomyomas may be associated with hamartomas in other organs as well.\(^{G1, \delta}\)

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Cardiac rhabdomyomas are the most common primary tumors in children.\(^{A3, B12, G6, M15}\) They may occur in siblings.\(^{S11}\) Presentation is frequently at birth or in the first few days of life with severe cardiac failure, the result of obstruction of cardiac pathways.\(^{S10}\) Cardiac rhabdomyomas are relatively common findings in infants presenting with incessant ventricular tachycardia.\(^{G1}\) At least one instance has occurred in which a rhabdomyoma of the right atrium caused atrial arrhythmias in an infant.\(^{G7}\) Occasionally the tumor is discovered somewhat later in a child known to have tuberous sclerosis, mental retardation, and in many cases, seizures.

Diagnosis can often be suspected based on clinical features and results of two-dimensional (2D) echocardiography (Fig. 18-7). Cardiac catheterization may be carried out to determine whether inflow to or outflow from the ventricles is obstructed. In some patients, no structural abnormality is found by any imaging technique, and diagnosis is inferred from the findings at electrophysiologic study of an area in the ventricle at which sustained monomorphic ventricular tachycardia can be induced.\(^{G1, \delta}\) Diagnosis has been made in the fetus by 2D echocardiography.\(^{B13}\)

NATURAL HISTORY

Little documentation exists concerning the natural history of patients with cardiac rhabdomyomas. Bass and colleagues determined by 2D echocardiography that 8 of 16 (50%; CL 36%-64%) infants with tuberous sclerosis had a cardiac rhabdomyoma.\(^{B4}\) Nir and colleagues corroborated a high prevalence of rhabdomyomas in patients with tuberous sclerosis.\(^{N9}\) It was previously assumed that mortality was high in patients with rhabdomyoma, due either to their tumor or to associated tuberous sclerosis. However, there is good documentation of spontaneous regression in number and size of these tumors.\(^{N9, T1}\) Nir and colleagues noted tumor regression in children younger than 4 years, less so in older children.\(^{N9}\)
In a 20-year experience, Smythe and colleagues noted regression of tumors in 100% of 24 patients studied by angiography or echocardiography. Twenty had complete resolution.

TECHNIQUE OF OPERATION

Because rhabdomyomas usually protrude into the right or left ventricular cavity, removal is done with the aid of CPB, hypothermic circulatory arrest, or both. Approach may need to be through the ventricular wall, but at times operation can be done through the atrioventricular or semilunar valve. Excision is limited to the area of the tumor. Occasionally, only the intracavitary portion is excised to relieve obstruction. The remaining intramyocardial portion will probably regress. In infants with incessant ventricular tachycardia, the only gross finding may be a grayish-white discoloration of the endocardium at the site identified by electrophysiologic mapping.

SPECIAL FEATURES OF POSTOPERATIVE CARE

Usual postoperative care is given (see Chapter 5). Catecholamine support may be necessary because of the extensive myocardial dissection.

RESULTS

With appropriate indications, results of surgical treatment are generally satisfactory. Black and colleagues operated on seven patients presenting with left ventricular outflow tract obstruction during a 27-year period; all survived. Importantly, during the same interval, 23 other patients with rhabdomyoma did not need surgical intervention, and all were alive at late follow-up. Spontaneous regression is likely to occur before age 2. In these patients and those treated surgically, if tuberous sclerosis has not developed, a lasting good result can be anticipated.

INDICATIONS FOR OPERATION

In the presence of known tuberous sclerosis and severe mental retardation with seizures, operation may be contraindicated, especially if the patient has multiple cardiac tumors and no cardiac symptoms. In the absence of tuberous sclerosis, an aggressive surgical approach is indicated if outflow tract obstruction or major ventricular arrhythmia is present. In patients without arrhythmias, observation may be warranted because of the possibility of spontaneous tumor regression. Should obstruction or arrhythmia occur, operation is indicated.

Section IV  Fibroma

DEFINITION

Cardiac fibromas are benign tumors, grossly resembling uterine leiomyomas, with a whorled appearance on cut section. Microscopically, cardiac fibromas consist of spindle cells mixed with collagen and elastic fibers. Mitotic figures are rare, and foci of dystrophic calcification are common. Controversy exists as to whether fibromas should also be considered hamartomas.

MORPHOLOGY

Fibromas occur almost exclusively within the ventricular myocardium and frequently in the ventricular septum. Patients with fibromas coming to surgical treatment tend to have large, bulky tumors that are not infiltrating. They are characteristically solitary, circumscribed, firm, gray-white, and often centrally calcified. They do not have a distinct capsule and may occasionally be multiple.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Clinical presentation is variable. Symptoms include dyspnea, syncope, heart failure, and chest pain. Ventricular tachycardia and sudden death have been reported. Currently, echocardiography is the most widely used modality for diagnosis. MRI and cardiac angiography may be useful in defining tissue characteristics and extent of tumor involvement.

NATURAL HISTORY

Natural history of untreated patients is unknown. The prevalence of asymptomatic ventricular fibromas is also unknown, and it is impossible to predict the exact risk of sudden death. The presumption is that these tumors eventually cause death from ventricular fibrillation or by obstructing ventricular inflow or outflow.

TECHNIQUE OF OPERATION

During CPB and appropriate myocardial management, incision is made through the epicardium and myocardium overlying the tumor. The tumor is enucleated by blunt and sharp dissection, which, even when the tumor is large, is possible. If the tumor involves the septum, reconstruction can be achieved by closing the septum in layers or with a prosthetic patch. Occasionally, mitral valve repair or replacement may be necessary. The ventricle is reconstructed by direct suture. When the tumor is very large and complete removal
seems impossible, partial removal may result in good palliation.\textsuperscript{57} In infants, children, and young adults who are otherwise in good health, cardiac transplantation should be considered if the tumor is deemed to be unresectable (see Chapter 21).\textsuperscript{V1}

**SPECIAL FEATURES OF POSTOPERATIVE CARE**

Usual postoperative care is given (see Chapter 5).

**RESULTS**

In a series of 18 patients reported by Cho and colleagues who were treated surgically and followed for up to 34 years, there was one operative death and no late death.\textsuperscript{C12} Fourteen patients were asymptomatic, one was in New York Heart Association functional class II, and two were in class III. There was no recurrence of tumor and no change in size of residual tumor in the one patient who had subtotal resection.

**INDICATIONS FOR OPERATION**

Diagnosis in a symptomatic patient (often an infant or child) is an indication for operation. Operation should be considered for asymptomatic patients with large tumors to prevent progressive cardiac deformity and atrioventricular valve dysfunction.\textsuperscript{C12}

---

**Section VI  Pheochromocytoma**

**DEFINITION**

Pheochromocytomas are potentially lethal, functionally active chromaffin tumors of the sympathetic nervous system that occur rarely within the pericardium and on the surface of the heart.

**HISTORICAL NOTE**

Occurrence of pheochromocytomas in the middle mediastinum and within the pericardium was unknown until 1960.\textsuperscript{N2,P5} Occurrence and treatment of cardiac pheochromocytomas were first discussed comprehensively by Orringer and colleagues in 1985.\textsuperscript{O4}

**MORPHOLOGY**

Cardiac pheochromocytomas are soft, fleshy tumors that are usually flattened by the pressure of the pericardium. They are typically benign and have large cellular trabeculae composed of mature pheochromocytes with marked cellular and nuclear pleomorphism. Nests of tumor cells may infiltrate the cardiac tissue. Chromaffin cells, from which these tumors are derived, normally are concentrated in the adrenal medulla, but they occur in small numbers along the aorta, in blood vessel walls, and in various organs including the heart. Pheochromocytomas produce large amounts of catecholamine, primarily nor-epinephrine, accounting for the hypertension characteristic of patients with these tumors.
CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Severe arterial hypertension is the characteristic finding in patients with pheochromocytomas. Markedly elevated urinary catecholamines are diagnostic. Localization of the pheochromocytoma in the middle mediastinum and heart is accomplished by a combination of CT imaging and scintigraphy with 131-I-metaiodobenzylguanidine or 111-indium diethylenetriamine pentaacetic acid octreotide and confirmed by MRI. \(^{A2,12,316,517}\)

NATURAL HISTORY

Little is known about natural history because of the rarity of cardiac pheochromocytomas. Presumably, it is that of pheochromocytomas and severe hypertension in general. Although pheochromocytomas are usually benign, at least one patient has been reported with widespread metastases. \(^{S10}\)

TECHNIQUE OF OPERATION

Preoperative preparation of the patient with \(\alpha\)- and \(\beta\)-adrenergic blocking agents is mandatory, and the anesthesiologist must be familiar with the intraoperative management of paroxysms of arterial hypertension and hypotension that may occur during the course of operation. Interestingly, these seem not to occur once CPB is established. Median sternotomy is probably the most useful incision, and CPB and cardioplegia are generally necessary. The tumor can be expected to be along the anterior surface of the heart and intimately related to the coronary arteries, including the left main coronary artery, or along the roof (superior aspect) of the left atrium and extending over the pulmonary veins and posterior left atrial wall, or in the area between the ascending aorta and pulmonary trunk. \(^{A2,94}\) The tumor usually cannot be enucleated, but must be dissected away from surrounding structures. It often has a large extracardiac collateral blood supply with potential risk of important hemorrhage. At times, a coronary artery or a portion of the left atrial wall must be included in the resection, and appropriate reconstruction will be necessary.

SPECIAL FEATURES OF POSTOPERATIVE CARE

Usual care after a cardiac surgical procedure is appropriate (see Chapter 5).

RESULTS

Removing the tumor returns the patient to a normotensive state and results in cure, except in the unusual circumstance when the tumor is malignant. In a review of 26 cases collected from the literature, 25 patients underwent reconstruction within the native heart and one had successful transplantation. \(^{J1}\) Mortality was 24% (CL 15%-36%), with five patients (20%, CL 11%-32%) dying of hemorrhage.

INDICATIONS FOR OPERATION

Diagnosis is generally an indication for operation.
be involved. Right heart sarcomas tend to be bulky and infiltrative, cause heart failure, and metastasize early.\textsuperscript{b17} Left heart sarcomas tend to be more circumscribed and less infiltrative, cause heart failure early, and metastasize later.\textsuperscript{b17} Sarcomas tend to metastasize widely.

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

Presenting symptoms are nonspecific and include fever, malaise, and weight loss. Presence of a pericardial effusion is not uncommon. Heart failure is a late manifestation, and distant metastasis may already be present. Echocardiography, CT, and MRI are used for diagnosis.

**NATURAL HISTORY**

Prognosis is poor for untreated patients with cardiac sarcomas, many of whom have distant metastases when first seen.\textsuperscript{v3} For patients with angiosarcoma who had medical therapy but not surgical resection, Neragi-Miandoab and colleagues reported that 90% were dead within 12 months.\textsuperscript{v6}

**TECHNIQUE OF OPERATION**

The tumor is removed as completely as possible. Radical excision of portions of the atria and ventricles may be necessary. For tumors involving the right heart, resection may include the superior vena cava, entire right atrium, tricuspid valve, right coronary artery, and up to about 30% of the right ventricular muscle mass.\textsuperscript{v5} For sarcomas of the left heart, autotransplantation has been recommended to permit radical tumor resection and adequate reconstruction.\textsuperscript{b17,c14,v5} Under a clinical trial (ESPERO) at the M.D. Anderson Cancer Center and Methodist DeBakey Heart and Vascular Center in Houston, Texas, all patients with cardiac sarcomas and no overt heart failure are given neoadjuvant chemotherapy preoperatively to reduce tumor bulk and destroy tumor cells at the periphery of the tumor.\textsuperscript{v5}

**SPECIAL FEATURES OF POSTOPERATIVE CARE**

Usual postoperative care is given (see Chapter 5).

**RESULTS**

Among a series of 27 patients with cardiac sarcoma treated surgically by the Houston group, operative mortality was 7.4% (2 patients).\textsuperscript{b2} Chemotherapy was administered to 19. At a median follow-up of 22 months, 12 patients were alive and 7 were tumor free. Among 24 patients who underwent operation with curative intent, median survival was 24 months. Patients who underwent surgical resection, radiofrequency ablation, or radiation treatment for tumor recurrence \((n = 7)\) had a median survival of 47 months. Patients \((n = 7)\) with no further intervention for recurrent disease had a median survival of 25 months.

**INDICATIONS FOR OPERATION**

Because many patients with cardiac sarcomas have evidence of metastatic disease on presentation, and because persistent tumor is often present at the limits of the surgical resection, indications for radical surgical treatment are not clearly defined. Surgical treatment combined with chemotherapy should be considered for younger patients without clear evidence for metastatic disease.

---

**Section IX  Carcinoid Heart Disease**

**DEFINITION**

Carcinoid heart disease is a manifestation of malignant carcinoid syndrome in which a unique form of fibrosis involves the endocardium, primarily of the right heart. \textit{Malignant carcinoid syndrome} is a symptom complex associated with carcinoid tumors of the gastrointestinal tract arising from argentaffin cells, which secrete large amounts of serotonin. Primary tumors are usually in the ileum, but may occur in the pancreas, biliary vessels, ovaries, and testes. The syndrome is characterized by flushing, telangiectasias, diarrhea, and bronchospasm and occurs in about 10% of patients with carcinoid tumors. Carcinoid heart disease occurs in approximately 50% of those who have the syndrome.\textsuperscript{b124}

**MORPHOLOGY**

Most patients with carcinoid heart disease have pathologic lesions limited to right-sided valves. These are glistening, white-yellow fibrous deposits, devoid of elastic fibers, located on the ventricular aspect of the tricuspid valve and downstream aspect of the pulmonary valve.\textsuperscript{b9,b13} The fibrous plaques result in constriction of the valve anulus and adherence of the valve leaflets to the right ventricular endocardium, in the case of tricuspid involvement, and the pulmonary trunk wall, in the case of pulmonary valve involvement. Thus, the dominant physiology is that of tricuspid regurgitation or pulmonary stenosis. The valve lesions morphologically resemble those resulting from appetite suppressants (fenfluramine and phentermine), because the lesions are not neoplasms and, in the case of carcinoid heart disease, not metastatic tumors.\textsuperscript{b14} In virtually all patients with carcinoid valve lesions, there are hepatic metastases from the primary gut tumor. (See “Carcinoid Tricuspid Valve Disease” under Morphology in Chapter 14 for a more detailed discussion.)

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

Patients have the classic cutaneous flushing of carcinoid syndrome and usually display a hyperdynamic circulation, although they are generally not hypertensive. Nearly all have a systolic murmur and may also have cardiomegaly. In 74 patients investigated by Pellikka and colleagues, all had tricuspid valve involvement, and 90% had moderate or severe tricuspid regurgitation.\textsuperscript{v6} By echocardiography, the valve leaflets are shortened and thickened and on color Doppler have a characteristic “dagger-shaped” spectral profile. Patients with carcinoid heart disease have greater serum levels of serotonin and tachykinins than patients with the syndrome but without cardiac involvement. Severity of cardiac involvement, in addition, tends to correlate with both serum serotonin
levels and higher urinary excretion of 5-hydroxyindoleacetic acid (5-HIAA).\textsuperscript{11}

**NATURAL HISTORY**

Survival in patients with carcinoid heart disease is lower than in patients with the syndrome but without cardiac involvement. Evolution of valve lesions may be rapid, leading to heart failure, although death is usually caused by progressive systemic disease.\textsuperscript{24}

**TECHNIQUE OF OPERATION**

Tricuspid valve replacement may provide palliation in some patients (see “Technique of Operation” in Chapter 14). Pulmonary valve replacement may also be beneficial in reducing right ventricular dysfunc-
tion.\textsuperscript{16,17} There are at least two reports of secondary fibrous carcinoid involvement of tissue valves used to replace tricuspid or pulmonary valves in patients with carcinoid syndrome.\textsuperscript{3,4} Balloon valvotomy may be palliative, but is likely to be followed by early recurrence of stenosis.

**SPECIAL FEATURES OF POSTOPERATIVE CARE**

Usual cardiac postoperative care is given (see Chapter 5); additionally, levels of urinary 5-HIAA are monitored.

**RESULTS**

Robiolio and colleagues reviewed 47 carcinoid valve replacement cases. Thirty-day mortality was 56% for patients older than 60 years and 0% for those 60 years or younger. Two patients survived beyond a decade.\textsuperscript{16}

**INDICATIONS FOR OPERATION**

Precise indications for valve replacement cannot be stated. The underlying disease is progressive, and operative mortality for valve replacement mortality is high in older patients. Therefore, a young individual with low comorbidity and important heart failure would likely present the best candidate for a satisfactory outcome.

Hypertrophic Obstructive Cardiomyopathy

**Definition**
Hypertrophic cardiomyopathy (HCM) is a genetic myocardial disorder characterized by left and/or right ventricular hypertrophy that is usually, but not always, asymmetric and is associated with microscopic evidence of myocardial fiber disarray and fibrosis.\(^{10,6,7}\) Degree of hypertrophy at any given site can vary substantially and influences clinical manifestations of the disease.

**Ventricular septal hypertrophy** is the most common type of asymmetric hypertrophy, with midventricular, apical, and other types occurring much less frequently.\(^{6}\) Forms interfering with left ventricular (LV) emptying, termed **hypertrophic obstructive cardiomyopathy** (HOCM) or (obsolete) **idiopathic hypertrophic subaortic stenosis** (IHSS), are of surgical importance and are characterized by a variable dynamic obstruction that is usually subaortic and is associated with abnormal **systolic anterior motion** (SAM) of the anterior leaflet of the mitral valve. The more commonly occurring nonobstructive forms are not amenable to surgical treatment except for cardiac transplantation (see Chapter 21). Prevalence of HCM in the general population is about 1 in 500 (0.2%).\(^{11}\)

**Historical Note**
Pathologic findings compatible with HOCM were described by two 19th-century French pathologists, Hallopeau and Liouville,\(^{11,15}\) and an early 20th-century German pathologist, Schmincke.\(^{7}\) In 1952, Davies described a family from Cardiff, Wales, with five of nine siblings affected and three dying suddenly who probably had this disease. Although these reports and the surgical report of Brock in 1957...
described diffuse muscular subaortic stenosis, the disease was first accurately categorized by Teare, a London pathologist, in 1958. Teare described both disproportionate thickening of the ventricular septum compared with the free wall and presence of myocardial fiber disarray in young people who died suddenly. These pathologic findings were rapidly confirmed and clinical features were further elucidated by Braunwald and colleagues, whereas Braunwald and colleagues called it idiopathic hypertrophic subaortic stenosis and Wigle and colleagues, muscular subaortic stenosis.

At that time, LV outflow tract obstruction was thought to be distinctive for the disease. That the anterior mitral leaflet contributed to the obstruction was first documented in 1964 by Fix and colleagues, who emphasized the importance of reduced LV compliance as the major determinant of cardiac dysfunction (‘inflow’ or diastolic obstruction) rather than outflow obstruction. Knowledge that nonobstructive HCM was much more common awaited introduction of echocardiography, which detected asymmetric septal hypertrophy (ASH), one of the hallmarks of the disease, as well as the presence or absence of SAM. During the early 1970s, ASH and SAM were thought to be specific for HCM but this is now known to be incorrect. Echocardiography not only established that HCM is relatively common, but also that it is usually genetically transmitted rather than sporadic.

Surgical awareness of the obstructive form of the disease began with Brock’s reports in 1957 and 1959. However, in his patients and in the first patient operated on at Mayo Clinic in February 1958, nothing was done surgically, because the nature of the disease was not understood. Credit for the first myotomy, consisting of a simple incision of the prominent anterior muscular ridge in the septum, probably belongs to Cleland. Myotomy was used by a number of other surgeons about this same time.

At Mayo Clinic, a left ventriculotomy was performed to allow adequate excision (myectomy) of muscle under direct vision. The few years the surgical approach to septal myectomy was modified in several ways. Dobell and Scott used a left atrial approach, exposing the hypertrophied septum by dividing the anterior mitral leaflet across its center, whereas Lillehei and Levy used a similar approach but detached the base of the anterior mitral leaflet near the anulus. Swan used a corkscrew to excise septal muscle from a limited LV approach. Julian and colleagues used a “fish mouth” LV incision that detached the lower part of the free wall from the septum and gave excellent exposure of the subaortic septal bulge, which was then excised. Cooley and colleagues developed an approach through the right ventricle used first by Harken, in which septal muscle was shaved off the right ventricular side, judging septal thickness by means of a finger inserted into the LV through the aortic valve.

None of these techniques is currently in use. Simple myotomy using an aortic approach was used for a time by the Toronto group. Later, they modified the procedure to include excision of muscle (myectomy) as advocated by Morrow. Other procedures have also been used, including mitral valve replacement by Cooley and colleagues, use of an LV-aortic valved conduit to bypass the obstruction, and a modified Konno procedure preserving the aortic valve (see “Modified Konno Operation” under Technique of Operation in Section II of Chapter 47).

MORPHOGENESIS AND MORPHOLOGY

Morphogenesis

HCM is caused by a missense mutation in one of at least 11 genes that encode the proteins of the cardiac sarcomere. These include mutations in the β-myosin heavy-chain gene (chromosome 14q11-q12), in cardiac troponin-T (chromosome 1), and in α-tropomyosin (chromosome 15q2). It is transmitted as an autosomal dominant trait, although nonfamilial cases probably occur as well.

Morphology

Muscular hypertrophy present in HCM involves the interventricular septum and LV, and is variable in its location and severity.

Ventricular Septum

In classic HOCM, hypertrophy is maximal in the cephalad portion of the ventricular septum (Fig. 19-1). Point of maximal thickening lies just apical (caudal) to the free edge of the anterior mitral leaflet in its open position. This muscular prominence (mound) tapers off gradually toward the LV-aortic junction and toward the apex. At the point opposite the free edge of the anterior mitral leaflet, LV endocardium is often thickened by a localized plaque of fibrous tissue that lies at right angles to the long axis of the outflow tract. Because it is present in both nonobstructive and obstructive forms of HCM, this plaque is presumably related to contact between the anterior mitral leaflet and septal bulge in diastole rather than systole, with the leaflet snapping open rapidly at the onset of diastole (in part because of high left atrial pressure) and contacting the ventricular septal prominence.

Ventricular septal hypertrophy is not always maximal in its anterior basal parts. Occasionally, it may be maximal at a site below the anterior mitral leaflet adjacent to the papillary muscles, producing midventricular hypertrophy leading to obstruction, to which the papillary muscles and free-wall hypertrophy contribute (Fig. 19-2). There is no SAM or mitral regurgitation. Apical LV aneurysm in the presence of normal coronary arteries occasionally occurs with midventricular hypertrophy. Hypertrophy may be confined to the posterior or apical septum. Localized apical hypertrophy is apparently most common among the Japanese. Occasionally the entire septum may be of uniform thickness.

Dynamic Morphology of Septum and Mitral Valve

When septal hypertrophy is classic, obstruction is sited in the LV outflow tract between the hypertrophied ventricular septum and anterior mitral leaflet. In systole the posterior mitral leaflet closes against the body of the elongated anterior leaflet at about the junction of the middle and free-edge thirds (rather than near the free edge as in the normal heart).
Chapter 19  Hypertrophic Obstructive Cardiomyopathy

Figure 19-1  Ventricular septal hypertrophy in hypertrophic obstructive cardiomyopathy. Longitudinal section of heart from a 32-year-old woman who died suddenly while receiving propranolol therapy. Hemodynamic investigation had confirmed presence of subaortic obstruction and mitral regurgitation, partially resulting from an abnormal mitral valve (insertion of anomalous papillary muscle [arrow] onto the ventricular surface of the anterior mitral leaflet). Note asymmetric hypertrophy with grossly thickened ventricular septum and anterior mitral leaflet, which is very thickened and fibrosed from repeated mitral leaflet–septal contact. There was microscopic evidence of extensive myocardial fiber disarray involving both septum and free wall of the left ventricle. (From Wigle and colleagues.  

The free-edge portion of the anterior mitral leaflet beyond the point of coaptation hinges (angulates) on the remainder of the leaflet in a cephalad direction toward the aortic anulus (Fig. 19-3). This brings the free edge of the anterior mitral leaflet in contact with the ventricular septum. This SAM of the anterior leaflet is a constant feature of classic HOCM; degree of movement correlates with severity of obstruction, as does diameter of the LV outflow tract at this point. Ventricular ejection is rapid and early, mostly within the first half of systole. SAM is temporally related to peak LV outflow gradient and to cessation of flow in the ascending aorta. The mechanism of SAM is probably multifactorial. Most likely, SAM is secondary to forward (anterior) displacement of the elongated mitral valve relative to the septum during systole, and to subsequent movement of the distal portion of the mitral valve apparatus. In association with marked septal hypertrophy opposite the mitral leaflet and rapid and early ventricular ejection, the Venturi effect of the high-velocity stream of blood carries the protruding edge of the anterior mitral leaflet toward the aortic anulus in early systole. As a secondary event, the higher pressure below the anterior leaflet then forces it further into the outflow tract. SAM is absent in nonobstructive HCM and when the obstruction is at a lower level. SAM can occur in transposition of the great arteries with intact ventricular septum (see “Left Ventricular Outflow Tract Obstruction” under Morphology in Chapter 52) and rarely in other disease states. SAM may also appear after mitral valve repair.

Left Ventricular Free Wall
In obstructive HCM with ASH, free-wall hypertrophy is more marked than in nonobstructive forms and is fairly uniform, particularly in the anterolateral and apical portions. There is, however, less thickening of the posterior free wall in almost all varieties of HCM. Thus, the ratio between the thick upper anterior part of the ventricular septum and the thinner posterior wall beneath the posterior mitral leaflet (the portion through which the beam passes in M-mode

Figure 19-2  Midventricular hypertrophy in hypertrophic obstructive cardiomyopathy. Cross-sectional slices of heart from a patient shown to have midventricular obstruction by hemodynamics, angiography, and echocardiography. Obstruction was at the level of the papillary muscles, where there was massive hypertrophy (second slice from left). Slice at left is from base of the heart; two slices at right are from the apex. The apex was the site of extensive myocardial infarction and aneurysm formation that was evidenced by a dyskinetic apical chamber on angiography and by persistent ST-segment elevation in leads V₄ to V₆ on the electrocardiogram. Coronary arteries showed no important luminal narrowing. The patient died of intractable ventricular arrhythmias. (From Wigle and colleagues.  

The free-edge portion of the anterior mitral leaflet beyond the point of coaptation hinges (angulates) on the remainder of the leaflet in a cephalad direction toward the aortic anulus (Fig. 19-3). This brings the free edge of the anterior mitral leaflet in contact with the ventricular septum. This SAM of the anterior leaflet is a constant feature of classic HOCM; degree of movement correlates with severity of obstruction, as does diameter of the LV outflow tract at this point. Ventricular ejection is rapid and early, mostly within the first half of systole. SAM is temporally related to peak LV outflow gradient and to cessation of flow in the ascending aorta. The mechanism of SAM is probably multifactorial. Most likely, SAM is secondary to forward (anterior) displacement of the elongated mitral valve relative to the septum during systole, and to subsequent movement of the distal portion of the mitral valve apparatus. In association with marked septal hypertrophy opposite the mitral leaflet and rapid and early ventricular ejection, the Venturi effect of the high-velocity stream of blood carries the protruding edge of the anterior mitral leaflet toward the aortic anulus in early systole. As a secondary event, the higher pressure below the anterior leaflet then forces it further into the outflow tract. SAM is absent in nonobstructive HCM and when the obstruction is at a lower level. SAM can occur in transposition of the great arteries with intact ventricular septum (see “Left Ventricular Outflow Tract Obstruction” under Morphology in Chapter 52) and rarely in other disease states. SAM may also appear after mitral valve repair.

Left Ventricular Free Wall
In obstructive HCM with ASH, free-wall hypertrophy is more marked than in nonobstructive forms and is fairly uniform, particularly in the anterolateral and apical portions. There is, however, less thickening of the posterior free wall in almost all varieties of HCM. Thus, the ratio between the thick upper anterior part of the ventricular septum and the thinner posterior wall beneath the posterior mitral leaflet (the portion through which the beam passes in M-mode
Fig. 19-3  Proposed mechanism of systolic anterior motion of anterior mitral leaflet in hypertrophic obstructive cardiomyopathy.  
A, At onset of systole, coaptation point (arrow) is in body of anterior and posterior leaflets.  
B-C, During early systole (B) and midsystole (C), there is anterior and basal movement of the residual length of the anterior leaflet (thick arrow), with septal contact and failure of leaflet coaptation (thin arrow) and subsequent mitral regurgitation directed posteriorly into the left atrium (stippled area).  (From Grigg and colleagues.)

Fig. 19-4  Left ventricular (LV) cineangiogram in right anterior oblique projection in hypertrophic obstructive cardiomyopathy. Note characteristic deformity of LV cavity, with septal muscle encroaching on anterior margin of outflow tract and the grossly hypertrophied papillary muscles contributing to virtual elimination of the mid-LV cavity in systole.  
A, Diastole. Dashed line crossing LV outflow area represents free-wall portion of mitral anulus, delineated by contrast medium trapped behind opened posterior leaflet.  
B, Systole. Lower dashed line outlines a radiolucent filling defect caused by contact between mitral leaflets and septum.
shape is characteristic of patients younger than age 40 and is rare in patients older than 65.1,2 When ventricular hypertrophy is located in the midportion of the ventricle, a dumbbell-shaped cavity results3; when it is confined to the apex, there may be complete obliteration of the lower half of the cavity and a spade-shaped basal portion.4 LV apical aneurysms are present in approximately 2% of patients with HCM and occur over a wide age range.5,6,10

Rarely the LV may become dilated in the late stages of HOCM. This dilatation may result from transmural myocardial infarction (MI)7,8 or severe progression of the disease process, with or without heart failure.9,10 Prognosis of patients with progressive LV wall thinning is poor, and concomitant cardiac failure is usually refractory to treatment.11,12 Most patients show an “hourglass” contour of the cardiac border, with midventricular hypertrophy and intracavitary gradients.

Histopathology of Left Ventricle
Microscopic findings in the hypertrophied ventricular septum are distinctive.13,14 Increased wall thickness is mainly caused by increased fibrous tissue, particularly in the ventricular septum but also in the free wall.15 Increase in muscle cell diameter and number of cell layers also contributes, with cell diameters being largest in layers closest to the cavity, perhaps because this is the site of greatest wall stress.11,13

In addition, numerous foci of disarrayed muscle cells are interspersed between areas of hypertrophied but normally arranged (parallel) cells.16,17 In areas of disarray, muscle cells are wider and shorter than those present in hypertrophied muscle in other diseases, with increased cellular branching, extensive side-to-side intercellular junctions, widened Z bands, and formation of new sarcomeres. There are also abnormalities in orientation of myofibrils.18,19 In obstructive forms of HCM, muscle cell disarray is confined to the ventricular septum, whereas in nonobstructive forms it may also occur in the LV free wall.20,21

Using a quantitative histologic method to determine extent of myocardial fiber disarray, Maron and Roberts found that the average degree of cell disarray in the ventricular septum of patients with HCM was 30%, compared with 1.5% in hearts with congenital or acquired cardiac disease or in normal hearts, and that when more than 5% of the relevant areas of the tissue section were involved, cell disarray was both highly sensitive (90%) and specific (93%) for HCM.22 By contrast, Bulkley and colleagues concluded that myocardial fiber disarray found in HCM was qualitatively and quantitatively similar in the LV of hearts with aortic atresia and a patent mitral valve and in the right ventricle of hearts with pulmonary atresia and intact ventricular septum.23 Thus, it is unlikely that cell disarray is a morphologic manifestation of a genetically transmitted myocardial defect in HCM24,25,26, rather, it is likely the result of uncoordinated muscular contraction occurring in these conditions.27,28

Histologic ventricular abnormalities in HCM lead to more forceful LV contraction and rapid early ventricular emptying. In addition, reduced distensibility (compliance) and impaired relaxation result in a prolonged early filling phase and a decrease in rate and volume of the rapid phase of LV filling. Consequently, there is a compensatory increase in the contribution of atrial systole to overall LV filling.29,30,31

Left Atrium
The left atrium is often dilated and thick walled as a result of decreased compliance of the LV and presence of mitral regurgitation.

Mitrail Valve
In obstructive forms of HCM, the mitral valve is positioned closer to the ventricular septum than in the normal heart.32 Mitral valve leaflets are disproportionately elongated and thickened, particularly the leading edge of the anterior leaflet.33,34 This is presumably the result of SAM. The mitral anulus forcefully constricts during systole, and this purse-string action gathers the mitral leaflets into folds.35,36

A further consequence of SAM is production of mitral regurgitation in mid- or late systole as the anterior leaflet moves forward (see Fig. 19-3). Studies by Bonow and by Wigle and colleagues indicate a direct relation between magnitude of the pressure gradient and degree of mitral regurgitation.37,38,39 It is likely that severity of mitral regurgitation, magnitude of the pressure gradient, and degree of prolongation of LV ejection time are determined by time of onset and duration of mitral leaflet–septal contact.37,38

Mitrail regurgitation occurs independently of SAM in about 20% of patients with HOCM.40,41,42 It can result from mitral valve prolapse, chordal rupture, anomalous attachment of a papillary muscle to the anterior leaflet, extensive anterior leaflet fibrosis resulting from repeated mitral leaflet–septal contact, congenital abnormalities, rheumatic disease, or mitral anular calcification.43,44,45 Presence of mitral regurgitation likely contributes to the exercise intolerance often present in patients with HOCM.46 Mitral anular calcification is frequently present in older patients with HOCM.47,48

Right Ventricle
The right ventricular chamber is distorted by the hypertrophied ventricular septum, which projects into the right ventricular outflow tract. This hypertrophy may cause an important pressure gradient in the right ventricular outflow tract and, in long-standing cases, hypertrophy of the free wall. Right ventricular hypertrophy may also occur secondary to pulmonary hypertension from long-standing left-sided heart failure and elevated left atrial pressure. Unverferth and colleagues demonstrated an important increase in amount of fibrous tissue in the right ventricular free wall in HCM, as well as an increase in myocyte cell diameter in the subendocardial layer.49

Coronary Arteries
In HCM, coronary arteries are larger in diameter than normal. Important coronary arteriosclerosis is present in about 5% of patients.49,50 Spray and colleagues and Maron and colleagues noted wall thickening and luminal narrowing of the intramural coronary arterial branches, located primarily in the ventricular septum and also occasionally in the left and right ventricular free wall in about half of patients with HCM.42,51 Muscular bridging of the left anterior descending coronary artery (LAD) during part of its course is more common in HCM than in normal hearts. The LAD may become totally occluded during systole at these sites52 or may have an irregular
sawtooth appearance.\textsuperscript{817} Septal perforating arteries may be obliterated or severely narrowed during systole. Hemodynamic effect of these changes is not known, although Maron and colleagues and Waller and colleagues have reported that transmural myocardial infarction occurs in HCM in the absence of arteriosclerotic coronary artery disease.\textsuperscript{59,63} Using thallium perfusion imaging and computed tomography, O’Gara and colleagues demonstrated that myocardial ischemia can occur in HCM both at rest and after exercise.\textsuperscript{61} This could be caused by systolic arterial compression or spasm, narrowing of intramural branches, inadequate capillary density, or reduction in diastolic coronary flow from impaired ventricular relaxation.

**Associated Lesions**

There is a specific association between HCM and diffuse lentiginosis.\textsuperscript{510} No evidence indicates that the latter is inherited.\textsuperscript{529} Association with essential hypertension noted in Brock’s original report is probably coincidental, although Wei and colleagues suggest that a “hypertrophic cardiomyopathy” with features indistinguishable from some forms of HCM can occur in a number of other disease states including severe-standing hypertension and severe aortic valvar stenosis.\textsuperscript{814,92} Similarly, there may be a coincidental association of HCM with other congenital or acquired cardiac diseases such as atrial septal defect and rheumatic heart disease. With HOCM, functional impairment of von Willebrand factor (a plasma glycoprotein required for normal hemostasis) is frequent and is closely and independently related to the magnitude of outflow obstruction.\textsuperscript{1,2} A resting peak gradient of 15 mmHg is sufficient to impair function of this glycoprotein and may result in abnormal spontaneous bleeding.

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

HOCM symptoms and signs are usually such that diagnosis can be made with confidence on clinical grounds. Subaortic or midventricular obstruction may be latent (provokable), labile, or persistent (obstruction at rest).\textsuperscript{81,96} In contrast, in nonobstructive HCM there may be no symptoms or signs, particularly in mild forms. In the text that follows, only obstructive HCM (HOCM) is discussed.

**Symptoms**

Symptoms associated with HOCM can occur at any age from infancy to beyond 70 years. They include angina, effort dyspnea, syncope, and dizziness on exertion, singly or in combination. However, these symptoms may not be related directly to the magnitude of LV outflow gradient. Rather, they are caused by a complex interaction of diastolic dysfunction, arrhythmias, myocardial ischemia, and outflow gradient.\textsuperscript{815}

Palpitation may occur, usually from atrial fibrillation, which may initially be paroxysmal but is permanent in about 10% of patients in the later stages of the disease. Onset of atrial fibrillation is usually heralded by a sudden increase in dyspnea and sometimes by heart failure and hypotension because of the rapid rate and loss of the atrial component of ventricular filling.\textsuperscript{82} Almost half of patients presenting with atrial fibrillation have a history of systemic embolism. Arrhythmia may also be caused by ventricular premature beats or bouts of ventricular tachycardia or supraventricular tachycardia, and can result in sudden death.\textsuperscript{534,54}

Later stages of HOCM are associated with severe and progressive heart failure with paroxysmal nocturnal dyspnea, orthopnea, and pulmonary edema. Rarely, ascites and peripheral edema develop in association with tricuspid regurgitation.

**Signs**

The three cardinal signs of HOCM are (1) late-onset systolic ejection murmur between the left sternal edge and apex, (2) bifid arterial pulse, and (3) palpable left atrial contraction.\textsuperscript{85}

The physical signs in typical cases of HOCM differ in important respects from other forms of aortic outflow obstruction. The pulse is jerky (bifid) with a rapid upstroke, in contrast to the anacrotic pulse of valvar aortic stenosis. An abnormal jugular a wave is frequently present, and occasionally, a short, low-pitched diastolic flow murmur that is enhanced by inspiration; both are the result of vigorous atrial contraction.\textsuperscript{812} The thrusting, overactive LV impulse is frequently double because of transmission of the forceful atrial contraction, which may also be audible as a fourth heart sound. Frequently, there is a third sound at the apex. Splitting of the second heart sound may be paradoxical, but this feature, as well as a gallop rhythm, is characteristically variable because of dynamic and variable obstruction. A mid-systolic murmur that is roughly proportional in intensity to the degree of obstruction is maximal between the left sternal edge and apex of the heart rather than in the aortic area, although it radiates to the base; a thrill may be present. The murmur increases in intensity after a Valsalva maneuver (or inhalation of amyl nitrite), because both increase the degree of obstruction. When important mitral regurgitation is present, the murmur is maximal at the apex and pansystolic. There is no aortic ejection click. Valvar calcification and an aortic diastolic murmur are also absent (except in occasional cases in which the valve is abnormal). Infants and young children presenting with severe HOCM may be cyanotic from reversal of shunt flow at the atrial level.\textsuperscript{876}

**Ventricular Function**

Although in early stages of HCM, LV systolic function is usually normal or occasionally supranormal, with high ejec tion fraction in both the obstructive and nonobstructive forms of the disease,\textsuperscript{96} in HOCM (i.e., in later stages), impaired systolic function of both left and right ventricles occurs, primarily as a result of myocardial fibrosis.\textsuperscript{82,73,96} Fibrosis can result from fibrous transformation of loose intra cellular connective tissue located between the myocardial fibers,\textsuperscript{73,97} or from myocardial ischemia and infarction caused by small-vessel or arteriosclerotic coronary artery disease.\textsuperscript{59,91} Myocardial fibrosis may result in thinning of the wall, reduction or loss of outflow obstruction, reduced ejection fraction, and increased end-systolic volume.\textsuperscript{96}

Diastolic dysfunction was initially attributed to decreased ventricular compliance.\textsuperscript{811,96} However, it now appears that impaired relaxation is the more important cause.\textsuperscript{96,97} Increased chamber stiffness increases diastolic pressure with respect to volume (dP/dV), and the diastolic pressure-volume curve is shifted upward and to the left.\textsuperscript{96}
Chapter 19  Hypertrophic Obstructive Cardiomyopathy

Electrocardiography

The electrocardiogram (ECG) in HOCM characteristically shows an LV strain pattern, although Q waves may be present, and rarely, minimal changes indicative of LV hypertrophy despite an important gradient. Occasionally the ECG shows complete right or left bundle branch block and more often left anterior hemiblock. Giant negative T waves in V1-V6 are typical of isolated apical hypertrophy. ECG features of left atrial enlargement are often noted, but those of right atrial enlargement less often.

Chest Radiography

Chest radiography shows mild to moderate cardiomegaly more often in HOCM than in other forms of aortic outflow obstruction. The aorta is typically small. The raised left atrial pressure may be reflected in the lung fields by evidence of pulmonary venous hypertension or frank interstitial edema.

Echocardiography

Transthoracic echocardiography (TTE) is the most important diagnostic study. Diagnosis can usually be established by M-mode echocardiography because, with rare exceptions, patients with familial HOCM have ASH, and all those with obstruction should demonstrate SAM, although this may appear only on provocation (e.g., after Valsalva maneuver). Standard echocardiography combined with Doppler color flow interrogation can be used to identify systolic and diastolic ventricular dysfunction, degree and direction of mitral regurgitation, presence of additional mitral valve abnormalities, and size of the left atrium. Transesophageal echocardiography (TEE) with Doppler color flow interrogation is invaluable for defining extent and level of outflow obstruction and abnormalities of the mitral valve (Fig. 19-5). It should be used preoperatively for planning the operative procedure and intraoperatively to assess its effectiveness (Fig. 19-6).

Exercise Echocardiography

Exercise echocardiography may identify LV outflow obstruction in symptomatic patients who would not otherwise be regarded as candidates for interventional treatment. Maron and colleagues reported on 320 patients with HCM judged to be eligible for exercise testing, of whom 201 underwent standard exercise testing with echocardiography; 119 had LV outflow tract gradients at rest of 50 mmHg or more and were not tested. In the 201 patients, LV outflow tract gradient increased from 4 ± 9 (median = 0) mmHg at rest to 45 ± 49 (median = 30) mmHg after exercise. In 106 patients (52%), gradients of 30 mmHg or more developed, including 76 (38%) that were 50 mmHg or more. Only a minority of

Figure 19-5 Transesophageal echocardiogram (frontal long-axis plane) demonstrating mechanism of mitral leaflet–septal contact and failure of mitral leaflet coaptation in midsystole. A, During diastole, mitral leaflets open. B-C, In early systole an abnormal coaptation point (arrow) is seen in body of anterior and posterior leaflets. D, During midsystole, anterior motion of both anterior and posterior leaflets occurs. E, At mid-late systole, anterior leaflet–septal contact is seen, resulting from anterior and basal movement (arrow) of anterior mitral leaflet. F, Frame during mid-late systole shows failure of coaptation of mitral leaflets (arrow). Key: LA, Left atrium; LV, left ventricle. (From Grigg and colleagues.)
The tip should be positioned near the base of the LV close to the mitral valve to avoid apical entrapment, which can produce a falsely high LV pressure.

LV end-diastolic pressure is usually increased, often greatly, because of transmission of a large left atrial wave (Fig. 19-7). Central and peripheral arterial pulse contours show a rapidly ascending limb with a short upstroke (0.06 to 0.085) but a total ejection time greater than 0.335. A secondary systolic atrial wave results in the characteristic “spike and dome” (bifid) pulse contour initially described by Benchimol and colleagues.

The beat following a ventricular ectopic beat shows an abnormal response—a reduced arterial pulse pressure (and exaggerated spike-and-dome contour) secondary to increased obstruction generated by the ectopic beat. Obstruction is increased by any maneuver that increases LV contractility or decreases LV preload or afterload. Whenever the obstruction increases, pulse pressure decreases and total LV ejection time increases.

Figure 19-6  Intraoperative transesophageal echocardiogram (frontal long-axis plane) before (upper panels) and after (lower panels) transaortic septal myectomy. Upper left panel, Systolic frame demonstrating anterior leaflet-septal contact with failure of mitral leaflet coaptation. Upper right panel, Same frame with Doppler color flow imaging demonstrating turbulent flow in aortic outflow tract and large jet of posteriorly directed mitral regurgitation arising from gap between the two leaflets. Lower left panel, Systolic frame demonstrating a widened left ventricular outflow tract after myectomy and abolition of systolic anterior motion of mitral valve. Note diminution in width of ventricular septum. Lower right panel, Same frame with Doppler color flow imaging demonstrating nonturbulent left ventricular outflow with marked reduction in severity of mitral regurgitation, with only a small residual jet. (From Grigg and colleagues.)

Cardiac Catheterization and Cineangiography

The diagnostic accuracy of echocardiography has substantially reduced the need for invasive studies in patients with HOCM. Cardiac catheterization and cineangiography are generally reserved for patients in whom echocardiographic studies are inconclusive, those in whom arteriosclerotic coronary artery disease is likely to be present, and those for whom surgical treatment (septal myectomy, dual-chamber pacemaker insertion, or cardiac transplantation) is being considered.

Right-sided heart catheterization will show any infundibular stenosis (occasionally severe) and elevation of pulmonary artery pressure, which may also be substantial because of high left atrial pressure. Retrograde left-sided heart catheterization will quantify and localize the obstruction. The catheter tip should be positioned near the base of the LV close to the mitral valve to avoid apical entrapment, which can produce a falsely high LV pressure. LV end-diastolic pressure is usually increased, often greatly, because of transmission of a large left atrial wave (Fig. 19-7). Central and peripheral arterial pulse contours show a rapidly ascending limb with a short upstroke (0.06 to 0.085) but a total ejection time greater than 0.335. A secondary systolic atrial wave results in the characteristic “spike and dome” (bifid) pulse contour initially described by Benchimol and colleagues. The beat following a ventricular ectopic beat shows an abnormal response—a reduced arterial pulse pressure (and exaggerated spike-and-dome contour) secondary to increased obstruction generated by the ectopic beat. Obstruction is increased by any maneuver that increases LV contractility or decreases LV preload or afterload. Whenever the obstruction increases, pulse pressure decreases and total LV ejection time increases.

This dynamic characteristic of the obstruction can be confirmed by various provocative maneuvers such as isoproterenol administration, exercise, and Valsalva maneuver, which...
increase the gradient, and by methoxamine administration, which decreases it.

Systolic LV outflow gradient often is not increased during exercise but becomes dramatically increased almost immediately after exercise.\(^3\) The increase usually becomes maximal 3 to 5 minutes into the recovery period. Presumably, increased systemic venous return prevents substantial reduction of LV volume (and increase in the gradient) during exercise despite increased myocardial contractility, heart rate, and cardiac output and a reduced systemic vascular resistance. After exercise, decreased venous return allows a reduction in LV volume and an increase in systolic gradient.\(^3\)

LV cineangiography is best performed in the left lateral view because in this position the cardiac apex moves caudally and does not overshadow the mitral area.

The prominent characteristic septal bulge can be seen to form the anterior boundary of the outflow tract and the anterior mitral leaflet to form its posterior boundary. SAM can usually be demonstrated when obstruction is present (Fig. 19-8).

Degree of mitral regurgitation can be assessed from the LV cineangiogram. However, multiple ectopic beats can make quantitation difficult. Coronary angiography should be added to the procedure in patients older than age 30 years in whom coronary artery occlusive disease is suspected or known to be present.

NATURAL HISTORY

In familial HCM, isolated ASH, identified by M-mode echocardiography, is an important part of the clinical spectrum and has the same genetic implications as HOCM. It is uncertain whether isolated ASH, an asymptomatic disease, develops into clinical obstructive cardiomyopathy (HOCM); if so, this sequence is uncommon after age 20 years.\(^1\)

HCM can present at any age from early infancy to the sixth or seventh decade. Echocardiographic studies of patients with HCM, including those with isolated ASH, suggest that obstruction is present in only about 20%. Infants and young children presenting with symptomatic HOCM represent the more severe end of the spectrum, with gross LV hypertrophy, frequent episodes of heart failure, and a high prevalence of sudden death.\(^1\) Progression of disease may be more rapid in children and young adults.\(^6\)

The natural history of HCM is typically variable. Although the clinical course is often stable over long periods, adverse events such heart failure, syncope, sudden cardiac death, and peripheral embolization can occur.\(^2\) Sudden onset of heart failure is frequently precipitated by atrial fibrillation, which

---

**Figure 19-7** Left ventricular (LV) and aortic pressure tracings in hypertrophic obstructive cardiomyopathy (HOCM). Peak systolic gradient is 60 mmHg. Aortic pressure pulse shows typical double contour (“spike and dome”). LV end-diastolic pressure is elevated in association with transmission of an a wave from the left atrium (arrow). The beat after an ectopic beat demonstrates reduced aortic pulse pressure characteristic of HOCM (center of tracing).

**Figure 19-8** Left ventricular cineangiogram in left lateral position showing systolic anterior motion of anterior mitral leaflet. A, Isovolumetric contraction. Anterior (a) and posterior (p) mitral leaflets are apposed in relatively normal systolic position, causing only slight narrowing low in left ventricular outflow tract despite prominent septal muscle (s) anteriorly. Aortic valve is still closed. B, Systolic ejection phase. Apposed free edges of mitral leaflets have risen to maximal level of obstruction, with anterior leaflet almost meeting the septal muscle. Despite severe obstruction (systolic gradient of 100 mmHg), there is no detectable mitral regurgitation.
may be associated with subsequent embolism. In patients with HOCM, correlation between symptomatic class and degree of obstruction has generally not been close, although in the multicenter trial reported by Shah and colleagues, there were no asymptomatic patients once the gradient exceeded 100 mmHg.\textsuperscript{51} Frank and Braunwald documented a substantially higher gradient in patients in New York Heart Association (NYHA) classes III and IV compared with those without symptoms.\textsuperscript{50} In the experience of Wigle and colleagues, presyncope and syncope on exertion are encountered most frequently in patients with HOCM.\textsuperscript{56}

Annual HCM-related mortality reported from referral centers has ranged from 4% to 6% in children and 2% to 4% in adults.\textsuperscript{52,53,54,56} (Figure 19-9). In contrast, studies involving largely unselected patients with HCM report annual mortality of 0.5% to 1.5%, similar to that for the adult general population.\textsuperscript{59,52,52,56}

Sudden cardiac death is common in patients with HCM.\textsuperscript{52} Risk factors for sudden death include a basal (resting) peak instantaneous gradient of at least 30 mmHg,\textsuperscript{54} young age, syncope, family history of malignancy, myocardial ischemia (particularly in the young), sustained ventricular tachycardia on electrophysiologic testing, and ventricular tachycardia on ambulatory monitoring.\textsuperscript{56} HCM is the most common association with unexplained sudden death in otherwise apparently healthy competitive athletes.\textsuperscript{52} Midventricular obstruction is an independent predictor of adverse outcomes especially for the combined endpoint of sudden death and potentially lethal arrhythmic events.\textsuperscript{55}

Neurologic death from cerebral embolism occurs in patients with permanent or paroxysmal atrial fibrillation or, infrequently, as a result of infective endocarditis on aortic and mitral valves.\textsuperscript{59} In the multicenter study by Shah and colleagues in patients with obstruction, but not operated on and followed for an average of 5.2 years, only one died from heart failure and two from infective endocarditis, but 23 from sudden cardiac death.\textsuperscript{510}

**TECHNIQUE OF OPERATION**

**Myectomy by Aortic Approach**

A full or partial upper median sternotomy is used, and cardiopulmonary bypass (CPB) is established in standard fashion (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2). During cooling, a left atrial drainage catheter is inserted through a purse-string suture in the right superior pulmonary vein near its junction with the left atrium. A catheter can also be placed into the coronary sinus through a purse-string suture in the wall of the right atrium for retrograde delivery of cardioplegic solution (see “Technique of Retrograde Infusion” in Chapter 3). The distal ascending aorta is clamped, and cardioplegic solution is infused through a needle in the ascending aorta (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3). The aorta is then opened through a transverse aortotomy or through an oblique incision that extends into the non-coronary sinus of Valsalva (Fig. 19-10, A). Stay sutures are applied to the edges of the aortotomy or to the aortic valve commissures to improve exposure. If additional myocardial protection is necessary, the coronary ostia can be cannulated and directly perfused with cardioplegic solution (see “Perfusion of Individual Coronary Arteries” in Chapter 3).

The right aortic cusp is retracted anteriorly against the sinus wall. Hypertrophied septum can be seen bulging down into the anterior aspect of the LV outflow tract (Fig. 19-10, B). A narrow ribbon retractor can be placed into the LV outflow tract and depressed posteriorly to avoid injury to the chordae tendineae and anterior leaflet of the mitral valve. Using a No. 15 (small rounded) scalpel blade, an incision is made deep into the septum, exactly beneath the nadir of the right coronary cusp and parallel to the long axis of the LV outflow tract. A second parallel incision in the septum is made as far leftward as possible without damaging the mitral valve (Fig. 19-10, C). As suggested by Morrow,\textsuperscript{545} a sponge stick can be pressed against the right ventricular free wall to depress the ventricular septum and bring it into better view through the aortotomy. Both incisions are then deepened and carried toward the LV apex as far as possible—often beyond visibility, because no structures can be damaged in this area. The two vertical incisions are then connected by a transverse incision beginning several mm below the right coronary cusp. This may prevent prolapse of the right coronary cusp and development of aortic regurgitation. With continuing pressure on the sponge stick, this transverse incision is extended downward into the ventricle until a thick, rectangular piece of septum has been excised (Fig. 19-10, D). In patients with important

![Figure 19-9](image-url) Freedom from hypertrophic cardiomyopathy (HCM)-related death among 273 patients with a left ventricular outflow gradient of at least 30 mmHg under basal conditions and 828 patients without obstruction at entry. (From Maron and colleagues.\textsuperscript{54})

**Note:** P = .001
hypertrophy of the adjacent left anterolateral free wall, a third incision is made beginning below the commissure between left and right coronary cusps and is directed toward the base of the anterolateral papillary muscle. Septal tissue between this incision and the primary trough already created is excised to further increase the cross-sectional area of the LV outflow tract (Fig. 19-10, E). Care is taken to remove any small pieces of muscle from the LV cavity; the left index finger is then passed through the valve into the cavity. If palpation of the septum confirms that the excision has traversed the entire length of the muscular obstruction (Fig. 19-10, F), operation is considered to be complete. The aortotomy is closed, and CPB is discontinued (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2).

In pediatric patients, HOCM has a more variable morphologic spectrum. The major site of obstruction may be subaortic, although it often occurs at the midventricular or apical level. Obstruction of the right ventricular outflow tract also occurs. Within the LV, hypertrophied muscle may extend onto the base of the anterior leaflet of the mitral valve, and

Figure 19-10  Technique of transaortic septal myectomy. A, Aorta is opened through oblique incision extending into noncoronary sinus of Valsalva (dashed line). B, Right aortic cusp is retracted against the aortic wall, exposing the hypertrophied septum. Dashed lines indicate initial incisions into the septum. C, Two parallel incisions are made in the septum: (1) beneath nadir of right coronary cusp and (2) as far leftward as possible. These incisions are joined by a transverse incision (dashed line), which is made several millimeters below the edge of the right aortic cusp. D, Rectangular channel created by septal myectomy.

Continued
these fibromuscular attachments may contribute to SAM of the anterior leaflet. When present, they should be carefully incised at both margins of the base of the anterior leaflet during the transaortic myectomy to reduce or eliminate abnormal SAM of the anterior leaflet.

**Adjuncts to Conventional Myectomy**

*Intraoperative TEE* facilitates performing septal myectomy by determining accurately the location and thickness of hypertrophied septum, detecting other lesions, assisting assessment of adequacy of the myectomy and correction of mitral regurgitation, and identifying complications such as ventricular septal perforation. Among 50 patients who underwent septal myectomy and in whom intraoperative echocardiography was used, 10 (20%; CL 14%-28%) required a second period of CPB for further resection of muscle because of persisting LV outflow tract gradients greater than 50 mmHg or for correcting more than moderate mitral regurgitation.

If adequate myectomy has been performed, there will be little or no residual gradient, SAM, or mitral regurgitation. *Direct measurements of LV and ascending aortic pressures* should be made after discontinuing CPB under stable hemodynamic conditions. If a residual gradient of more than 10 to 15 mmHg is present, CPB should be reestablished and additional muscle resected.

*Extended myectomy and reconstruction of the subvalvar mitral apparatus* have been proposed by Messmer. The septal myectomy is deeply extended into the LV cavity, wider...
toward the apex than the base, thus providing access to the base of both papillary muscles. These are mobilized down to the apex, and all hypertrophied portions and muscular trabeculae are resected. In theory, mobilization of malpositioned papillary muscles from the adjacent myocardium permits the mitral valve leaflets to be deflected away from the LV outflow tract during systole. A similar technique has been reported by Maron and colleagues for managing outflow obstruction in the midventricular region that results from muscular apposition created by anomalous chordae tendinae or anomalous insertion of a papillary muscle directly into the anterior mitral leaflet without interposition of chordae tendinae. In the latter instance, the papillary muscle is incised and separated from the ventricular septum or free wall down to its base. If an accessory muscle is present in the LV outflow tract, it is excised by amputating it at its base and severing the fibrous attachments to the anterior mitral leaflet.

Plication of the anterior leaflet of the mitral valve with myectomy, first proposed by McIntosh and colleagues, has been performed in patients judged at operation to be at increased risk for a suboptimal hemodynamic result because of morphology of the mitral valve (increased mobility, size, or length of anterior leaflet with respect to LV outflow tract dimension) and potential for its anterior leaflet to protrude into the myectomy trough during systole. Plication can be performed through the aortic valve either in the horizontal direction or vertically (tip of leaflet to base) using several interrupted polypropylene sutures.

Anterior leaflet extension by insertion of a pericardial patch into the body of the anterior leaflet has been employed by some groups. This maneuver increases leaflet stiffness, causes lateral displacement of the secondary chordae tendinae, and functions hemodynamically as a spinnaker sail to eliminate SAM. The effectiveness of leaflet plication and extension in reducing LV outflow tract obstruction and SAM has not been evaluated in large clinical trials.

Apical myectomy has been proposed for treatment of severely symptomatic patients with apical HCM and for patients with midventricular obstruction. Through an incision in the apex of the left ventricle lateral to the left anterior descending coronary artery, excision of ventricular muscle at the apex and midventricular levels is performed with the objective of increasing the LV end-diastolic volume and improving LV compliance. Postoperative hemodynamic studies in 14 of a series of 44 patients reported by Schaff and colleagues using this technique, showed a significant (P = .002 or less) decrease in LV end-diastolic pressure, increase in LV diastolic volume index, and increase in stroke volume. Five-year survival was 81%.

Modified Konno Operation
When echocardiography or initial visual examination through the aortic valve shows that muscular obstruction is deeper (more toward the apex) in the LV outflow tract than usual, or when there is residual muscular obstruction inferiorly after creating a trough, a modified Konno operation can be performed (see “Modified Konno Operation” under Technique of Operation in Section II of Chapter 47). The modified Konno operation may occasionally be selected preoperatively as the preferred procedure because of severity and location of obstruction.

Mitrail Valve Replacement
The role of mitral valve replacement in managing patients with HOCM remains incompletely defined. Cooley and colleagues have shown that excising the anterior mitral leaflet relieves LV outflow tract obstruction in most patients. McIntosh and colleagues showed that in comparing patients undergoing mitral valve replacement, septal myectomy, or septal myectomy combined with plication of the anterior mitral leaflet, the greatest reductions in resting and provable outflow tract gradients and in LV end-diastolic pressure occurred in those who had mitral valve replacement. Mitral valve replacement may be necessary for patients who have intrinsic disease of the mitral valve that is not typically associated with HOCM. This includes patients with rheumatic or severe myxomatous or degenerative disease that is not amenable to repair. A concomitant septal myectomy should be performed in most patients.

If mitral valve replacement is performed, all chordal attachments between papillary muscles and mitral valve leaflets must be severed (see Fig. 19-10, F and G). The entire anterior leaflet of the mitral valve must be excised. If hypertrophied and contributing to obstruction, the papillary muscles are excised. The small size and at times abnormal shape of the LV cavity require use of a low-profile prosthesis, most often a mechanical valve.

Mitrail Valve Repair
Other structural abnormalities of the mitral valve besides those typically associated with HOCM exist in approximately 7% of patients undergoing surgical treatment of HOCM. Mitral valve repair is feasible in 50% to 60% of these patients using conventional reparative techniques. Anuloplasty rings should be avoided, however, to prevent SAM. If anuloplasty is necessary, flexible or rigid bands on the posterior leaflet are preferred.

SPECIAL FEATURES OF POSTOPERATIVE CARE
The patient is cared for with the principles and protocols described in Chapter 5. Marked LV hypertrophy reduces ventricular compliance to such an extent that left atrial pressures of 16 to 18 mmHg may be required early postoperatively for adequate preload. Digitalis glycosides and the β-adrenergic receptor agonist isoproterenol should be avoided because they increase myocardial contractility and may increase residual outflow tract gradient. Hypovolemia and nitroglycerin, which can reduce LV volume and exaggerate any residual gradient, should also be avoided. Atrial fibrillation may be poorly tolerated, so measures should be taken to reduce its probability of occurrence and to treat it aggressively if it develops. This can be best accomplished by use of β-adrenergic receptor blocking agents (e.g., propranolol), calcium antagonists (e.g., verapamil, diltiazem), or amiodarone.

RESULTS
Early (Hospital) Death
In the larger surgical series of patients treated in the 1980s and early 1990s, hospital mortality ranged from 0% to 6%. Mortality has remained somewhat higher with concomitant coronary artery bypass grafting and valve
PART IV  Other Cardiac Conditions

Modes of Death
Cardiac failure, sudden death, ventricular arrhythmias, and stroke are the most common cardiovascular modes of death after discharge from the hospital.

Incremental Risk Factors for Premature Death
Older age at operation is a risk factor for early and late death. However, many elderly patients not only survive, but also exhibit marked hemodynamic and symptomatic improvement. Addition of mitral valve replacement or repair to myotomy or myectomy is a risk factor for late death. In separate series, female gender, preoperative syncope, increased NYHA functional class, documented coronary artery disease, preoperative atrial fibrillation, concomitant procedures, mitral valve replacement, development of complete heart block, and persisting outflow tract gradients greater than 15 mmHg were incremental risk factors for late death.

Myocardial Changes
The effect of surgical reduction of LV outflow tract obstruction on cardiac structure and function has been demonstrated. Deb and colleagues demonstrated a significant decrease in LV mass and mass index assessed by TTE in 60 patients following septal myectomy. This favorable remodeling occurred early after operation and persisted beyond 2 years. Among 150 patients followed for a median of 1.8 years and for up to 20 years after septal myectomy, substantial improvement in LV diastolic filling as determined by mitral inflow Doppler velocity signals was observed. Menon and colleagues reported a significant (P < .0001) decrease in echocardiographically determined mean left atrial volume index among 32 young patients (mean age 12.5 years) after septal myectomy. This reduction correlated closely with decrease in severity of mitral regurgitation (P = .04) Cannon and colleagues noted a reduction in oxygen consumption and corresponding reduction in coronary blood flow, and a change from lactate production during pacing to lactate consumption, in the anterior portion of the LV and septum. The
changes were more marked in patients with high coronary flow reserve before reoperation.

Conduction Disturbances

Complete heart block occurs in from 2.5% to 10% of patients.\textsuperscript{18,15,41,44,58,59,60,61,62} When complete right bundle branch block is present preoperatively, creating left bundle branch block (LBBB) at operation results in complete heart block.\textsuperscript{3,5} Complete LBBB develops in approximately 50% of patients postoperatively.\textsuperscript{18,5,62} In a recently reported series of 325 patients undergoing isolated septal myectomy, pacemakers were required in 7 (3%) with normal preoperative conduction, in 15 (30%) with preexisting conduction abnormality, and in 10 (77%) with right bundle branch block.\textsuperscript{18} In this series, new permanent pacemakers were implanted in 19 additional patients during follow-up, which averaged 3.6 ± 2.8 years and extended to 8 years. Freedom from pacemaker insertion at 8 years was 79%.

Perioperative Myocardial Infarction

Perioperative myocardial infarction occurs occasionally at sites remote from the myotomy and can occur without associated coronary arterial occlusive disease.\textsuperscript{59} With current techniques for intraoperative myocardial preservation, occurrence of myocardial infarction is low.

Iatrogenic Defects

Ventricular septal defect (VSD) is created in up to 3% of patients treated by transaortic myotomy or myectomy.\textsuperscript{16,44,75} In recently reported series from experienced centers, the frequency is less than 1%.\textsuperscript{58,61,10} McIntosh and colleagues believe that an iatrogenic VSD is more likely to occur when the septum is relatively thin (<18 mm).\textsuperscript{31} VSD may not be detected until some weeks after operation and could then be the result of septal infarction rather than surgical perforation.\textsuperscript{52} A VSD may contribute to hospital mortality and may be large enough to require subsequent repair.\textsuperscript{16,3,5}

Aortic valve regurgitation can occur after operations for HOCM. It occurred postoperatively in 5% of 115 patients (CL 3.1%-8.3%) reported by Mohr and colleagues and in 4% of 525 patients (CL 3.1%-5.1%) operated on exclusively through the aortic root by Brown and colleagues.\textsuperscript{16,44} In the latter series, regurgitation developed within 6 months of operation in more than half the patients. Sasson and colleagues, using pulsed or color Doppler echocardiography to quantify severity of aortic regurgitation, found the prevalence of aortic regurgitation to be 54% in 52 patients who were studied a mean of 7.8 years postoperatively.\textsuperscript{52} Clinically evident aortic regurgitation was present in only 12% of these patients. The authors noted that although initially trivial, regurgitation may progress over time, but it was well tolerated in all patients who were studied. In the experience of Brown and colleagues, a small aortic anulus (≤21 mm in diameter) and a low mitral–septal contact lesion increased the probability of postoperative regurgitation, probably in both cases the result of increased operative difficulty and increased retraction and possible injury of aortic valve cusps.\textsuperscript{16} Loss of support of the right coronary cusp as a result of excising septal muscle beneath it may result in aortic regurgitation,\textsuperscript{52} as may altered velocity, direction, and dynamics of the turbulent jet of blood in the outflow tract.\textsuperscript{52} These observations emphasize the importance of considering alternative approaches to the obstruction, or mitral valve replacement in patients in whom the aortic anulus is small or the area of obstruction is difficult to expose through the aortic root. Avoiding resection of the first few mm of ventricular muscle beneath the right coronary cusp may prevent subsequent cusp prolapse and aortic regurgitation.

Postoperative Pressure Gradients

Adequate myectomy substantially reduces preoperative gradients,\textsuperscript{58,44,3,5,61,52,59,62} although on provocation a mild gradient can be demonstrated in about 25% of patients.\textsuperscript{56,58,52} In those in whom a gradient is present preoperatively only on provocation, these maneuvers do not produce a gradient postoperatively.\textsuperscript{56} In addition, operation almost always abolishes abnormal postectopic response and abnormal arterial pulse contour. In patients with several postoperative evaluations extending over many years, residual gradient either remains the same or diminishes (Fig. 19-13, A).\textsuperscript{56,3,51,18}

\begin{figure} 
\centering 
\includegraphics[width=\textwidth]{fig19-13.png} 
\caption{Effectiveness of isolated septal myectomy as assessed longitudinally by echocardiography. Dot on y axis is preoperative value, and dashed line leads to immediate post-myectomy value at time zero. Dots are grouped “independent” point estimates, and solid line enclosed within 68% confidence limits (equivalent to ±1 standard error) is average response corrected for repeated measures. A, Peak left ventricular outflow tract (LVOT) gradient. B, Systolic anterior motion (SAM) of septal leaflet of mitral valve. (From Smedira and colleagues.\textsuperscript{51})} 
\end{figure}
When gradients and symptoms persist after inadequate myectomy, reoperation is advised. The procedure can be a repeat myectomy through the aortic root, a modified Konno procedure preserving the aortic valve, or—particularly when the ventricular septum is less than 18 mm thick on echocardiographic assessment—mitral valve replacement.\textsuperscript{M31,M41}

Systolic Anterior Motion of the Mitral Valve

Both echocardiography and cineangiography show reduction or abolition of SAM of the mitral valve in most patients, and this is generally sustained (see Figs. 19–6, 19–13, B).\textsuperscript{G8,S18,W6} In addition, grooves created by myectomy and reduced thickness of the myectomy site are demonstrable by these techniques\textsuperscript{S5} and may result in enlargement of the LV outflow tract.\textsuperscript{B9,S23}

Mitrail Regurgitation

Mitrail regurgitation is usually abolished or substantially reduced after adequate myotomy or myectomy (see Fig. 19–6).\textsuperscript{L9,G8,N9} Persistent important mitral regurgitation usually suggests a coexisting myotic lesion such as mitral valve prolapse, spontaneous chordal rupture, or damage from infective endocarditis.\textsuperscript{N16}

Symptomatic Status

Many reports indicate striking symptomatic improvement in patients who have undergone adequate myotomy or myectomy.\textsuperscript{B18,H7,M16,M29,M44,S9} Most patients promptly become completely asymptomatic or complain of mild effort dyspnea only, and syncope is usually abolished.\textsuperscript{M44} Approximately 80% to 90% of patients are in NYHA functional class I or II postoperatively.\textsuperscript{B18,H7,M44,S6,S8,S18} No strong evidence indicates that late recurrence of symptoms is related to recurrence of obstruction. Patients who die late from arrhythmia or cerebral embolization are usually asymptomatic before the event, and in those dying in heart failure, deterioration is frequently rapid. The longer the follow-up, the greater the number of patients dying in heart failure from progression of the disease process (impaired diastolic relaxation).

Atrial fibrillation adversely affects symptoms as well as long-term survival.\textsuperscript{W15} Surgical relief of obstruction in HOCM does not consistently abolish chronic atrial fibrillation or permit successful cardioversion. When this rhythm occurs as a new feature in later stages of the disease, there is further symptomatic deterioration and, if anticoagulants are not given, a high probability of thromboembolism. Although surgical and catheter-based ablation procedures for this atrial fibrillation have been performed,\textsuperscript{M27,S30} the combined Cleveland, Rio de Janeiro, Venice, and San Francisco experience suggests that atrial fibrillation recurrence after these procedures is frequent.\textsuperscript{K3}

Left Ventricular Function and Structure

Preoperative resting ejection fraction, greatly increased in patients with HOCM (76% ± 9%), is reduced postoperatively ($P < .001$) to 67% ± 18%, a figure that lies well within the range of normal.\textsuperscript{B6} Preoperatively, during exercise, ejection fraction falls to within the normal range (71% ± 14%) and postoperatively falls slightly (66% ± 18%). These data do not suggest that important damage to the LV results from a transaortic myectomy. LV cavity size and wall thickness are decreased, as are left atrial pressure and volume.\textsuperscript{M43,N2,W16}

INDICATIONS FOR OPERATION

Septal myectomy should be considered for any patient who remains symptomatic (NYHA class III or IV) after appropriate medical therapy ($\beta$-adrenergic receptor blockade, calcium antagonists, disopyramide), septal ablation (see “Special Indications and Controversies”), pacemaker therapy, and who has an important LV subaortic gradient (≥50 mmHg) at rest or after physiologically based provocation with exercise, caused bySAM with septal contact.\textsuperscript{M37} In the extensive experience of Wigle and colleagues, successful operation (total relief of obstruction at rest or on provocation) provides substantially more hemodynamic and symptomatic benefit than any currently available medical therapy.\textsuperscript{N6} Increased age and severe symptoms are not contraindications to operation.

Atrial fibrillation is also an indication for operation. Elimination of the obstruction and coexisting mitral regurgitation can result in a decrease in left atrial size, particularly in younger patients.\textsuperscript{M39} This size reduction may be an effective form of antiarrhythmic therapy for these individuals.\textsuperscript{W6} A maze procedure can also be used to treat the atrial fibrillation if it remains refractory to drug treatment (see Chapter 16).

These indications may be extended to include less symptomatic patients with severe gradients, particularly if there is substantial coexisting mitral regurgitation or a history of syncope or unexplained cardiac arrest.\textsuperscript{B7} as well as to asymptomatic younger patients with gradients greater than 100 mmHg. Septectomy can be justified because of low operative risk and potential to reduce risk of sudden death.

Because most patients with HOCM achieve satisfactory relief of LV outflow tract obstruction and relief of symptoms with sepal myectomy, and because of the disadvantages of a prosthetic mitral valve, mitral valve replacement is reserved for specific situations. These include a ventricular septum that is thin (<18 mm) or has unusal morphology,\textsuperscript{M29,M31} inability to achieve an adequate myectomy,\textsuperscript{M29} structural abnormalities of the mitral valve that are not amenable to repair and are associated with moderate or severe mitral regurgitation, and recurrence or persistence of ventricular outflow obstruction after previous myectomy.\textsuperscript{K1,K31,K4} Mitrail valve replacement may be appropriate therapy for midventricular obstruction when extended myectomy is ineffective or substantial mitral regurgitation persists after adequate myectomy.\textsuperscript{K7} There is general agreement, even among its advocates, that mitral valve replacement should be reserved for severely symptomatic patients with a substantial (≥50 mmHg) resting LV outflow gradient who fulfill these criteria.\textsuperscript{K10}

Because coronary artery bypass grafting alone does not relieve symptoms in patients with HOCM and coronary artery occlusive disease,\textsuperscript{N15,S27} myectomy and bypass grafting are indicated when the two conditions coexist.

SPECIAL SITUATIONS AND CONTROVERSIES

Alternative Therapies

Percutaneous Transluminal Septal Myocardial Ablation

Ablation of septal myocardium by percutaneous transluminal infusion of alcohol into the appropriate septal branches of the
LAD results in infarction and localized thinning of the basal septal myocardium, enlargement of the LV outflow tract, and reduction of the outflow gradient.\textsuperscript{51,56} No randomized trials comparing alcohol septal ablation with septal myectomy have been performed. Zeng and colleagues conducted a meta-analysis of three studies with adequate data to compare the two methods of treatment and demonstrated similar early mortality, reduced intraventricular septal thickness, increased LV end-diastolic dimension, and short-term improvement in NYHA functional class.\textsuperscript{21} Septal ablation was associated with less reduction in the LV outflow tract gradient and greater need for permanent pacing (21\% vs. 4.4\%) than was surgical myotomy.

A study from Toronto General Hospital comparing 48 patients undergoing myectomy with 54 having septal ablation demonstrated substantial clinical improvement in both groups.\textsuperscript{82} However, after propensity adjustment, patients treated with alcohol ablation had higher postprocedure resting ($P = .002$) and provocable ($P = .004$) outflow tract gradients, more SAM ($P = .01$), and higher NYHA classification ($P = .05$) at most recent follow-up. Substantially more patients achieved the defined optimal outcome after myectomy (survival, NYHA functional class I, no postprocedure pacemaker, and follow-up resting LV outflow gradient of <20 mmHg) than after septal ablation (73\% vs. 22\%, $P = .001$). A high prevalence of SAM (78\%) was also noted among 37 patients from Massachusetts General Hospital who had septal ablation.\textsuperscript{78} Patients with persistent SAM had more anterior malposition of the mitral valve and less reduction in mitral regurgitation than those without SAM.

Sorajja and colleagues from Mayo Clinic observed a procedural complication in 27\% (death 1.5\%, CL 0.5\%-3.5\%; sustained ventricular arrhythmias 3\%, CL 1.5\%-5.4\%; tamponade 3\%, CL 1.5\%-5.4\%; pacemaker implantation 20\%, CL 16\%-24\%) of 134 patients treated with alcohol septal ablation.\textsuperscript{21} This was more than combined complications of 5\% (death, tamponade, ventricular arrhythmia, pacemaker implantation) among an age- and sex-matched cohort of patients who underwent myectomy ($P = .0001$). Four-year survival was similar in the two groups, but survival free of severe symptoms was significantly lower for patients having septal ablation who were 65 years of age or younger (Fig. 19-14).

Myectomy can be successfully performed after failed alcohol ablation, but with a higher risk of heart block than in cases where only surgery is performed. Otherwise, alcohol ablation does not appear to adversely affect surgical outcome.\textsuperscript{21}

\textsuperscript{546} From Maron and colleagues.\textsuperscript{546}
In general, alcohol ablation should be reserved for specific patient subgroups such as the elderly, those with significant comorbidity and relative contraindications to myectomy, and those with a strong preference for avoiding operation (Table 19-1).11,30,31

**Dual-Chamber Pacing**

Dual-chamber (DDD) pacing decreases the subaortic pressure gradient and relieves associated symptoms in some patients with HOCM.11,30,31 The mechanism by which the gradient is decreased is uncertain but may be related to decreased septal motion, which results in increased LV outflow tract area and reduced SAM of the anterior mitral leaflet, late activation of the basal septum, or decreased LV contractility.17,36 Not all patients respond favorably to pacing.11,30,31 Two studies with follow-up extending to 10 and 12 years have demonstrated sustained improvement in symptoms and reduction of the LV outflow tract gradient in most patients.11,36 In the study by Topilski and colleagues,17 positive results were attributed to periodic assessment and optimization of pacemaker function. DDD pacing may be of particular value in the elderly and other patients who are not candidates for myectomy or septal ablation (see Table 19-1).

**Cardioverter-Defibrillator**

Patients with HOCM and unexplained syncope, cardiac arrest, and ventricular tachycardia or fibrillation should be considered for implantation of a cardioverter-defibrillator in combination with myectomy or other surgical procedures.44 Implantation may be indicated in some patients with non-obstructive HCM who have a history of cardiac arrest or unexplained syncope and in whom physiologic testing is positive.44,36

**Cardiac Transplantation**

Cardiac transplantation should be considered for suitable candidates with HOCM who have not responded to maximal medical and surgical therapy. These patients usually have intractable symptoms of heart failure associated with dilated ventricular cavities.315

**Left Ventricular–Aortic Conduit**

A valved conduit from the apex of the LV to the thoracic or abdominal aorta has been inserted in patients with HOCM.11,31,36,38 This procedure should be used only when other methods of surgical treatment are infeasible.

Cardiomyopathy is a cardiac muscle disease process that leads to clinical myocardial dysfunction. The disease process results in morphologic changes in the heart that are typically classified as (1) dilated cardiomyopathy, (2) ischemic cardiomyopathy, (3) hypertrophic cardiomyopathy, (4) restrictive cardiomyopathy, and (5) arrhythmogenic right ventricular (RV) dysplasia. Clinical manifestations, predictors of survival and functional outcome, and therapeutic objectives focus on the clinical and pathophysiologic condition termed heart failure.

Section I Heart Failure

DEFINITION

Heart failure is a clinical syndrome that represents a complication or common final pathway of many heart diseases in which defective cardiac filling (diastolic heart failure) or impaired contraction (systolic heart failure) or emptying results in the heart’s inability to pump a sufficient amount of blood to support tissue metabolism, or to be able to do so only with elevated filling pressures. It is commonly characterized by secondary organ abnormalities in the skeletal muscles (fatigue), lungs (dyspnea on exertion and sometimes at rest), and kidneys (salt and fluid retention).

HISTORICAL NOTE

William Withering drew attention to the use of foxglove, Digitalis purpurea, in his classic treatise An Account of the Foxglove and Some of Its Medical Uses: With Practical Remarks on Dropsey and Other Diseases in 1785. He began using an old family remedy for dropsey—swelling of the limbs—and determined that the active ingredient of the herbal concoction was derived from foxglove leaves. After 10 years’ experience, he published use of digitalis in treating dropsy, anasarca, and hydrops pectoris. Withering advised digitalis primarily as a diuretic, assuming this was its principal action. He also recognized a powerful action on the heart, quieting and slowing its rate. Cushey, writing about digitalis in 1925, noted that much literature was published regarding its actions until 1810, thereafter, clinical use of digitalis remained unchanged for 100 years.

William Heberden, writing in 1802 about diagnosis and treatment of dropsy, stated “A dropsey is very rarely an original distemper, but is generally a symptom of some other, which is too often incurable; and hence arises its extreme danger.” He recommended removing “stagnating water” by purging and diuretic salts. He knew of digitalis and used it in his practice.

Bertin made an important distinction in 1833 between hypertrophy and dilatation of the heart. He noted that dilatation does not constantly accompany thickening (hypertrophy) of the myocardium. He proposed classifying hypertrophy using “simple” to describe a heart whose walls were thickened without dilatation of chambers, “eccentric” to describe increased wall thickness with dilatation of chambers, and “concentric” to describe increased wall thickness and diminished cavity size.

In 1870, J. Milner Fothergill won the Hastings Gold Medal of the British Medical Association for an essay about digitalis. His text on heart disease and treatment provides a glimpse of heart failure treatment in 1872. He stated, “The treatment of [cardiac] dilatation taxes all the powers that can be brought to bear on it, and the success which attends our efforts is very limited indeed.” He recommended “rest, nutritious and easily-digestible diet, … and a residence in a hospital ward for a few weeks.” In addition to rest and abstaining from all exertion, he recommended treatment with digitalis.

When William Osler published The Principles and Practice of Medicine in 1892, treatment of heart failure included “complete bed rest, a carefully regulated diet, and use of aromatic spirits of ammonia, sulphuric ether, and stimulants.” Digitalis was used more selectively. “Morphia” (morphine) was used. Even “strychnia” (strychnine) was given. Cautious use of nitroglycerine was also recommended.

Understanding of heart failure advanced in the 20th century. Paul D. White used the term congestive heart failure to refer to insufficiency of the myocardium in his classic text Heart Disease, published in 1931. Mechanisms and causes of heart failure became more refined. Treatment consisted of:

- Rest
- Digitalis
- Diuretic drug therapy
- Other drugs, including cathartics and hypnotics
- Other measures, including venesection

Diuretics that were useful at that time were theobromine, mercury, certain salts, and parathormone.

By the 1950s, rapid advances were being made in treating diseases of the circulation. Heart failure treatment included not only rest but intermittent exercise to prevent phlebothrombosis and enhance efficacy of diuretic therapy. Dietary sodium restriction was understood. Digitalis was available as powdered leaf and in several purified compounds and was the mainstay of heart failure treatment. Mercurial diuretics were the most effective. These drugs were given parenterally and acted by diminishing reabsorption of chloride by the renal tubules. Their action was enhanced by intravenous administration of aminophylline. Chlorothiazide became available for oral use and was thought to be an effective diuretic. Oxygen therapy was found to be useful. Other measures were still in use, such as sedation with morphine, venesection, thoracentesis, puncture of legs, and radiiodine to induce hypothyroidism.

Loop diuretics were introduced in the late 1960s. For the first time, efficacious diuretic agents were available. Ethacrynic acid, the first of the loop diuretics, is a phenoxyacetic acid derivative; furosemide is a sulfonamide derivative. These drugs selectively inhibit sodium chloride reabsorption in the thick ascending limb of the loop of Henle. Other sulfonamide derivatives were subsequently introduced. These diuretics have become the basis for treating heart failure.

MORPHOLOGY AND MORPHOGENESIS

Cardiac Remodeling

Cardiac remodeling is the central feature of the failing heart. One of the principal mechanisms by which the heart
The basic cellular feature of cardiac remodeling is myocyte hypertrophy, which includes both an increase in myocyte size and presence of additional sarcomeres, whose qualitative aspects differ according to the inciting pathologic conditions. Early stages of myocardial hypertrophy are characterized by increases in number and size of mitochondria in cardiac myocytes and in number of myofibrils. The myocardial cell, therefore, is larger and longer.

Transition from compensatory hypertrophy to heart failure is related to alterations in cell organization and changes in coronary blood flow to the increased cell mass of the hypertrophied ventricle. Myocardial capillary density and coronary reserve are reduced, resulting in myocardial ischemia that is most pronounced in the subendocardium. Ischemic myocyte injury associated with replacement fibrosis impairs systolic and diastolic function and accelerates heart failure. At a more advanced stage of hypertrophy, subtle changes of cellular organization and contour occur. Long-standing hypertrophy disrupts both cellular organization and Z-band architecture. Late stages of hypertrophy are characterized by loss of contractile elements with breakdown of Z bands, loss of normal parallel arrangement of sarcomeres, deposition of fibrous tissue, and tortuosity of T tubules.

When the remodeling process leads to segmental or global ventricular dilatation, the increased curvature results in increased wall tension, as predicted by the Laplace relationship. Increased wall tension induces increased myocardial oxygen consumption, impairs subendocardial blood flow, and decreases arrhythmia thresholds. Increasing degree of remodeling has been correlated with worsening prognosis.

Fetal Gene Activation

Growth factors present in the embryonic heart but dormant in the normal adult heart are reactivated by myocyte hypertrophy. In the embryonic heart, growth factors provide the stimulus for normal cell division and heart growth. Withdrawal of growth factors inhibits the cell cycle and favors repair in the normal adult heart. The fetal gene repertoire responds to myocyte hypertrophy with induction of β myosin heavy chain (MHC), atrial natriuretic factor, and repression of α-MHC, among others. Loss of α-MHC content contributes directly to reduced contractility in heart failure. Excitation-contraction coupling is compromised by alterations in the phosphorylation status of troponin-I; and defects in calcium ATPase and calcium release channels impair contractility and promote β-adrenergic desensitization.

The environment of continuous growth signals promoted by the fetal gene profile produces cell dysfunction and eventually cell death, likely related to apoptotic mechanisms. Alterations in the extracellular matrix of the myocardium include replacement fibrosis.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Pathophysiology

Heart failure begins after an event produces an initial decline in pumping capacity of the heart. Once the injurious event is initiated, three major forces can contribute to chronic heart failure: intrinsic myocardial damage, abnormal load on one or both ventricles, and extrinsic forces.

The major causes of intrinsic myocardial damage include myocardial infarction secondary to ischemic heart disease, inherited conditions that affect the contractile apparatus, infiltrative myocardial diseases, autoimmune injury, infection, metabolic abnormalities (e.g., hyperthyroidism), and toxic agents (e.g., alcohol, certain chemotherapeutic agents). Abnormal loading conditions may result from chronic pressure overload (e.g., chronic hypertension, aortic stenosis) or volume overload (e.g., mitral regurgitation, aortic regurgitation, intracardiac shunts, extracardiac fistulae between arterial and venous circulations). Extrinsic forces include constrictive pericarditis, severe anemia, and substrate-inducing chronic tachycardia.

These conditions initially evoke a variety of compensatory mechanisms that, in the short term, restore cardiovascular function to a normal homeostatic range in which the patient is asymptomatic. Such compensation is termed adaptive. Over time, however, sustained activation of these compensatory systems becomes maladaptive and can lead to secondary damage of ventricular myocardium, worsening ventricular remodeling, and eventually cardiac decompensation and death. Changes in configuration of the ventricular chamber that are also detrimental to cardiac function include dilatation, change in shape (increased sphericity), thinning of the wall, and inflow valve regurgitation.

Cardiorenal-Hemodynamic Mechanisms

A common early manifestation of heart failure is excessive salt and water retention resulting from abnormalities of renal blood flow attendant reduction of cardiac output and vasoconstriction. Sympathetic nervous system up-regulation increases cardiac afterload and heart rate and decreases renal perfusion. Reduced renal perfusion alerts receptors in renal arterioles, activating the renin-angiotensin-aldosterone system. Renal and tissue renin stimulates production of angiotensin I. Angiotensin converting enzyme (ACE) catalyzes conversion of angiotensin I to angiotensin II. Angiotensin II and aldosterone blood levels are increased, causing vasoconstriction and retention of salt and water. Angiotensin II induces vasoconstriction of efferent arterioles, increasing glomerular filtration pressure despite reduced renal blood flow. This increase in sympathetic activity is initially compensatory for reduction in renal blood flow, but over time becomes maladaptive, accelerating cardiac remodeling.

Neurohormonal Mechanisms

As cardiac output and tissue perfusion are reduced, complex neurohormonal responses are evoked for maintaining arterial perfusion (Fig. 20-1). This compensatory (adaptive) mechanism is initially beneficial in maintaining tissue perfusion as cardiac output declines, but the process actually increases hemodynamic burden and oxygen requirements of the heart, eventually becoming detrimental (maladaptive). Circulating levels of norepinephrine may be markedly increased, and there is increased activity of adrenergic neurons that cause vasoconstriction and increase afterload of the failing ventricle. Over time, density of adrenergic receptors and concentration of norepinephrine in the myocardium are reduced. These changes are accompanied by reduced activity of adenylate cyclase, which lowers intracellular concentrations
Figure 20-1 The facets of heart failure; physiologic responses. Key: ACE, Angiotensin-converting enzyme; RAS, renin-angiotensin system; TNF, tumor necrosis factor.

Heart failure may progress as a result of overexpression of compensatory biologically active molecules that exert toxic effects on the myocardium. A variety of molecules have been implicated as sufficiently toxic to contribute to heart failure, including norepinephrine, angiotensin II, endothelin, aldosterone, and tumor necrosis factor. These molecules are of neuroendocrine origin, but may also be produced by a variety of cell types within the heart, including the myocyte itself.

Symptoms and Signs
Heart failure can be an acute decompensation or a chronic progressive disease. It is usually associated with decline in...
cardiac output. The consequence of elevated left ventricular (LV) preload and pulmonary capillary pressure is dyspnea. Cardiac remodeling is generally accepted as a determinant of the clinical course of heart failure. An approach to classification has been proposed that reflects the progressive nature of the clinical syndrome.

Evolution of the disease is identified by four stages of heart failure (Box 20-1). This classification complements the New York Heart Association (NYHA) functional classification, which gauges severity of symptoms primarily in stages B and C. The classification suggests that patients with heart failure are expected to advance from one stage to the next unless progression of the disease is slowed or stopped by treatment.

### NATURAL HISTORY

Heart failure is estimated to affect more than 5 million people in the United States alone and accounts for 1 to 3 million hospitalizations per year, or about 5% to 10% of all hospital admissions. The number of individuals with heart failure is increasing, with 400,000 to 700,000 new cases diagnosed each year, and the frequency is expected to increase two to three times during the next decade. About 3% of the adult population is treated for heart failure. Occurrence of heart failure increases with age; 6% to 10% of people older than age 65 are affected, and it is the most common cardiac diagnosis in this patient population.

Heart failure results in nearly 300,000 deaths per year in the United States, 60% sudden. Sudden death may be completely unexpected (one third of patients), a consequence of rapid deterioration (one third of patients), or a result of progression of chronic heart failure (one third of patients). About one third of patients die within 1 year of initial heart failure diagnosis, with nearly 80% dead within 6 years.

Cost of treating patients with heart failure is enormous, estimated at more than $40 billion per year, or more than 5% of the healthcare budget. Of that total, about $20 billion goes directly for medical costs, $500 million of which is spent on drugs for treating heart failure.

### TREATMENT OF HEART FAILURE

When a specific treatable medical disorder is responsible for heart failure, specific treatment of the underlying condition is a critical component of initial therapy (see Section VII).

#### Pharmacologic Therapy

Standard guidelines for evaluating and treating heart failure have been published. A fundamental goal is to slow or reverse ventricular remodeling. Intense medical therapy, which has evolved over the last 20 years, demonstrably improves survival. ACE inhibitors, new-generation β-blockers, and aldosterone improve survival, attributed in part to their reverse remodeling effects.

Current treatment of heart failure, based on various pathophysiological theories, recognizes that no single model explains all aspects of the heart failure syndrome and therefore attempts to use all clinical models to develop effective therapeutic strategies. Most patients with symptomatic LV dysfunction should be routinely managed with a combination of four categories of drugs: a diuretic, an ACE inhibitor, a β-adrenergic blocker, and digitalis. Diuretics and spironolactone are used to treat congestion and fluid retention related to cardiorenal mechanisms. Short-term intravenous inotropic support, intravenous vasodilators, or both, are used to treat cardiocirculatory mechanisms. Long-term inotropic support is achieved using digoxin. Intermediate and long-term strategies are directed at neurohormonal mechanisms using carvedilol, a β1-, β2-blocker with antioxidant properties, and ACE inhibitors. When ACE inhibitors are not tolerated, angiotensin receptor blockers may be effective.

#### Pacing Therapy for Conduction Abnormalities

Worsening of LV systolic function is frequently accompanied by impaired electromechanical coupling, which further diminishes systolic function. About 20% to 30% of patients with symptomatic heart failure have a prolonged P-R interval or an intraventricular conduction disorder characterized by wide QRS (left bundle branch block) and a discoordinate contraction pattern. Prolonged P-R interval may result in early contraction of the atria and mitral regurgitation during the diastolic phase, reducing ventricular filling. Proper timing of the P wave relative to mitral valve closure by cardiac pacing may provide more appropriate ventricular filling time.

Prolonged QRS and delay of conduction may result in contraction of the base of the heart well in advance of the LV lateral wall and apex. This may cause paradoxical septal motion and mitral valve regurgitation. Biventricular pacing (also termed cardiac resynchronization therapy) allows simultaneous electrical stimulation of the RV and LV using an implantable pacing system. A discoordinate contraction pattern of the ventricles may be resynchronized by pacing the lateral wall of the LV synchronous with pacing the apex of the RV. Optimal aortic pulse pressure occurs when the peak of left atrial pressure coincides with start of the LV contraction as a result of optimal preload mechanisms. In addition
to optimizing left atrial–to-LV mechanical timing, favorable response to both LV and biventricular stimulation may result from improved synchrony of RV and LV contraction.A10

**Implantable Cardioverter-Defibrillator Therapy**

In patients with advanced heart failure, the potential for fatal ventricular arrhythmias has prompted consideration of implantable cardioverter-defibrillator (ICD) therapy over chronic anti-arrhythmia drugs.

**RESULTS**

**Pharmacologic Therapy**

The effect of various therapeutic interventions has been evaluated in a number of clinical trials in patients with LV systolic dysfunction. Both ACE inhibitors and β-blockers, acting individually or synergistically, reduce morbidity and mortality in heart failure patients treated with diuretics and digoxin. Agents such as ACE inhibitors that inhibit neurohormonal activation relieve symptoms, reduce hospitalizations, and prolong survival.35 An increasing dose of ACE inhibitor or adding spironolactone to an ACE inhibitor may further improve prognosis. The optimal dose of β-blockers is unknown. Digoxin continues to be a mainstay of heart failure treatment and has been shown to decrease heart failure–related hospitalizations, but there is no evidence that it decreases mortality. It is not known whether digoxin is effective when added to a β-blocker.

**Pacing Therapy for Conduction Abnormalities**

Shortening of the P-R interval correlates with improved functional class and increased oxygen consumption.A3 Resynchronization therapy with biventricular pacing has been shown to improve symptoms in patients with moderate to advanced heart failure.1,3 Several randomized multicenter trials have examined its effects on functional status, quality of life, and hemodynamics in patients with dilated cardiomyopathy. These studies have demonstrated clinical improvement correlated with narrowing of the paced QRS complex, decrease in interventricular conduction delay, and a trend toward increase in duration of ventricular filling.6,8,2 Clinical benefits appear to be maintained over 12 months in patients with both sinus rhythm and atrial fibrillation.1,1,4 Biventricular pacing incorporating antitachycardia options or an ICD appear to be the future direction of pacing therapy.3,13

**Implantable Cardioverter-Defibrillator Therapy**

Large prospective, randomized multicenter trials have identified patient populations for whom ICD therapy provides survival benefit even in the absence of prior cardiac arrest or sustained ventricular tachycardia.82

**INDICATIONS**

**Pacing Therapy for Conduction Abnormalities**

The 2008 American College of Cardiology (ACC)/American Heart Association (AHA) Practice Guidelines recommend the following indications for cardiac resynchronization therapy (CRT) in patients with severe systolic heart failure.82

**Class I**

1. For patients who have LV ejection fraction (LVEF) of 35% or less, a QRS duration of 0.12 seconds or more, and sinus rhythm, CRT with or without an ICD is indicated for treatment of NYHA functional class III or ambulatory class IV heart failure symptoms with optimal recommended medical therapy. (Level of Evidence: A)

2. For patients who have LVEF of 35% or less, with NYHA functional class III or ambulatory class IV symptoms, who are receiving optimal recommended medical therapy and have frequent dependence on ventricular pacing, CRT is reasonable. (Level of Evidence: C)

3. For patients with LVEF of 35% or less, with NYHA functional class I or II symptoms, who are receiving optimal recommended medical therapy and are undergoing implantation of a permanent pacemaker or ICD with anticipated frequent ventricular pacing, CRT may be considered. (Level of Evidence: C)

4. CRT is not indicated for asymptomatic patients with reduced LVEF in the absence of other indications for pacing. (Level of Evidence: B)

**Class III**

1. CRT is not indicated for patients whose functional status and life expectancy are limited predominantly by chronic noncardiac conditions. (Level of Evidence: C)

**Implantable Cardioverter-Defibrillator Therapy**

The 2008 ACC/AHA Practice Guidelines indicate the following indications for ICD therapy in patients with severe systolic heart failure.82

**Class I**

1. LVEF less than 35% due to prior myocardial infarction (MI) who are at least 40 days post-MI and are in NYHA functional class II or III (Level of Evidence: A)

2. Nonischemic dilated cardiomyopathy who have an LVEF of 35% or less and are in NYHA functional class II or III (Level of Evidence: B)

3. LV dysfunction due to prior MI who are at least 40 days post-MI, have an LVEF less than 30%, and are in NYHA functional class I (Level of Evidence: A)

4. Nonsustained ventricular tachycardia (VT) due to prior MI, LVEF less than 40%, and inducible ventricular fibrillation (VF) or sustained VT at electrophysiological study (Level of Evidence: B)
**Class IIa**

ICD implantation is reasonable for patients:

1. With unexplained syncope, significant LV dysfunction, and nonischemic dilated cardiomyopathy (Level of Evidence: C)
2. Who are nonhospitalized and awaiting transplantation (Level of Evidence: C)
3. With cardiac sarcoidosis, giant cell myocarditis, or Chagas disease (Level of Evidence: C)

**Class IIb**

ICD therapy may be considered in patients with:

1. Nonischemic heart disease who have an LVEF of 35% or less and are in NYHA functional class I (Level of Evidence: C)
2. A familial cardiomyopathy associated with sudden death (Level of Evidence: C)
3. LV noncompaction (Level of Evidence: C)

**Class III**

ICD therapy is not indicated for patients:

1. Who do not have a reasonable expectation of survival with an acceptable functional status for at least 1 year, even if they meet ICD implantation criteria specified in the Class I, IIa, and IIb recommendations above (Level of Evidence: C)
2. With drug-refractory heart failure who are not candidates for cardiac transplantation or CRT (Level of Evidence: C)

---

**Mitral Valve Repair**

In an earlier era of cardiac surgery (1980s and early 1990s), mitral valve surgery was generally considered ill advised for patients with severe mitral regurgitation in the setting of markedly depressed LV function. It was hypothesized that the sudden increase in ventricular afterload by transforming a regurgitant mitral valve into a competent one would induce acute failure of an already dysfunctional LV. Over the last 15 years, results of mitral valve repair or replacement in this setting have progressively improved.

**Partial Left Ventriclectomy**

In 1996, Batista introduced the concept of surgically reversing the remodeling process in dilated cardiomyopathy with a procedure termed *partial left ventriculectomy.* The basis for the operation was the Laplace law, which relates wall tension to chamber radius. It was reasoned that reduction of LV size would improve cardiac function. Theoretically, reduction in LV volume reduces wall tension and improves contractility, with restoration of a more normal volume/mass relationship. Initially, only LV posterior wall was removed. Later, resection was sometimes extended to include the papillary muscles and mitral valve.

Although it is true that reducing chamber radius will reduce wall stress for a given pressure, it is not obvious from this explanation alone that volume reduction will increase the heart’s pumping capacity. The potential limitation of this procedure is that it removes functioning, though weakened, myocardium. Systolic wall stress is reduced, and LVEF may improve with reduction of ventricular chamber radius, but it may be associated with a deleterious effect on diastolic compliance that neutralizes any beneficial effect and may actually reduce net ventricular pumping capacity.

**Alternative Therapies**

**Dynamic Cardiomyoplasty**

Dynamic cardiomyoplasty is use of an electrically stimulated skeletal muscle that is wrapped around part of the heart to augment or restore contractility of the ventricles. It was introduced experimentally by Kantrowitz and McKinnon in 1959 and developed for use in humans by Carpenter and Chachques in 1958. Although it is true that reducing chamber radius will reduce wall stress for a given pressure, it is not obvious from this explanation alone that volume reduction will increase the heart’s pumping capacity. The potential limitation of this procedure is that it removes functioning, though weakened, myocardium. Systolic wall stress is reduced, and LVEF may improve with reduction of ventricular chamber radius, but it may be associated with a deleterious effect on diastolic compliance that neutralizes any beneficial effect and may actually reduce net ventricular pumping capacity.

**Ventricular Shape Change and Constraint Devices**

Chaudhry and colleagues used a prosthetic jacket of knitted polyester mesh to provide passive LV constraint in a canine heart-failure model produced by intracoronary microembolization. The prosthetic jacket prevented progressive LV remodeling and abolished functional mitral valve regurgitation. This led to the Acorn Cardiac Support Device (Fig. 20-2) for use in humans (Acorn Cardiovascular, St. Paul, Minn.).

**Direct Cardiac or Aortic Compression Devices**

Devices to assist the failing heart by direct compression of the heart (to shift end-systolic pressure–volume relationship) or aorta have been designed to avoid blood–foreign surface interaction of the assist device.
Less than 25% of patients have familial disease.\textsuperscript{M1} Several families have been described in which some members have dilated cardiomyopathy, and in some of these the inheritance is X-linked.\textsuperscript{B8} In these, onset seems to be early (second and third decades) in men and late (sixth decade) in women. Most asymptomatic relatives of patients with dilated cardiomyopathy and LV enlargement have histopathologic and immunopathologic findings similar to those of patients with established disease.\textsuperscript{M1,M6}

Dilated cardiomyopathy is characterized pathophysiologically by impaired ventricular systolic function.\textsuperscript{B14,B15,B16,G3} However, particularly late in the disease, decreased LV compliance may develop. Both end-diastolic and end-systolic ventricular volumes are increased.

All forms of cardiomyopathy may have a nonspecific prodromal phase lasting weeks or months that suggests an infectious process.\textsuperscript{K11} Then symptoms of left, right, or biventricular failure develop and progress to chronic heart failure.\textsuperscript{S6}

**Chest Radiography**

Chest radiography may be normal or show cardiomegaly, which can be extreme.

**Two-Dimensional Echocardiography**

Two-dimensional echocardiography has become standard for evaluating ventricular function.\textsuperscript{B6,J3,L3} It is excellent for diagnosing systolic dysfunction characterized by segmental or global reduction of systolic wall motion. As many as one third of patients with heart failure, however, have normal systolic function. This implicates diastolic dysfunction as a major pathophysiologic abnormality in these patients. Doppler color flow interrogation is a practical, noninvasive method for diagnosing and following patients with diastolic dysfunction.\textsuperscript{N2} Methods used to evaluate it are based on analysis and interpretation of flow velocity across the mitral valve.

**Cardiac Catheterization**

Cardiac catheterization usually reveals nonspecific findings. Right, left, or biventricular ejection fractions are reduced, and the diastolic pressure contour often has the square root sign characteristic of pericardial constriction. Endomyocardial biopsy may be useful in excluding other conditions in patients believed to have dilated cardiomyopathy. However, positive diagnosis of dilated cardiomyopathy from biopsy is rarely possible.\textsuperscript{O2}

**NATURAL HISTORY**

Approximately 5 to 8 of every 1,000,000 people are diagnosed with dilated cardiomyopathy each year. It can develop at any age but is more common among patients aged 20 to 60 years. Some 10% of patients are diagnosed after age 65. It occurs three times more frequently in males and blacks than in females and whites. About 80% of patients are dead within 10 years of onset.\textsuperscript{F11} Despite heterogeneity of its etiology, there is considerable correspondence among different estimates of survival with this condition.

The course is variable, with some patients dying within 1 to 2 years of the evident onset of disease; a few have an even
more fulminating course. Cardiac autoantibodies may play a functional role, and their removal may induce hemodynamic improvement. A few patients recover spontaneously, most commonly when cardiomyopathy is related to acute myocarditis. Spontaneous recovery is increasingly recognized following prolonged periods of support with LV assist devices (LVAD; see Chapter 22). Mode of death is usually chronic cardiac failure. Occasionally, death is due to intractable ventricular arrhythmias and sometimes is sudden (see Section I). Important risk factors for death include marked cardiomegaly, ventricular arrhythmias, pulmonary hypertension, and elevated right atrial pressure. Thromboembolism is particularly common when the LV is greatly dilated and in patients with atrial fibrillation.

TECHNIQUE OF OPERATION

Cardiac Transplantation

Cardiac transplantation is widely used as a treatment for end-stage dilated cardiomyopathy. Technique of operation is described in Chapter 21.

Mitral Valve Repair

Mitral regurgitation in cardiomyopathy has two major mechanistic components: anular dilatation as part of overall LV enlargement, and abnormal separation of the papillary muscles (Fig. 20-3). Details of mitral anuloplasty and management of the subvalvar apparatus are discussed in Chapters 10 and 11.

Partial Left Ventriculectomy

Partial left ventriculectomy consists of full-thickness LV free-wall resection between the papillary muscles, extending from the mitral anulus to LV apex. In the presence of mitral regurgitation, the mitral valve is repaired or replaced, usually through the ventriculectomy incision.

Alternative Therapies

Dynamic Cardiomyoplasty

The latissimus dorsi muscle is transferred as a muscle flap through a window in the chest wall made by partial removal of a rib. It is used as a wrap around the heart for reinforcement or as a substitute for a defect in the ventricular wall. Electrodes are implanted on the muscle flap and connected to an electrical stimulator, which paces contractions synchronously with myocardial contraction.

A variation of dynamic cardiomyoplasty is an auxiliary blood pump formed from a pedicled graft of latissimus dorsi muscle (skeletal muscle ventricle) connected to the circulation in a cardiac assist configuration. It has shown some promise in experimental heart failure. Adaptive conditioning by electrical stimulation enables the skeletal muscle to perform a portion of cardiac work without fatigue. Such skeletal muscle pumps have been able to maintain blood pressure greater than 80 mmHg for up to 4 years in dogs, without compromising viability of the working muscle. Although this work is experimental, clinical application for cardiac assist may eventually become feasible.

Ventricular Shape Change and Constraint Devices

The LV is a conical structure, whereas the RV is a crescent-shaped chamber wrapped to the right side of the LV. In the presence of systolic heart failure, progressive ventricular enlargement distorts the normal shape as well as the Frank-Starling pressure-volume relationship. The dilated ventricle also increases wall stress based on the Laplace law relating radius, pressure, and wall tension. All these pathologic phenomena could theoretically be abated by surgical techniques or devices that prevent further ventricular enlargement.

Animal studies showing that native pericardium provides constraint to deformation of the ventricles provided the physiologic concept behind cardiomyoplasty and passive ventricular constraint. Although dynamic cardiomyoplasty was originally touted as a procedure to augment systolic ventricular contraction, subsequent clinical studies demonstrated that the constraining effect of the muscle wrap was the primary
beneficial effect.\textsuperscript{K1} In the late 1990s, application of the cardiac constraining principle stimulated development of multiple devices designed to change LV shape or restrain ventricular dilatation in heart failure.

**Direct Cardiac or Aortic Compression Devices**

Direct cardiac or aortic compression devices have the advantages of simplicity of application during unstable circulatory conditions and ease of removal after recovery from heart failure or at transplantation. The CardioSupport system (Cardio Technologies Inc., Pine Brook, N.J.) is a cufflike structure that surrounds both ventricles from apex to atrioventricular groove. It is applied under negative pressure (−200 mmHg) to provide a vacuum seal. Compression bladders are inflated and deflated in synchrony with cardiac contraction, timed from epicardial electrocardiogram (ECG) electrodes.

The Heart Booster (Abiomed, Danvers, Mass.) is a cufflike device consisting of several parallel compression tubes covering both ventricles and held in place with surgical adhesive. A hydraulic drive system fills and empties the compression tubes. Both of these compression systems are in the development phase.

The Kantrowitz CardioVad (LVAD Technology Inc., Detroit, Mich.) is an experimental system operating on the principle of diastolic augmentation, like an intra-aortic balloon catheter and pump. The blood pump is an inflatable bladder sutured into the wall of the descending thoracic aorta via left thoracotomy, with the patient on cardiopulmonary bypass (CPB). There is direct blood contact with the textured surface of the inflatable bladder, which is expected to become covered with pseudointima. The pump is worn externally and provides a stroke volume of up to 60 mL via a transcutaneous tube.\textsuperscript{12}

The C-Pulse (Sunshine Heart Inc., Sydney, Australia) is a counterpulsation device that is wrapped externally around the ascending aorta, avoiding direct blood contact. The inflatable cuff and a sensing wire are attached to an external pneumatic driver that inflates and deflates the cuff in sequence with the ECG signal to provide timed counterpulsation. Implantation is performed via median sternotomy and does not require CPB. The system can be turned on and off by the patient as required. This device is intended for use in ambulatory patients with advanced NYHA class III or early class IV symptoms.

**RESULTS**

**Cardiac Transplantation**

Results of transplantation are detailed in Chapter 21.

**Mitral Valve Repair**

Bolling and colleagues reported a hospital mortality of less than 2% and 1-year survival of 82% following mitral valve anuloplasty using an undersized flexible ring in the presence of severe LV systolic dysfunction, with preoperative LVEF ranging from 8% to 25%.\textsuperscript{811} Patients experienced improved NYHA class, LVEF, and exercise oxygen consumption, and reduced end-systolic and end-diastolic volumes. Perhaps the most persuasive evidence supporting the safety of mitral valve repair or replacement in the setting of severely depressed LV function came as an offshoot of the multi-institutional ACORN trial for the Acorn cardiac constraining device.\textsuperscript{B5} One arm of the study included patients with poor ventricular function, dilated cardiomyopathy, and severe mitral regurgitation. Hospital mortality among patients undergoing mitral valve repair or replacement with or without a constraining device was 1.6%, and 12- and 24-month cumulative survival was 86% and 85%, respectively. Mitral valve surgery was associated with reduced LV end-diastolic and end-systolic volumes, decreased LV mass, increased LVEF, and decreased sphericity. Postoperative functional mitral regurgitation remained stable over midterm follow-up, with more than 80% of patients having 0 or 1+ mitral regurgitation at 6 to 18 months.

These and other reports indicate that in the present era, with optimal myocardial protection and appropriate preoperative management of heart failure, patients can undergo mitral valve repair in the presence of severe LV dysfunction (LVEFs as low as 10%) with low anticipated hospital mortality. Nevertheless, long-term benefit remains controversial. A retrospective analysis by Wu and colleagues failed to demonstrate a survival benefit conferred by mitral valve anuloplasty.\textsuperscript{S6}

**Partial Left Ventriculectomy**

Batista and colleagues reported clinical improvement following partial left ventriculectomy in patients with dilated cardiomyopathy and advanced heart failure.\textsuperscript{B6} Batista was joined by other colleagues to report a combined series of patients having partial left ventriculectomy to treat advanced heart failure.\textsuperscript{B5} Although the procedure initially generated considerable enthusiasm as an alternative to cardiac transplantation, surgical mortality was considerably higher than after transplantation, and subsequent composite freedom from death, need for ventricular assist support, and cardiac transplantation was low at 2 years.\textsuperscript{F7,S12,S14} Franco-Cereceda and colleagues at Cleveland Clinic noted that perioperative mortality was low (3.2%; CL 1.0%-7.5% of 62 patients), but a ventricular assist device was required in 18% (CL 13%-24%) of cases; survival at 3 years was 64%.\textsuperscript{F7} LVEF showed only small initial improvement that declined with time, and failure (relisting for transplant, NYHA class IV symptoms, or death) was common (74%) during the first 3 years after operation.\textsuperscript{F7,S8,S12} The challenge in part appeared to be patient selection.

Frazier and colleagues reported a combined institutional series of 42 patients with dilated cardiomyopathy treated by partial left ventriculectomy.\textsuperscript{F9} Cardiac output and LVEF improved minimally. Changes in myocyte hypertrophy and fibrosis were postulated to be related to clinical results. Lundehemer and colleagues\textsuperscript{L6} showed the healed scar was 4 cm wide and reached 2 to 12 mm beyond the surgical suture line. In addition, myocardial fibers were misaligned. Konertz and colleagues\textsuperscript{K1} reported 49 patients with 5 early deaths (10%: CL 6%-17%).\textsuperscript{K8} Functional improvement was better in patients with ischemic etiology (88% NYHA functional class I or II) than idiopathic dilated cardiomyopathy (56% NYHA class I or II). These authors proposed use of stress echocardiography to identify patients with segmental wall motion abnormalities who would be better treated by an infarct exclusion operation, reserving partial left ventriculectomy for patients with a global wall motion abnormality. They also proposed evaluating ventricular function in response to dobutamine infusion as a means of predicting improved function after partial ventriculectomy.
Thus, initial enthusiasm for partial left ventriculectomy was dampened by mixed results after operation, with a high prevalence of early failure. Despite the lack of current interest in this procedure, good functional results can be obtained in some patients.

**Alternative Therapies**

**Dynamic Cardiomyoplasty**

Long-term studies of patients having cardiomyoplasty have shown improvement in quality of life and functional class following dynamic cardiomyoplasty. However, clinical improvement has not correlated with changes in LVEF or cardiac output. Kass and colleagues suggested that benefits derived from cardiomyoplasty may be primarily due to passive constraint of the heart rather than to an active squeezing assist effect. There have been late deaths from ventricular arrhythmias, mainly ventricular fibrillation, so antiarrhythmic drugs or implantable cardioverter-defibrillators are needed. Consequently, dynamic cardiomyoplasty has not found a place in routine treatment of cardiac failure.

**Ventricular Shape Change and Constraint Devices**

In a multi-institutional randomized trial in the United States, the Acorn Cardiac Support Device implanted via median sternotomy was compared with continued optimal medical therapy for patients with dilated cardiomyopathy and NYHA class III heart failure. Compared with the medical group, the cardiac support device group had greater reduction in LV end-systolic and end-diastolic volumes and greater improvement in LV sphericity and quality-of-life measures. Nevertheless, both groups had similar LVEFs, occurrence of repeat hospitalizations, and mortality.

Other constraining devices that have entered clinical trials, but without current U.S. Food and Drug Administration (FDA) approval, include the Myosplint device (Myocor, Maple Grove, Minn.), which alters the LV short axis into two bilobed spheres, producing a reduction in wall stress; and the Paracor device, a nitinol mesh coated with polyurethane that is slipped over the heart via a small thoracotomy.

**Direct Cardiac or Aortic Compression Devices**

The CardioSupport system, which provides epicardial compression, has been used in experimental animals for up to 7 days without adverse events. Initial feasibility studies of the C-Pulse device in patients demonstrated predictable augmentation of coronary flow and reduction of LV afterload, decrease in heart failure symptoms, and improved cardiac performance. A multicenter trial to assess safety and performance is in progress.

**INDICATIONS FOR OPERATION**

**Cardiac Transplantation**

Indications for cardiac transplantation are presented in Chapter 21.

**Mitral Valve Repair**

Isolated mitral valve repair is not advisable in the setting of deteriorating cardiac performance requiring inotropic support or overt cardiogenic shock. A high operative mortality would be expected under these circumstances. These patients, if unresponsive to other measures, are better served by a strategy utilizing mechanical circulatory support (see Chapter 22) or cardiac transplantation (see Chapter 21).

In the absence of acute cardiac decompensation or chronic inotrope dependence, surgical mitral valve repair can be considered in patients who remain symptomatic despite optimal medical therapy when mitral regurgitation is severe. However, because long-term studies have not yet demonstrated a survival and functional benefit from mitral valve surgery in this setting, consensus has not been reached regarding specific patient subsets who should undergo mitral valve surgery. More routine application of mitral valve repair in dilated cardiomyopathy with severe mitral regurgitation will depend on demonstration of survival benefit, a more favorable functional outcome, evidence of sustained competence or near competence of the mitral valve, evidence of hemodynamic benefit, and reverse remodeling following repair.

**Partial Left Ventriculectomy**

As originally described, partial left ventriculectomy was indicated for patients in NYHA class IV heart failure from dilated cardiomyopathy. Currently, in countries where cardiac transplantation is available, this procedure has been largely abandoned. However, in countries or regions without access to these more complex and expensive therapies, this procedure may be advisable for patients with marked LV dilatation (end-diastolic dimension of 7 cm or more) and class IV heart failure despite optimal medical therapy.

**Alternative Therapies**

**Dynamic Cardiomyoplasty**

Dynamic cardiomyoplasty is not indicated for routine treatment of heart failure.

**Ventricular Shape Change and Constraint Devices**

To date, no ventricular constraining device has received FDA approval in the United States, and supplemental trials are in progress.

**Direct Cardiac or Aortic Compression Devices**

These devices are intended for short-term use (<7 days) for any cause of cardiogenic shock.
Section V  Restrictive Cardiomyopathy

DEFINITION

Restrictive cardiomyopathy is a cardiac muscle disease that results in impaired ventricular diastolic function with loss of compliance and is usually accompanied by diffuse ventricular hypertrophy. The most common example of restrictive cardiomyopathy is endomyocardial fibrosis (or obliterator cardiomyopathy), a form of restrictive cardiomyopathy in which the pathologic process—chronic inflammation—is restricted to the endocardium.

HISTORICAL NOTE

This condition has been known to exist for many years, but its in vivo differentiation from chronic constrictive pericarditis became possible only when modern cardiac diagnostic methods became available. Endomyocardial fibrosis began to receive serious study during the late 1940s. D’Arbela, Brockington, and Davies and their colleagues identified the similarity between the tropical zone form of the disease (Davies endocardial fibrosis) and that of the temperate zone (Löffler endocarditis) during the 1960s and 1970s. Metras and colleagues have first reported by Prigent and Dubost and their colleagues in 1973. D8,P8

MORPHOLOGY

The ventricular walls are excessively rigid, resulting in restrictive filling and reduced left, right, or biventricular diastolic volume with normal or near-normal systolic function. Microscopically, fibrosis and myocyte hypertrophy are usually present. Often there is no morphologic suggestion as to etiology. However, restrictive cardiomyopathy may be secondary to amyloid infiltration and other processes, with or without eosinophilia.

Endomyocardial fibroelastosis consists of fibrous endocardial lesions involving primarily the inflow portions of right and left ventricles, along with the posterior wall and apex. The atrioventricular valves are often involved and regurgitant. The outflow tract of the ventricle is usually spared. The heart may be more or less normal in size or somewhat enlarged, but massive cardiomegaly is rare, as is ventricular hypertrophy. Although both ventricles are commonly involved, 40% of patients have purely LV involvement, and 10% purely RV involvement. Metras and colleagues have described a more localized form of the disease that affects only the LV papillary muscles and presents as isolated mitral regurgitation.

Microscopically, a thick layer of hyalinized fibrous tissue is usually seen in the endocardium. Calcification may be present, and thrombi may cover the inner portion of the involved ventricle. The myocardium is minimally affected. These changes may be associated with eosinophilia (Löffler syndrome). In addition to evidence of chronic inflammation, an anomalous lymphatic pattern has been observed, connected to the distal coronary circulation.

Endomyocardial fibrosis is of unknown etiology. There has been speculation as to the possible role of a diet high in bananas, malnutrition, and immunologic responses from various infections. About 50% of patients undergoing resection reveal molecular evidence of a number of infective-agent genomes of unknown importance to pathogenesis. In a subset of patients, antimyosin antibodies against specific myocardial proteins have been identified, and immunosuppressive therapy in such patients has been suggested. These antibodies against C-terminal sequences may mediate the disease in a similar fashion as Chagas disease.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

The primary physiologic abnormality in restrictive cardiomyopathy is severe impairment of ventricular compliance. Generally, ventricular systolic function is unimpaired. Pathophysiologically, this condition simulates chronic constrictive pericarditis to such an extent that the two conditions are separated hemodynamically with great difficulty.

Endomyocardial fibrosis is pathophysiologically complex. Early in this process, there are only scattered areas of fibrosis, with little hemodynamic effect. As progressively increasing endomyocardial fibrosis develops, with consequent restriction of ventricular filling, ventricular end-diastolic pressures elevate, as do pulmonary or systemic venous pressures, depending on which ventricle is involved. Involvement of the atrioventricular valves then adds valvar regurgitation to the already impaired hemodynamic state.

When endomyocardial fibrosis involves both ventricles, RV failure usually dominates the clinical picture, with liver enlargement, ascites, and peripheral edema in association with tricuspid regurgitation. There are often pleural and pericardial effusions. RV endomyocardial fibrosis is characterized by distinctive findings of right atrial enlargement, as well as hepatomegaly, ascites, and peripheral edema. With isolated LV involvement, there are features of LV failure and often mitral regurgitation. There is usually a third heart sound.

Chest radiography shows cardiomegaly, usually attributable to right atrial enlargement and pericardial effusion. Calcification may be seen diffusely within the ventricles. Echocardiography reveals enlarged atria, ventricular cavity obliteration, and at times, mitral and tricuspid regurgitation. Mitral and tricuspid valve Doppler inflow velocities reveal a restrictive pattern with short deceleration time. Magnetic resonance imaging is particularly valuable in detecting delayed endocardial enhancement. Cardiac catheterization confirms the diagnosis, with physiologic findings of cardiac restriction (see Section I of Chapter 23) dominating the findings. Angiography often reveals obliteration of the apex of the involved ventricle, which in the RV may mimic Ebstein anomaly. The LV may show an apical diverticulum.

NATURAL HISTORY

Generally, symptoms are of long duration, with death delayed for 5 to 20 years after abnormalities of cardiac function become apparent. However, the natural history of patients with restrictive cardiomyopathy has not been well defined.
Endomyocardial fibrosis tends to affect children and young adults. It occurs primarily in Uganda, Nigeria, and India. However, cases have been sporadically reported in many countries, including the United States. The natural history of patients with this type of cardiomyopathy is generally unfavorable, characterized by a slowly deteriorating course and death within 5 to 10 years, often within 1 to 2 years.

**TECHNIQUE OF OPERATION**

Resection of endocardial fibrosis is performed using CPB and cold cardioplegic myocardial protection (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2 and “Methods of Myocardial Management during Cardiac Surgery” in Chapter 3). In left-sided disease, the mitral valve and interior of the LV are exposed through the usual incision for valve repair or replacement in the right side of the left atrium (see “Technique of Operation” in Section I of Chapter 11). When exposure is unsatisfactory, an approach through the right atrium and across the atrial septum is used; only if no other approach is possible is a left ventriculotomy used. The thickened and fibrotic endocardium in the inlet and apical portions of the LV are excised. Endocardectomy is as extensive as needed, but no attempt is made to remove the fibrotic plaque in one block. Localizing the pathology to the inlet and apical portions in the ventricles facilitates the surgical procedure. Often the tensor apparatus of the mitral valve must be sacrificed as part of the excision, and the valve is often regurgitant preoperatively. Therefore, in most patients, mitral valve replacement is part of the procedure (see “Mitral Valve Replacement” under Technique of Operation in Section I of Chapter 11).

Approach is through the right atrium in cases of isolated RV involvement. The procedure described is carried out, often associated with tricuspid valve replacement. However, whenever possible, a 5-mm strip of endocardium is left on the ventricular septum along the anulus of the tricuspid valve, particularly in the region of the anteroseptal commissure, to avoid damage to the bundle of His.

**RESULTS**

In general, risk of death after operation has been 10% to 20%, and greater in patients with biventricular disease. Metras and colleagues have reported 4 hospital deaths (20%; CL 10%-33%) among 20 patients operated on in Côte d’Ivoire (Ivory Coast).

Functional results of operation are good. In most patients, the hemodynamic state of the LV returns to normal after surgical treatment of the left-sided form of the disease. However, in RV endomyocardial fibrosis, despite clinical improvement, the hemodynamic status of the ventricle usually remains abnormal. RV endocardectomy may be complicated by complete heart block, but Metras and colleagues have avoided this in most cases by being conservative with the endocardial resection beneath the tricuspid valve.

**INDICATIONS FOR OPERATION**

Operation is indicated for patients whose disability has progressed to NYHA class III or IV.

The method for blood vessel anastomoses, Carrel reported transplantation of kidneys into experimental animals. Little was done in the years after these reports, and the next work on the subject was in two reports from Dederer working in Mann’s laboratory at Mayo Clinic in 1918 and 1920. His experiments were not successful, but Williamson later commented that Dederer’s short-term success in two members of the same litter of puppies “seems very suggestive that there are biological phenomena which may be instrumental in the failures that have so frequently been attributed to mechanical difficulties.” In 1926, Williamson reported further studies on renal transplantation. He noted that autologous kidney transplants functioned satisfactorily for months, but that renal allografts functioned for only days. Although Williamson described the histologic condition of failed renal allografts as representing a form of glomerular nephritis, he also concluded that “the failure of homogeneous kidney transplants seems attributable to a biological incompatibility between the donor and recipient.” In 1926, Williamson reported further studies on renal transplantation. He noted that autologous kidney transplants functioned satisfactorily for months, but that renal allografts functioned for only days. Although Williamson described the histologic condition of failed renal allografts as representing a form of glomerular nephritis, he also concluded that “the failure of homogeneous kidney transplants seems attributable to a biological incompatibility between the donor and recipient.” Work continued in Mann’s laboratory, but even by 1934, Wu and
Mann had not increased the understanding of failure of the transplanted kidney.\textsuperscript{91b}

Twenty-two years then elapsed before report of successful transplantation of the human kidney between identical twins.\textsuperscript{107,110} In the interim, the work of Medawar during World War II revolutionized the understanding of transplantation. Although antigens and antibodies were to some extent understood, at least to the point that they were involved in various types of infectious disease, Medawar was the first to develop concepts of immunology applicable to transplantation. His work was a result of the British government’s research program early in World War II directed toward devising new methods of skin coverage for children extensively burned by the bombings of the Battle of Britain in 1939. His first paper in 1944 described his classic experiments with skin transplants in rabbits.\textsuperscript{112} He found that reaction of the rabbit to transplantation of skin from another rabbit was very different from the benign reaction to transplantation of its own skin from one site to another, just as Williamson and others had found in the case of the kidney. Medawar determined that the skin transplant from another rabbit developed a cellular infiltrate that destroyed the transplant in 7 to 10 days. Medawar termed this process rejection, and it is the analog of cellulary mediated acute rejection of cardiac transplantation as it occurs today. In the same paper, he also described second-set rejection, which occurred when later a second transplant of skin was made to the same rabbit from the same donor rabbit. This second skin graft was destroyed in 5 to 6 days, more rapidly than in first-set rejection. Medawar deduced that preformed antibodies were responsible for second-set rejection, which may be somewhat analogous to humorally mediated hyperacute rejection occurring rarely after cardiac transplantation.

In this and a second classic paper, Medawar developed a number of fundamental concepts.\textsuperscript{118} He confirmed his deduction that rejection under some circumstances was mediated by cells (lymphocytes) and in others by humoral antibodies. He recognized that the observed phenomena were the result of enormous genetic diversity among individuals. He hypothesized that second-set rejection implied immunologic recollection of past events. Methods for preventing rejection soon began to be discussed and studied, and Medawar suggested in the early 1950s that the recently discovered corticosteroids may help prevent rejection. However, techniques of immunosuppression developed slowly, and in the interim, at Peter Bent Brigham Hospital in Boston in 1955, Merrill and colleagues performed the first successful human kidney transplant. Based on immunologic concepts developed by Medawar, they chose identical twins for this procedure.\textsuperscript{107,110} This successful case had been preceded at Brigham Hospital by extensive investigations and some clinical renal transplantation between genetically diverse individuals, with poor success. This work was summarized by Hume and colleagues in 1955.\textsuperscript{118}

In 1960, Merrill and colleagues reported successful transplantation with mild immunosuppression between nonidentical twins.\textsuperscript{110} It was not until 1962 that Murray and colleagues were able to report successful “kidney transplantation in modified recipients,” and in this experience are reported the beginnings of modern immunosuppressive therapy.\textsuperscript{118,119} Caine and Murray showed experimentally in 1961 that azathioprine prolonged the survival of kidney transplant recipients.\textsuperscript{118,119}

Subsequently, intensive study has considerably improved immunosuppression techniques, including development of cyclosporine and other agents.

When Shumway completed his training during the late 1950s at the University of Minnesota in the early era of cardiac surgery, he went to Stanford University and began developing an experimental program in cardiac transplantation. Lower and Shumway first reported successful experimental orthotopic cardiac transplantation in 1960, just at the time when renal transplantation was becoming established.\textsuperscript{110} This work was confirmed by Kondo and colleagues, who also achieved prolonged survival.\textsuperscript{110}

In 1964, Hardy and colleagues performed the first heart transplant into a human, using a chimpanzee heart.\textsuperscript{113,115} Hardy’s team had pursued laboratory investigations in cardiac transplantation for the previous 8 years.\textsuperscript{114,116,118,119,127} They had planned to use a human donor, but the selected recipient (a 68-year-old man in shock from end-stage ischemic cardiomyopathy with respiratory failure, obtundation, and a freshly amputated gangrenous leg) was too close to death to await a donor. Thus, Hardy and his team elected to use a chimpanzee donor (as a xenotransplant, a graft from an individual of a different species than the recipient), based on studies of chimpanzee renal transplants in humans.\textsuperscript{115} The xenotransplanted heart contracted well on cardiopulmonary bypass (CPB), but was apparently too small to support the circulation unassisted. The patient died approximately 1.5 hours after discontinuation of CPB.

The first human-to-human heart transplant (allograft) was performed in Cape Town, South Africa, by Christiaan Barnard on December 3, 1967.\textsuperscript{114} The recipient was Louis Washkansky, a 53-year-old ex-boxer with end-stage ischemic cardiomyopathy. Three days after the Cape Town operation, Adrian Kantrowitz performed the second human heart transplant in Brooklyn.\textsuperscript{115} The recipient was an 18-day-old neonate with Ebstein anomaly, refractory heart failure, and previous aortopulmonary shunt for severe cyanosis. The patient received the heart of an anencephalic infant, but died 5 hours later of cardiac failure and refractory acidosis. On January 2, 1968, Barnard performed the third human heart transplant on Philip Blaiberg, a 46-year-old dental surgeon with refractory heart failure, severe coronary artery disease, and a large left ventricular aneurysm. He became the first long-term survivor, living for 18 months. Norman Shumway performed the fourth heart transplant 4 days later, and this patient died 2 weeks later. After this, other heart transplants followed rapidly in a number of institutions. By the end of 1968, cardiac transplantation had been performed in 102 patients in 50 different institutions in 17 countries. The results were generally poor, with 60% mortality by the eighth postoperative day and a mean survival of only 29 days.\textsuperscript{127}

Although cardiac transplantation was then started in yet more centers around the world, few patients were more than short-term survivors. This resulted in reduced clinical use, so by the early 1970s, cardiac transplantation had largely disappeared from clinical practice. An exception to this was the program at Stanford, where clinical and experimental transplantation continued at a steady pace and generated a continuous stream of new information. The report of Caves and colleagues describing a method of transvenous endomyocardial biopsy was an important clinical advance because it allowed monitoring cardiac allograft rejection on a serial basis.\textsuperscript{127} As a result, in about 1980, cardiac transplantation...
began to reappear as a viable therapeutic modality. Another major reason for its greater success was the knowledge of immunosuppression that came from research and from experience with renal transplantation.

Cyclosporine A, introduced for immunosuppression in 1981, accelerated the evolution of cardiac transplantation from the experimental phase to a clinically useful treatment modality for patients with advanced heart failure. Cyclosporine is a fungal metabolite first isolated from Tolypocladium inflatum Gams in 1972. Its marked immunosuppressive properties were discovered by Borel in 1972. 

Distant heart procurement programs also increased activity and improved success in cardiac transplantation. Watson and colleagues in 1977 showed the feasibility of such programs, and he and Thomas reported good clinical results using distant donors.

Since 1980, published data on more than 80,000 cardiac transplantations from over 300 cardiac transplant programs have been reported in the voluntary registry of the International Society for Heart and Lung Transplantation (ISHLT). A declining number of cardiac transplantations have been reported internationally, from a high of nearly 5000 in 1995 to less than 4000 by 2006. Cardiac transplantation in the United States has remained stable at about 2200 per year. At the same time, the number of patients on waiting lists has grown to more than 4100.

**IMMUNOLOGIC BASIS OF HEART TRANSPLANTATION**

Detection of Nonself

Biological variation between individuals occurs at the macro level, cellular level, and molecular level. Analysis of the structure of proteins and the genes that code for them indicates that some molecules can be unique to each individual. Genetically determined differences in the amino acid sequence of proteins result in alteration of their three-dimensional structure and charge; it is variation in the protein peptide components that allows the immune system to distinguish cells originating from nonself. Although individual variability may not alter a protein’s function, molecules that vary in this fashion from one individual to another are said to be polymorphic. Protein polymorphism is not the only manner by which self can be distinguished from nonself, but it is the predominant feature that drives rejection in clinical cardiac transplantation.

The effector mechanisms by which cells of the immune system eliminate nonself are operative during allograft rejection and are part of the immune response that defends humans from invasion by infectious agents or toxins. Two components of the immune system, the innate immune system and the adaptive immune system, participate in responding to nonself molecules themselves.

**Specificity of Antigen Receptors**

A unique feature of the immune system is that each T lymphocyte carries only one type of antigen receptor on its surface, and each antigen receptor is specific for a single antigen (peptide). A lymphocyte contains an average of about 200,000 antigen receptors on its surface, all identical and specific for a single antigen. Given the huge number of foreign antigens an individual may encounter, survival depends on an adequate variety (repertoire) of lymphocyte antigen receptors to combat invasion by foreign (nonself) peptides.

The actual process by which an antigen receptor identifies a bound peptide as “nonself” is mysterious. Specific receptors apparently do not discriminate between self and nonself in terms of antigen recognition, but rather, self/nonself discrimination is a function of lymphocyte populations that contain a large number of antigen receptors. During the period of immunologic development, the process of selection takes place among T cells while they develop in the thymus, in which potential harmful lymphocytes that could react with self-antigen are usually eliminated. Certain disease states develop when this process is incomplete. A small population of lymphocytes are cross-reactive, their antigen receptors binding to more than one antigen.

**Major Histocompatibility Complex Molecules**

The proteins primarily involved in the immune response to organ transplantation are called major histocompatibility complex (MHC) antigens. T lymphocytes recognize only antigenic peptides contained within the MHC-binding groove on the surfaces of antigen-presenting cells. In each species, MHC antigens have unique names. Human MHC antigens are termed human leukocyte antigens (HLA). The MHC
consists of a group of genes on the short arm of chromosome 6 that code for a number of proteins expressed on the cell surface (Fig. 21-1). These genes are polymorphic in that individuals vary in the exact nucleotide sequence of the genes and therefore the specific amino acid sequence of the protein products. Therefore, for any individual MHC gene, there are likely to be multiple variations (also called alleles) of that gene distributed within a population of individuals.

In the context of transplantation, it is important to differentiate between donor and recipient MHC molecules. Donor MHC molecules are a source of antigen in that they are ingested by the recipient antigen-presenting cells and processed into peptides that are subsequently loaded into recipient MHC molecules for presentation to recipient T cells. The more extensive the difference in amino acid sequence between donor and recipient MHC molecules, the more likely it is that the donor MHC molecule will be broken into peptides that are recognized as nonself. In the special case of direct antigen presentation (see “T Lymphocytes” in later text), intact donor class II MHC molecules on donor antigen-presenting cells or donor endothelial cells within the transplanted heart may play an important role in T-cell activation.

The functions of MHC molecules are closely related to their three-dimensional structure and high degree of polymorphism. Within their three-dimensional structure, there is a distinct groove formed by two α helices that lie on top of a β-pleated sheet. This groove represents the domain in which peptides are processed when they are presented to a T cell. A T cell will respond only to an antigenic peptide contained in the MHC peptide-binding groove of an antigen-presenting cell. The polymorphism of the MHC molecule lies in and around the protein-binding groove, creating differences among individuals by different side grooves that may project into and out of the MHC groove for processed peptides.

The MHC complex proteins are broadly subdivided into groups called class I, class II, and class III. Class I and class II proteins are most commonly considered in the context of transplantation and have similar overall three-dimensional shapes.

The human MHC class I molecules routinely typed for solid organ transplantation are called A, B, and C. Class I molecules are expressed on the surface of virtually all nucleated cells, although with varying levels of expression. The highest surface density is found on lymphocytes, with lower expression on fibroblasts, muscle cells, and endothelial cells. However, certain cytokines such as interferon (IFN)-γ can increase the level of MHC expression on these other cells. This inducibility of MHC molecules likely plays an important role in initiating and perpetuating a rejection episode. As inflammatory mediators are released during a rejection episode, it is likely the level of MHC expression on donor vascular endothelial cells and muscle cells increases further, augmenting the antigenic stimulation.

MHC class I molecules consist of two polypeptide chains: a larger highly polymorphic α chain coded by a gene in the MHC complex on chromosome 6, and a smaller nonpolymorphic β chain called β2-microglobulin that is coded by a gene on chromosome 15 (Fig. 21-2). The α1 and α2 domains form a peptide-binding region in which they interact three dimensionally to form a platform of eight strands forming a β-pleated sheet flanked by two long α-helical regions forming the floor and walls of the peptide-binding groove. Within this region, peptide fragments of eight or nine amino acids present in the peptide-binding groove. The α3 domain is highly constant among class I MHC molecules, and the interaction between the α3 domain and that of β2-microglobulin helps maintain the correct confirmation of the MHC molecule for cell-surface stability. The α3 domain interacts with the CD8 molecule on the surface of T cells, which generally restricts the recognition of antigens displayed in the groove of class I HLA molecules to CD8+ T cells.

The primary class II molecules related to solid organ transplantation are called HLA-DR, HLA-DP, and HLA-DQ. These molecules are composed of an α chain and a β chain, each of which contains two domains designated α1 and α2 and β1 and β2, expressed as transmembrane proteins (Fig. 21-3). The α1 and α2 domains form the structure of the
antigenic peptide-binding groove. The $\beta_2$ domain interacts with CD4 molecules, which generally restricts the presentation of antigen in the groove of class II MHC molecules to CD4$^+$ T cells.

**Antigen Processing**

Two basic pathways exist for the processing of antigen that subsequently is displayed on the cell surface in the peptide-binding groove of a MHC molecule. The exogenous pathway involves proteins originating from outside the cell that present with MHC class II molecules (Fig. 21-4). This pathway is the principal vehicle for processing and presenting alloantigens following organ transplantation. It is initiated when the antigen binds to the surface of the antigen-presenting cell, which then internalizes the protein via receptor-mediated endocytosis or phagocytosis. Once the peptide (which may be either MHC class I or II) is loaded into the binding groove of the class II molecule, it is transported to the cell surface for presentation to T cells. Any protein from the donor organ can serve as an antigen.

The *endogenous pathway* involves proteins that originate inside the cell, in which proteins complex with MHC class I molecules and are presented to T cells (Fig. 21-5). This pathway appears to have a minor role in transplant rejection, and theoretically any cell (not just antigen-presenting cells) can use it in the presentation of internal peptides on MHC class I molecules. This pathway is typically used in the body’s defense against intracellular pathogens, such as viruses whose proteins can be degraded and presented on the cell surface, resulting in the cell’s destruction by cytotoxic CD8$^+$ T cells.

**T Lymphocytes**

T lymphocytes represent the most important component of the immune response to transplanted organs (Box 21-1). They are defined by presence of a CD3 molecule (part of the T-cell antigen receptor) on their surface and generally...
with either CD4 or CD8 surface molecules. The two basic subtypes of T lymphocytes are T helper (T\textsubscript{H}) cells and cytotoxic T cells. The T\textsubscript{H} lymphocyte expresses CD4 molecules on its surface and functions primarily to detect nonself antigens by means of its T-cell receptors. When activated, it can also recruit other cells (CD8\textsuperscript{+} T cells, other CD4\textsuperscript{+} T cells, B cells, phagocytes, neutrophils, and other inflammatory cells) into the immune response (Table 21-1).

Cytotoxic T lymphocytes differ from T\textsubscript{H} cells in that they express CD8 molecules on their surface. The cytotoxic T lymphocyte functions primarily as an effector cell that kills target cells (cells that express nonself antigens in the groove of a class I MHC molecule), and under special circumstances may suppress other cells (prevent their activation). The T-cell receptor allows the T lymphocyte to detect the presence of a nonself antigen by providing the capability of binding to antigen and MHC molecules in a specific manner. This receptor allows detection of nonself MHC antigens in the transplanted heart. Each T-lymphocyte clone has a T-cell receptor that is unique with respect to the receptors of other T-cell clones and has a unique T-cell genetic sequence. The pool of unique T cells constitutes the T-cell repertoire, which includes more than $10^{12}$ unique T-cell receptors in a given individual.

The portion of the T-cell receptor that interacts with the antigenic peptide–MHC complex is a heterodimer of two covalently linked polypeptide chains designated \( \alpha \) and \( \beta \) (Fig. 21-6). The \( \alpha \) and \( \beta \) chains each have a variable region (V-region) that contains a highly variable amino acid sequence.

---

**Box 21-1 T-Cell Facts**

- The thymus is required for T-cell development.
- When mature, all T cells express CD3 surface molecules.
- Peripheral T cells express CD4 or CD8 molecules, but not both.
- CD4 and CD8 surface markers identify T-cell populations with different immunologic capabilities.
- T cells regulate antiviral and antifungal cellular immune responses.
- T cells regulate activation and differentiation of B cells and switching of antibody secretion from IgM to other classes.

*From Kirklin and colleagues.*

Key: MHC, Major histocompatibility complex.
The α and β chains are associated with membrane-bound proteins called the CD3 complex. It is required for expression of T-cell receptor on the cell surface and is responsible for transduction of a membrane signal when the T-cell receptor complex interacts with antigen. Ability of a lymphocyte to respond to the presence of a specific antigen is termed recognition.

T cells recognize antigen only in the presence of self-MHC. T\(_{\text{H}}\) cells, which initiate the cellular response to transplant antigens, respond to antigen that is associated with an MHC complex on the cell surface through a process called antigen presentation. This process is limited to certain cell types called antigen-presenting cells. A presenting antigen must first be internalized within the antigen-presenting cell, broken down into 7 to 13 amino acid polypeptides, which are physically associated with MHC molecules, and exported to the cell surface as a complex. T\(_{\text{H}}\) cells respond only to those cells that express class II molecules on their surface. Cytotoxic T cells (CD8\(^{+}\)) respond to cells that have class I MHC molecules on their surface.

**Antigen-Presenting Cells**

Because cytotoxic T cells recognize antigens only on the surface of other cells that have class I MHC surface molecules, a functionally distinct class of cells has been identified that presents antigen to T lymphocytes. These antigen-presenting cells process antigens by breaking them down into individual peptides, inserting the peptides into the MHC molecule, and transporting them to the cell surface (Box 21-2). Cells that function as antigen-presenting cells are dendritic cells, macrophages, and B cells. Dendritic cells are the most efficient antigen-presenting cells because they have a large surface area, increasing the probability of contact with T lymphocytes. Dendritic cells are present throughout most lymphoid and nonlymphoid tissues and possess a high density of surface MHC class II molecules. Antigen-presenting cells also provide a second signal that is necessary for T-cell activation, which is the binding of another molecule on the surface of the T cell in addition to the binding of the T-cell receptor by an antigen-MHC complex.

**Box 21-2 Antigen-Presenting Cells**

- Derived from bone marrow
- Process peptides and present antigen to T cells
- Transport foreign antigens to lymph nodes for interaction with T cells
- Express adhesion molecules that facilitate T-cell receptor binding to the peptide/major histocompatibility complex
- Provide co-stimulatory “second signals” to activate the T cell

From Kirklin and colleagues.

**B Lymphocytes**

B lymphocytes arise from bone marrow and do not express CD4 or CD8 molecules on their surface. They use surface immunoglobulins rather than T-cell receptors for detecting antigen, and the end product of B-cell activation is differentiation into antibody-secreting plasma cells and memory B cells (B cells capable of generating an immune response when there is subsequent exposure to the same antigen). Immunoglobulins (antibodies) are produced by B cells that have differentiated into plasma cells. They consist of four polypeptide chains in two pairs, each consisting of a heavy chain and a shorter light chain (Fig. 21-7). The end of the molecule is called a variable region because the genes that code for the heavy and light chains are composed of segments that join together imprecisely. The other end of the heavy chain, called the constant region, contains sites for biologically important activity such as complement activation. The heavy chain constant regions form the basis for classifying immunoglobulins into isotypes IgG, IgA, IgM, IgD, and IgE.

**Natural Killer Cells**

Natural killer (NK) cells are structurally similar to T and B lymphocytes, but are not antigen specific and do not express either a T-cell receptor or immunoglobulin. These cells are called natural killer cells based on their ability to spontaneously lyse tumor cells in vitro. In vivo, they can lyse target...
cells without the requirement for prior immunization. They can lyse cell targets that lack surface expression of MHC molecules. NK cells represent about 15% of peripheral lymphoid cells.

Cytokines

Soluble molecules called cytokines play an important role in the immune response by stimulating secretion of proteins that alter the behavior or property of cells and facilitate recruitment of immunologic cells from distant locations. Unlike hormones, cytokines generally act locally and are not usually found in circulation in large quantities because of their short half-life. Although numerous cytokines have been identified that have diverse biological actions (Table 21-2), cytokines in transplantation are particularly important in mediating inflammatory processes and regulating T-cell responses. Cytokine production is one of the hallmarks of T-cell activation. Prominent cytokines in the immunologic response to transplantation include interleukin (IL)-2, IL-6, tumor necrosis factor (TNF), and IFN-γ.

Adhesion Molecules

Adhesion molecules are proteins formed within cells and secreted into the environment of these cells. They function to maintain structural integrity and position of body cells and promote adhesion of leukocytes to surrounding structures. Adhesion molecules include integrins (adhesion molecules that maintain cells in position by attaching one end of the integrin to the cytoskeleton of the cell and the other end to molecules of the extracellular matrix), selectins (adhesion molecules that mediate rolling of leukocytes along the vascular endothelium), and Ig superfamily adhesion molecules. Adhesion molecules mediate the initial interaction of T cells with antigens, their migration, and their retention within a transplanted organ.

Activation of Immune System Following Cardiac Transplantation

The inciting event is placing the donor heart into the recipient and perfusing it with native blood elements following aortic clamp removal. Within minutes, large quantities of donor cells, protein (some of which is soluble MHC molecules), and cellular fragments are carried to the spleen and lymph nodes, which are highly efficient in filtering antigen and trapping antigen within resident antigen-presenting cells. These cells enter the paracortex of the lymph node, which is populated by T cells, macrophages, and dendritic cells. If the T cells have a receptor capable of binding to MHC molecules containing a particular peptide, they will be activated, after which they interact with B cells, inducing the initial stages of B-cell activation. In addition, donor antigen-presenting cells migrate from the heart and encounter T cells as they circulate through the lymphoid tissues. Donor antigen-presenting cells also line the endothelial surfaces of the donor heart vasculature. Donor alloantigens containing foreign MHC complex molecules can be presented to the recipient T cells in two ways: directly and indirectly (Table 21-3). Direct recognition of donor antigens by T lymphocytes involves direct engagement between the recipient T-cell receptor and the donor antigen-presenting cell (also called passenger lymphocytes). Even though these antigen-presenting cells are nonspecific, the structural similarities are sufficient to allow binding with either helper or cytotoxic T lymphocytes, because both MHC class I and II molecules will be expressed. In this method of donor antigen presentation, the specific antigen presented in the groove of the complex is often unimportant because the donor antigen-presenting cell will be identified as nonspecific.

When shed MHC molecules from the donor organ are processed and presented by recipient antigen-presenting cells to recipient T cells, the process is termed indirect allorecognition. The exogenous pathway of processing and presenting alloantigens is generally operative in the indirect allorecognition process.

The presentation of donor antigen to T lymphocytes results in T-cell activation. T-cell activation occurs in concert with changes in the expression of various cell surface molecules, secretion of soluble factors, and a change in cell morphology. Once activated, the T* cell clone proliferates and releases cytokines that expand the immune response.

B-Cell Activation

B-cell activation begins with capture of antigen by immunoglobulin molecules on the B-cell surface. The antigen is then internalized, degraded, processed into peptides, and loaded into the groove of MHC class II molecules delivered to the cell surface.

When the B-cell encounters a CD4+ T cell that has the appropriate T-cell antigen receptor for binding to the antigen-MHC complex on the B-cell surface, the T cells engage in a process termed mutual activation. B-cell differentiation into immunoglobulin-producing plasma cells
requires antigen-specific signals through B-cell receptors
(immunoglobulin) expressed on the cell surface and antigen-
specific T-cell help in forming a co-stimulator signal and
cytokine stimulation.

**Cellular Rejection**

Cytotoxic T lymphocytes (CD8+) that are specific for graft antigens play an important role in the effector phase leading to acute rejection. Like T_{H1} cells, cytotoxic T cells are not activated with a single signal, but rather require the binding of multiple surface molecules that transmit additional signals through the cell membrane. This process requires engagement by allogenic histocompatibility molecules or by an antigenic peptide MHC complex, with an additional signal via a co-stimulator molecule such as CD28. This series of signals serves to activate cytotoxic T-lymphocyte precursors that then proliferate and differentiate into cytotoxic T

requires antigen-specific signals through B-cell receptors (immunoglobulin) expressed on the cell surface and antigen-specific T-cell help in forming a co-stimulator signal and cytokine stimulation.
lymphocytes in response to IL-2. Once a cytotoxic T lymphocyte receives the appropriate signals, it can administer a lethal hit to a target cell that results in cell death either through exocytosis (release of destructive granules into the target cell) or induction of apoptosis.

**Humoral Rejection**

*Humoral rejection* refers to production of antibodies or activation of complement in response to exposure to an alloantigen. B lymphocytes mediate the response, and antibodies can react with antigens in solution or on the cell surface. Antibodies associated with humoral rejection are generally IgM and IgG. Effector mechanisms associated with humoral responses include neutralization (blocking of relative sites or binding of receptors on a target cell), opsonization (antibodies acting as a “tag” that can be recognized by phagocytic cells), and complement activation. The most extreme form of humoral rejection is *hyperacute rejection*, mediated by preexisting antibodies that, upon entry into the donor heart vasculature following aortic clamp removal, rapidly bind to the vascular endothelium. These antibodies fix complement, which causes direct lyses of endothelial cells, and elaboration of complement components induces a massive infiltration of granulocytes. The subsequent massive cell necrosis and tissue swelling can lead to organ destruction within minutes.

### CLINICAL FEATURES

**Recipient Evaluation and Selection**

The general approach to patients referred for possible cardiac transplantation is listed in Box 21-3. If patients were selected primarily on the basis of highest expected posttransplant survival and quality of life at 1, 5, and 10 years, transplantation would be recommended for less ill patients whose survival is acceptable with medical or nontransplant surgical therapy. Alternatively, if transplantation were reserved only for patients closest to death from end-stage heart disease, the associated noncardiac organ dysfunction would drastically reduce patient and graft survival, compromising effective use of organs. Thus, some balance must be achieved between survival benefit to the recipient and maximal use of donor organs (in terms of organ survival).

Because of ongoing controversies, experts in the field have periodically convened to promote standardization of selection criteria. There is general consensus that the prognosis for survival and quality of life of patients with New York Heart Association (NYHA) class IV heart failure symptoms who do not improve with medical or surgical therapy are sufficiently poor that transplant should be considered. The major dilemma in decision making involves patients who are converted from class IV to class III/II by appropriate medical therapy. The decision-making process for this large group of patients is critically important because (1) the available supply of organs is inadequate to provide even a small fraction with transplantation, (2) allocation of a donor heart to a patient with a relatively better prognosis would deprive a more seriously ill patient with a short life expectancy (but preserved noncardiac organ function) the opportunity for transplantation at a time when his or her benefit would still be maximal, and (3) cardiac transplantation is not curative, is associated with its own chronic morbidity and survival limitation, and should therefore not be offered to patients with intermediate- or long-term survival approaching that of transplantation.

Identifying factors that predict mortality in ambulatory patients with advanced heart failure has been hampered by the complexity and variability of the heart failure syndrome, evolving nature of medical treatment for heart failure, retrospective nature of most studies, infrequent application of appropriate multivariable analysis, and almost uniform lack of patient-specific predictive models. Nevertheless, numerous risk factors have been identified (but poorly quantified) that are associated with adverse outcome in ambulatory patients with advanced heart failure (Box 21-4). Despite many clinical studies of heart failure, few variables consistently predict duration of survival (or freedom from rapid deterioration) in advanced heart failure patients undergoing transplant.

### Box 21-3  Approach to Potential Candidate for Heart Transplantation

- Address potentially reversible causes and components of heart failure
- Evaluate severity of heart failure and functional capacity
- Tailor medical therapy to improve symptoms and reduce mortality
- Assess risks of deterioration or sudden death
- Identify indications for transplantation
- Exclude contraindications to transplantation
- If heart transplantation is recommended, continue heart failure management with periodic reevaluation

Modified from Kirklin and colleagues.

### Box 21-4  Factors Associated with Increased Mortality in Heart Failure Patients

**Clinical**

- Heart disease etiology
- Heart disease duration
- History of syncope

**Hemodynamic**

- Lower left ventricular ejection fraction
- Lower right ventricular ejection fraction
- Higher pulmonary capillary wedge pressure
- Higher right atrial pressure
- Lower cardiac index
- Inotropic support required

**Functional Capacity**

- Higher New York Heart Association functional class
- Lower oxygen consumption at peak exercise \( V_{\text{O}_2 \text{ max}} \)
- Shorter distance covered during 6-minute walk

**Neurohumoral/Metabolic**

- Elevated plasma norepinephrine
- Elevated plasma renin activity
- Elevated atrial natriuretic peptide
- Leukocytosis
- Lower serum sodium

**Ventricular Arrhythmias**

- Noncardiac organ system function
- Renal dysfunction
- Elevated hepatic enzymes

Modified from Kirklin and colleagues.
Normal cardiac function is restored. A few programs have operated, and they have the potential for good quality of life if patients may be selected if their noncardiac organ systems are transplantable to patients younger than age 65. Older patients. Recipients older than age 60 years have a survival similar to younger patients.

In properly selected patients, heart transplantation are listed in part of their disease complex. The general contraindications to transplantation are listed in Box 21-6.

Evaluation of Comorbid Conditions

Noncardiac comorbidity may adversely affect longevity or quality of life after transplantation, independent of, or as a complex interaction with, graft function (Box 21-5). Of particular interest is the effect of chronic immunosuppression on natural history of these comorbid conditions. For many such conditions, there is a paucity of secure information upon which to base rational decisions about so-called relative contraindications, owing to the small numbers of patients available for analysis and reluctance to allocate a limited resource to those whose comorbid conditions constitute a major part of their disease complex. The general contraindications to heart transplantation are listed in Box 21-6.

**Age**

In the absence of other life-limiting noncardiac conditions, the appropriate upper age limit becomes an ethical rather than medical decision. In properly selected patients, recipients older than age 60 years have a survival similar to younger patients. Nonetheless, some programs limit heart transplantation to patients younger than age 65. Older patients may be selected if their noncardiac organ systems are normal, their cognitive function is totally intact, they have a strong will to live, their family support system is well developed, and they have the potential for good quality of life if normal cardiac function is restored. A few programs have addressed this issue by allocating only older donor hearts (>50 years) to elderly recipients.

**Pulmonary Vascular Resistance**

The critical feature of elevated pulmonary vascular resistance (Rp) is pulmonary systolic pressure at completion of CPB during the transplant operation. The donor right ventricle generally poorly tolerates a systolic afterload of more than about 50 mmHg, and overt right ventricular dysfunction usually occurs above a pressure of 55 to 60 mmHg, potentially resulting in acute right ventricular failure and death. Tolerance of the donor right ventricle to elevated afterload conditions (secondary to increased Rp) is partly a function of donor right ventricular reserves, ischemic/reperfusion injury, and possibly donor/recipient size ratio.

The majority of adult patients with advanced heart failure secondary to ischemic or dilated cardiomyopathy have a reactive component of elevated Rp that is directly responsive to left atrial (or pulmonary capillary wedge) pressure. When

**Box 21-5 Patient Factors Associated with Increased Morbidity and Mortality after Cardiac Transplantation**

- Pulmonary hypertension (>6 Wood units not responsive to vasodilators or not decreasing to <3 to 4 Wood units, pulmonary artery systolic pressure > 70 mmHg, transpulmonary gradient > 15 mmHg)
- Infection, active, untreated: HIV positive
- End-organ disease, irreversible:
  - Hepatic
  - Renal
  - Pulmonary (FEV₁ < 1.5 L·sec⁻¹)
- Pulmonary infarction, recent
- Age > 60 years
- Diabetes mellitus with end-organ damage (without end-organ damage also increases risk)
- Peripheral arterial disease or cerebrovascular disease (risk related to severity)
- Gastrointestinal disease:
  - Chronic active hepatitis
  - Diverticulitis, recent
  - Peptic ulcer disease with active bleeding
- Obesity (>120% of ideal body weight)
- Malignancy (within 5 years, high risk; remote, less risk)
- Osteoporosis
- Psychiatric disorder:
  - Affective or schizophrenic
  - Personality disorder, including medical noncompliance
- Substance abuse:
  - Tobacco
  - Alcohol
  - Controlled drug
- Lack of social support

Modified from Renlund. Key: FEV₁, Forced expiratory volume in 1 second; HIV, human immunodeficiency virus; PA, pulmonary artery.

---

**Box 21-6 Contraindications to Cardiac Transplantation**

**General Contraindications**

Presence of any noncardiac condition that would itself shorten life expectancy or increase risk of death from rejection or complications of immunosuppression.

**Specific Contraindications**

- Older age (>about 65 years)
- Active infection
- HIV positive
- Active peptic ulcer disease
- Chronic active hepatitis
- Recent diverticulitis
- Diabetes mellitus with end-organ damage
- Severe peripheral arterial or cerebrovascular disease
- Coexisting active neoplasm (within 5 years, high risk; removed, low risk)
- Morbid obesity (>140% of predicted ideal body weight)
- Creatinine clearance < 40 to 50 mL·min⁻¹, effective renal plasma flow < 200 mL·min⁻¹
- Bilirubin > 2.5 mg·dL⁻¹ when not due to reversible hepatic congestion, transaminases > 2 × normal
- Severe pulmonary dysfunction with FVC and FEV₁ less than about 40% of predicted, especially with intrinsic lung disease
- Pulmonary artery systolic pressure > 60 mmHg, mean transpulmonary gradient > 15 Wood units
- Acute pulmonary thromboembolism
- Severe osteoporosis
- Smoking within last 6 months
- High risk of life-threatening noncompliance:
  - Inability to make strong commitment to transplantation
  - Cognitive impairment severe enough to limit comprehension of medical regimen
  - History of marked depression or emotional instability
  - Psychiatric instability severe enough to jeopardize incentive for adherence to medical regimen
  - Recurring alcohol or drug abuse
  - Failure to establish stable address or telephone number
  - Previous demonstration of repeated noncompliance with medical therapy or follow-up
  - Lack of independent family or social support system

May be relative or absolute, depending on severity or program philosophy.

May be suitable for cardiac transplantation if inotropic support and hemodynamic management produce a creatinine level < 2 mg·dL⁻¹ and creatinine clearance > 50 mL·min⁻¹. Transplantation may also be advisable as combined heart–kidney transplant.

Requires liver biopsy to exclude cirrhosis or other intrinsic liver disease.

These apply only if the increased resistance is largely nonreactive (fixed).

Key: FEV₁, Forced expiratory volume in 1 second; FVC, forced vital capacity.
elevated Rp is primarily reactive, it falls rapidly after transplantation. If the donor heart left atrial pressure is normal, pulmonary artery systolic pressure, transpulmonary gradient, and Rp return to near-normal levels within 1 week of transplant, with little further change during the coming year.\textsuperscript{225}

It is generally recognized that operative risk progressively increases as Rp rises. Other risk factors interact with Rp to create a higher or lower risk for a given level of resistance. In general terms, an Rp greater than about 5 Wood units (WU) or a transpulmonary gradient (mean pulmonary artery pressure minus pulmonary capillary wedge pressure) above 14 mmHg that is unresponsive to pulmonary vasodilators and inotropic agents (used to test reversibility of pulmonary vascular hypertension) is a major contraindication to orthotopic cardiac transplantation.\textsuperscript{225} To define the reactive component of any elevation of pulmonary resistance, a standard part of the cardiac transplant evaluation is right heart catheterization to document cardiac and pulmonary pressures (and Rp).\textsuperscript{210} If Rp is elevated, a sustained favorable hemodynamic response (Rp < about 4 WU) to pulmonary vasodilator therapy (e.g., milrinone, prostaglandin E\textsubscript{1}, nitroprusside, nitroglycerin, nitric oxide) suggests a suitable risk for cardiac transplantation.

When Rp remains elevated and medical therapy (sometimes over days to several weeks on continuous intravenous [IV] infusions) fails to reduce pulmonary artery systolic pressure below about 60 mmHg, secure conclusions about pulmonary reactivity cannot be made. In that instance, implanting a left ventricular assist device may be warranted to force reduction of left atrial pressure and promote reversal of the reactive component.

Renal Dysfunction Multiple studies have shown that pre-existing renal dysfunction is a major risk factor for mortality after cardiac transplantation. A serum creatinine level of 2 mg·dL\textsuperscript{-1} and a creatinine clearance of less than 50 mL·min\textsuperscript{-1} portend a worse prognosis in adults following cardiac transplantation, particularly because of the necessity for cyclosporine or tacrolimus immunosuppression, with their associated nephrotoxic effects. A major dilemma often exists in estimating the likelihood that renal dysfunction is secondary to severe low cardiac output and aggressive diuretic therapy, or whether it is secondary to intrinsic renal disease. There is no specific level of serum creatinine or creatinine clearance that differentiates between these.

Effective renal plasma flow (ERPF), obtained by nuclear medicine techniques, is a useful adjunct to creatinine clearance. An ERPF of less than 200 mL·min\textsuperscript{-1} generally indicates important underlying intrinsic renal disease affecting the distribution of renal blood flow and likely represents a major risk factor for cardiac transplantation.

Infection Presence of active infection is a traditional absolute contraindication to cardiac transplantation if the infection is life threatening and not readily reversible with antibiotic therapy. Clearly, transplantation would be ill advised in the presence of an important pneumonia, central nervous system (CNS) infection, intraabdominal sepsis, or active bloodstream sepsis, because the likelihood of these infectious conditions progressing to a life-threatening state following the immunosuppression of transplantation would be high. However, certain infections, such as mediastinitis following implantation of a ventricular assist device, driveline infections, or in some cases, partially treated endocarditis,\textsuperscript{229} are consistent with good outcome following cardiac transplantation, albeit at a higher risk of posttransplant mediastinal infection and fatality.

Prior Malignancy All patients should be screened appropriately for malignancies by a chest radiograph, mammogram, prostate-specific antigen, abdominal ultrasound, and complete physical examination. A history of malignancy increases the risk of a subsequent fatal malignancy following cardiac transplantation.\textsuperscript{117} However, if there is no evidence of residual, recurrent, or metastatic disease for a sufficient period to consider the malignancy cured, cardiac transplantation should be considered. Although the suitable period differs among malignancies, in general, a malignancy-free interval of 5 years is considered long enough to proceed with transplantation. Rarely, patients with cardiac neoplasms may undergo successful transplantation if there is no evidence of metastases or extension of the cancer beyond the surgical resection areas necessary for transplantation (see Chapter 18). This is, however, a contentious subject because malignant cardiac neoplasms can metastasize during the waiting period for organ allocation.

Squamous cell or basal cell carcinoma of the skin represents a curable condition with a low probability of metastasis if completely excised. Thus, this malignancy, if completely excised, does not require an extended wait prior to cardiac transplantation.

Donor Evaluation and Selection

The donor becomes available when brain death has occurred, and criteria enumerated by the Ad Hoc Committee of the Harvard Medical School are generally used.\textsuperscript{226,24} The donor must be completely unresponsive, without reflexes or movements of breathing. Two flat electroencephalograms obtained 24 hours apart are sometimes required.

Once a potential donor has been identified, other criteria apply. The donor should be younger than about age 60 years (although occasionally hearts from older donors are used for elderly recipients) and without documented prior myocardial infarction. Coronary angiography is recommended in all potential donors older than age 45 years; the heart is generally not used for transplantation if there is important arteriosclerotic coronary obstruction. A history of smoking also prompts coronary angiography as part of the process of donor selection.

There should have been no prolonged episodes of profound hypotension or cardiac arrest after injury, because poor donor heart function after transplantation is likely to follow such an event. However, echocardiography often allows the heart to be used if ventricular performance is good. Important ventricular arrhythmias usually eliminate a donor.

Two-dimensional transthoracic or, occasionally, transesophageal echocardiography (TEE) is performed to evaluate cardiac morphology, ventricular performance, and cardiac valve function. The heart should have good contraction and be free of any segmental wall motion abnormalities. Global or regional hypokinesis and valvar heart disease preclude use of the heart. Severe left ventricular hypertrophy and cardiac contusion with wall motion abnormality disqualify the donor. Minor cardiac malformations such as patent foramen ovale or a small ventricular septal defect may be corrected and the heart used.

Any evidence of sepsis must be sought, and if found, the heart is rejected. Hearts from donors who are positive for
human immunodeficiency virus are not used. Hearts from donors who test positive for hepatitis C are not used unless the recipient is also positive. Active malignancy in the donor disqualifies use of the heart for transplantation except in cases of primary malignant brain tumor. Death resulting from carbon monoxide poisoning, with a carboxyhemoglobin level greater than 20%, eliminates the donor heart from use. History of IV drug abuse usually disqualifies the donor, but occasionally exceptions are made. There should not be a great disparity between size of donor and recipient, although donor hearts from males of about 75 kg or greater are usually suitable for larger recipients up to about 110 kg.

Findings on physical examination relative to the heart should be normal, and a 12-lead electrocardiogram is examined to exclude the possibility of preexisting Q-wave abnormalities and conduction defects. Nonspecific ST- and T-wave changes may be caused by head injury, hypothermia, and vasopressor agent, and do not per se contraindicate use of the heart. If there is any suggestion of hypotension or cardiac injury, serum cardiac enzymes are obtained and should be normal or at most mildly elevated.

Once this screening has been performed and the heart found acceptable, managing the donor becomes intense. Hypotension, hypothermia, and diabetes insipidus are frequent physiologic results of brain death and make careful attention to volume replacement essential, but excessive crystalloid infusion can produce right ventricular distension and lung damage from extravascular water. Active warming may be required to counteract hypothermia.

The decision to use a specific donor is based in part on the feasibility of keeping cardiac ischemic time to less than about 6 hours, because prolonged ischemic time is a risk factor for acute graft dysfunction.

**Effect of Brain Death on Myocardial Function**

The effect of brain death on the myocardium has been of considerable interest for two important reasons: (1) there is a low but important prevalence of primary graft failure following cardiac transplantation, and (2) many potential donor hearts are not used because of donor heart dysfunction. Successful strategies to improve dysfunctional donor hearts would increase the number of hearts available for transplantation.

Myocardial injury by catecholamine infusión and stress stimulation of the nervous system are central to understanding donor heart dysfunction. Epinephrine infusión can cause cardiac hypertrophy, and experimental catecholamine infusión produces a characteristic histologic appearance of myofibrillary degeneration, also known as **contraction band necrosis**. Its histologic features are distinct from coagulation necrosis, the predominant histologic pattern seen in acute myocardial infarction. In coagulation necrosis, myocardial cells die without obvious contraction bands, calcification appears late, and a predominant polymorphonuclear cell response occurs. Coagulation necrosis is not seen histologically for many hours or even days after the onset of the infarction. In contrast, myofibrillar degeneration is histologically detectable early after onset, and the myofibrils die in a hypercontracted state with obvious contraction bands.

This lesion can also be seen in humans when the mode of death involves considerable stress, such as physical assault in which death occurred from the assault but not from life-threatening injuries. This suggests an association between catecholamine release and myofibrillar degeneration. Experimental intracerebral and subarachnoid hemorrhages can also produce these myocardial lesions.

Brain death is frequently accompanied by massive release of endogenous catecholamines. In animal models, blood epinephrine and norepinephrine levels may increase 100- to 500-fold within 10 seconds of experimental brain injury, with a correlation between magnitude of catecholamine release and severity of injury. In humans, catecholamine levels after brain death have been highly variable, likely related to individual variability in neurohumoral response and the mechanism and rapidity of the catastrophic intracranial event. In Novitsky’s baboon model, rapid increase in intracranial pressure was accompanied by marked increases in mean arterial, pulmonary wedge, and central venous pressure within 15 minutes, and by a threefold to sevenfold increase in blood norepinephrine and epinephrine levels. A relationship between noradrenaline levels and increases in the plasma level of creatine kinase (CK)-MB has been demonstrated after acute head injury in man.

The physiologic response to this post–brain death catecholamine storm may result from the interplay between coronary vasoconstriction and repercussion in association with oxygen-derived free-radical generation. Oxidation products of catecholamines may induce myocardial injury, probably resulting from peroxidation of membrane phospholipids. Catecholamine storm may also induce myocardial injury by oxygen-derived free radicals generated by repercussion of myocardium that has been rendered ischemic by severe coronary vasoconstriction.

**Immunologic Aspects of Transplant Testing**

**ABO Compatibility**

The ABO blood group antigens are carbohydrate structures carried on glycoprotein and glycolipid components of cell surfaces and tissues throughout the body, most notably on the surface of erythrocytes. In the human heart, blood group antigens are confined to the vascular endothelium and mesothelial cells on the surface of the epicardium. In individuals who lack one or more of the ABO antigens, natural antibodies against the absent antigen appear during the first 6 months of life and are present permanently thereafter.

An accepted requirement for successful cardiac transplantation is identical or compatible blood groups between donor and recipient. If an allograft containing A or B blood antigens on its endothelial surfaces is transplanted into a recipient who has naturally occurring anti-A or anti-B antibody, hyperacute rejection or accelerated aggressive acute rejection will likely occur. When a donor and recipient display ABO incompatibility, circulating antidendor hemagglutinins rapidly bind to endothelial cells and promote platelet deposition, granulocyte activation, and thrombosis, resulting in hyperacute rejection. Although transplantation in the presence of ABO incompatibility (donor heart A into recipient blood group B or O, B into A or O, AB into A, B, or O) would be expected to produce universal hyperacute rejection, there are notable exceptions (see also “ABO-Incompatible Infant Heart Transplantation” in Section II). Considerable variability exists among individuals in the level of blood group antigen expression in tissues, such as on cardiac endothelium.

A specific exception to ABO incompatibility may be donors of A₂ blood group. Blood group A contains
subgroups A1 and A2. Subgroup A1 acts like blood group A in its propensity for producing hyperacute rejection when transplanted into an ABO-incompatible recipient. However, donor subgroup A2 may be less prone to producing hyperacute rejection because the A2 antigen is not readily displayed on the endothelial surfaces of the heart. Skin grafts from A2 donors are not hyperacutely rejected when transplanted into B or O recipients. A clinical trial of A2 kidneys transplanted into O recipients produced graft outcome similar to ABO-compatible transplants. The mechanism may relate in part to the two different galactosaminyltransferases produced by A1 and A2 genes, resulting in a qualitative difference in the type of core saccharide-based A antigens.

**Tissue Typing**

HLA antigens play a central role in the immune response, and the HLA genes are the most polymorphic known in the human genome. *Haplotype* refers to the set of genes on any one chromosome. Every individual has two haplotypes (one from each parent) for the genes on the short arm of chromosome 6 that code for the MHC complex. Each haplotype contains antigens determined by the HLA-A, HLA-B, HLA-C, HLA-DR, and other loci. The two haplotypes for an individual make up the HLA phenotype, which is the complete list of HLA antigens possessed by that individual. Studies of kidney graft survival have demonstrated a substantial survival benefit when the HLA antigens are matched between donor and recipient. Some benefit in freedom from rejection has also been demonstrated for heart transplantation related to the number of HLA mismatches.

Some studies suggest a higher probability of rejection with HLA-DR* S* and HLA-DQ mismatching in heart transplantation. However, because of the time limitations imposed by the current state of cardiac preservation during organ procurement and the scarcity of organs, donor hearts are currently not selected on the basis of prospective histocompatibility testing.

**Panel Reactive Antibodies**

In addition to HLA typing, the transplantation evaluation process includes routine examination of serum from a prospective transplant recipient for presence of circulating anti-HLA antibodies, also called *humoral sensitization*. Sensitization is established by documenting the presence of circulating anti-HLA antibodies by the panel reactive antibody (PRA) test. The most common cause of sensitization is pregnancy. Other common causes include prior blood transfusion, prior transplantation, or insertion of a ventricular assist device. Occasionally a patient will demonstrate a positive PRA with anti-HLA antibodies and no obvious sensitizing event. These antibodies may represent cross-reactivity between bacterial or viral epitopes and HLA antigens.

**Crossmatching**

The crossmatch at transplantation is typically the final test of immunologic compatibility between donor and recipient prior to making the decision to transplant. The goal of the crossmatch is to prevent hyperacute rejection and accelerated severe acute rejection during the first 5 to 7 days after transplantation. The crossmatch tests the reactivity of recipient sera (with its potential anti-HLA antibodies) against donor lymphocytes obtained from peripheral blood or lymph node. With current crossmatch techniques, hyperacute rejection is extremely rare. In practice, a pretransplant prospective crossmatch is often omitted when a recent PRA is 0% because of the very low probability of hyperacute or accelerated acute rejection in that setting and because of the additional time prior to transplantation needed to obtain a crossmatch. In that instance a retrospective crossmatch is usually obtained in the hours following transplantation to make a final determination of the presence of antidonor antibodies.

A positive complement-dependent lymphocytotoxic T-cell and B-cell crossmatch is a strong predictor of hyperacute or severe accelerated acute rejection. However, presence of a negative cytotoxic crossmatch does not guarantee protection against hyperacute or severe early rejection. It has been hypothesized that minimal clonal expansion of T* i * and T* i * subsets of T cells plus B cells is sufficient to produce a brief IgM (or IgM followed by IgG) response that is promptly down-regulated, and detectable levels of IgG may not be present (thus producing a negative crossmatch). However, with sustained stimulation following transplantation, B-cell clones expand and express increased affinity for the HLA antigen. Substantial clonal expansion then occurs with T1, T2, and B-cell proliferation and the production of antibody. Serum anti-HLA antibodies become predominantly IgG with sustained levels, and further antibody response is readily inducible with reexposure to even small amounts of these HLA antigens.

**Virtual Crossmatch**

With the current precision of flow cytometry technology in identifying circulating anti-HLA antibodies in potential recipients, many transplant centers omit formal crossmatching (with the considerable time requirement) in the presence of low PRAs, and rely instead on a comparison of HLA typing of the donor with identified anti-HLA antibodies in the recipient. If there are no donor antigens against which recipient antibodies are likely to react, it is generally safe to proceed with transplantation.

**TECHNIQUE OF OPERATION**

**Donor Heart Procurement**

Most donors are donating multiple organs including the heart. Therefore, the donor is prepared from neck to mid-thigh. Preferably, a central venous line and an arterial catheter are placed because marked hypotension may occur while mobilizing the abdominal organs.

A long midline incision is made from jugular notch to pubis. Volume replacement continues as needed because considerable bleeding from incisions is frequent as a result of the donor’s vasodilated state. After median sternotomy, a self-retaining retractor is inserted. While other organ procurement teams proceed, the pericardium is opened and usual stay sutures applied. The heart is examined for evidence of cardiac injury, congenital anomalies, coronary arteriosclerosis, or other acquired heart disease. The ascending aorta is dissected and mobilized as far as the brachiocephalic takeoff. The superior vena cava (SVC) is completely mobilized, including any pericardial reflection onto it. A purse-string suture is placed on the ascending aorta for cardioplegia infusion.

When cardectomy is ready to begin, 200 units · kg\(^{-1}\) of heparin are given, and the cardioplegia needle is inserted into
the ascending aorta and secured. In this setting, the cardioplegic solution is infused by gravity. Cold University of Wisconsin (UW) solution is commonly used as the myocardial preservation solution, but other intracellular- or extracellular-type solutions provide effective preservation.

If a central line is in place, it is withdrawn. The SVC is clamped and later divided as far distally as possible. The right or left superior pulmonary vein (or left atrium above the entrance of the left pulmonary veins if lung procurement is planned) is partially divided to permit escape of blood from the heart (Fig. 21-8). If lungs are also being harvested, the left atrium is incised for egress of pulmonary preservation solution, and later a cuff of left atrium is left around the right and left pulmonary veins for the lung allografts. The inferior vena cava (IVC) is divided, leaving part of it with the liver. After several cardiac ejections to completely empty the heart, the aorta is occluded just proximal to the brachiocephalic artery. Infusion of the cardioplegic solution is begun. Cardioplegic infusion pressure is monitored digitally while 1 to 2 L of solution is infused. Ice-cold saline or slush solution is poured into the pericardium.

Coronary sinus effluent is allowed to escape into the pericardial sac through the open IVC. Cardiectomy proceeds by dividing the right pulmonary veins at the pericardial reflection. The heart is retracted superiorly and to the right to expose the left pulmonary veins (Fig. 21-8, B), which are divided at the pericardial reflection. Downward traction alongside the aorta and pulmonary trunk exposes the maximal length of these vessels. The aorta is divided distal to the origin of the brachiocephalic artery (Fig. 21-8, C). The left pulmonary artery is divided at the pericardial reflection. The right pulmonary artery is divided. All that remains to be divided is connective tissue behind the left atrium at the pericardial reflection and lymphatic tissue, which lies between the left atrium and the tracheal bifurcation.

The heart is removed from the body and immersed in cold preservation solution. A few minutes are spent to trim the heart and prepare it for implantation. The right pulmonary veins are joined by incision, as are left pulmonary veins. The left atrium is opened posteriorly between the pulmonary veins to provide maximum length for the left atrial suture line. The aorta is separated from the pulmonary trunk. The pulmonary trunk is opened at its bifurcation to preserve maximum circumfer-ence that may be needed to match a dilated recipient vessel. The cardiac chambers are thoroughly irrigated with cold isotonic solution and inspected to ensure absence of debris or anatomic anomalies. The organ is placed in triple sterile plastic bags filled with preservation solution and transferred to an ice chest for transport.

Orthotopic Cardiac Transplantation

Biatrial Technique

In addition to the usual preparations for cardiac operations (see Chapters 2, 3, and 4), a large-gauge triple-lumen catheter is placed through the left internal jugular vein after anesthesia induction. The right internal jugular vein is left undisturbed if possible to preserve it as access for future endomyocardial biopsies. After endotracheal intubation, a TEE probe is placed for later monitoring during de-airing maneuvers and for assessing ventricular function. The heart is exposed through a median sternotomy. In the presence of previous cardiac operations, femoral artery and vein catheters are inserted percutaneously in case acute cardiac decompensation requires insertion of an intraaortic balloon pump or emergency institution of CPB.

When arrival of the donor heart is imminent, CPB is established with separate caval cannulation. Additional time is allotted if extensive dissection is necessary. The aorta is clamped and the caval tapes secured. The right atrium is incised just above the level of the entrance of the IVC, anterior to the sulcus terminalis. The incision is carried around to the IVC, leaving the cava below the cut surface of the right atrium. The interatrial septum is incised and carried superiorly until it meets the roof of the left atrium. The left atrial incision is then carried leftward, leaving a generous cuff of left atrium above the entrance of the left pulmonary veins. A cardiotomy sump is placed into the left atrium when the interatrial septum is incised, and the great arteries are divided proximally to expose the underlying left atrium. These arteries are accurately dissected free from one another to facilitate great vessel anastomoses.

The donor heart is removed from the ice chest, and fluid from the inner bag cultured. The roof of the left atrium is dissected free from the posterior aspect of the right and left pulmonary artery segments. The aorta is dissected from the pulmonary trunk, which is then divided just proximal to its bifurcation unless additional pulmonary artery is necessary for reconstruction. A cuff of left atrium is created by incising through the pulmonary vein orifices (Fig. 21-9, A). The right atrium is prepared by incising through the inferior vena caval orifice and extending the incision toward the base of the right atrial appendage approximately equidistant from the sulcus terminalis and the atrioventricular groove (Fig. 21-9, B).

During implantation, perfusate temperature is generally 28°C, with intermittent topical cooling using 4°C saline ice slush. No additional cardioplegic solution is infused. The left atrial anastomosis is constructed first using continuous 3-0 polypropylene suture (Fig. 21-9, C). When constructing it, the first few stitches are placed “at a distance” before lowering the donor heart into the pericardial space. The remainder of the entire left atrial anastomosis is constructed in an evert-ing fashion to provide endothelium-to-endothelium apposition, thereby reducing the chance of thrombus formation along the suture line. Construction of the far-leftward portion of the anastomosis along the left pulmonary veins is often facilitated by retracting the donor ascending aorta inferiorly with a traction suture. The right atrial anastomosis is also constructed with continuous 3-0 polypropylene suture. In the area over the interatrial septum, the suture lines are partially overlapping (Fig. 21-9, D). Each chamber is filled with cold saline before securing the suture lines.

The aortic anastomosis is constructed with continuous 4-0 polypropylene suture after the donor and recipient aortas are cut to appropriate length. A cardioplegia catheter to be used as a “needle vent” for aspirating air is placed in the donor ascending aorta. Air is evacuated from the heart through the aortic suture line, and the suture line secured. The aortic clamp is removed with strong suction on the needle vent.

This is a critical period during the operation because the donor heart is being reperfused after a prolonged period of global ischemia. It is useful to infuse one or two ampules of adenosine just prior to aortic clamp removal to facilitate maximal dilatation of the subendocardial arterioles during early reperfusion. In most instances, the donor heart will
Figure 21-8 Donor cardiectomy for orthotopic cardiac transplantation. A, Inferior vena cava is divided at its junction with right atrium. Most of the intrapericardial inferior vena cava is left behind attached to the liver, because nearly all these operations are for multiorgan procurement. Right pulmonary vein is incised to vent the left heart. (When lungs are being harvested, left atrioventricular groove is generously incised to provide egress of the pulmonary preservation solution). Aorta is occluded when the heart empties. Cold cardioplegic solution is administered through the catheter to the aortic root to achieve total electromechanical arrest. B, Heart is retracted superiorly, exposing pulmonary veins and left pulmonary artery. These are divided. C, Aorta, superior vena cava, and right pulmonary artery are divided at or above the pericardial reflection for maximal length on recipient great arteries. All that remains to be divided is connective tissue behind the left atrium at pericardial reflection. The heart is taken from the body and aorta and pulmonary trunk separated, atrial septum checked for defect, and cardiac valves and cardiac chambers inspected. It is packed in saline solution in triple sterile bags for transport.
Figure 21-9  Orthotopic cardiac transplantation, biatrial technique. A, Creating donor heart left atrial cuff by incising through pulmonary vein orifices. B, Creating donor heart right atrial cuff. Incision begins at orifice of inferior vena cava and extends toward right atrial appendage approximately halfway between sulcus terminalis and atrioventricular groove. C, Left atrial anastomosis is commenced.

begin rhythmic contractions within 1 to 3 minutes of clamp removal. If ventricular fibrillation or tachycardia occurs, the heart should be promptly defibrillated. An esmolol hydrochloride infusion is initiated temporarily if marked sinus tachycardia or frequent ventricular arrhythmias occur during early reperfusion. Esmolol is particularly useful in this setting because it reduces myocardial oxygen consumption when the heart is recovering from the period of ischemia, and its duration of action is very short; thus, its effects will have dissipated before discontinuation of CPB.

When a gentle sinus rhythm is established, preparations are made for the pulmonary artery anastomosis. (Some surgeons prefer to complete this anastomosis before removing the aortic clamp.) The pulmonary artery segments are cut to an appropriate length and the anastomosis constructed, usually with 4-0 or 5-0 polypropylene suture (Fig. 21-9, E).

The remainder of the operation is conducted as usual during rewarming, and CPB is gradually discontinued after thoroughly de-airing the heart through the aortic needle vent while examining it for residual air with TEE. Immediately before and after discontinuing CPB, the function of each ventricle is assessed with TEE, and appropriate interventions made if necessary to improve function.
Figure 21-9, cont’d  D, Right atrial anastomosis is commenced on interatrial septum. This suture line overlaps the atrial septal portion of the left atrial anastomosis. E, Aortic and pulmonary trunk anastomoses are completed. (From Kirklin and colleagues.14)

Bicaval Technique

Preparations for and initiation of CPB are identical to those for the biatrial technique. The SVC cannula should be placed 1 cm or more superior to the cavo–right atrial junction to facilitate the SVC anastomosis. If multiple implantation techniques are used at a given institution, clear communication to the donor procurement team is necessary to ensure the harvesting of all available donor SVC up to entrance of the brachiocephalic vein.

General conduct of the operation is the same as for the biatrial technique. Following aortic clamping, caval tapes are secured, and an incision made in the left atrium anterior to the right pulmonary veins as for mitral valve surgery. The incision is extended under the IVC and superiorly to the level of the right pulmonary artery. A cardiotomy sump is placed into the left atrium, and a generous cuff of right atrium adjacent to the IVC opening is retained. Within the right atrium, this cuff usually involves an incision through or immediately inferior to the coronary sinus orifice. With the cautery on a low setting, pericardial attachments are freed up from the IVC cuff, and this area is separated from the cut edge of the left atrium to facilitate implanting the donor heart.

Similarly, a cuff of right atrium adjacent to the entrance of the SVC is created, and its attachments to the underlying pulmonary trunk are divided to facilitate ease of later anastomosis. Commonly, implantable cardioverter-defibrillator leads are present in the recipient heart and are frequently densely adherent to the interior surface of the SVC. These should be freed up, mobilized, pulled as far as possible into the surgical field, and divided. This allows them to retract back into the upper SVC (where adhesions to the leads are uncommon) for ease of later extraction through the defibrillator pocket. The great arteries are divided proximally, and the remainder of the incisions along the inferior, superior, and left lateral aspects of the left atrium are as for the biatrial technique. A cuff of left atrium should be preserved above the entrance of the left pulmonary veins (Fig. 21-10, A).

Implantation begins with the left atrial anastomosis, which starts inferiorly, moving toward the left pulmonary veins (Fig. 21-10, B). Whenever possible, an everting suture technique should be used to promote direct endothelial apposition and avoid potential thrombus formation that might be more likely with an inverting anastomosis. When the suture line approaches the left atrial appendage in the donor heart, the geometry should be briefly reevaluated to ensure that the donor SVC will lie appropriately for the SVC anastomosis. If the recipient’s left atrium seems considerably larger than the donor’s, the base of the donor’s left atrial appendage can be incised slightly to lengthen it. When this suture line reaches the area of the right pulmonary veins, it is generally completed with the second arm of a 3-0 polypropylene suture. The left atrium is filled with cold saline solution and the suture line secured. Throughout implantation, cold saline slush is applied to the donor heart to minimize the tendency for metabolic activity.

The IVC anastomosis is constructed next, usually with 4-0 polypropylene suture. If the donor heart is considerably smaller than the recipient heart, it is particularly important to retain a sizeable cuff of right atrium near the IVC to prevent tension on that anastomosis.

Although various strategies have been used for the remainder of the anastomoses, we recommend proceeding with the aortic anastomosis next, after appropriately trimming lengths of donor and recipient aorta to allow nice geometric reconstruction of the new ascending aorta. Using continuous 4-0 polypropylene suture, a standard end-to-end anastomosis is constructed (Fig. 21-10, C). A double suture line technique, in which the first line is a continuous everting mattress suture followed by a simple running suture, is particularly hemostatic. Before securing the suture line, air is evacuated from the heart by vigorous expansion of the lungs, and the suture line is secured.

During rewarming, after a stable sinus rhythm has been established, the SVC anastomosis is constructed with
Figure 21-10 Orthotopic cardiac transplantation, bicaval technique. **A,** Right atrium is divided to create superior and inferior vena caval cuffs. Great vessels are divided as in biatrial method. **B,** Commencement of left atrial anastomosis. **C,** Completion of bicaval transplant technique, showing inferior vena caval, superior vena caval, aortic, and pulmonary trunk anastomoses. (From Kirklin and colleagues. 114)

Continuous 5-0 polypropylene suture. It is important to avoid excessive redundancy in creating the new SVC, because any kinking of the caval pathway can result in a venous pressure gradient. The pulmonary end-to-end anastomosis is constructed as in the biatrial technique.

**General Intraoperative Considerations**

In patients with a previous sternotomy, particularly with previous bypass surgery, the likelihood of acute severe cardiac decompensation is greatly increased if there is inadvertent injury to the patient’s saphenous or internal thoracic artery graft. In this situation, routine insertion of a percutaneous femoral artery catheter for arterial pressure monitoring is advantageous. Should decompensation occur, a guidewire for inserting an intraaortic balloon pump can be rapidly accomplished, or CPB established with a percutaneously inserted arterial cannula. In situations in which sternotomy is considered very high risk, a guidewire can also be placed in the femoral vein for percutaneous venous cannulation if necessary.

In preparing every donor heart prior to implantation, the area of the fossa ovalis should be specifically examined. If a patent foramen ovale is identified, it must be surgically closed. Failure to do so has resulted in severe hypoxemia and right-to-left shunting early after cardiac transplantation in a
situation of right ventricular dysfunction, particularly in the presence of elevated pulmonary artery pressure.56

Tricuspid regurgitation detected by Doppler echocardiography is common after orthotopic cardiac transplantation. This may relate to geometry of the newly constructed right atrium; an association has been suggested between larger relative size of the donor right atrium to the recipient’s and the likelihood of tricuspid regurgitation.51 Thus, consideration should be given to excising excess right atrial tissue, particularly on the lower side of the anastomosis, without jeopardizing the sinoatrial node. Less commonly, mitral valve regurgitation has been observed, associated with the “snowman” configuration formed by the donor-recipient left atrial anastomosis.51,55

During construction of the left atrial suture line, the orifice of the left pulmonary vein should be observed. Excessive protrusion of tissue from the suture line with an inverting technique can potentially obstruct pulmonary venous inflow and may also be thrombogenic. In extreme cases, surgically induced cor triatriatum secondary to anastomotic obstruction of pulmonary venous inlet has been reported.51,56

Sinus node dysfunction occasionally occurs. Therefore, specific attention to avoiding damage to the sinoatrial node is important during harvesting and implantation. The ligature on the SVC should be placed 1 to 2 cm above the superior cavo–right atrial junction. The incision in the donor right atrium should be kept well above the sulcus terminalis to avoid damaging the sinoatrial node while constructing the lower right atrial suture line.

Kinking of the pulmonary trunk may occur if the length of the newly constructed pulmonary trunk is redundant.14 Therefore, care must be taken to trim sufficient donor and recipient pulmonary trunk to avoid redundancy after constructing the anastomosis. The newly constructed pulmonary trunk is particularly vulnerable with an oversized donor heart relative to the size of the recipient’s pericardial space. Redundancy that results in kinking of the pulmonary trunk can produce an important gradient across the pulmonary anastomosis with resultant severe right ventricular hypertension.

Adverse neurologic events can occur. Mural thrombus may be potentiated by an excessively inverting suture line, particularly in the left atrium. Effective and complete deairing of the heart is extremely important to minimize the risk of cerebral embolism. When systemic vascular resistance is low following heart implantation, flow rates during CPB must be adequate. Although the precise level of perfusion pressure and flow rate that contribute to neurologic events has not been clearly defined, systemic mean perfusion pressure should be maintained at 40 mmHg or greater during rewarming, with a perfusion flow rate of 4.2 to 4.8 L·min⁻¹.

In the presence of important right ventricular dysfunction during rewarming, a second left atrial catheter is placed for infusion of inotropic agents, and prostaglandin E₁ and other vasodilator agents can be infused into the central venous lines. If this is not successful and pulmonary hypertension is present, nitric oxide55,58,11 can be used as an inhalational agent.

SPECIAL FEATURES OF POSTOPERATIVE CARE

Usual care given to patients after cardiac surgery (see Chapter 5) is applied to patients who have received a cardiac transplant. Generally, subsystems function normally, and little or no special therapy is required. Cardiac function of the donor heart is usually good but is subject to influences of total denervation and consequences of myocardial ischemia attending explant and transplant. Cardiac denervation may temporarily lower heart rate; consequently, a chronotropic catecholamine agent may be indicated. Isoproterenol in doses of 0.01 to 0.1 µg·kg⁻¹·min⁻¹ or atrial pacing can be used to maintain an appropriate heart rate for patient age and size. Generally, the effects of β-adrenergic agents are unchanged.

Cardiac ischemia results in reduced diastolic compliance, so somewhat higher cardiac filling pressures may be required for optimal function. Impaired systolic function and contractility may also be observed, manifested by increased left atrial or pulmonary artery wedge pressure. Inotropic support is often required for 2 to 5 days, depending on function of the donor heart.

Acute distention and failure of the right ventricle resulting from excessive right ventricular afterload is occasionally observed, most commonly in the presence of preexisting recipient pulmonary hypertension or reactive pulmonary vasoconstriction from CPB or protamine administration. Various agents may dilate pulmonary vasculature, but the most effective combination appears to be milrinone at 0.3 to 1 µg·kg⁻¹·min⁻¹ and nitric oxide. Rarely, right ventricular mechanical support is required.

Aspirin, 325 mg daily, is given as soon as oral intake is begun and is continued indefinitely to counteract (at least in part) the tendency of the donor heart to develop coronary arteriosclerosis. Iron supplementation (ferrous sulfate 325 mg three times daily) is given until hematocrit is stable. A histamine H₂-receptor antagonist is administered routinely to counteract adverse effects of steroids on the gastric mucosa.

Immunosuppressive Modalities

Immunosuppressive modalities in transplantation are designed to reduce intensity of the immune response to a degree that allows acceptance of the allograft, yet provides sufficiently low toxicity to permit prolonged survival. Pharmacologic agents have evolved from general suppression of the recipient’s immunologic defenses to selective blockade of intracellular immune events that maximize graft acceptance while minimizing toxicity.

Three situations require specific combinations of immunosuppressive therapies: (1) initial high-dose immunosuppression to facilitate graft acceptance, minimize the chance of early rejection, and potentially favor induction of tolerance; (2) maintenance therapy for chronic acceptance of the allograft; and (3) augmented immunosuppression to reverse episodes of acute rejection. Specific immunotherapeutic modalities are being evaluated to prevent or reverse chronic rejection in the form of allograft vasculopathy.

The immune response to transplantation is highly dependent on T-cell activation and proliferation.59 The cellular events of T-cell activation are of great importance because many current immunosuppressive drugs target specific intracellular pathways of T-cell activation. A summary of modalities that interfere with specific phases of the allograft-induced immune response is given in Table 21-4.

Although there is considerable variability among institutions, the general strategy involves induction therapy
followed by maintenance therapy with initial “triple-drug” immunosuppression followed by gradual tapering or withdrawal of the steroid component. Induction therapy generally includes one of two approaches:

1. Daclizumab or basiliximab, which block IL-2 receptors
2. Antithymocyte globulin or OKT3, which targets the T-cell receptor and causes it to be removed from the cell surface or induces destruction of the entire cell through multiple mechanisms

Maintenance immunosuppression generally includes immunosuppressive agents from three general classes, comprising the triple-drug strategy:

1. Cyclosporine and tacrolimus interfere with calcium-mediated signaling via calcineurin, which blocks production and release of IL-2, which is essential for proliferation of cytotoxic T\(\text{H}\) cells.
2. Mycophenolate mofetil, azathioprine, methotrexate, and cyclophosphamide are often referred to as **anti-proliferative agents** because of their basic action of interfering with T-cell proliferation.
3. Adrenocorticosteroids, usually methylprednisolone or prednisone, have multiple mechanisms of action. In addition to an antiinflammatory effect, they inhibit transcription of multiple cytokines, impair macrophage function, and decrease circulating lymphocytes.

### Adrenocortical Steroids
Corticosteroids are generally administered intraoperatively before cardiac transplantation and constitute a portion of the maintenance strategy. Some centers continue at least low-dose prednisone therapy indefinitely, but an effective alternative strategy is to rapidly reduce and withdraw steroids in the early postoperative period. A summary of the important features and dosing of corticosteroids is found in **Box 21-7**.

#### Cyclosporine
Viability of heart transplantation as a therapeutic option for end-stage heart disease is directly linked to clinical availability of cyclosporine in 1979.\textsuperscript{533,617} Clinical features and dosing of cyclosporine are summarized in **Box 21-8**. Animal studies suggest that cyclosporine may be most effective when given before the antigenic challenge, a situation perhaps related to lower serum lymphokine concentration before onset of rejection. Absorption of cyclosporine is somewhat variable, but peak blood levels are achieved by about 3.5 hours. Bioavailability of the oral solution at steady state is about 30%. Approximately 90% of circulating cyclosporine is protein bound, and half-life is about 20 hours. Cyclosporine is eliminated primarily by the liver, with only about 6% by the kidneys. Cyclosporine blood concentration can be importantly affected by administration of other drugs, as summarized in **Table 21-5** and **Box 21-9**.

Renal toxicity, the major toxicity of cyclosporine, occurs in 25% to 38% of patients, manifested in the acute phase by

Key: GI, Gastrointestinal.

Chapter 21 Cardiac Transplantation

Box 21-7 Corticosteroids

**Clinical Use**
- Maintenance immunosuppression
- Pulse therapy for acute rejection

**Mechanism**
- Antinflammatory action
- Inhibits IL-2 production by impairing gene transcription
- Suppresses antigen-presenting cell function, reduces adhesion molecule expression, inhibits leukocyte transmigration, inhibits lymphocyte proliferation

**Dose**
- **Maintenance Immunosuppression**
  - Individual protocols are highly variable. A standard regimen is an initial prednisone dose of 20-40 mg daily tapered to an every-other-day dose of approximately 0.1 to 0.2 mg·kg⁻¹ or no steroids by 6 months. Some programs use no maintenance corticosteroids.
  - Daily steroids (approximately 0.1 to 0.2 mg·kg⁻¹·day⁻¹) are maintained in the setting of recurrent rejection.

- **Treatment of Acute Rejection**
  - 500-1000 mg methylprednisolone IV daily for 3 days or prednisone 2-3 mg·kg⁻¹ PO for 3 days with or without rapid taper thereafter

**Target Levels**
- None available

**Adverse Effects**
- Diabetes, bone disorders, obesity, cushingoid changes, decreased wound healing, cataracts, peptic ulcer disease, hypertension, psychiatric disorders

From Kirklin and colleagues.634

*See Section II for pediatric treatment.

Key: IL, Interleukin; IV, intravenously; PO, orally.

Box 21-8 Cyclosporine

**Clinical Use**
- Chronic maintenance immunosuppression, usually combined with azathioprine or mycophenolate mofetil, with or without corticosteroids

**Mechanism**
- Calcineurin blockade, inhibition of interleukin (IL)-2 production, inhibition of T-cell proliferation

**Dose**
- Initial oral dose of 25-50 mg twice daily and, if renal function remains normal, rapidly increase over 3-4 days to achieve whole blood trough level of 300-400 ng·mL⁻¹

**Target Levels**
- 0-3 months posttransplant: 250-350 ng·mL⁻¹
- 3-6 months posttransplant: 200-300 ng·mL⁻¹
- 6-12 months posttransplant: 150-250 ng·mL⁻¹
- >12 months posttransplant: 50-150 ng·mL⁻¹

**Toxicity**
- Nephrotoxicity, neurotoxicity, hypertension, hypercholesterolemia, hepatotoxicity, hyperkalemia, renal tubular acidosis, hypermagnesemia, hyperuricemia, hypertrichosis, gingival hyperplasia

Box 21-9 Drugs That Decrease Cyclosporine Blood Levels by Induction of Cytochrome P450 System

- Rifampin
- Isoniazid
- Phenytoin
- Phenytoin
- Carbamazepine

From Kirklin and colleagues.634

Oliguria and elevated blood urea nitrogen and creatinine levels. These effects are largely initiated by renal arteriolar vasoconstriction, which occurs mainly at the level of the preglomerular arterioles.62,64 The intrarenal renin-angiotensin system may contribute to both nephrotoxic and hypertensive effects of cyclosporine, because cyclosporine stimulates renin synthesis and release from renal juxtaglomerular cells and afferent arteriolar vessel wall.62,63 Chronic cyclosporine nephrotoxicity is characterized by patchy glomerular sclerosis with interstitial fibrosis and thickening of capillary basement membranes. Once chronic renal damage has occurred, it is usually unresponsive to a decrease in cyclosporine dosage or drug withdrawal. Common drugs that increase nephrotoxicity of cyclosporine are listed in Table 21-6.

Less severe adverse side effects include reversible hepatotoxicity, fluid retention, hirsutism (20%-45%), gum hypertrophy (9%-16%), hypertension (53%), tremor (20%-50%), and rarely, late development of lymphoma (although this may result from overimmunosuppression with multiple agents).

**Tacrolimus**

Tacrolimus (initially called FK506) was first isolated in 1984 from the bacteria Streptomyces tsukubaensis.66 It was first used clinically in 1989 as replacement therapy for cyclosporine in liver transplantation.67 Tacrolimus is a macrolide compound unrelated to cyclosporine and with different binding sites. However, their basic immunosuppressive effects are similar. Tacrolimus gains its immunosuppressive effect by binding to a protein called FKBP-12, and it is the FKBP-12–tacrolimus complex that blocks calcineurin. In general, both the immunosuppressive effects and toxicity of tacrolimus exceed that of cyclosporine, possibly related to its binding affinity to FKBP, which is much greater than the binding affinity of cyclosporine to cyclophilin, the binding protein for cyclosporine.

From Kirklin and colleagues.524  
*Drugs that act by increasing cyclosporine blood levels are not included in this table.*

A major side effect of tacrolimus that differs from cyclosporine is its marked tendency to induce diabetes. Unlike cyclosporine, gingival hyperplasia and hirsutism are rare with tacrolimus. Although unproven, there appears to be a higher propensity for lymphoproliferative malignancies with tacrolimus. Clinical features and dosing of tacrolimus are listed in Box 21-10.

Azathioprine

Azathioprine was thought to be only of historical interest when cyclosporine became available, but it was soon shown that triple-drug therapy was advantageous. Azathioprine again became part of the immunosuppression protocol along with cyclosporine and adrenocortical steroids. It is an imidazole derivative of 6-mercaptopurine. Mycophenolate mofetil has largely replaced azathioprine as the antiproliferative component of triple-drug immunosuppression. Clinical features and dosing of azathioprine are listed in Box 21-11.

Mycophenolate Mofetil

Mycophenolic acid, the immunologically active metabolite of mycophenolate mofetil, potently inhibits guanine synthesis, a critical enzyme in de novo synthesis of purines, by producing reversible noncompetitive inhibition of inosine monophosphate dehydrogenase. Blockade of this pathway for de novo DNA synthesis is unique to human lymphocytes, because most human cells can also synthesize purines for DNA through an alternative salvage purine pathway. Thus, human lymphocytes are uniquely susceptible to the action of mycophenolate mofetil.

Mycophenolate mofetil has greater antiproliferative potency than cyclosporine and has a potentially favorable effect on preventing allograft vaculopathy.103 Its clinical features and dosing are summarized in Box 21-12.

Cyclophosphamide

Cyclophosphamide is an alkylating agent derived from nitrogen mustard; it interferes with DNA replication by alkylating and cross-linking DNA strands. Both B cells and T cells are affected, with greater toxicity on B cells. This feature has prompted substitution of cyclophosphamide for other antiproliferative agents (mycophenolate mofetil or azathioprine) in the presence of antidonor antibodies and recurrent rejection. Its clinical features and dosage are listed in Box 21-13.

Methotrexate

Methotrexate is primarily an antineoplastic agent that has proved effective in treating leukemia, psoriasis, and adult rheumatoid arthritis. It is an analog of folic acid and binds competitively to the enzyme dihydrofolate reductase. This folic acid antagonist inhibits purine synthesis, resulting in inhibition of lymphocyte proliferation as well as other rapidly dividing cell lines. Methotrexate has important effects on both humoral and cellular immunity,126,121,158 and has been used as an effective adjunct to standard immunosuppression for recurrent or persistent acute rejection.519,116 Clinical features and dosing are summarized in Box 21-14.

Sirolimus

Sirolimus is a natural product of the actinomycete Streptomyces hygroscopicus, first isolated from a soil sample collected on Easter Island in 1965.38,55 Sirolimus is a macrolide antibiotic with a structure similar to tacrolimus but with a different mechanism of action. It belongs to a new class of immunosuppressive agents called target of rapamycin (TOR) inhibitors. TOR is a cytoplasmic enzyme that plays a critical role in converting signals from the T-cell surface to the cell nucleus for stimulation of growth and proliferation of
**Box 21-11  Azathioprine**

**Clinical Use**
Maintenance immunosuppression usually combined with either cyclosporine or tacrolimus, with or without steroids.

**Mechanism**
Impairs lymphocyte proliferation by inhibiting purine synthesis.

**Dose**
When used with cyclosporine or tacrolimus, maximum oral dose of 2-2.5 mg·kg⁻¹·day⁻¹. Dose reduced as necessary to maintain white blood cell count above 3000·mL⁻¹.

**Target Levels**
Blood levels not monitored.

**Adverse Effects**
Myelosuppression (leukopenia most common, rarely accompanied by thrombocytopenia and/or anemia). Bone marrow suppression effects may be additive with other myelosuppressive drugs. Hepatic toxicity, pancreatitis, alopecia (uncommon). Malignancies, especially cutaneous, may be more common with chronic therapy. Concomitant use of allopurinol, an inhibitor of xanthine oxidase, may increase myelosuppression. When using allopurinol, azathioprine dose should be reduced to 25% to 33% of pre-allopurinol dose.

From Kirklin and colleagues. ⁶³⁴

**Box 21-12  Mycophenolate Mofetil**

**Clinical Use**
Chronic maintenance immunosuppression with cyclosporine or tacrolimus, with or without corticosteroids. Replaces azathioprine in chronic immunosuppression regimen.

**Mechanism**
Hydrolyzed to mycophenolic acid, the active immunosuppressive component, which inhibits inosine monophosphate dehydrogenase, thereby inhibiting de novo purine synthesis. Selective inhibitory effects on T- and B-cell proliferation.

**Dose**
Begin at 500 mg IV or twice daily PO and progressively increase to a target dose of 1500-1750 mg twice daily if tolerated (gastrointestinal symptoms).

**Target Levels**
2-5 ng·mL⁻¹.

**Adverse Effects**
Gastrointestinal: nausea, vomiting, abdominal pain, diarrhea, loss of appetite, rarely gastric ulceration, gastritis, gastrointestinal bleeding, jaundice, pancreatitis. Leukopenia (uncommon), effects may be additive with other myelosuppressive agents.

From Kirklin and colleagues. ⁶³⁴

**Box 21-13  Cyclophosphamide**

**Clinical Use**
Maintenance immunosuppressive agent; may be substituted for azathioprine if antibody-mediated rejection suspected.

**Mechanism**
Inhibits lymphocyte proliferation by interfering with DNA replication. Inhibits B-cell response.

**Dose**
When used with cyclosporine or tacrolimus, maximum dose is generally 1-1.5 mg·kg⁻¹·day⁻¹. Dose is reduced as necessary to maintain white blood cell count above 3000·mL⁻¹.

**Target Levels**
Blood levels not monitored.

**Adverse Effects**
Myelosuppression with maximal effect at approximately 7-10 days. Bone marrow suppression effects may be additive with other myelosuppressive drugs. Hemorrhagic cystitis, alopecia, gastrointestinal distress, interstitial pneumonitis (rare).

From Kirklin and colleagues. ⁶³⁴

**Box 21-14  Methotrexate**

**Clinical Use**
Maintenance immunosuppressive agent may be substituted for azathioprine or added to mycophenolate in the presence of recurrent or persistent acute rejection.

**Mechanism**
Folic acid antagonist with antiproliferative effects on lymphocyte and other rapidly dividing cell lines.

**Dose**
Adults: 1-5 mg every 8-12 hours for 3 doses per week, generally administered for 3 to 12 weeks as adjunctive therapy.

**Target Levels**
Blood levels are not monitored.

**Adverse Effects**
Major toxicity is bone marrow suppression resulting in leukopenia, anemia, and thrombocytopenia. Other myelosuppressive agents such as azathioprine should be discontinued or reduced when administering methotrexate. Close monitoring of leukocyte counts is important because fatal infection associated with profound bone marrow suppression has occurred in cardiac transplant recipients. Most common side effects include gastrointestinal distress, hepatic toxicity, nephrotoxicity, stomatitis, and hypersensitivity pneumonitis.

From Kirklin and colleagues. ⁶³⁴
lymphocytes. TOR appears to play an important role in both cellular and humoral effector functions. Like cyclosporine and tacrolimus, sirolimus is a prodrug that binds to an immunophilin to exert its immunologic effects. In contrast to cyclosporine and tacrolimus, sirolimus inhibits neither calcineurin phosphates nor production of T-cell cytokines. Instead, it inhibits cell proliferation stimulated by growth factors. The net effect is selective blockade of cytokine signal-mediated cell division and proliferation with arrest of the cell cycle in the G1 phase. Thus, sirolimus acts synergistically with cyclosporine and tacrolimus.

Sirolimus can be combined with cyclosporine or tacrolimus in place of azathioprine or mycophenolate, or it can be added as a fourth agent to control recurrent or refractory rejection. In the presence of important renal dysfunction, it may be substituted for either cyclosporine or tacrolimus and used in combination with steroids and mycophenolate, although risk of rejection is likely increased with this combination. Caution should be observed in administering sirolimus in the first few weeks after transplantation because it may importantly impair wound healing. Its clinical features and toxicity are summarized in Box 21-15.

### Box 21-15 Sirolimus

#### Clinical Use
Maintenance immunosuppression as replacement for a calcineurin inhibitor or as a fourth agent

#### Mechanism
- Inhibition of TOR
- Inhibits T-cell differentiation and proliferation
- Inhibits B-cell activation and proliferation
- Inhibits mesenchymal cell proliferation
- Preserves T-cell apoptosis

#### Dose
2-5 mg · day⁻¹ PO

#### Target Levels
Whole blood trough level of 5-15 ng · mL⁻¹

#### Adverse Effects
- Hypercholesteremia
- Elevated triglycerides
- Thrombocytopenia (dose related)
- Interference with wound healing

Common adverse effects of sirolimus include thrombocytopenia and anaphylaxis. Its clinical features and dosing of ATG are summarized in Box 21-16.

### Box 21-16 Antithymocyte Globulin

#### Clinical Use
Antirejection prophylaxis (induction therapy), steroid-resistant or recurrent rejection, rejection with hemodynamic compromise

#### Mechanism
- Polyclonal anti-T-cell antibody preparation that blocks surface receptors (inhibits TCR/antigenic peptide interaction), impairs effectiveness of antigen-presenting cells, destroys T lymphocytes

#### Dose
Specifics regarding dosage, premedications, and hypersensitivity testing vary according to specific antithymocyte preparation.

#### Monitoring
- T-cell counts below 10% of pretreatment levels, but not routinely measured in many transplant centers

#### Adverse Effects
- Thrombocytopenia, arthralgias, edema, hives, fever, chills; vary according to preparation
- Rarely major systemic reactions, including hypotension, anaphylaxis, respiratory distress, serum sickness

From Kirklin and colleagues. Key: TCR, T-cell receptor.

Viral infections, particularly cytomegalovirus. Therefore, prophylactic valganciclovir should be administered following a course of ATG therapy.

The current available commercial preparation in the United States is a rabbit ATG (thymoglobulin). The reconstituted preparation contains 5 mg of thymoglobulin, of which greater than 90% is rabbit gamma immune globulin. The standard dose of 1.5 mg · kg⁻¹ · day⁻¹ is infused through a central venous catheter over 4 to 6 hours and administered for 5 to 14 days. Clinical features and dosing of ATG are summarized in Box 21-16.

#### Monoclonal Antibodies
Monoclonal antibodies offer a potential advantage over polyclonal preparations (which lack specificity) because their specificity provides a means by which certain cell surface molecules can be targeted. The mechanism by which immunosuppression and associated side effects occur depends on the target of the antibody and isotype and species used to generate the antibody. Monoclonal antibodies are typically derived from mice or rats, but some antibodies, such as the current anti-IL2 receptor drugs, are “humanized” in that the portions of the genes that do not code for the antigen-binding regions of the mouse monoclonal antibody have been removed and replaced with portions of a human antibody molecule. This tends to decrease the allergenic side effects of the monoclonal preparation.

#### OKT3 (Anti-CD3)
The CD3 antigen is present on essentially all mature T lymphocytes and is closely linked to the antigen recognition site of the T-cell receptor. Following engagement of the T-cell receptor to an antigen outside the cell, the CD3 complex transmits an intracellular signal that initiates T-cell activation.
**Box 21-17  OKT3**

**Clinical Use**
Antirejection prophylaxis (induction therapy), steroid-resistant or recurrent rejection, rejection with hemodynamic compromise

**Mechanism**
Monoclonal anti-CD3 antibody that blocks alloantigen recognition by modulating or depleting CD3 molecules from T-cell surfaces

**Dose**
2.5-5 mg IV daily, usually for 7-14 days

**Monitoring**
Measurement of T-cell markers, with a target suppression of CD3+ cells to an absolute cell count of <10 cells · mL−1 and less than 5% of total lymphocytes

**Adverse Effects**
Cytokine release syndrome: fever, chills, headache, nausea, myalgias, mild hypertension; rarely, bronchospasm and profound hypotension
Production of antimurine antibodies
Increased susceptibility to cytomegalovirus infection and posttransplant lymphoproliferative disorder, particularly with repeat or prolonged administration

From Kirklin and colleagues.

OKT3 is a murine monoclonal antibody specific for the portion of the CD3 complex involved in transmembrane signaling following binding of an antigen-MHC complex. Because CD3 is expressed only on T cells, administration of OKT3 depletes CD3 cells from the peripheral blood in 30 to 60 minutes. Although some of the cells undergo phagocytosis with subsequent removal by the reticuloendothelial system, many T lymphocytes undergo modulation, in which shedding or capping of the CD3 complex occurs without cell death. When OKT3 is discontinued and antibody level falls below therapeutic levels, T lymphocytes can reexpress the CD3 molecule on the T-cell receptor complex within a few hours. This phenomenon of rapid reappearance of CD3+ cells soon after discontinuation of therapy (which does not occur after treatment with polyclonal ATG), coupled with clinical observations of occasional acute rejection within 1 week of ending OKT3 therapy, have prompted some programs to routinely augment steroid doses for several days after completion of OKT3 therapy.

OKT3 is used primarily as induction therapy or in treating acute or refractory rejection. Its clinical features and dosing are summarized in Box 21-17.

**Anti-CD25 (Basiliximab, Daclizumab)** The two anti-CD25 antibodies currently available, basiliximab and daclizumab, are humanized IgG1 monoclonal antibodies that bind specifically to the α chain (Tac subunit) of the high-affinity IL-2 receptor on activated T lymphocytes. They contain approximately 90% human and 10% murine antibody sequences. These antibodies compete with the cytokine IL-2 for occupancy of the IL-2 receptor. Secretion of IL-2 by an activated T cell serves to recruit other T cells by stimulation and clonal expansion of a specific T-cell population. These anti–IL-2 receptor monoclonal antibodies are designed to be used with a calcineurin blocking agent (cyclosporine or tacrolimus) to decrease the amount of IL-2 that would be available for any unblocked IL-2 receptors. Clinical features and dosing of anti-CD25 monoclonal antibodies are presented in Box 21-18.

**Box 21-18  Anti-CD25 Monoclonal Antibodies**

**Clinical Use**
Anti-rejection prophylaxis (induction therapy)

**Mechanism**
Monoclonal anti-CD25 antibody against the interleukin (IL)-2 receptor on T lymphocytes

**Dose**
Basiliximab: administer 20 mg IV following completion of cardiopulmonary bypass. A repeat dose of 20 mg IV is administered on postoperative day 4.
Daclizumab: administer 1 mg · kg−1 IV within 24 hours before transplantation and every 14 days for 4 additional doses.

**Monitoring**
None is used clinically.

**Adverse Effects**
No serious adverse reactions have been reported.

From Kirklin and colleagues.

Plasmapheresis involves removing blood from the patient, separating plasma by centrifugation or membrane filtration, and reconstituting the remaining blood to the original volume with fresh plasma or 5% albumin. In treating acute rejection, plasmapheresis has been effective in removing antibodies (antibody-mediated rejection) as well as soluble mediators potentially released during acute rejection, including IL-1, IL-6, TNF-α, and the anaphylatoxin C3a. Some of these mediators, such as TNF-α and IL-1, have a direct depressant effect on myocyte contractility, and improved ejection fraction following plasmapheresis has been observed frequently in the setting of hemodynamically compromising rejection.

The technique of plasmapheresis requires a large-bore indwelling catheter inserted into the internal jugular, subclavian, or femoral vein. Although complement-mediated reactions occasionally occur during plasmapheresis, side effects are generally mild. The potential for bleeding complications appears to be low as long as the fibrinogen level is maintained above 100 mg · dL−1.

When used clinically to treat rejection with hemodynamic compromise, plasmapheresis is generally performed for 3 successive days as long as the fibrinogen level remains above 100 mg · dL−1.

When antidonor antibodies are identified in the recipient, plasmapheresis is also used following cardiac transplantation, usually at weekly intervals until these antibodies are no longer detectable.

**Immunoabsorption**
Whereas plasmapheresis is a passive process in which immunoglobulins pass through the filtration membranes with the
Photopheresis

Photopheresis is an immunomodulatory therapy based on leukapheresis. It involves drawing blood, separating the whole blood by centrifugation, and returning the red cells and plasma to the patient. Leukocytes are treated with 8-methoxypsoralen, a photosensitizing agent, and exposed to ultraviolet light in the photoactivation chamber. These treated leukocytes are then returned to the patient (Fig. 21-11).

The mechanism of action of photopheresis has not been clearly delineated, but available evidence suggests that photopheresis induces apoptosis of leukocytes that, when reinjected into the patient, are phagocytized by dendritic cells in the circulation and in lymphoid tissue. The photoactivation process induces cross-linking of DNA, which is known to induce apoptosis of lymphocytes, monocytes, macrophages, and B cells. Recent data suggest that virtually all cells become apoptotic following extracorporeal photopheresis, even terminally differentiated and slowly proliferating or non-proliferating cells such as antigen-presenting cells. Studies of extracorporeal photopheresis in a mouse heart transplant study by George and colleagues suggest that photopheresis alters the composition of recipient T lymphocytes toward a greater preponderance of T-regulatory cells, which promote down-regulation of graft-infiltrating T cells. In the mouse model, the majority of photopheresis-treated cells are phagocytized in the spleen and liver within 24 hours. Extracorporeal photopheresis reduces the infiltration of graft-specific T cells without affecting the frequency of graft-reactive T cells in the peripheral lymph nodes. Thus, based on these studies, extracorporeal photopheresis appears to alter the composition of recipient T cells toward a greater preponderance of T-regulatory cells, down-regulating a greater proportion of graft-infiltrating T cells.

A clinical study of photopheresis indicated that among patients at high risk for rejection, risk of hemodynamically compromising (HC) rejections or rejection-related death per 100 patients-year \(^3\). The upper curve (“Pre-photo risk”) represents the hazard function for this event among high-risk patients for rejection prior to photopheresis. The next lower curve (“Post-photo risk”) represents the hazard function for this group of patients following photopheresis. The lowest curve represents risk of HC rejection or rejection death among patients at low risk for rejection. (From Kirklin and colleagues.)

removed plasma, immunoabsorption involves removing specific antibodies using columns containing immunoabsorbents that specifically bind to immunoglobulins. Some centers use immunoabsorption techniques in the presence of recipient anti-HLA class I antibodies against the donor heart. Improved ejection fraction and decrease in PRA following acute vascular rejection have been reported with this therapy.
against the allograft. The result is an increase in the proportion of natural regulatory T cells in the cardiac allograft.

**Total Lymphoid Irradiation**

Total lymphoid irradiation (TLI) is low-dose radiotherapy that targets lymphoid tissues, including the cervical, axillary, mediastinal, periaortic, and iliofemoral lymph nodes, thymus, and spleen. Nonlymphoid tissue is shielded during treatment. The exact mechanisms by which TLI induces the immune response remain unclear, but it is known that radiation induces cell death from alterations in configuration of DNA, producing chromosomal breakage, translocations, and damage to purine and pyrimidine base pairs. Both T cells and B cells are susceptible to radiation injury.

TLI therapy, usually in combination with other immunosuppressive modalities, induces an initial depression in lymphocyte count that recovers after 3 to 4 months. However, the distribution of T-cell subpopulations and their expression of surface antigens show long-term changes. Some have hypothesized that TLI induces a population of natural suppressor cells that have similarities to NK cells.

TLI dosage includes three separate fields that provide radiation to all major lymphoid-bearing areas. These areas are treated with a total target dose of 800 cGy using twice-weekly doses of 80 cGy each. Azathioprine or other myelosuppressive agents are discontinued just prior to initiation of TLI to reduce radiation-induced bone marrow suppression. The treatment schedule is adjusted according to white blood cell and platelet counts.

TLI has been used extensively for refractory or severe rejection in both cardiac and renal transplantation. Donor-specific unresponsiveness to donor antigens has been demonstrated 18 to 30 months following renal transplantation with pretransplant TLI and ATG. TLI therapy has been effective in decreasing rejection frequency in adults and children following cardiac transplantation.

The most common toxicity includes leukopenia and thrombocytopenia, which are usually reversible with temporary cessation of therapy. An unknown long-term risk of malignancy may exist. A specific risk of fatal acute megakaryocytic leukemia was noted in one large series of patients treated with TLI after cardiac transplantation, with actuarial prevalence of 9% at 5 years.

**RESULTS**

**Rejection**

**Mechanisms**

Cardiac allograft rejection represents the histologic and clinical result of the immunologic response (see “Immunologic Basis of Heart Transplantation” earlier in this section) to cardiac transplantation. Potential target cells within the heart include, among others, myocytes and endothelial cells of the coronary vasculature. Donor peptide antigens provide the stimulus for the recipient alloimmune response through their presentation by donor antigen-presenting cells (donor vascular endothelial cells and so-called passenger leukocytes) and recipient antigen-presenting cells. Multiple redundant immunologic pathways exist for activation of the immune response and subsequent attack on the donor organ. The presentation of donor antigens (by antigen-presenting cells) to the appropriate recipient T cells leads to T-cell activation and clonal proliferation in the presence of appropriate co-stimulatory molecules. The vascular endothelium participates directly in the rejection process by recruiting immune cells to the allograft. Up-regulation (increased concentration on the cell surface) of endothelial molecules induces circulating activated lymphocytes to stick to the endothelial surface and migrate into the interstitial spaces of the allograft. Activated T cells generate and release cytokines, which together with up-regulation of T-cell surface receptors induces proliferation of immune cells and recruitment of macrophages. If unabated by immunosuppressive agents, these events result in release of powerful biological effectors of myocyte injury and necrosis, recognizable by histologic examination.

Success of cardiac transplantation (and organ transplantation in general) is based on the premise that immunosuppressive modalities can effectively suppress those aspects of the immune system that, when stimulated by donor HLA antigens, ultimately lead to destruction of the donor heart. The process of controlling and potentially preventing otherwise fatal allograft rejection to promote long-term survival and function of the transplanted heart involves initial immunosuppression, chronic maintenance immunosuppression, and augmentation or adjustment of immunosuppression during episodes of identified acute rejection. Because immunosuppressive agents have considerable toxicity, long-term patient survival requires a combination of immunosuppressive agents that act in concert or even synergistically against those aspects of the immune system that threaten the allograft, while minimizing their toxic effects on the overall immune system (which would set the stage for infections and malignancies) in other organ systems.

The difficulty of this task is confounded by considerable variability among patients with respect to the intensity of their immune response against the allograft and their susceptibility to immunosuppression-related morbidity.

Despite the current profound understanding of the immune response to transplantation and the myriad drugs available for targeted immunosuppression, many details of the precise inciting factors for acute rejection remain enigmatic. Patients can experience long periods (sometimes years) of apparent immunounresponsive (clinical and histologic absence of rejection criteria), only to suddenly experience a vigorous and potentially fatal immunologic attack, with no known precipitating event. The tendency for patients to display overt evidence of rejection only episodically is incompletely understood, but extensive clinical experience supported by surveillance endomyocardial biopsies indicates that the rejection process occurs in “waves” of heightened immunologic activity within the allograft. Although infectious agents (particularly viral) and possibly stress have been implicated at times, an inciting stimulus is usually never identified.

**Pathology of Allograft Rejection**

The technique of endomyocardial biopsy, based on techniques first described by Caves histologic examination of myocardial tissue, has provided the gold standard for diagnosing rejection since 1972. The histologic grading system for rejection initially developed by Billinghan at Stanford was further refined in 1990 by the International Society of Heart and Lung Transplantation (ISHLT), most recently in 2005 (Table 21-7). Rejection grades are based mainly on amount of inflammatory infiltrate and presence of myocyte damage (see Table 21-7). The major histologic...
categories of acute rejection are cellular, humoral, and hyperacute rejection.

**Acute Cellular Rejection** Histologically, acute cellular rejection is a mononuclear inflammatory response, predominantly lymphocytic, directed against the cardiac allograft. Usually both ventricles are equally involved, and thus sampling of the right ventricular septum is usually representative of histologic changes occurring elsewhere in the heart. The key identifying histologic feature of cellular rejection of sufficient severity (moderate) to warrant augmentation of immunosuppression is the presence of myocyte damage.

**Humoral (Microvascular) Rejection** In heart transplantation, humoral rejection refers to rejection resulting from immunoglobin (antibody) directed against donor antigens located on the endothelial surface of the allograft coronary microvasculature. Immunoglobin and complement are localized in the microvasculature of the transplanted heart—arterioles, capillaries, and venules. The resulting inflammatory process with neutrophils and macrophages involves the vessel wall. These inflammatory changes can be seen on endomyocardial biopsy. The hallmarks of microvascular rejection are endothelial cell activation, increased vascular permeability, and in severe forms, microvascular thrombosis and myocardial cell degeneration. Immunofluorescence studies are currently the primary modality for identifying fibrinogen, IgG, IgM, and complement components in the endomyocardial biopsy, which indicates humoral rejection. Histologic and immunofluorescence criteria for identifying humoral rejection are summarized in Table 21-8. However, it should be noted that the reproducibility of these studies is considerably less than the standard histologic methodology for identifying acute cellular rejection.

**Hyperacute Rejection** Hyperacute rejection (currently rarely observed) consists of a violent lethal immunologic attack on the allograft triggered by preformed antibodies against HLA epitopes in the donor heart or antibodies against the ABO system (in the event of inadvertent transplantation across a major blood group incompatibility). Rarely, hyperacute rejection may result from antienothelial antibodies. Activation of the complement cascade produces severe endothelial cell damage, platelet activation, initiation of the clotting cascade, and widespread microvascular thrombosis, all of which leads uniformly to graft loss. The process begins within minutes of graft reperfusion in the operating room. With current techniques of identifying preformed anti-HLA antibodies and crossmatching, hyperacute rejection is rarely observed.

**Other Diagnostic Modalities**
Although electrocardiographic analysis, cytoimmunologic monitoring, and a variety of radionuclide techniques have been investigated, echocardiography is the primary modality (other than endomyocardial biopsy) routinely used for rejection surveillance.

The most important application of echocardiography is identifying systolic dysfunction. Even though left ventricular rejection remains within normal limits during 95% of histologic rejection episodes, acute rejection is overwhelmingly the major cause of acute reduction in systolic function of the transplanted heart after initial recovery from transplantation. Other causes include advanced allograft vasculopathy, nonspecific unexplained graft failure without rejection or vasculopathy, and rarely infection. When acute depression of systolic function (ejection fraction < 50%) is observed without another clearly identified cause, acute cellular or humoral rejection should be assumed to be present and appropriately treated, with or without confirmation from endomyocardial biopsy.

**Temporal Pattern and Risk Factors for Rejection**
Although allograft rejection is the major biological phenomenon that limits long-term survival after cardiac...

transplantation, an understanding of the temporal pattern and risk factors for rejection is handicapped by the time of onset and resolution as well as the actual presence of rejection. Although endomyocardial biopsy is the gold standard for identifying rejection, it only allows intermittent sampling rather than continuous surveillance. The potential for sampling error, the reality of rejection episodes that spontaneously resolve and are never identified histologically, and the general practice of decreasing the frequency of endomyocardial biopsies after the first year complicate our understanding of this event. For practical purposes, most clinicians and investigators define a rejection episode as a clinical event that is usually, but not always, accompanied by an abnormal myocardial biopsy and results in acute and temporary augmentation of a patient’s immunosuppression.

The frequency of rejection episodes tends to decrease with increasing time from transplantation, related in part to the acquired state of partial unresponsiveness achieved with current maintenance immunosuppression. Approximately two thirds of patients have one or more identified rejection episodes within the first year (Fig. 21-13). The hazard function (instantaneous risk) for initial rejection peaks at 1 to 2 months, then rapidly decreases thereafter, merging with a low constant risk of rejection after about 1 year.

Of greater concern are those patients who suffer recurring rejection, with the need for repeated augmentation of immunosuppression, possibility of hemodynamic compromise secondary to graft dysfunction, increased risk of infection, and potential contribution to allograft vasculopathy. Risk factors for earlier initial rejection and for increased cumulative rejection during the first year are listed in Tables 21-9 and 21-10. Risk factors for recurrent rejection during the first posttransplant year are listed in Table 21-11.

High-Risk Forms of Rejection

The highest-risk form of rejection is hyperacute rejection, discussed in the preceding text. Certain other forms of acute rejection are associated with risk of graft loss and death. These forms may be primarily cellular or humoral, with considerable overlap because they are categorized by the method of identifying rejection (Box 21-19).

When vasculitis (transmural anterior wall infiltration of lymphocytes and monocytes with or without neutrophils) is identified on endomyocardial biopsy, or when there is evidence of humoral rejection by immunofluorescence studies, an increase in subsequent mortality has been identified, with 1-year mortality exceeding 30% in some studies. Similarly, when aggressive histologic grades of cellular rejection (Grade 3B or 4) are identified on endomyocardial biopsy, the likelihood for progression to hemodynamic compromise and graft loss is high without prompt aggressive immunosuppressive intervention.

Figure 21-14 Mortality after rejection with hemodynamic compromise. Upper curves represent actuarial survival after rejection associated with severe hemodynamic compromise, stratified according to biopsy score at beginning of rejection. “Low score” includes biopsy scores of 2 or less and “High score” biopsy scores of 3A or higher. Lower two curves represent hazard function for death after onset of rejection, stratified by biopsy score. Dashed lines enclose 70% confidence limits. Key: CTRD, Cardiac Transplant Research Database. (From Mills and colleagues.11)

Approximately 5% of rejection episodes are accompanied by hemodynamic compromise, as evidenced by clinical signs of low cardiac output, decreased ejection fraction on echocardiography, or decreased cardiac output. When inotropic agents are required to support the circulation, this serious form of rejection can be rapidly fatal if not promptly reversed. Although the mechanism of depressed systolic function is unclear, experimental studies indicate that IL-1, IL-2, and TNF may contribute.11,12,13,31 When hemodynamic compromise is associated with acute cellular rejection histology, mortality from rejection within the subsequent 2 years is about 20%. Prognosis is particularly ominous when clinical rejection with hemodynamic compromise is associated with absence of cellular rejection on biopsy, because it indicates a higher likelihood of humoral rejection. Such patients have a risk of death exceeding 50% within 2 years (Fig. 21-14).11,12,13,31

In the presence of circulating antidonor HLA antibodies, the probability increases that acute rejection will involve humoral components,11 which increases risk of subsequent rejection-related death or graft loss.11

Identifying a Rejection Episode

A major part of care after cardiac transplantation is directed toward identifying rejection. Endomyocardial biopsy remains the most important method of identification and, along with echocardiographic evaluation, is generally performed every 7 days for the first 4 to 6 postoperative weeks. Thereafter, biopsy frequency is gradually reduced to every 3 to 4 months. However, physicians caring for these patients must be aware that subtle symptoms may be the only clue to the beginning of a rejection episode. These include unexplained fever, joint pain, personality change, and any symptom that can result from cardiac failure. These are an indication for emergency endomyocardial biopsy and immediate institution of therapy if results are positive.

Treatment of Acute Rejection

When a rejection episode is identified during the first postoperative month, particularly when accompanied by any hemodynamic deterioration, treatment includes hospitalization. Otherwise, treatment can be accomplished on an outpatient basis with close surveillance.11 Decision about an inpatient or outpatient setting for treatment and the details of the treatment itself need to be made by experienced transplant physicians.

Augmenting steroid therapy is the mainstay of treating an acute rejection episode (see “Immunosuppressive Therapy” in text that follows). When the patient is treated as an outpatient, the daily prednisone dosage is increased to 100 mg in adults for 5 days. Generally, the dose is then reduced by 10 mg · day−1 until the previous maintenance dose is reached.

When treatment is given in the hospital, methylprednisolone is administered IV (usually into a peripheral vein) for 3 days in a dose of 1000 mg · day−1 (or 15 mg · kg−1 if the patient weighs < 50 kg). This is followed by prednisone 100 mg by mouth (PO) for 2 days, which is reduced thereafter by 10 mg daily until the prior maintenance dose is reached.

If the rejection episode is unresponsive, recurrent early after transplantation, or associated with high-risk features, ATG for 5 to 7 days may be added. Other measures that may be used for an unremitting episode include changing from azathioprine to mycophenolate mofetil, changing from cyclosporine to tacrolimus, treating with pulse steroids without a taper, methotrexate, plasmapheresis, photopheresis, and even total lymphoid irradiation. Decisions regarding treatment modality depend on histologic grade of biopsy, left ventricular dysfunction, time since transplantation, and prior modalities used.

When the rejection episode is believed to have been resolved, another endomyocardial biopsy is obtained. If only mild rejection is present, the episode is considered to have resolved, but this is confirmed by frequent biopsies over the next 3 months.

When the hemodynamic state becomes unstable and the rejection episode is severe and unremitting, maximal treatment must be directed toward the immunosuppressive modalities described earlier while simultaneously supporting the circulation with inotropic agents. A general therapeutic strategy for rejection with hemodynamic compromise is outlined in Box 21-20. When treating recurrent or severe rejection with augmented immunosuppression, the increased risk of infection and of tumor formation, particularly lymphomas, must be appreciated and surveillance methods heightened.

Infection

The Immunocompromised Host

The requirement for long-term immunosuppressive therapy and the resultant immunocompromised host predispose
Box 21-20 Therapeutic Strategy for Rejection with Hemodynamic Compromise

- Always consider this a life-threatening event.
- Methylprednisolone 1 g IV and daily for 3 days.
- Prompt inotropic support (preferably with dopamine, milrinone, or dobutamine, depending on blood pressure and heart rate) to maintain effective cardiac output.
- If cardiac output is clinically depressed and/or there is more than mild decrease in ejection fraction (<35%), place Swan-Ganz catheter for hemodynamic monitoring.
- Prompt plasmapheresis (patients > 15 kg) and daily for 3 days.
- Cytolytic therapy with thymoglobulin or OKT3.
- Heparinize.
- Continue maintenance immunosuppression.
- Schedule photopheresis.

From Kirklin and colleagues.

Risk Factors, Prevalence, and Evaluation

Approximately 40% of recipients suffer one or more infections requiring IV antibiotics, hospitalization, or both during the first year after transplantation. In the current era, most infections are successfully treated, with an overall mortality from infection of less than 5% during the first year. Risk factors for developing posttransplant infection are listed in Table 21-12.

Data from Smart and colleagues. Key: CTRD, Cardiac Transplant Research Database; VAD, ventricular assist device.

Figure 21-15 Hazard function (instantaneous risk over time) for first infection of each major category of infectious agent. Key: TCRD, Transplant Cardiologists Research Database. (From Miller and colleagues.)

Heart transplant recipients to unusual organisms that may induce aggressive and sometimes fatal infections. A broad range of organisms may be involved, including the usual pathogens, organisms that are not usually a cause of infection except in immunocompromised hosts, and endogenous and donor-transmitted organisms. A proactive policy to detect infection is necessary because of the frequent blunting of usual infection signs and symptoms secondary to blunting of the normal inflammatory response by immunosuppressive medications. Infectious complications are closely linked to other posttransplant adverse events, such as malignancy (Epstein-Barr virus), allograft vasculopathy (cytomegalovirus), and acute rejection.

Risk Factors, Prevalence, and Evaluation

Approximately 40% of recipients suffer one or more infections requiring IV antibiotics, hospitalization, or both during the first year after transplantation. In the current era, most infections are successfully treated, with an overall mortality from infection of less than 5% during the first year. Risk factors for developing posttransplant infection are listed in Table 21-12. In the current era, most infections are successfully treated, with an overall mortality from infection of less than 5% during the first year. Risk factors for developing posttransplant infection are listed in Table 21-12. The time course differs for various categories of infectious agents, with bacterial infections predominating during the first month and viral infections predominating thereafter (Fig. 21-15). Bacterial and viral infection each account for about 40% of infections during the first year, whereas about only 5% are fungal or protozoal. The periods of greatest risk for bacterial, viral, protozoal, and fungal infections have particular relevance in terms of diagnostic procedures and expectant therapy. Because of the tendency for febrile responses to be attenuated in the early phase of infectious diseases by corticosteroids (frequently part of maintenance immunosuppression), even low-grade fevers should precipitate thorough investigation for infectious etiologies.

Lung and urinary tract are the most common sites of infection during the first year, accounting for about 35% and 25% of infections, respectively. Despite the prevalence of certain disease types or locations, unusual organisms, locations, and modes of presentation must always be considered in the immunocompromised patient. Initial investigation should include a careful and thorough history and physical examination, chest radiogram, complete blood cell count, and bacterial, viral, and fungal blood cultures. Other cultures should be directed by the initial evaluation. Any new or worsening pulmonary infiltrate should prompt early bronchoscopy with bronchoalveolar lavage and transbronchial biopsy. Pneumocystis carinii and cytomegalovirus are the most common nonbacterial pathogens detected on bronchoalveolar lavage. If biopsy and lavage do not produce a likely etiologic organism, open lung biopsy should be considered. Fever during the first posttransplant month should also prompt thorough evaluation of the sternotomy wound, including computed tomographic scanning. The risk of sternal infection is increased with use of a ventricular assist device as bridge-to-transplant therapy.
Bacterial Infections

The most common bacterial infections in the early postoperative period are pneumonias, indwelling IV line infections, and (less commonly) wound infections. Patients requiring ventilator support immediately before transplantation are at high risk for posttransplant pneumonia. Central venous catheters should be removed within the first 5 days posttransplantation when feasible, because bacteremia is common with prolonged indwelling central catheters. Sternal wound infections account for about 5% of serious early infections, and the risk of mortality associated with mediastinal infection approaches 20%. Early, aggressive sternal debridement and pectoralis muscle coverage play a critical role in controlling infection, enabling early mobility and reducing mortality.

Viral Infections

Cytomegalovirus (CMV) is the predominant viral pathogen causing disease in the first 3 months after cardiac transplantation. Prevalence of a positive CMV serology ranges from 40% to 80% in transplant recipients prior to transplantation. Risk factors for development of posttransplant CMV infection include use of a heart from a donor positive for CMV serology when transplanted into a CMV-negative recipient, and use of induction therapy with monoclonal antibodies or ATG. Risk of CMV transmission is reduced by using leukocyte filters when transfusing blood and by using prophylactic valganciclovir for the first several months after transplantation.

CMV infection can affect multiple organs, resulting in many clinical presentations, including a symptomatic rise in antibody titer, a systemic febrile illness with malaise and lethargy, identification of CMV antigenemia in an asymptomatic patient, or localized disease in a specific organ. The most common site for localized disease is the lung (usually with pulmonary infiltrate, shortness of breath, and hypoxemia), followed by the gastrointestinal tract (fever, diarrhea, ulceration, and occasionally major gastrointestinal bleeding). Hepatic involvement is manifest as hepatitis. Ophthalmic involvement may result in chorioretinitis with possible subsequent blindness. CMV infection is associated with accelerated rates of allograft vasculopathy and rejection. Any CMV infection should be considered life threatening and requires specific aggressive therapy. The therapy of choice for preserving renal function and reducing bone marrow suppression is valganciclovir.

Epstein-Barr virus (EBV) is discussed later in this section under “Malignancy.”

Parvovirus infection requires special mention because of its association with bone marrow depression and development of pancytopenia in children. Parvovirus may result in fifth disease, with a typical blotchy maculopapular rash and mild systemic symptoms. The diagnosis may be confirmed by use of polymerase chain reaction studies of the parvovirus gene in circulating lymphocytes or bone marrow tissue. Treatment with hyperimmune globulin is usually effective.

Fungal Infections

Opportunistic fungal infections account for a small percentage of infections, but invasive fungal infection carries a mortality of 30% or more. Although there is an early posttransplant peak of risk (see Fig. 21-15), invasive fungal infection can occur at any time following transplantation. Its development usually results from breakdown of specific and nonspecific host defenses, such as breaching of skin and mucosal barriers, immunosuppression with impairment of nonspecific defenses (phagocytic cells), disruption of humoral and cellular immunity, and fungal overgrowth in the presence of prolonged broad-spectrum antibiotic administration. The most frequently occurring fungal infections are due to Candida, Aspergillus, Pneumocystis jirovecii (carinii), and Cryptococcus neoformans. Candida is more commonly involved in sternal wound or bloodstream infections from breakdown of mucosal barriers. Aspergillus infections are primarily pulmonary, and cryptococcal infections involve the CNS (but can be disseminated). P. jirovecii is an organism of low virulence in non-immunocompromised patients, found in the lungs of humans and a variety of animals. The taxonomy of P. jirovecii has been controversial, but it is currently grouped with fungi rather than protozoa. It remains unclear whether patients with pneumocystic pneumonia represent primary or reactivation infections, because no reliable skin test or serology assay is available. Therefore, continuous prophylaxis may be indicated for patients with prior pneumocystic infection. Patients typically present with worsening diffuse pulmonary infiltrates, progressive hypoxemia, and marked dyspnea. Silver stains of pathologic specimens from bronchoalveolar lavage are diagnostic. The preferred therapy is high-dose trimethoprim/sulfamethoxazole for 4 to 6 weeks. Pulmonary support with mechanical ventilation may be required, and renal function must be closely observed during treatment. A CMV infection commonly occurs with Pneumocystis pneumonia, and therefore empirical therapy is warranted while results of CMV stains of pathologic specimens and CMV cultures are pending.

Protozoal Infections

Although protozoal infections can occur in any immunocompromised patient, toxoplasmosis is of specific importance in heart transplantation, because it most often occurs as a donor-transmitted disease when a seronegative recipient receives an infected organ. Disease onset occurs 4 to 8 weeks after transplantation and may be manifested as myocarditis, fever, pneumonitis, or (rarely) encephalitis. Therapy of choice includes pyrimethamine and sulfadiazine. Untreated symptomatic toxoplasmosis in cardiac transplant recipients is usually fatal.

Infection Prophylaxis

Antimicrobial prophylaxis after heart transplantation is an integral part of infection prevention, and the benefit has clearly outweighed the disadvantages (toxicity and antimicrobial resistance). A recommended antimicrobial prophylaxis for heart and heart lung transplantation is outlined in Table 21-13.

Prevention of infection by active immunization is recommended for specific conditions, using killed vaccine only.

Malignancy

Neoplastic disorders after cardiac transplantation arise from three major causes: preexisting malignancies, transmission of malignancy from donor to recipient, and de novo malignancy arising after transplantation. As noted in Box 21-6, preexisting malignancy is a relative contraindication to cardiac transplantation unless there is a prolonged malignancy-free interval and strong clinical evidence of cure.
However, incomplete information is available to clearly predict the likelihood of recurrence of a preexisting malignancy based on malignancy-free interval and type of malignancy. In a compilation of nearly 150 heart and heart-lung transplant recipients with preexisting malignancies treated an average of 7 years prior to transplantation, persistence or recurrence of the malignancy occurred in nearly 20%. The incidence of de novo recipient malignancy is approximately 100 times that of the non–age-controlled general population.

The prevalence and risk (hazard function) for various malignancies related to the interval following transplantation is depicted in Fig. 21-16. Less than 5% of patients develop malignancy during the first year after cardiac transplantation, with the vast majority being either lymphomas (one third) or skin neoplasms (one third). However, in the setting of chronic immunosuppression, risk of fatal malignancy gradually increases over subsequent years (Fig. 21-17).

Posttransplant lymphoproliferative disorder (PTLD) requires separate discussion because of its unique relationship to organ transplantation. PTLD is believed to originate from EBV infection of the recipient’s B lymphocytes, through blood transfusions or community contacts, or through replication of latent EBV in a recipient in the presence of chronic immunosuppression. The abnormal EBV-specific susceptibility induced by immunosuppression allows the increased burden of EBV to infect recipient B cells and induce their transformation into expanding B-cell clones, which can become neoplastic.

A number of risk factors have been identified for development of PTLD (Box 21-21). Among heart transplant recipients, risk of a pretransplant EBV-seronegative patient developing PTLD is 25 to 30 times greater than in patients who are seropositive prior to transplantation. Of particular importance is the increased risk of PTLD that has been documented with prolonged use of cytolytic therapy such as OKT3 and (likely) antithymocyte globulin. Although unproven, it has been hypothesized that OKT3 results in generation of inflammatory cytokines such as TNF, which may promote EBV transcription and reactivation from a latent state.

Various histologic classifications of lesions in PTLD have been published and include a disease spectrum ranging from plasmacytic hypoplasia (preservation of lymph node architecture and usually a benign course) at one end to monoclonal non-Hodgkin lymphoma, with clearly malignant

### Figure 21-16  Malignancy after heart transplantation for various malignancies. Upper curves represent parametric estimates of freedom from malignancies; lower curves are corresponding hazard functions. Key: CTRD, Cardiac Transplant Research Database; PTLD, posttransplant lymphoproliferative disorder. (From DeSalvo and colleagues.)
implications, at the other. Diagnosis of PTLD requires tissue biopsy, with sufficient tissue to allow assessment of cell type, clonality, biological studies, and architectural background. Clinical presentation of PTLD is widely variable, ranging from an infectious mononucleosis–like illness to specific symptoms related to the organ system involved. Symptomatic lymphadenopathy is a common presentation. PTLD involving the gastrointestinal tract may result in necrosis, bleeding, proliferation, and obstruction. CNS involvement can be either a localized disease or a result of dissemination of systemic PTLD. Pulmonary involvement frequently manifests as multiple nodules.

Optimal treatment of PTLD remains controversial because of absence of consensus in defining the pathology, a clear relationship between morphologic features and clinical course, large treatment trials, and relatively small numbers at any one institution. The basic options for treatment include (1) reduction of immunosuppression, (2) surgical extirpation, (3) chemotherapy, (4) antivirals, (5) anti–B-cell antibodies, and (6) cell-based therapies. The cornerstone of primary therapy involves reducing immunosuppression, with close subsequent monitoring of allograft function and frequent surveillance endomyocardial biopsy for rejection. Isolated disease amenable to surgery should be treated with extirpation. Disseminated disease usually requires additional chemotherapy or anti–B-cell monoclonal antibody administration.

Expected survival after diagnosis of PTLD is highly variable, depending on interval after transplantation, morphologic features, and anatomic location(s). It ranges from approximately 45% to 80% at 2 years. Multivisceral disease, late PTLD, and CNS involvement are associated with worse outcome.

### Survival

Survival at 1 year has gradually improved over the past several decades and currently approaches 85% (Fig. 21-18). Risk of death is greatest during the first 3 months after operation. After 1 year, there is a constant mortality of about 4% per year. Survival at 5 years is approximately 70%, at 10 years 50%, and at 15 years 30%. Median survival is 10 years. For patients alive at 1 year, median survival is 13 years. Survival after retransplantation is discussed under “Cardiac Retransplantation” later in this section.

The most dramatic improvement in survival after heart transplantation over the past 25 years has been during the first 3 to 6 months (see Fig. 21-18). Despite the obvious importance of long-term survival to patients and their families, survival at 1 year has been a benchmark for comparison of institutions as well as eras.

### Modes of Death

Mode of death during the first year and thereafter differ considerably and therefore merit separate discussion. During the first 12 months after transplant, early graft failure, rejection, and infection account for more than 60% of deaths. This is reflected in the hazard functions for specific modes of death during the first 3 months (Fig. 21-19) and cumulative mode-specific mortality during the same period (Fig. 21-20). After the first year, infection and rejection account for less than 25% of primary causes of death, and allograft coronary disease and malignancy for nearly 50% (Figs. 21-21 and 21-22).

### Risk Factors for Death

#### General Risk Factors

Among adult transplant recipients, multiple conditions or factors have been identified that are associated with increased risk of mortality during the first posttransplant year (Table 21-14). Temporary circulatory support is a major risk factor, producing a threefold increase in early mortality. In contrast, the incremental risk associated with long-term pulsatile left ventricular assist device use was
a clear overall risk factor for premature death after cardiac transplantation. Survival after cardiac transplantation is highest among patients with a negative flow cytometry cross-match to both HLA class I (T- and B-cell) antigens and HLA class II (B-cell) antigens (Fig. 21-23). Risk of death appears to be less when the blood type of the recipient and donor is identical, but the effect is a weak one. There is evidence that donor and recipient gender do not affect outcomes, but when there is donor-recipient size mismatch (e.g., smaller female donor into larger male recipient), 1-year survival may be adversely affected. Improvement in survival that occurred when triple-drug immunosuppression began (=1983) supports the idea that the immunologic response is a dominant determinant of outcomes.

In reviewing this list of risk factors, it is important to note that some powerful risk factors not identified in large multivariable analyses are apparent in other studies. Further details about additional risk factors are included in text that follows.

Histocompatibility and Other Patient-Donor Interactions Basic immunologic incompatibility between humans is statistically significant, but clinically of small importance. When survival was adjusted for covariables, an analysis of patients undergoing transplantation from 2002 through 2006 predicted only a 1.3-fold increase in 1-year mortality with pretransplant support using a long-term durable device. Cardiac retransplantation is a major risk factor (see later text in this section), but few such operations are performed.

Figure 21-22 Competing outcomes analysis of specific modes of death during the first 10 years after transplantation in the Cardiac Transplant Research Database (CTRD), 1990 to 1999 (n = 7283). (From Costanzo and colleagues.)
Recipient Age  Patient age has been a risk factor for death after cardiac transplantation, particularly at very young age and advanced age. An age of 1 to 60 years is a weak determinant of survival.

High Pulmonary Vascular Resistance  High Rp has also been a risk factor for death, usually early after transplantation. The nature of the relationship between elevated Rp (or increasing transpulmonary gradient) and mortality risk is a continuous one, with progressive increase in risk as Rp rises. Preoperative response of Rp to vasodilator therapy has additional predictive value (For details of Rp, see “Evaluation of Comorbid Conditions” earlier in this section.)

Preoperative Status of the Patient  Patients whose cardiac output is importantly depressed before operation are at increased risk of death after transplantation. When organ dysfunction is substantial and does not recover from the effects of the low cardiac output state sufficiently rapidly after transplantation, mortality is markedly increased. The kidney is particularly vulnerable to even brief periods of low cardiac output.

The lung also appears to recover slowly from preoperative damage. Being on a ventilator up to the time of transplantation is a risk factor for death after transplantation.

When inotropes or mechanical circulatory assistance before transplantation bring the patient to operation in a reasonably good hemodynamic state, survival is similar to that of other cardiac transplant recipients. Nevertheless, having a left ventricular assist device implanted before cardiac transplantation raises the risk of death during the first year by about 25% (P = .02).

Global Myocardial Ischemic Time (Donor Heart)  With current techniques of donor heart preservation, global myocardial ischemic time does not become an important risk factor until it exceeds about 240 minutes. Risk of death is increased considerably with ischemic times of 5 to 6 hours. Speculatively, the explanation for the much longer safe ischemic time in the setting of cardiac transplantation than in reoperative cardiac surgery may be the uniformly cold temperature of the globally ischemic donor heart and possibly its complete lack of collateral circulation.

Current information suggests that the safe global myocardial ischemic time for donor hearts is considerably prolonged by preparing and storing the heart in UW solution, which has an ionic concentration similar to intracellular fluid and contains antioxidants and high-molecular-weight molecules. Use of this solution for both cardioplegia and cold storage appears to result in maintenance of high levels of high-energy phosphates and decreased lactate production. Strategies for the initial phase of reperfusion may further increase safe ischemic time of donor hearts (see “Cold Cardioplegia, Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3.)

Era  The risk of cardiac transplantation decreased during the 1980s following introduction of cyclosporine and adoption of protocols that included triple-drug therapy. Further improvement in early and late survival after cardiac transplantation and has been attributed to more precise immunosuppression agents and regimens, less severe graft coronary disease, statin drugs, and better understanding of infection complications, with greater choice of antibiotic and antiviral agents.
Coronary artery disease begins to develop early after the recipient receives the transplanted heart; virtually all patients who survive more than 1 year have some histopathologic evidence of coronary artery disease. The first step in the process appears to be concentric intimal thickening from myofibroblast proliferation and fibrosis. Within 1 to 2 years, aggregates of lipid-filled cells accumulate within the intima, and well-formed lipid cores consisting of cholesterol clefts and free-lying lipid debris (atherosclerotic plaques) can be seen. These atherosclerotic lesions are indistinguishable from those of spontaneous arteriosclerosis. Coronary vasodilator reserve is well preserved as long as the diffuse coronary artery disease has no areas of narrowing greater than about 30%. This may explain occasional occurrence of sudden death in cardiac transplant patients who have had good exercise capacity until the fatal event. However, during rejection episodes, coronary vasodilator reserve is severely impaired. Speculatively, the resulting myocardial ischemia may play a major role in producing myocardial changes and symptoms during rejection episodes. The reduction appears to be reversible in most instances.

Pathogenesis of these important lesions is uncertain, but the etiologic factors likely include a major immunologic component as well as nonimmunologic factors. The frequency with which lymphocytes are seen within the intima and adventitia of the coronary arteries of transplanted hearts supports an immunologic component. Also, patients who produce anti-HLA antibodies after cardiac transplantation have reduced survival and a greater prevalence of coronary artery disease than those who do not. A strong tendency to arteriosclerosis in the patient, as evidenced by important coronary artery disease in the native heart, may be a risk factor for this problem, as may hyperlipidemia and hypertension. Vascular endothelial damage in the cardiac allograft, perhaps beginning as early as the time of donor brain death, may set up an inflammatory response that primes the endothelium for cumulative injury during the subsequent stages of ischemic cold storage.

### Allograft Coronary Artery Disease

Accelerated coronary artery disease is the third most common cause of death after cardiac transplantation, following only infection and acute rejection. Furthermore, about 60% of retransplantation procedures are performed because of advanced coronary artery disease. Most patients with this disease fail to experience typical angina, which may be related to the likelihood that the cardiac allograft remains denervated permanently (see “Cardiac Function” later in this section). Life-threatening ventricular arrhythmias, heart failure from myocardial ischemia, silent myocardial infarction, and sudden death are usually the first signs of progression to advanced coronary artery disease in a transplanted heart.
reperfusion, and allorecognition in the recipient. Methods developed to protect cardiomyocyte function may be deleterious to vascular endothelium. Hyperkalemic (>30 mEq·L\(^{-1}\)) cardioplegic solutions exert a variable degree of injury to endothelium depending on the cation concentration and time of exposure. No preservation solution has proven to be superior (including UW), calling attention to the need for improved endothelium-protective agents. A summary of clinical risk factors are summarized in Table 21-17. Potential nonimmunologic risk factors are summarized in Box 21-22.

Two different types of lesions develop, both of which can be recognized cineangiographically. Type A lesions are discrete stenoses of the proximal and middle thirds of epicardial arteries, usually the result of arteriosclerotic plaques; about one third are complicated by luminal thrombi. Type B lesions are predominantly in the distal one third of the course of coronary arteries, forming long tubular constrictions. They appear to be the result of concentric fibrous intimal thickening and infrequently are associated with thrombi. It is this aspect of accelerated coronary artery disease that is most prevalent and most insidious. Small vessels of the coronary tree, 100 µm or less, are usually not involved. By angiographic assessment, the incidence of allograft coronary artery disease has been estimated at 10% to 15% per year, with a prevalence of about 50% by 5 years after transplantation. Freedom from mild, moderate, and severe coronary artery disease over 5 years in a large cohort of patients in the 1990s is depicted in Fig. 21-25. From Kirklin and colleagues.

Coronary artery disease in the transplanted heart has decreased over time, even though more than 70% of patients remain on adrenocorticosteroids 4 years after transplantation. This is attributed in part to a decrease in incidence of rejection and death resulting from rejection. Graft coronary artery disease appears to be reduced by better immunosuppression regimens. It has also been suggested

From Kirklin and colleagues.
that coronary artery disease may have been stabilized or retarded by use of diltiazem, other medications to control hypertension (which occurs in 67% by 1 year), and lipiddowering agents for control of hyperlipidemia (which occurs in 39% by 1 year and 41% by 4 years).33

Percutaneous coronary intervention (PCI) is often used as a palliative intervention, with midterm results similar to those of the nontransplant population for more proximal and discrete lesions. Multiple PCI procedures are often necessary as the disease progresses, and atherectomy and intracoronary stents are increasingly applied to allograft vasculopathy.18,54

Coronary artery bypass grafting has a limited role, except with left main or isolated proximal left anterior descending artery stenosis. With diffuse and severe coronary involvement, retransplantation is the best option to prolong survival (see “Retransplantation” later in this section).

Other Complications

Renal Dysfunction

Renal dysfunction following cardiac transplantation has two distinct manifestations: acute posttransplant renal failure and chronic renal dysfunction. Acute renal failure generally occurs in the setting of reduced renal reserves before transplant (generally associated with a glomerular filtration rate < 50 mL·min⁻¹ in the adult) with superimposed early graft dysfunction or introduction of posttransplant calcineurin inhibition with either cyclosporine or tacrolimus. Initial administration of cyclosporine or tacrolimus can induce a rapid and intense vasoconstriction of preglomerular afferent arterioles, which is likely mediated by an increase in sympathetic tone, activation of the renin-angiotensin system, decreased production of vasodilator molecules, and increased production of vasoconstrictor molecules.1,36

Initial vasoconstriction results in a decrease of renal blood flow and glomerular filtration rate, both of which are dose related and reversible. Specific vasoconstrictors linked to cyclosporine administration include endothelin and thromboxane.

Chronic renal dysfunction following cardiac transplantation is primarily related to chronic administration of either cyclosporine or tacrolimus. Data from the ISHLT Heart and Lung Registry indicate that approximately 20% of patients have renal dysfunction at 1 year, and 25% of patients exhibit important renal dysfunction by 4 years.11 At 4 years, about 7% of patients have a serum creatinine level greater than 2.5 mg·dL⁻¹, and about 2% are on chronic dialysis.22 Proximal tubular cells appear susceptible to injury from calcineurin inhibitors, induced by either sustained ischemia secondary to drug-related vasoconstriction or direct toxic effects of cyclosporine on tubular cells.22 These effects promote the influx of inflammatory cells into the interstitium, with resultant fibroblast proliferation and chronic scar formation. The afferent arteriolar lesions associated with cyclosporine or tacrolimus affect not only the glomeruli, but also tubules and interstitium.2,3,11

Treatment of persisting renal dysfunction (serum creatinine > 2 mg·dL⁻¹) should include reducing levels of cyclosporine and tacrolimus to the lowest levels consistent with freedom from rejection. Patients with important renal dysfunction who have a history of minimal allograft rejection should be considered for conversion to a sirolimus-based immunosuppressive regimen, which may have a renal-sparing effect if initiated before renal dysfunction is progressive. However, conversion from cyclosporine or tacrolimus late in the progression of renal dysfunction rarely reverses renal damage. When chronic dialysis is required, consideration for renal transplantation is advisable if allograft function is good and other nonrenal subsystems are intact.

Glucose Intolerance

Hyperglycemia is the direct result of adrenocorticosteroid use for immunosuppression. Reducing or eliminating corticosteroids is the most helpful intervention. Glucose intolerance is also a common complication of tacrolimus therapy. It may be necessary to use oral hypoglycemic medications and occasionally begin insulin therapy in some patients.

Hypertension

Hypertension occurs in 70% to 90% of patients on cyclosporine immunosuppression. Occurrence of hypertension is somewhat less (30%-50%) when tacrolimus is used. Its relationship to renal insufficiency and graft arteriosclerosis is not known. Blood pressure consistently measured in excess of 140/90 mmHg should be treated. Angiotensin-converting enzyme (ACE) inhibitors or calcium channel blockers are employed in conventional doses. Use of ACE inhibitors may have an additive effect with cyclosporine or tacrolimus to cause hyperkalemia. Calcium channel blockers decrease metabolism of cyclosporine and must be used judiciously and with monitoring of cyclosporine levels and appropriate dose adjustment. Diuretics may also be used in addition to primary antihypertensives. Other medications may be required in combination for patients not controlled by ACE inhibitors and calcium channel blockers.

Hyperlipidemia

Hyperlipidemia is common after cardiac transplantation and requires treatment in about 50% of patients.66 An abnormal lipid profile has been associated with increased risk of coronary events.15 Diet and exercise pattern modification are first-line treatments of abnormal lipid metabolism. Reduction of prednisone dose is helpful. Total cholesterol level greater than 220 mg·dL⁻¹ or low-density lipoprotein cholesterol greater than 120 mg·dL⁻¹ should be treated using a statin drug such as lovastatin; 10 mg daily is the usual starting dose, recognizing that in combination with cyclosporine, there is increased risk of rhabdomyolysis.

Osteoporosis

Osteoporosis begins before operation in patients having cardiac transplantation and may be due to their prolonged inactivity or prolonged use of heparin.67 Corticosteroid administration in the form of high-dose prednisone accelerates the problem after transplantation. Bone loss is greatest in the lumbar vertebrae and is rapid during the first 6 months. Vertebral compression fractures may result from this bone loss. Aseptic necrosis of the femoral head has also been noted. Patients at high risk should be treated before transplantation. High-risk factors for osteoporosis include female gender, older age, white or Asian race, thin or small body frame, prolonged immobility, early menopause (<40 years), postmenopause, glucocorticoid use, family history, low calcium intake or deficiency, excessive alcohol or caffeine intake, tobacco use, scoliosis, and use of a variety of drugs commonly taken by patients waiting for cardiac transplantation, including furosemide, warfarin, and heparin.
Postmenopausal women are given estrogen replacement. Calcium salts (calcium carbonate 1000 to 2000 mg·day⁻¹) and calcitrol beginning at 0.25 µg every other day and increasing to 0.5 µg·day⁻¹ are given before transplant and thereafter. Calcitrol (10 mg daily) may also increase bone density.⁵¹²

**Biliary Disease**

Biliary disease can affect as many as 8% of patients after cardiac transplantation, a prevalence 17 times higher than in the general population.⁶³ Increased risk of cholelithiasis is explained by reduced gallbladder emptying related to vagotomy and use of cyclosporine, which is both cholestatic and cholelithogenic. Laparoscopic cholecystectomy solves this problem and is well tolerated.

**Cardiac Retransplantation**

There is general agreement that survival after retransplantation is inferior to that following primary transplantation.⁵⁵ Risk factors for death include early retransplantation (within 6 months of primary transplant) and retransplantation for acute rejection or early allograft failure. The incidence of infection and rejection are similar following primary transplant and retransplantation.

**Cardiac Function and Quality of Life**

**Cardiac Function**

Successful cardiac transplantation allows dramatic functional improvement in most patients with advanced heart failure. The cardiac allograft affords profound circulatory rehabilitation that is often immediately apparent. Yet cardiac allografts do not function normally, even though more than 90% of surviving recipients have no activity limitation.⁶¹⁴ In the absence of recurring rejection, important allograft vasculopathy, or poorly controlled hypertension, the transplanted heart performs at rest in a similar (although not identical) manner as a healthy age- and sex-matched normal heart, but major physiologic abnormalities manifest during exercise.

Multiple factors contribute to reduced exercise reserves. Normal heart cardiectomy for transplantation severs both afferent and efferent nervous system connections. Afferent denervation affects sensory receptors in the cardiopulmonary region that exert a tonic restraining influence on sympathetic outflow to the heart and peripheral circulation.⁶⁴ Absence of these afferent fibers in the transplanted heart produces a reduced augmentation of peripheral vascular resistance and blunted plasma norepinephrine response to an abrupt decrease in central venous pressure (circulating blood volume).⁶¹₃,⁶₅ Afferent nervous pathway interruption also impairs renin-angiotensin-aldosterone regulation, which normally acts to decrease renin antidiuretic hormone secretion when blood volume is increased.⁶⁶,⁶⁸ Interruption of these afferent neural fibers results in a loss of this feedback mechanism, which normally counterbalances sympathetic renal stimulation. Chronically increased stimulation of the rennin-angiotensin-aldosterone axis creates a chronic volume-expanded state. The general decrease in vagal inhibitor effect on sympathetic output may also aggravate the hypertensive tendency after transplantation.⁵⁵

**Quality of Life**

Cardiac transplantation produces prompt and sustained improvement in the health status and perception of general well-being among most patients with advanced heart failure. The effect of cardiac transplantation on quality of life during the first 5 years has been examined in all four of its major domains (Table 21·18).

**INDICATIONS FOR ADULT CARDIAC TRANSPLANTATION**

In the final analysis, cardiac transplantation is advisable if the expected survival, quality of life, and functional outcomes are superior to other therapeutic options for advanced heart failure. The generally accepted indications for adult cardiac transplantation are listed in Box 21·24.

Heart transplantation is recommended for selected patients with advanced heart failure whose life expectancy with medical or other surgical therapies is less than 50% at 2 years. Rarely, cardiac transplantation is recommended for patients with longer expected survival but whose quality of life related to the heart failure syndrome is particularly poor despite optimal medical or surgical therapies.
Cardiac Transplantation should be reserved for those patients most likely to benefit in terms of both life expectancy and quality of life. When allocating a scarce resource such as a donor heart, a balance must be achieved between appropriate use of the resource to maximize graft survival and maximizing patient survival in those with the poorest expected outcome with other available therapies.

The stated goals of organ allocation embrace two basic concepts: fairness and utility. The concept of fairness is complex, but basically states that all patients with end-stage heart disease of equivalent severity have an equal chance of obtaining a heart transplant. Unfortunately, quantifying the probability of death for various patient subsets is currently not possible, and specific criteria for listing are not uniform among institutions.

The concept of utility must also be considered in judging any allocation algorithm. This concept embodies the notion that a precious resource like transplant organs should be used to maximally extend life. Inherent is the notion that transplantation should only be offered to patients for whom transplantation would substantially and importantly improve survival over other therapeutic options. Thus, if likely duration of survival is importantly reduced by the presence of major noncardiac organ dysfunction or comorbidities (which would either be unaffected or worsened by therapies required following transplantation), then the utility of transplantation would be unfavorable.

Based on these concepts, national organ procurement agencies establish algorithms for selecting recipients when an organ donor is identified. In the United States, this agency is the United Network for Organ Sharing (UNOS), which includes committees of transplant experts who work together to establish the rules for organ allocation.

The current allocation system in the United States gives strong priority to those patients whose heart failure is severe enough to require continuous inotropic therapy or mechanical circulatory support. Because of poor survival in higher-risk subsets and paucity of available organs, current indications for cardiac retransplantation are generally limited to (1) chronic severe cardiac allograft vasculopathy with symptoms of ischemia or heart failure or asymptomatic moderate or severe left ventricular dysfunction, and (2) chronic graft dysfunction with symptoms of progressive heart failure in the absence of active rejection.\(^{35}\)

---

### Box 21-24 Indications for Adult Cardiac Transplantation

1. Cardiogenic shock or low cardiac output state requiring mechanical assistance (respirator, IABP, VAD, TAH) with reversible organ-system damage
2. Heart failure (refractory low cardiac output state) requiring continuous inotropic support
3. NYHA class III-IV with marked, progressive functional limitation despite optimal medical therapy and poor 12-month prognosis (\(VO_2 < 14 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}\) or serial decrease, clinically unstable)
4. Recurrent or rapidly progressive heart failure unresponsive to optimal medical therapy
5. Severe hypertrophic or restrictive cardiomyopathy, NYHA class IV symptoms
6. Refractory angina pectoris despite optimal medical therapy (beta-blocker, calcium blocker, nitrates) not amenable to coronary revascularization or transmyocardial cardiac laser revascularization because of diffuse distal disease, or severe LV dysfunction. Objective documentation of myocardial ischemia within the first two stages of a standard Bruce exercise protocol
7. Recurrent life-threatening ventricular arrhythmia refractory to medical treatment or insertion of ICD (frequent firings or prolonged electromechanical dissociation after cardioversion)
8. Cardiac tumors, unresectable with low probability of metastasis

Modified from Renlund.\(^{86}\)

Key: IABP, Intraaortic balloon pump; ICD, implantable cardioverter-defibrillator; LV, left ventricle; NYHA, New York Heart Association; TAH, total artificial heart; VAD, ventricular assist device; \(VO_2\), maximal oxygen consumption.

---

### SPECIAL SITUATIONS AND CONTROVERSIES

#### Cardiac Transplantation for Cardiac Neoplasm

Complete excision of cardiac sarcoma or other cardiac neoplasm may be difficult to achieve because of anatomic location. Resection of the entire heart and orthotopic cardiac transplantation have been described for treating an otherwise unresectable cardiac tumor. Cardiac explantation, extracorporeal resection of the tumor with cardiac reconstruction, and cardiac autotransplantation are described in Chapter 18.

Another approach to consider for these patients is cardiectomy and replacement with total artificial heart, either as a permanent implant or as a bridge to transplantation after several months, to determine freedom from metastatic disease (see Chapter 22).
Cardiac Xenotransplantation

The continuing shortage of cardiac allografts has focused attention and research on using a species other than human as a source of hearts for transplantation. Adams and colleagues reviewed past clinical experience with cardiac xenotransplantation, including the highly publicized Baby Fae transplant performed by Bailey in 1984 (baboon to human) and the xenotransplant reported by Czaplicki in 1992 (pig to man after cross-circulation removal of preformed antibodies). They concluded that improved understanding of the immunologic barriers to cross-species transplantation has narrowed the gap between laboratory research and clinical application.

Hearts from nonprimates are destroyed within minutes after transplantation into humans because of hyperacute rejection by expression of α-galactose disaccharide (Gal) carbohydrate on vascular endothelium. Humans have circulating natural antibodies against this antigen. Once anti-Gal antibodies bind to the xenograft, the complement cascade is activated, triggering endothelial cell dysfunction, platelet aggregation, and vascular thrombosis, referred to as acute vascular rejection. In addition, there is absence of complement regulatory proteins and mechanisms to control complement activation in xenografts. Donor organs from primates do not express Gal on the endothelium and thus do not undergo hyperacute rejection in human recipients. Rejection, however, occurs within days to weeks after transplantation. Research in developing transgenic pigs has been directed toward genetically altered animals that express human complement regulatory proteins (CRP) and down-regulation of Gal expression on the porcine endothelium. Recipient strategy research has been focused on reduction of anti-Gal circulating antibody levels using extracorporeal immunoadsorption, IV injection of Gal carbohydrates to bind and neutralize circulating natural antibodies, and total lymphoid irradiation or porcine bone marrow transplantation to induce tolerance.

A number of scientific and ethical obstacles remain. Even though primate transplantation is not accompanied by hyperacute rejection, these grafts ultimately fail by acute vascular rejection, a process that is poorly understood. There are no effective therapies to control acute xenograft vascular rejection, but the complex immunologic responses are being elucidated and may allow development of specific therapeutic strategies to prevent xenograft rejection. Animal rights issues have moved xenograft transplant away from primate donors toward transgenic pig donors, which seems to cause less public disfavor, presumably because pigs have been domesticated for dietary consumption, can be grown to appropriate size, and have been used for other medical purposes. Xenosis, the possible transmission of infectious diseases from animal to human, could in turn expose the general population to disease previously unknown to humans. This threat is not easily dismissed. Porcine endogenous retroviruses are particularly important because these viruses have been shown to infect human cells in vitro. No human disease, however, has yet to be associated with these viruses.

Cardiac xenotransplantation remains a dream, but the goal may eventually be achieved. It is anticipated that initial clinical experiments will be as bridge to allotransplantation and probably will be applied as a heterotopic placement of the graft.

Section II  Cardiac Transplantation for Congenital Heart Disease and Pediatric Patients

HISTORICAL NOTE

On December 6, 1967, 3 days after Christiaan Barnard performed the first human-to-human heart transplant, Adrian Kantrowitz performed the second, in Brooklyn, New York, for an 18-day-old neonate with Ebstein anomaly, refractory heart failure, and previous aortopulmonary shunt for severe cyanosis. The donor was an anencephalic infant. The recipient died 5 hours after the transplant of heart failure and refractory acidosis. Bailey and colleagues at Loma Linda transplanted a baboon heart into a newborn infant, “Baby Fae,” with hypoplastic left heart syndrome on October 26, 1984. The baby survived 20 days. This single experience renewed intense scientific interest in the possibility of xenotransplantation, while at the same time arousing intense public debate over the issue of primate donors for human transplantation. Ironically, the Baby Fae experience did not lead to another cardiac xenotransplant procedure in the coming decade, but it did signal the emergence of neonatal heart transplantation as an option for end-stage neonatal heart disease. Over the following decade, the Loma Linda group generated a landmark experience with superb survival after infant cardiac transplantation.

CLINICAL FEATURES

Many clinical features noted for adult cardiac transplantation (see Section I) pertain to young patients with some exceptions.

Infant ABO-Incompatible Heart Transplants

Infants in the first few months of life manifest a deficiency in certain types of B-cell responses. Although such responses to protein antigen stimulation are generally competent early in life, antibody production to T-independent carbohydrate antigens is notably deficient. This finding is particularly relevant to development of natural antibodies directed against nonself A or B blood group antigens. Available evidence suggests that these natural ABO antibodies develop as a cross-reaction to similar carbohydrate epitopes on intestinal Escherichia coli in normal gut flora. This deficiency in the ability to produce antibodies against carbohydrate antigens is manifest during early infancy by the absence of natural anti-A or anti-B blood group antibodies until approximately age 4 to 6 months.

The paucity of available donors for neonates and small infants requiring cardiac transplantation and this relative neonatal immune deficiency stimulated West and colleagues in Toronto to consider the possibility of ABO-incompatible cardiac transplantation to expand the donor pool for neonatal transplantation. In 2001, they reported successful application of this strategy in 6 infants who received ABO-incompatible hearts. Most underwent transplantation before onset of isohemagglutinin anti-A or anti-B antibody production. Standard immunosuppressive strategies were
However, at the pericardial reflection the aorta usually assumes a position anterior and to the right of the pulmonary trunk. These malpositions are most easily addressed by harvesting from the donor an extended length of the aorta including the arch and pulmonary artery, including the bifurcation, and extensively separating and mobilizing the ascending aorta from the recipient’s pulmonary trunk. This allows a gentle arch of donor ascending aorta to overlie the pulmonary trunk reconstruction, with an anastomosis near the native brachiocephalic artery. The native pulmonary trunk can be partially or completely oversewn and an incision extended into the left pulmonary artery to create an anatomic position suitable for connection with the donor pulmonary trunk.

Anomalies of Systemic Venous Return

**Left Superior Vena Cava Draining to Coronary Sinus**

When the left SVC drains to the coronary sinus, the simplest approach is to leave it attached to the atrium and preserve the course and connection of the coronary sinus to the right atrium at cardiectomy (Fig. 21-26). If a biatrial transplant is selected, care must be taken to avoid narrowing the coronary sinus by the left atrial anastomosis. In the presence of a diminutive or absent right-sided SVC, this method of reconstruction may prevent endomyocardial biopsy via the left SVC because of the sharp angulation required for the bioprobe to access the right ventricular septum.

In general, mean systemic perfusion pressure should be maintained at 40 mmHg or greater during rewarming after heart transplantation with a perfusion flow rate of 2.5 to 3.0 L·min$^{-1}$·m$^{-2}$ in pediatric patients.

**Venous Cannulation**

In the presence of multiple previous operations and difficult venous cannulation, some surgeons prefer to use initial cannulation of the right atrium and subsequent direct venous cannulation while cooling, particularly if a left SVC is present. Individual caval cannulation eliminates the need for prolonged periods of circulatory arrest during transplantation. In patients with separate hepatic drainage, these veins are allowed to drain directly into the pericardium for collection by a cardiotomy sucker. Care must be taken to avoid obstructing hepatic venous drainage by a snare around the inferior vena cava (IVC). In patients with heterotaxy syndrome and azygos continuation of the IVC, the right and left hepatic veins often drain separately, and it is important to leave a cuff of atrium around the entrance of the hepatic veins to facilitate connection of the right atrium to the donor graft.

**Arterial Cannulation**

In neonates with hypoplastic left heart syndrome the pulmonary trunk and ductus are commonly cannulated, but an attractive alternative is to use a 3.5-mm polytetrafluoroethylene (PTFE) graft sewn onto the brachiocephalic artery. This permits regional cerebral circulation while implanting the donor aorta, avoiding periods of circulatory arrest. A flexible wire-reinforced cannula is desirable for arterial cannulation whenever arch reconstruction is required, because the cannula can be positioned away from the operative field (see “Arterial Cannulation” in Chapter 2).

**Malpositions of the Aorta**

In patients with a malposed ascending aorta or transposed great arteries, the ascending aorta may be distinctly leftward and relatively short compared with a normal dextroposed aorta. The pulmonary trunk is often posterior and rightward.

Figure 21-26  Appearance of left superior vena cava draining into coronary sinus following cardiectomy for cardiac transplantation. (Courtesy Pedro J. del Nido, MD, Boston, Mass.)
donor SVC and brachiocephalic vein should be harvested. An extracardiac reconstruction can be accomplished by anastomosing the donor brachiocephalic vein to the cut end of the recipient left SVC, followed by a direct right SVC anastomosis to donor right SVC (Fig. 21-27).

Alternatively, an intracardiac pathway can be constructed using the recipient’s left atrial appendage or PTFE to redirect drainage from the left SVC to the right atrium. The biatrial implantation technique is then employed, in which the left atrial and right atrial septal anastomoses deviate slightly leftward at the opening of the left SVC tunnel into the new right atrium. This technique may be less prone to kinking and thrombosis than the extracardiac reconstruction (Fig. 21-28).

Anomalies of Inferior Vena Caval Drainage

Anomalies of systemic venous drainage are common. Separate drainage of the hepatic veins to the left atrium requires creating a baffle within the left atrium to divert left hepatic drainage back to the right atrium (Fig. 21-29). The baffle must be positioned in a manner that avoids pulmonary venous obstruction. PTFE or pericardium is convenient for constructing this tunnel. A bicaval or biatrial implantation technique can then be used (see Section 1).

Anomalies of Pulmonary Veins and Atrial Septum

In the presence of uncorrected partial or total anomalous pulmonary venous connection, standard transplant procedures must be modified (see Section 1). In the presence of anomalous connections of the right upper pulmonary veins to the SVC, a recommended option is to use a modification of the Warden procedure, in which the SVC is divided and oversewn just cephalad to the pulmonary veins, and the septum is excised along with the explanted heart. The left atrial incision is fashioned to include the right atrial wall at its junction with the SVC. The entrance of the anomalous pulmonary vein is then incorporated with the left atrial anastomosis. The donor SVC is then anastomosed end to end to the recipient’s SVC.

In the presence of previous Mustard or Senning procedures (see Chapter 52) the entire interior baffle is removed and the interatrial septum reconstructed with PTFE in preparation for a biatrial connection. Alternatively, the venae cavae can be divided at their connection to the native heart and a bicaval implantation performed.
Complex Combinations of Anomalous Systemic and Pulmonary Venous Drainage

In the setting of multiple previous operations and unexpected anomalies of pulmonary or systemic venous return, little or no native tissue may be available for reconstruction. Any anomalous locations of entry into the atrial mass can be managed expeditiously by cutting the ventricular mass off the underlying atria, leaving all available atrial tissue in place while the surgeon assesses reconstructive options. Any interatrial septum is excised, leaving a “common atrium.” Any systemic venous opening to the left of the midportion of the open atria can be moved to the midline and repartitioned or tunneled with PTFE patch material so as to drain to the right side. Any pulmonary veins entering to the right of a midatrial (interatrial) septum can be repartitioned with a patch of PTFE that replaces part or all of the septum, such that there is a cut edge of PTFE partition (septum) near the midportion of the atria. The pulmonary veins drain under this partition to the left side of the atria. Then, a standard orthotopic implantation method can be used in which a newly created edge of atrial “septum” is available for the left and right atrial “septal” suture lines, such that all pulmonary venous blood drains to the left side, and all systemic venous blood drains to the right side.

Dextrocardia

In patients with isolated dextrocardia, in which the apex of the ventricles is rightward with atrial situs solitus, orthotopic cardiac transplantation can usually be performed in standard fashion. There may be rotation of the great vessels, but extensive mobilization of the aorta and pulmonary trunk allows rather standard anastomoses for the transplanted heart. Occasionally, secondary to limited space available on the left side of the pericardium, the left pleural space can be widely opened and the diaphragmatic pericardial attachments taken down partially on the left side to accommodate the apex of the transplanted heart.

Situs Inversus

Situs inversus is a unique surgical challenge because of the need to reroute systemic and pulmonary pathways and reposition the great vessels. Management of the great vessels is accomplished as discussed under “Malpositions of the Aorta” earlier in this section. Reconstruction of the systemic venous and pulmonary venous pathways can be accomplished using either the biatrial or bicaval technique.

The simplest method uses a bicaval technique in which the pulmonary vein orifices and the posterior aspect of the left atrium are isolated as a single unit with a circumferential cuff of left atrium, just as in a standard bicaval technique. Incisions in the left-sided right atrium are planned such that autologous right atrial tissue can be used to construct a partial tube from the left-sided opening of the IVC rightward along the diaphragm to provide a connection with the donor IVC opening within the right atrium.

In the presence of a normal brachiocephalic vein, a long segment of donor SVC and brachiocephalic vein is harvested to allow a right-sided anastomosis from donor SVC to the underside of the recipient brachiocephalic vein. Alternatively, the donor SVC and brachiocephalic vein can be anastomosed directly to the mobilized recipient left SVC (Fig. 21-30).

Figure 21-30 Final appearance of implantation of a situs solitus donor heart into a situs inversus recipient. Ascending aortic anastomosis is shortened, allowing superior venous drainage system to be draped over the great arteries. Key: BV, Brachiocephalic vein; LIVC, left inferior vena cava; L SVC, left superior vena cava; SVC, superior vena cava. (Courtesy Leonard L. Bailey, MD, Loma Linda, Calif.)

The general sequence of operation is transection of the SVC, including a small rim of right atrium, followed by incision of all available right atrial tissue anteriorly to the tricuspid valve and posteriorly to the interatrial septum, which is left intact and in continuity with the IVC orifice. The great vessels are divided proximally, and the left atrium is incised and the cardiac mass excised, leaving a cuff of left atrium around all the pulmonary venous orifices. The great vessels are mobilized as described above. Native atrial tissue is used to construct a partial tube (using a Hegar dilator if needed) for the IVC that reaches beyond the lower right corner of the left atrial remnant. If insufficient pericardial space is available for the donor ventricular apex, the pericardial attachments to the diaphragm on the left side are partially taken down, avoiding injury to, or cautery close to, the phrenic nerve.

Implantation involves a standard left atrial anastomosis followed by the IVC anastomosis between the constructed tube and the donor IVC orifice. The donor and recipient aorta are then trimmed appropriately to provide a tension-free anastomosis, after which de-airing and de-clamping are carried out as usual. The SVC reconstruction and pulmonary artery anastomosis (with an incision extended onto the left pulmonary artery as needed) are performed while rewarming.

Alternatively, a biatrial technique can be used by removing all interatrial septum and reconstructing the septum as described earlier in this section under “Complex Combinations of Anomalous Systemic and Pulmonary Venous Drainage.” Autologous tissues can also be used to create internal baffles to achieve the same result (Fig. 21-31).
new graft during reperfusion. In addition, excessive pulmonary blood flow may initiate pulmonary dysfunction, pulmonary hypertension, and right ventricular dysfunction. For these reasons, coiling these vessels in the catheterization laboratory immediately prior to transplantation is preferable whenever possible. Alternatively, ligation of collaterals at transplantation may be accomplished by dividing the posterior pericardium following cardiectomy (see “Managing Sources of Pulmonary Blood Flow on Cardiopulmonary Bypass” in Chapter 38).

When the pulmonary trunk requires replacement, it is advisable to perform this reconstruction before the aortic or SVC anastomosis (Fig. 21-32). After the left atrial connection is completed, the donor pulmonary arteries are connected to the recipient’s pulmonary arteries, after which the aortic and cavocaval or right atrial anastomoses are completed.

**Anomalies of Aortic Arch**

Residual or congenital defects of the aorta are often encountered, along with arch hypoplasia, interruption, or hypoplastic
Chapter 21 Cardiac Transplantation

Common to all, however, is hypoplasia of the left ventricle and ascending aorta (Fig. 21-33). The aortic arch is also small in most cases, and there may be associated coarctation of the aorta. The right ventricle and pulmonary trunk are usually large, and the ductus arteriosus continues to the descending aorta. It must be identified relative to the left pulmonary artery. The right atrium may be enlarged from high pressure and flow through a patent foramen ovale. The SVC and IVC usually connect normally.

Although a major portion of the transplant operation for this condition has traditionally been performed during circulatory arrest, alternative strategies are available to minimize or eliminate circulatory arrest to reduce the potential for neurologic damage. Prior to CPB, a 3.5-mm PTFE graft is anastomosed to the brachiocephalic artery and clamped. The patient is heparinized, and CPB is initially established with the arterial cannula inserted into the PTFE tube and secured with silk ties (this is a standard technique used by some surgeons for first-stage palliation of hypoplastic left heart syndrome; see Technique of Operation in Chapter 49). A second arterial cannula is inserted into the distal pulmonary trunk and passed well into the ductus arteriosus for distal aortic perfusion. Upon initiating CPB, a snare is secured.

Hypoplastic Left Heart Syndrome

Patients presenting with hypoplastic left heart physiology without prior palliation may have a spectrum of anomalies. Common to all, however, is hypoplasia of the left ventricle and ascending aorta (Fig. 21-33). The aortic arch is also small in most cases, and there may be associated coarctation of the aorta. The right ventricle and pulmonary trunk are usually large, and the ductus arteriosus continues to the descending aorta. It must be identified relative to the left pulmonary artery. The right atrium may be enlarged from high pressure and flow through a patent foramen ovale. The SVC and IVC usually connect normally.

Although a major portion of the transplant operation for this condition has traditionally been performed during circulatory arrest, alternative strategies are available to minimize or eliminate circulatory arrest to reduce the potential for neurologic damage. Prior to CPB, a 3.5-mm PTFE graft is anastomosed to the brachiocephalic artery and clamped. The patient is heparinized, and CPB is initially established with the arterial cannula inserted into the PTFE tube and secured with silk ties (this is a standard technique used by some surgeons for first-stage palliation of hypoplastic left heart syndrome; see Technique of Operation in Chapter 49). A second arterial cannula is inserted into the distal pulmonary trunk and passed well into the ductus arteriosus for distal aortic perfusion. Upon initiating CPB, a snare is secured.
around the ductus to exclude the pulmonary arteries from arterial perfusate inflow.

Bicaval venous cannulation is employed as for the standard biatrial implantation technique, although initial cannulation of the right atrium may be employed if there is hemodynamic instability prior to initiating CPB. The perfusate is cooled to bring the nasopharyngeal temperature to 14° to 16°C and bladder temperature to 18°C. During the cooling phase, the hypoplastic ascending aorta is clamped and the heart excised as for biatrial implantation. Once the target body temperatures are achieved, the perfusate temperature is set at 16° to 18°C and low-flow perfusion is established at 1.0 to 1.5 L·min⁻¹·m⁻² for the remainder of the implantation.

The donor heart has been procured to include the entire aortic arch and some of the descending thoracic aorta. The aortic arch of the donor is tailored by excising approximately one fourth of the superior aspect of the aortic circumference, beginning distal to the take-off of the donor brachiocephalic artery. The length of donor aortic arch is then tailored to fit the aortic arch of the recipient.

The left atrial anastomosis is constructed with continuous 4-0 or 5-0 polypropylene suture as in the standard biatrial implantation. The perfusate flow is then reduced to about 0.5 L·min⁻¹·m⁻² and the recipient brachiocephalic artery clamped proximal to the PTFE graft to allow continuation of regional cerebral perfusion during arch implantation. The arterial cannula through the ductus is clamped and removed, and the ductus is ligated proximally and divided. Inferior traction on this ligature facilitates the arch reconstruction. The native aorta is divided near the brachiocephalic artery and the proximal ascending aorta remnant removed. The aortic arch is opened through its inferior aspect, extending the incision past the ductus into the upper portion of the descending thoracic aorta to encompass any coarcted segment. All ductal tissue in the upper descending thoracic aorta is removed.

The donor aortic arch is anastomosed to the recipient aortic arch with continuous 6-0 polypropylene suture. The most difficult portion of the repair is the anastomosis of the distal aortic arch of the donor to the apex of the aortotomy in the upper portion of the descending thoracic aorta of the recipient. Accuracy and complete hemostasis in this area are critical for two reasons. First, inclusion of residual ductal tissue or failure to extend the incision far enough distally could result in stenosis and recurrent coarctation; second, bleeding from this area can be difficult to control later. Exposure of this area is facilitated by placing a C-clamp on the distal aorta to prevent back bleeding, which can obscure the surgical field. Upon completion of the aortic reconstruction, CPB can be continued through the native brachiocephalic artery cannulation, or a cannula can be placed through the stump of the donor brachiocephalic artery for the remainder of the procedure. After de-airing the arch and heart, the suture lines are secured, and the aortic clamp is removed while suction is placed on the needle vent. During rewarming, the right atrial anastomosis and pulmonary trunk end-to-end anastomoses are constructed using 5-0 polypropylene suture.

Transplant after Fontan Operation
These patients are often very ill, with ascites, malnutrition, and marked venous hypertension. Multiple prior sternotomies are the norm, and specific plans are essential for establishing CPB rapidly in the event of cardiac bleeding during sternotomy. Exposure of a femoral artery and vein is advisable if the patient is large enough for femoral cannulation. If percutaneous femoral cannulae are planned in the event of an emergency, the groin should be inspected for scars of previous cutdowns or multiple catheterization procedures. If scarring is present, surgical exposure of the femoral artery and vein are advisable, because passage of dilators over a guidewire in a previously operated groin can be difficult.

The bicaval technique is employed with direct caval venous cannulation. The SVC is detached from the pulmonary artery (prior bidirectional Glenn), and the right atrial or IVC connection to the pulmonary trunk or underside of the right pulmonary artery is disconnected. Defects in the pulmonary artery are preferably reconstructed with donor pulmonary artery tissue or thin bovine pericardium.

The reconstructive requirements are often such that maximal length of SVC and brachiocephalic vein (if a left SVC is present) should be harvested from the donor, along with sufficient length of pulmonary artery branches to meet the reconstructive needs of the recipient pulmonary arteries.

SPECIAL FEATURES OF POSTOPERATIVE CARE
See Section I and Chapter 5.

Immunosuppression
Although cyclosporine remains the most commonly used anticalcineurin agent in adult heart transplantation, tacrolimus is the more common agent among pediatric patients (Box 21-25).

Surveillance for Rejection
In neonates and infants undergoing cardiac transplantation, repeated surveillance of cardiac biopsies may not be feasible because of limitations of vascular access. In this age group, echocardiographic variables have been identified that are generally predictive of acute rejection.²²³,²²⁴,²²⁵,²²⁶

Infection Prophylaxis
Prevention of infection by active immunization is recommended for specific conditions, using killed vaccine only.²²¹ Recommended childhood immunizations are given in Table 21-19.

RESULTS
Among pediatric patients, survival has progressively improved through the early part of the last decade (2000-2010), with less discernible survival improvement since then (Fig. 21-34).²²⁷ Among patients who survive the first posttransplant year, late survival is clearly superior in those transplanted during the first year of life (Fig. 21-35). Survival is the same as in adult transplant recipients once the patient reaches about 11 years of age. Patients with congenital heart disease have approximately twice the risk of early mortality compared with cardiomyopathy patients.²²⁷ The single greatest risk factor for early pediatric mortality is pretransplant support with extracorporeal membrane oxygenation, which increases
**Corticosteroids**
For neonates and small infants (<7 kg), generally 100 mg methylprednisolone IV daily for 3 days. For older infants and children, methylprednisolone 15 mg·kg\(^{-1}\)·day\(^{-1}\) IV daily × 3 or prednisolone 2-4 mg·kg\(^{-1}\)·day\(^{-1}\) PO × 3 with or without a subsequent taper.

**Cyclosporine**
Initial oral dose of about 0.3 mg·kg\(^{-1}\)·day\(^{-1}\)·day\(^{-1}\) twice daily. If renal function stable, gradually increase to oral dose of about 1 mg·kg\(^{-1}\)·day\(^{-1}\) in 3 divided doses. If renal function remains normal, rapidly increase over 3–4 days to achieve target trough levels.

**Tacrolimus**
0.05-0.15 mg·kg\(^{-1}\)·day\(^{-1}\) PO or sublingual in two divided doses. Once stable renal function is verified after initial 1-2 days of therapy, dosage can be rapidly increased to attain target level (with continued surveillance of renal function).

**Azathioprine**
2 to 2.5 mg·kg\(^{-1}\)·day\(^{-1}\). Dose reduced as necessary to maintain the white blood cell count of 3000 per mL or greater.

**Mycophenolate Mofetil**
Begin at 5 mg·kg\(^{-1}\) IV or twice daily PO and progressively increase to a target dose of 20-23 mg·kg\(^{-1}\) twice daily if tolerated (gastrointestinal symptoms). When administered IV, dose is equivalent to the oral dose.

**Cyclophosphamide**
1-1.5 mg·kg\(^{-1}\)·day\(^{-1}\). Dose reduced as necessary to maintain the white blood cell count of 3000 per mL or greater.

**Methotrexate**
5-10 mg·m\(^{-2}\)·week\(^{-1}\) in 3 every-12-hour doses.

**Sirolimus**
Loading dose: 3 mg·m\(^{-2}\) followed by Maintenance dose: 1 mg·m\(^{-2}\)·day\(^{-1}\).

**Antithymocyte Globulin**
Specifics regarding dosage, premedications, and hypersensitivity testing vary according to specific antithymocyte preparation.

**OKT3**
0.1-0.2 mg·kg\(^{-1}\) with dose adjustment by T-cell markers.

**Anti-CD25 Monoclonal Antibodies**
Basiliximab: Administer 12-mg doses using the same schedule as in adults
Daclizumab: 2 mg/kg

Data from Kirklin and colleagues.\(^{314}\)

the risk nearly fivefold. Risk of early death appears to increase considerably and progressively with age less than about 1 year. However, among neonates who survive the first year, long-term survival is particularly favorable,\(^{32}\) likely related to relative immaturity of their immune system at the time of transplant.

General survival and risk factors are similar for adult and pediatric heart retransplantation.

**INDICATIONS FOR PEDIATRIC CARDIAC TRANSPLANTATION**

More than 80% of cardiac conditions leading to cardiac transplantation in the pediatric population are either cardiomyopathies or congenital heart disease, with congenital heart disease not amenable to correction or palliation now comprising approximately 40% of all pediatric listings for transplantation.\(^{32}\)

The congenital cardiac malformations considered for cardiac transplantation range from unrepaird complex disease in the newborn to repaired or palliated congenital heart disease with ventricular dysfunction in the adult.\(^{32,22,24,9,15,2}\) Cardiac transplantation is currently not recommended as routine primary therapy for any cardiac malformation, but severe coronary anomalies, cardiac valve regurgitation, or ventricular dysfunction can favor primary transplantation or referral after initial palliation in selected infants with complex congenital heart disease.
Survival after pediatric transplants performed between January 1982 and June 2006, stratified by era. (From Kirk and colleagues.)

Among infants, hypoplastic left heart syndrome is currently treated at most institutions with staged operations in the Fontan pathway. In general, patients with this condition are referred for cardiac transplantation when right ventricular dysfunction or tricuspid regurgitation, or both, are severe either prior to or following initial surgical palliation. In older children and adolescents, failure of staged single-ventricle palliation is the most common form of congenital heart disease referred for cardiac transplantation (Table 21-20).

The relatively small number of pediatric patients who are referred for cardiac transplantation, and the variety of conditions that can progress to cardiac failure, have limited the ability to generate specific guidelines for transplant referrals (Box 21-26). Recent consensus guidelines from the American Heart Association suggest the following recommendations for patients with cardiomyopathies or previously repaired congenital heart disease:

- A need for ongoing IV inotropic or mechanical circulatory support for poor ventricular function and low cardiac output
- Progressive deterioration of ventricular function or functional status despite optimal medical care with digitalis, diuretics, ACE inhibitors, and β-blockade
- Malignant arrhythmias or survival after arrhythmia-induced cardiac arrest unresponsive to medical treatment, catheter ablation, or an implantable cardioverter-defibrillator

Certain situations specific to pediatric patients contraindicate cardiac transplantation, as recommended by the American Heart Association Council on Cardiovascular Disease in the Young:

- Restrictive cardiomyopathy associated with reactive pulmonary hypertension
- Progressive pulmonary hypertension secondary to systemic ventricular failure that could preclude cardiac transplantation at a later date
- Growth failure secondary to severe heart failure unresponsive to conventional medical treatment
- Unacceptably poor quality of life secondary to heart failure
- Progressive deterioration in functional status or presence of certain high-risk conditions following the Fontan procedure

Heart transplantation for pediatric heart disease is not efficacious when heart disease is associated with severe irreversible disease in other organ systems, or when it is part of a severe irreversible multisystemic disease process. Multiorgan transplantation may be considered.

Orthotopic heart transplantation for pediatric heart disease is not efficacious when heart disease is associated...
with severe irreversible fixed elevation of pulmonary vascular resistance.

- Heart transplantation is not feasible in the presence of severe hypoplasia of the central pulmonary arteries or pulmonary veins.
- The limited supply of pediatric donors, especially infant donors, makes heart transplantation not a feasible standard therapy for any specific congenital heart lesion.

**Section III  Heart-Lung Transplantation**

**HISTORICAL NOTE**

The first combined heart-lung transplant procedure was performed by Denton Cooley in Texas on September 15, 1969. The patient was a 2-month-old infant who survived only 14 hours. C. Walton Lillehei performed the same procedure in an adult patient in New York 3 months later, and that patient survived 8 days. After a sustained experimental investigation of heart-lung transplantation, Bruce Reitz and colleagues at Stanford performed the first successful combined procedure in 1981. Long-term survival became possible with the availability of cyclosporine, and the first successful series of patients undergoing heart-lung transplantation was published by Reitz and colleagues the following year.  

**CLINICAL FEATURES**

Recipient Evaluation and Selection

All the standard recipient selection criteria for isolated heart transplantation apply to patients considered for heart-lung transplantation. However, certain issues unique to this therapy require special mention. Because a heart-lung block is used that could otherwise potentially benefit three individuals with advanced heart or lung failure, there is an added responsibility to select heart-lung transplant recipients with sufficient overall reserves to both benefit from the procedure and have a good probability for midterm survival. In addition, the magnitude of heart-lung transplantation and the associated overall stress on other subsystems are, in most instances, greater than those for isolated heart or lung transplantation.

**Age**

A clear relationship between death after heart-lung transplantation and older age has not been formally demonstrated, but recipients older than age 60 are rarely selected.

**Previous Thoracic Surgery**

Major bleeding from adhesions in a previously operated thoracic space is a strong risk factor for morbidity and mortality after heart-lung transplantation. This in part relates to major transfusion requirements, potentially destabilizing effects of ongoing bleeding on cardiac function immediately after transplantation, and difficulties in identifying and preserving the phrenic nerves in the presence of dense adhesions. As a result, some centers decline patients for heart-lung transplantation if they have undergone prior thoracotomy, particularly if bilateral. With experience, patients with prior thoracotomy and sternotomy can safely undergo heart-lung transplantation (see **Technique of Operation**), but they should have well-preserved noncardiac organ function and be younger, generally less than age 50 years.

**TECHNIQUE OF OPERATION**

Preoperative and Intraoperation Preparation

Preoperative preparation for heart-lung transplantation is the same as for orthotopic heart transplantation. In the setting of no prior cardiothoracic operation, the procedure is performed through a median sternotomy. However, when one or both pleural spaces have been previously entered, a bilateral anterior thoracotomy is preferred as in the technique of bilateral lung transplantation. This allows safer dissection and control of bleeding from adhesions in both pleural spaces. A pericardial flap is developed by incising the pericardium laterally and inferiorly, leaving about 5 cm of pericardium over the superior vena cava as the base for an autologous pericardial flap to be placed around the tracheal anastomosis. Cautery must be avoided in the vicinity of either phrenic nerve, because heat-transmitted injury would catastrophically impair postoperative pulmonary function.

**Removal of Native Heart and Lungs**

CPB is established, the aorta clamped, and a standard cardiectomy performed as for bicaval orthotopic cardiac transplantation (see **“Orthotopic Cardiac Transplantation”** under Technique of Operation in Section 1). If pulmonary venous return is excessive, appropriate reduction of perfusate temperature to profound hyperthermic levels is instituted to allow intermittent low-flow perfusion to facilitate dissection and avoid excessive blood loss (see Section IV of Chapter 2). Otherwise, perfusate temperature is generally 28°C.

Beginning on the left side, an incision is made in the pericardium just anterior to the pulmonary veins as far below the phrenic nerve as possible. In the absence of dense adhesions, a pedicle of pericardium containing the phrenic nerve is developed inferiorly almost to the diaphragm and superiorly just to the level of the left pulmonary artery to avoid damaging the phrenic nerve. The left atrium is divided posteriorly in its midportion, and a cuff of left atrium along with the left pulmonary veins is dissected free and passed under the pericardial pedicle (Fig. 21-36, A). The left pulmonary artery is dissected circumferentially proximal to its branches and divided. The lower lobe of the left lung is reflected superiorly, and the inferior pulmonary ligament is divided with cautery. The posterior pulmonary attachments are divided, and the lung is mobilized away from the vagus nerve. The left mainstem bronchus is isolated by dividing lymphatic tissue with cautery and hemoclips, and the bronchus is stapled and divided. The left lung is passed off the surgical field.

Similarly, the pericardium on the right side is dissected immediately above the pulmonary vein, and the pericardial pedicle is mobilized. The inferior pulmonary ligament is mobilized, right pulmonary artery dissected circumferentially and divided, and posterior pulmonary attachments divided. The lung is gently freed from the area of the vagus nerve without cautery, and the right mainstem bronchus is isolated,
stapled, and divided. After removing both lungs, stumps of right and left pulmonary arteries are mobilized and the pulmonary trunk excised, leaving a generous cuff around the area of ligamentum arteriosum and left recurrent laryngeal nerve. The bronchial stumps are mobilized to the level of the carina with careful hemostasis of bronchial arteries (Fig. 21-36, B). Complete hemostasis is critical to achieve throughout the pleural space and mediastinum before implanting the heart-lung block.

Implantation of the Heart-Lung Block

The heart-lung block is prepared on a back table by dividing the donor trachea approximately 2 cm above the carina. It is important to leave the membranous portion slightly longer than the cartilaginous portion, because it tends to retract slightly after division. The anatomic position of each lung is beneath the pericardial pedicle on each side, but in the presence of dense adhesions from prior operation, both lungs can safely be placed anterior to the phrenic nerves, which avoids additional dissection. In that instance, the pulmonary veins are divided outside the pericardium leaving the intrapericardial pulmonary veins and posterior left atrial wall intact. This may, however, require additional mobilization of tissue anterior to the phrenic nerves to allow the lungs to sit nicely in each pleural space.

The tracheal anastomosis is facilitated by placing silk stay sutures on the donor trachea after dividing it just above the carina. It is important to avoid any additional dissection superior to the point of division in order to preserve all possible blood supply to the tracheal anastomosis. The anastomosis is constructed with continuous 3-0 polypropylene sutures in adults and 4-0 polypropylene sutures in children (Fig. 21-36, C). An air-tight anastomosis must be achieved.
without necrosis of the membranous portion and without turning excessive amounts of tissue into the tracheal lumen. The pericardium is wrapped around the trachea and sutured to the thick lymphatic tissue anterior to the suture line. Gentle inflation of the lung while immersing the tracheal anastomosis in saline allows validation of an air-tight suture line. During implantation of the heart-lung block, the organs are covered with ice slush to maintain topical hypothermia.

The inferior and superior vena caval and aortic anastomoses are constructed, as in the bicaval orthotopic heart transplant technique (see “Orthotopic Cardiac Transplantation” under Technique of Operation in Section I). During rewarming, after suture lines are completed, the lungs are gently ventilated, and CPB is discontinued as usual. Nitric oxide is used in the presence of any reperfusion-induced pulmonary hypertension.

SPECIAL FEATURES OF POSTOPERATIVE CARE

Posttransplant management is similar to that for heart transplantation, except for additional protocols to enhance pulmonary graft function. Fiberoptic bronchoscopy is routinely performed in the operating room at the end of the procedure to clear any secretions and examine the tracheal anastomosis. It should be performed again just prior to extubation and as indicated thereafter.

Because of potential ischemia-reperfusion injury and lymphatic disruption, a reimplantation response—evidenced by pulmonary perihilar haziness on chest radiograph and increased oxygen requirement—is common 2 to 5 days following heart-lung transplantation. Diuresis and fluid restriction is the primary therapy. When this process persists 1 week or more, acute rejection should be considered, with transbronchial biopsy assessment of suspected rejection.

Current immunosuppression protocols for heart-lung transplantation are similar to those for isolated heart transplantation with the exception of the steroid protocol (see Box 21-7). Although unproven, higher-dose prednisone is considered deleterious to tracheal healing, and oral prednisone is initiated at a dose of about 0.4 mg·kg⁻¹·day⁻¹ with a rapid taper.

Surveillance for and management of lung rejection includes the same protocols that have been established for isolated single and double lung transplantation.

RESULTS

Survival

Survival is generally inferior to isolated heart transplantation, with a 1-year survival of approximately 80% and 10-year survival of 30% to 40%. Early graft failure is the most common cause of death in the first month, and infection remains the major cause of mortality thereafter, accounting for approximately one third of deaths after the first month. As in isolated lung transplantation, bronchiolitis obliterans accounts for 20% to 40% of mortality observed after the first year.

INDICATIONS FOR HEART-LUNG TRANSPLANTATION

The current general indications for heart-lung transplantation are (1) Eisenmenger syndrome with an uncorrected intracardiac defect, (2) uncorrectable congenital heart disease with atresia or diffuse severe hypoplasia of the pulmonary arteries and progressive heart failure, (3) coexistence of severe cardiopulmonary disease with advanced heart or lung failure, and (4) severe heart failure with left ventricular dysfunction and secondary pulmonary hypertension unresponsive to vasodilator therapy.

In the current era of limited donor availability combined with the success achieved in single and double lung transplantation, isolated lung transplantation is the preferred therapy for advanced lung failure associated with emphysema, usual interstitial pneumonitis, and suppurative lung disease, including cystic fibrosis. Primary pulmonary hypertension refractory to medical therapy is currently preferentially treated with bilateral lung transplantation instead of combined heart-lung transplantation.

The natural history of Eisenmenger syndrome—characterized by excessive muscularization of the pulmonary vasculature that results in marked irreversible elevation of pulmonary vascular resistance and reversal of a previously left-to-right shunt at the atrial, ventricular, or aortopulmonary level, resulting in right-to-left shunting and cyanosis—has not been characterized well enough to allow data-driven decisions regarding timing of referral for heart-lung transplantation. The time course of deterioration in this condition is slow, with 25-year survival exceeding 40%.

In general, the timing of listing for heart-lung transplantation is based on:

- Worsening cyanosis
- Right ventricular failure—particularly with marked ascites and peripheral edema—that is unresponsive to diuretic therapy
- Worsening oxygen saturation, particularly once it reaches 60% with exertion
- Progressive fatigue and dyspnea, particularly if repeated phlebotomy is required

Section IV Heterotopic Heart Transplantation

DEFINITION

The term heterotopic cardiac transplantation is used to describe placing the heart in a nonanatomic position (as opposed to the orthotopic or normal anatomic position). Although this term when used in the clinical setting has become synonymous with intrathoracic placement of the donor heart in parallel with the native heart, the terms “auxiliary” and “parallel” were used in the original publications of this technique. Heterotopic transplantation of the heart as an auxiliary pump was first described in the early 1960s. Since that time, heterotopic transplantation has found divergent roles as an experimental model and in clinical practice.

HISTORICAL NOTE

Heterotopic cardiac transplantation was first performed clinically in 1974 in South Africa, and it was used exclusively in
Cape Town for many years. A number of putative advantages of heterotopic transplantation over orthotopic transplantation were believed to justify this procedure:

- Support of a dysfunctional donor heart (due to a long ischemic time) by the native heart until donor heart recovery occurs.
- Management of elevated pulmonary vascular resistance with a heterotopic heart so that the native right ventricle can continue to support the right side of the circulation after transplantation.
- Use of a small donor heart for a larger recipient.
- Potential to function as a “built-in assist device” at the time of hemodynamically significant acute cardiac rejection.
- Support of the native heart with development of coronary vasculopathy, as protection against sudden cardiac death until retransplantation can be undertaken.
- In the rare circumstances when native cardiac failure may result from a process such as acute myocarditis, for which there is potential for recovery and subsequent removal of the heterotropic transplant.

The initial clinical experience of heterotopic cardiac transplantation in Cape Town included use of the donor heart purely for left ventricular assistance, with the donor pulmonary trunk being anastomosed to the recipient right atrium for donor coronary sinus venous return. Heterotopic transplantation was subsequently altered in favor of biventricular support. In 1983, Cooper and colleagues reported two patients who underwent heterotopic heart transplantation with donor heart ischemic times of 8 hours and nearly 13 hours, respectively, preserved with a portable hypothermic perfusion apparatus. Initial donor heart function was poor for approximately 20 hours, the circulation being supported by the recipient’s own heart until the donor heart recovered.

**TECHNIQUE OF OPERATION**

**Donor Heart Procurement**

The donor heart is procured in the standard way except that the entire ascending aorta and aortic arch are harvested. The orifices of the right pulmonary veins are oversewn with continuous 5-0 polypropylene suture. The inferior vena caval orifice is also oversewn, taking care to avoid impinging on the coronary sinus. The partition between the left superior and inferior pulmonary veins is excised and the incision extended slightly into the base of the left atrial appendage as necessary to create an opening as large as the mitral valve orifice. In addition, the entire superior vena cava and proximal brachiocephalic vein is harvested.

**Heterotopic Cardiac Transplantation**

A standard median sternotomy is made in the recipient. The right pleural space is widely opened to accommodate the donor heart. The pericardium is opened in the midline, and a pericardial flap for support of the transplanted heart is fashioned by making two perpendicular incisions on the right side that stop approximately 2 cm from the phrenic nerve. Careful hemostasis of this flap is important because it is not accessible after the heart is implanted. Great care must be taken to avoid any coagulation near the phrenic nerve. Small bleeding points at the extent of these pericardial incisions should be controlled with fine polypropylene sutures.

CPB is established with separate caval cannulation and moderate hypothermic (25°-28°C) perfusion. Myocardial preservation of the native heart is extremely important because most of the pulmonary ventricular function will arise from the native right ventricle, and the native left ventricle may be required to contribute to systemic support early after transplant. The aorta is clamped and multidose cardioplegic techniques used for the native heart, as in standard cardiac operations (see Chapter 3). Intermittent topical cooling with cold saline is employed. A left atriotomy is made in the interatrial groove as for standard mitral valve surgery (see Chapter 11), except that the incision does not extend under the superior or inferior vena cava. The opening in the donor left atrium is anastomosed to the corresponding opening in the native left atrium using continuous 3-0 polypropylene suture.

The donor superior vena cava is then anastomosed end to side to the anterolateral aspect of the recipient superior vena cava near the junction of the native right subclavian and brachiocephalic veins. This anastomosis is constructed with continuous 5-0 polypropylene suture, and the opening should be as large as the circumference of the donor superior vena cava (Fig. 21-37, A). This will provide access for endomyocardial biopsies of the donor right ventricle. The donor aorta is then anastomosed end to side to the anterolateral aspect of the native aorta with continuous 4-0 polypropylene suture (Fig. 21-37, B). Air is thoroughly evacuated from both hearts, and the aortic clamp removed with the same attention to details of reperfusion as in orthotopic cardiac transplantation. While rewarming, the donor pulmonary artery is lengthened with an appropriate-sized woven collagen-impregnated polyester graft, which is then anastomosed end to side to the anterior aspect of the native pulmonary trunk (Fig. 21-37, C). The remainder of the operation is completed as usual, taking care to leave atrial and ventricular pacing wires on both native and transplanted hearts for use postoperatively if necessary.

Use of the direct superior vena cava connection simplifies passing an endomyocardial biopsy forceps into the donor right ventricle. Infection of the pulmonary artery conduit is a potential risk of heterotopic transplantation using this method, and this complication, requiring removal of the conduit and replacement with an aortic allograft, has previously been described. An alternative technique involves ligation of donor superior vena cava and a direct connection between the donor pulmonary trunk and the recipient right atrium, which would receive coronary sinus return from the donor heart.

**SPECIAL FEATURES OF POSTOPERATIVE CARE**

Permanent anticoagulation is required after heterotopic cardiac transplantation, because the native heart is a source of thrombus that may be ejected through the native aortic valve. Despite adequate anticoagulation, systemic emboli can still occur. Presence of a mechanical valve in the native heart increases risk of thrombosis and is regarded as a contraindication to heterotopic heart transplantation.
INDICATIONS FOR HETEROPTIC HEART TRANSPLANTATION

In the current era, there are two basic indications for heterotopic transplantation. First, this procedure should be considered when there is marked elevation of recipient pulmonary vascular resistance, with systolic pressure greater than about 60 mmHg and little or no pulmonary reactivity despite pharmacologic intervention. The situation is particularly dangerous for orthotopic transplantation if the pulmonary artery systolic pressure remains above 55 mmHg when the pulmonary capillary wedge pressure is below about 20 mmHg. Second, heterotopic transplantation may be considered when the donor heart is from a considerably smaller donor than the recipient (in body surface area). The limits of safe orthotopic cardiac transplantation from a smaller donor into a larger recipient are not well established, but the risk is known to be increased when a smaller female heart is transplanted into a considerably larger male recipient, and probably from a smaller-sized young teenage donor into a larger adult male recipient. It should be emphasized that every effort should be made to find a suitable teenage recipient for a teenage donor before resorting to this extreme procedure in an adult recipient.

Mechanical circulatory support (MCS) is a means of imparting energy for forward flow of blood in the body by manmade devices. Its intent is to remove some or all work of cardiac output from either or both left and right ventricles. Mechanical circulatory support devices (MCSDs) can be used to provide temporary ventricular assistance after cardiac surgery, with the assumption that ventricular function will recover rather quickly (days). Durable mechanical devices can be used for prolonged (months to years) circulatory support with the intent of bridge-to-transplant support, bridge to recovery (with the expectation of sufficient ventricular
recovery to allow device explantation), or permanent (destination) therapy.

Mechanical pumping mechanisms can be placed internally (implantable) or external to the body (paracorporeal). Their power source can be electric or pneumatic, located outside the body or completely within it, with electric power conducted transcutaneously. Their pump flow characteristic can be pulsatile or continuous flow.

This chapter does not include use of biological means for MCS nor passive (non–energy imparting) devices used primarily to address ventricular remodeling (see Chapter 20). This chapter also does not include short term temporary devices.

HISTORICAL NOTE

Early descriptions of mechanically supporting human circulation date back at least to the early 19th century in the writings of LeGallois. Carrel and Lindberg as well as Demikhov reported experimental application of mechanical support systems in animal models in the 1930s. However, major interest in mechanical support of human circulation would await the dawn of open heart surgery in the 1950s.

With successful application of cardiopulmonary bypass (CPB) for a cardiac surgical operation by Gibbon in 1953 and the subsequent first successful series of cardiac operations using CPB by Kirklin and colleagues at the Mayo Clinic, the stage was set for rapid proliferation of the technology of temporary MCS (in this case the heart-lung machine) for repair of cardiac malformations. Failure to successfully wean some patients from CPB stimulated surgeons to seek additional methods of mechanical support while awaiting myocardial recovery. Roller-pump technology was complicated by trauma to blood elements and difficulty in modulating pump speed in response to fluctuations in atrial filling pressures. The first application of a true ventricular assist device (VAD) was attributed to Michael DeBakey, who in 1966 reported the successful application of a pneumatically driven diaphragm pump for 10 days in a 37-year-old woman unable to be weaned from CPB following aortic and mitral valve replacements. Cooley subsequently reported the first successful bridge to transplantation in a 47-year-old man for 64 hours while awaiting heart transplantation with a pneumatically driven artificial heart, the Lioitta Heart, developed by the DeBakey-Baylor-Rice research team.

MCS research focused on pneumatic, electric, and even nuclear-powered designs through the 1980s. The experimental work of Kolff, Olsen, Jarvik, and others paved the way for the first permanent total artificial heart implant in Dr. Barney Clark by DeVries and his team in 1982. Five patients received permanent total artificial hearts under a U.S. Food and Drug Administration (FDA) protocol, with a maximum reported survival of 620 days. The close scrutiny of this initial trial of the Jarvik-7 total artificial heart stimulated intense and sometimes acrimonious debate among ethicists, economists, and healthcare experts about the application of expensive and human-intensive technologies in end-of-life situations.

Just as open heart surgery using CPB paved the way for early application of MCS, cardiac transplantation provided the stimulus for proliferation of ventricular assist systems as a bridging therapy to transplantation. With nearly 30% of patients dying while awaiting cardiac transplantation in the early 1980s, a clear need developed for effective and durable MCSDs that could safely support patients until suitable donor hearts could be identified. The improving outcomes following cardiac transplantation and the scarcity of available organs provided the impetus for a major collaborative effort among the heart transplantation community, the National Institutes of Health (NIH), and scientists and clinicians dedicated to the development of durable MCS systems. In 1984, Oyer, Portner, and colleagues reported the first successful cardiac transplant following bridging with a Novacor (WorldHeart Corp., Oakland, Calif.) left ventricular assist device (LVAD). Hill and colleagues subsequently published successful transplantation following support with a Pierce-Donachy pneumatic LVAD. About the same time (1985), Copeland and colleagues performed the first planned total artificial heart implant as a bridge to transplantation. Continuing advancements in mechanical support over the ensuing decade led to the first FDA-approved implantable device as a bridge to transplantation in 1994.

Despite the early focus on MCS as a bridging therapy to transplantation, the clear intent of the scientific and engineering community was the development of devices capable of long-term safe circulatory support. The landmark feasibility study of long-term mechanical support was the Randomized Evaluation of Mechanical Assistance for Treatment of Congestive Heart Failure (REMATCH) trial. As reported by Rose and colleagues in 2001, the HeartMate VE VAD provided significant survival benefit at 1 and 2 years compared with medical therapy for patients with very advanced heart failure who were not suitable for cardiac transplantation. This NIH-sponsored multi-institutional trial provided the impetus for FDA approval of this device for so-called destination therapy in 2002. This set the stage for multiple clinical trials in the application of long-term mechanical support.

In recent years, device technology has increasingly focused on smaller, simpler, and likely more durable continuous flow (rotary) pumps that lack the pulsatile characteristics of earlier “first-generation” pumps. Following the earlier experimental work of Saxton, Andrews, Wampler, DeBakey, and others, recent clinical applications have focused on axial flow and centrifugal pumps.

BIOLOGICAL BARRIERS

General Concepts

A biomaterial is a natural or artificial material that remains in contact with one or more internal components of the human body for the purpose of replacing organ function or treating an abnormal condition. Biocompatibility refers to the effect of a specific biomaterial on exposed host tissues, whereas hemocompatibility refers to the specific effects of a biomaterial or circulatory support system on blood components, coagulation cascade, and the tendency for thrombus formation. Successful blood pump design requires special knowledge of microlevel interactions between blood elements and the contact surface as well as macrolevel considerations that include choice of prosthetic valves (if required), inflow and outflow port design, and blood flow pathways within the pump. The ideal biocompatible surface for blood is functioning endothelium, but the creation of a functioning endothelial layer on a bioprosthetic surface remains elusive. Minimizing thrombogenicity requires avoidance of highly
thrombogenic biomaterials, specific features of pump design, and pharmacologic inhibition of the coagulation cascade. The requirement for blood-exposed pump components that minimize thrombogenicity has limited compatible materials for blood-exposed surfaces to titanium, polymers (primarily polyurethanes), silicone, graphite, and pyrolytic carbon. A fundamental concept for the understanding of blood-pump surface interaction is the process of protein adsorption to biomaterial surfaces. Following exposure of pump surfaces to circulating blood in vivo, a protein layer develops that covers the biomaterial surface. The make-up of this protein layer is determined by the protein composition of the patient’s blood, the chemical composition of the biomaterial surface (more specifically, surface charge and hydrophobicity), and surface topography (rough vs. smooth surface, porous vs. nonporous). Concentration of proteins in blood, net protein charge relative to the biomaterial surface, distribution of charges on the protein surface, and ability of the protein to undergo conformational changes all contribute to the propensity for a given protein to adsorb to the pump surface. Protein interactions with the biomaterial vary over time and are therefore dynamic. The change in composition of proteins that adsorb to the pump surface over time is termed the Vroman effect. The specific details of these protein-surface interactions contribute directly to the likelihood of pump thrombogenicity, because these proteins are biologically active and can initiate platelet adhesion and activation and trigger coagulation cascades.

Both smooth and rough surface designs have been used successfully in pump design. The textured titanium surface of the HeartMate pulsatile LVAD stimulates the formation of a thin, stable coagulum that, although counterintuitive, has proven effective in minimizing development of pump thrombus.

Application of computer simulations called computational fluid dynamics (CFD) analyses has greatly facilitated the ability to predict the effects of shear stresses in the pump flow pathway and areas of relative stasis on platelet activation and thrombus formation.

The Coagulation System

Contact between the pump surfaces and specific plasma proteins, including factor XII (Hageman factor), prekallikrein, and factor XI, can initiate the coagulation cascade via the intrinsic clotting system (also called the contact system) particularly in areas of relative blood stagnation (Fig. 22-1).

The additional critical component of thrombus formation is platelet adhesion, aggregation, and activation. Normal endothelium is antithrombogenic, in part related to active biochemical reactions involving nitric oxide and prostacyclins. In areas of low shear rates, fibronectin functions as the adhesive system for platelets, whereas von Willebrand factor (factor VIII) is the active adhesive protein for platelets at high shear rates, particularly in combination with fibrinogen. Adhesion of platelets to vascular subendothelium is facilitated by von Willebrand factor, which forms a bridge between collagen fibrils in the vessel wall and platelet receptors. Following contact activation, platelets undergo changes in shape in which they display spreading pseudopods and release the contents of their α granules (which contain fibrinogen, fibronectin, thrombospondin, von Willebrand factor, β-thromboglobulin, platelet factor IV, and platelet-derived...
growth factor), which stimulate thrombin generation. Platelet aggregation is stimulated by the release of adenosine diphosphate (ADP). Under laminar flow conditions, the released granule contents cannot accumulate, but when flow is nonlaminar, platelets are more likely to aggregate and accumulate. As newly recruited platelets release their granular contents, thrombin formation is facilitated by the generation of fibrinogen/fibrin bridges. Increasing thrombin generation accelerates the formation of thromboxane A2 and the release of ADP, which further promotes conversion of fibrinogen to fibrin and platelet activation and aggregation. Damaged red cells from shear stress–induced hemolysis also release ADP, further perpetuating platelet activation.

Preserved vascular endothelial cell function is critical for prevention of intravascular thrombus. Synthesis and release of prostacyclins inhibits platelet activation. Thrombomodulin, an endothelial cell product, neutralizes the procoagulant properties of thrombin and activates protein C, a potent anticoagulant that destroys factors Va and VIIIa. Antithrombin III binds to the endothelial cell plasma membrane and inactivates thrombin.

Specific discussion on anticoagulation therapy for pumps can be found in Special Features of Postoperative Management.

Immunologic Responses to Mechanical Circulatory Support

It remains controversial whether VADs differ in their propensity to induce an immunologic response. In vitro studies of the textured titanium surface of the HeartMate XVE indicate that T lymphocytes (probably activated helper T cells) in the neointimal surface lining express strong immunoreactivity for CD3, CD4, and CD25 (interleukin [IL]-2 receptors). Demonstrated defects in T-cell function post implant induce T-cell apoptosis and possibly decreased resistance to infection.

A major disadvantage of MCS as a bridge to transplantation is the frequency of patient sensitization against foreign HLA antigens, which increases the likelihood of developing anti-HLA antibodies against a potential donor (positive cross-match). Although the pump surface has been implicated in this process, it is more likely that transfused blood products, particularly platelets, account for sensitization. Platelets exhibit high concentrations of major histocompatibility complex (MHC) class I and class II HLA antigens (in contrast to red blood cells), and patients receiving more than 6 platelet units are more likely to develop immunoglobulin (Ig) G antibodies against MHC class I antigens.

ENGINEERING CONCEPTS IN PUMP DESIGN

General Concepts

Specific technologic barriers challenging successful MCS include development of corrosion-resistant materials with minimal toxicity and a high level of structural integrity, management of specific blood-contacting surfaces to minimize thrombogenicity and damage to blood elements, blood pump design, and methods to store energy.

Energy to generate flow from circulatory assist pumps requires conversion of either electrical or pneumatic energy (compressed gas) into kinetic energy (energy of motion). Pulsatile or volume-displacement pumps are usually driven by electric motors that either transfer power directly to a pusher plate mechanism or compress gas or liquid in order to transfer energy to the blood sack or pusher plate. Continuous flow (rotary) pumps use electric motors to transmit kinetic energy to the blood.

The principles of Starling’s law also apply to circulatory pumps, in that the pump must respond to higher inflow into the pump by increasing output. As in the natural heart, this balance is maintained in pulsatile pumps by variations in stroke volume or pump rate.

The major cause of hemolysis in blood pumps is rapid acceleration or deceleration of red cells through the pump, which can induce red cell membrane fracture. In general, pump-induced hemolysis is considered acceptable if the plasma free hemoglobin is maintained at less than 19 mg/dL. The rate of pressure increase and flow-channel velocities are maintained at levels designed to avoid high shear stress.

Proper application of fluid dynamics is critical to minimize thrombus formation. Because blood stasis—particularly flow cessation—promotes clot formation, stationary vortex flow must be avoided because the central stagnant portion of the vortex can become a nidus for thrombus formation.

Power sources and alarms must provide reliability and durability backed up by software programs designed to activate appropriate alarm systems when deviations from normal function occur. Approximately 1.6 watts of power are needed to pump 6 L/min at 120 mmHg. Power in excess of 1.6 watts is both wasted and converted to heat that must safely dissipate within the body.

Pulsatile (Volume Displacement) versus Continuous Flow (Rotary) Pumps

Major pump designs in clinical use today are either pulsatile (volume displacement) or continuous flow (rotary) pumps, which include axial flow and centrifugal pump design. The main features of these basic pump designs are summarized in Table 22-1. Pulsatile pumps cyclically change the internal volume of a pumping chamber, displacing a specific volume of blood with each ejection. Such pumps require one-way valves to generate forward flow, typically utilizing valves in the inflow and outflow portions of the pump. In hermetically sealed (not vented to the atmosphere) pulsatile pumps, cyclic displacement of blood volume within the pumping chamber must be accompanied by an equal increase of volume elsewhere within the casing. This usually occurs via a compliance sack placed outside the device but within the patient.

Continuous flow pumps consist of a rotating component that has one or more impellers (usually a disk or cylinder with vanes that propel blood forward). One or more bearings support the impeller. The assembly comprising all rotating elements is termed the pump rotor. As the impeller rotates, it imparts rotational velocity to the blood, and this rotational energy must be converted into pressure energy to achieve forward blood flow. To facilitate this process, additional stationary blades or other structures redirect the swirling blood to create pressure and forward blood flow. In axial flow pumps, the stator typically consists of stationary blades, whereas the stator of a centrifugal pump typically consists of a scroll-shaped passage or volute.

Figure 22-3  Relationship between pump flow and pressure differences across inlet and outlet orifices of HeartMate II pump during cardiac cycle. Key: \(P_{\text{aort}}\), Aortic pressure; \(P_{L}\), left ventricular pressure. (Diagram courtesy David Farrar, PhD; Thoratec Inc., Pleasanton, Calif. From Antaki and colleagues.\textsuperscript{a2})

The forward flow of blood through an axial flow pump is determined primarily by the speed of the rotor (pump speed) and the pressure difference across the inlet and outlet orifices of the pump. In the absence of obstruction to pump inflow, pressure at the outlet orifices (aorta) always exceeds inlet pressure (left ventricle). At any given pump speed, blood flow through the pump \textit{increases} as the pressure difference across the inlet and outlet orifices \textit{decreases}. At any pressure difference across inlet and outlet orifices, blood flow will increase with increasing pump speed. The relationship among flow, pressure, and pump speed is predicted by a series of flow pressure curves called \textit{HQ curves} (Figs. 22-2 and 22-3). Under physiologic conditions, inlet pressure to the axial flow pump changes in a cyclic fashion during systolic and diastolic phases of the left ventricle. In most situations, even in the presence of severe left ventricular dysfunction and absence of opening of the aortic valve, continuous flow devices contribute some degree of pulsatility to the aortic pressure waveform secondary to the changing differential pressure across the inlet and outlet orifices. Nonpulsatile blood flow occurs in situations of ventricular fibrillation, operation of the pump at too high a pump speed, or with negative inflow pressure causing left ventricular collapse around the inflow orifice.

Assessment of left ventricular volume status during axial flow pump support is facilitated by echocardiography, in which ventricular filling, presence or absence of aortic valve opening, and any tendency toward left ventricular chamber...
collapse around the inflow cannula (suction event) can be assessed. Ideally, pump speed should be adjusted to permit intermittent aortic valve opening, which minimizes the risk of a suction event and may promote more effective washout of the sinuses of Valsalva, decreasing the likelihood of thrombus formation along the aortic valve. However, optimal operating conditions for exercise reserve and promotion of reverse remodeling remain controversial.\textsuperscript{813,G5,H1}

**Bearings and Seals**

Proper design of bearings and seals within devices has provided a major challenge in the progress of MCS. Bearings are devices that provide support, guide movement, and reduce friction of motion between fixed and moving parts. A moving part may be a bladder or pusher plate in a pulsatile pump, or a rotary impeller in a rotary pump. Bearings pose a risk of wear, and therefore failure, secondary to continuous physical contact between solid components. Bearings that remain dry (without direct contact to blood) require special seals that are themselves subject to wear and failure. More recent second-generation pumps avoid seals by using blood itself as the lubricant fluid, with so-called blood-immersed bearings. The third generation of rotary pumps incorporates electromagnetic levitation; these magnetic bearings provide support through magnetic force fields.

**DURABLE CIRCULATORY SUPPORT DEVICES**

**Pulsatile Ventricular Assist Devices**

**Paracorporeal Ventricular Assist Devices**

Paracorporeal assist devices have a pump positioned outside the body cavity, with inflow and outflow cannulae that traverse the skin and subcutaneous tissues. The most commonly employed paracorporeal pump suitable for outpatient use is the Thoratec (Thoratec Corp., Pleasanton, Calif.) VAD.

The Thoratec paracorporeal ventricular assist device (PVAD) can be used for support of the left ventricle (LVAD), right ventricle (RVAD), or both ventricles (BVAD) (Fig. 22-4). The Thoratec PVAD received FDA approval for bridge-to-cardiac transplantation therapy in 1995 and has been implanted in more than 3000 patients.\textsuperscript{H3} The PVAD has a 65-mL stroke volume polyurethane chamber with two mechanical valves. The pneumatic driver applies alternating positive and negative air pressure to achieve a clinical beat rate of 40 to 110 beats/min. The PVAD is positioned on the anterior abdominal wall, with cannulas traversing the skin and mediastinum to provide connections to the heart and great vessels (Fig. 22-5). The device can be pneumatically actuated in an ambulatory setting with a portable TLC-II (Thoratec) driver. The TLC-II was approved for home discharge by the FDA in 2003.

Chronic anticoagulation with warfarin is required, with a target international normalized ratio (INR) of 2.5 to 3.5. Aspirin or other antiplatelet therapy is usually added to the anticoagulant regimen. Anticoagulation usually begins with heparin following cessation of bleeding, but some protocols recommend avoidance of heparin completely in the early anticoagulation phase.

**Intracorporeal Assist Devices**

**Thoratec Implantable Ventricular Assist Device** The Thoratec implantable ventricular assist device (IVAD) is designed to provide all the same features as the PVAD, with pump placement in the intracorporeal position (Fig. 22-6). The IVAD has the same pumping chamber, mechanical valves, and stroke volume as the PVAD. The major differences in the IVAD include a smooth, polished titanium housing for implantability, lighter weight (339 g vs. 417 g), and a narrower 9-mm percutaneous lead, compared with the 20-mm paracorporeal driveline. An optical sensor detects when the pump is full or empty. Internal implantation is appropriate for patients with a body surface area (BSA) greater than about 1.6 m\textsuperscript{2}. The same anticoagulation regimen is used as for the PVAD.

**HeartMate XVE Left Ventricular Assist Device** The largest experience with durable pulsatile VADs stems from the HeartMate XVE LVAD, a variant of which was first
Chapter 22 Mechanical Circulatory Support

introduced in 1986 with pneumatic power. More than 5000 patients have been treated with this device over the past 20 years, and it was used in the REMATCH trial, which led to its approval in the United States for permanent MCS therapy.

The HeartMate LVAD (Fig. 22-7) is a positive-displacement pump made of titanium with a polyurethane diaphragm and a pusher-plate actuator that converts electrical energy to mechanical energy. It may be powered pneumatically or electrically, but only the vented electric version (XVE) is currently used. Cannulation involves a left ventricular apical cannula and an outflow graft to the ascending aorta. Two porcine valves provide directional flow.

The vented electric system is powered by an electric motor that rotates and displaces a pusher-plate that compresses the blood sack to initiate ejection. Air displaced by the diaphragm is vented to the atmosphere by a venting apparatus incorporated into the percutaneous driveline. The vent site provides a portal for pneumatic activation in the event of electrical failure. Power is supplied by two external batteries and an external controller.

Maximum stroke volume is 83 mL, and pumping may be performed in a fixed-rate or “automatic” mode, in which the stroke volume is maintained at a level of 97% full by varying the rate in response to preload. If the rate is adjusted manually, stroke volume should be maintained between 70 and 80 mL, because slower stroke volumes increase the potential for thrombogenesis.

The most unique feature of the HeartMate XVE device is the blood pumping surface, which consists of titanium microspheres and a fibrillar texture that promotes formation of a “pseudointima” that is resistant to thrombogenesis. The neo-intimal surface that develops is composed of collagen as well as cells derived from circulating progenitors of fibroblasts, myofibroblasts, monocytes, macrophages, and endothelial cells. Anticoagulation requirements for the XVE pump are unique among current MCS systems. The textured titanium surface creates a thrombo-resistant pump that requires only aspirin for effective anticoagulation. This creates a special indication for this pump in the setting of clinical comorbidities likely to produce bleeding complications during VAD support.

Unfortunately, the major advantage of minimal anticoagulation requirements is currently outweighed by the poor long-term durability of this pump. With the current iteration of the XVE, bearing wear is a major source of device malfunction. Typically, the HeartMate XVE develops signs of bearing wear within 18 to 24 months (Box 22-1). Pump stoppage can be expected within days to weeks of the onset of signs of important bearing wear. When bearing wear is accompanied by transient pump stoppage or repetitive alarms, the patient can be switched to the pneumatic drive mode in the hospital setting while plans are made for surgical pump exchange. In the event of pump stoppage at home, emergent hand pumping can safely support the patient during transport to the hospital.

**Novacor Left Ventricular Assist Device** The Novacor LVAD (WorldHeart Corp., Oakland, Calif.; Fig. 22-8) holds a special place in the history of MCS as one of the first devices designed for permanent device support. In 1984, the Novacor was the first durable pump used as a successful bridge to transplantation. Implantation in over 1600 patients worldwide, the Novacor has demonstrated high system reliability in the outpatient setting, with a low incidence of device malfunction.

The pump drive unit incorporates a dual pusher-plate pump mechanism coupled to a pulsed solenoid energy
Converter driver. The percutaneous drive line contains the vent tube. Two porcine valves are incorporated in the inflow and outflow conduits.

Thromboembolic complications have been the major weakness of the Novacor device, despite standard anticoagulation with warfarin and antiplatelet agents. The primary source of particulate embolization was likely a friable pannus that often developed in the inflow conduit. Subsequent design modifications to include expanded polytetrafluoroethylene (PTFE) have importantly reduced embolic events. In a multi-institutional analysis, the incidence of embolic stroke was 5.3% during an average support duration of 162 days using the modified inflow conduit.

Continuous Flow Ventricular Assist Devices

Rotary (continuous flow) pumps differ from volume displacement pumps in that instead of employing a chamber that changes volume and ejects blood via unidirectional valves, rotary pumps impart forward flow by rotating impellers with no valves. (See also discussion of continuous flow technology in Engineering Concepts in Pump Design.) These pumps are electrically driven and have the distinct advantages of small size and smaller drive lines. In contrast to volume displacement pumps, rotary devices are more afterload sensitive; at constant pump speed, the flow drops with increased systemic vascular resistance (see Fig. 22-2). The absence of inflow and outflow valves in rotary pumps improves overall pump durability and simplicity but removes a key failsafe feature of one-way valves: pulsatile pumps typically have a mechanism for hand pumping in the event of an electrical failure, but no such hand pumping device is available for rotary pumps. Specifically, pump stoppage with rotary pumps induces varying degrees of “aortic insufficiency,” with nothing to prevent reversal of flow from aorta into ventricle during diastole. If not promptly corrected, this rare event is frequently fatal in the setting of advanced heart failure, which invariably accompanies pump implantation.

Although continuous flow pumps are usually not pulsatile to a degree that produces a palpable pulse (unless the native heart is rejecting), these rotary pumps typically produce some pulsatility in blood pressure (as measured with an indwelling arterial line) due to changing pump flows throughout the cardiac cycle.

Rotary pumps currently in clinical use are of two major types: axial flow and centrifugal flow. The designations axial and centrifugal refer specifically to the design of the impeller, without reference to the orientation of inlet or outlet ports. It is the rotation of the impeller that imparts rotational velocity to the blood, creating forward flow. Pure axial flow pumps act like a fan, adding energy by deflecting flow in the circumferential direction. Centrifugal pumps typically contain disk-shaped impellers, with blood entering at the center of the impeller and exiting radially at the periphery. Typically, axial pumps feature inlet and outlet ports that are opposed 180 degrees from each another, and centrifugal pumps have ports oriented perpendicular to each other. Within this spectrum of pumps lies a continuum of mixed flow pumps, incorporating aspects of axial and centrifugal design.

HeartMate II

Axial flow pumps in current use in clinical practice contain many features represented in the HeartMate II (Thoratec Corp., Pleasanton, Calif.), the only rotary pump currently approved (as of March 2011) by the FDA (Fig. 22-9). The blood pump component of the HeartMate II is composed of a straight titanium tube that houses the inlet stator, the fixed component that forms the pivotal housing for the rotor; the rotor, the rotational component that includes the impeller blades; the rotor magnet, which generates the magnetic field to induce impeller movement; and the outlet stator, which converts the radial velocity of blood flow to an axial direction (Fig. 22-10). The other major pump components include the inlet cannula, implanted into the left ventricular apex, and the outlet cannula, which returns blood from the pump outlet to the ascending aorta.

The system driver sends electric power and operating signals to the pump and receives pump information. The wearable driver is powered by either a power base unit or two 12-volt rechargeable batteries that generally provide 2 to 4 hours of power. Power transmitted to the electric motor within the hub of the rotor creates a spinning magnetic field. The pump rotor spins on two bearings located at the inlet and outlet stators. The rotor that spins within the magnetic field is the only moving component of the device. Ceramic bearings are washed by the flow of blood. Operating pump speed ranges from 6000 to 15,000 rpm and is capable of generating blood flow up to about 8 L/min. The approximate pump weight is 350 g, with a length of 7 cm and diameter of 4 cm.

Special features of the HeartMate II pump include a flexible joint between the intraventricular portion of the cannula...
and its connection to a titanium elbow that joins the pump. The flexible portion of the inlet cannula reduces the risk of malalignment of the intraventricular portion of the inlet cannula with respect to the ventricular cavity. The inlet cannula design reduces torque on the intraventricular portion of the inlet cannula. An extension in the length of the intraventricular rigid cannula improves reliability of continuous flow throughout the cardiac cycle and at various levels of left ventricular filling. The pump rotor, blood tube within the pump housing, and inlet and outlet stators are smooth titanium surfaces. The inlet and outlet elbows and the intraventricular cannula are textured with titanium microsphere coatings similar to the design of the HeartMate XVE.\(^{23,35}\)

**MicroMed-DeBakey Left Ventricular Assist Device**

The MicroMed-DeBakey LVAD (MicroMed Cardiovascular Inc., Houston, Tex.) is an axial flow pump which consists of an elbow-shaped inflow cannula that inserts into the left ventricular apex, a pump housing unit, a Dacron outflow graft which connects to the ascending aorta, and an ultrasonic flow probe that encircles the outflow grafts and provides direct measurement of pump flow (Fig. 22-11). The pump impeller is actuated by an electromagnet and is the only moving part of the pump system. Wiring from the pump and the flow probe are contained in a flexible driveline that connects to the portable controller. External components include a controller system that operates the pump and a clinical data acquisition system. A potential advantage of this pump is the presence of a flow probe that allows accurate rather than estimated pump flow. Only the pediatric version of this pump (DeBakey Child) is FDA approved, but the adult version has been extensively used in Europe.

**Jarvik 2000 Left Ventricular Assist Device**

This and the remaining continuous flow pumps discussed are not yet FDA approved in the U.S. The Jarvik 2000 (Jarvik Heart Inc., New York, N.Y.) is an electrically powered,
CorAide Left Ventricular Assist Device

The Arrow CorAide LVAD (Cleveland Clinic Lerner Research Institute, Cleveland, Ohio) is a centrifugal-flow electrically powered third-generation LVAD (Fig. 22-13). The pump can be operated in a fixed-speed mode or an automatic-control mode in which the pump speed varies according to heart rate and systemic blood pressure. The pump and electrical cable weighs about 300 g and operates at speeds between 2000 and 3000 rpm. Pump flow rates are up to 8 L/min. Blood contact surfaces are fabricated from titanium. The rotating assembly uses a combination of magnetic forces and hydrodynamic forces for suspension, in which there is no surface contact with the bearings. A unique apical cuff clamp allows positioning and fixation of the apical cannula to optimize pump flow.

axial-flow blood pump that provides continuous flow from the left ventricle to the ascending or descending thoracic aorta (Fig. 22-12). A unique feature of this device is the placement of the axial flow pump within the left ventricular cavity. The overall system consists of the blood pump, a Dacron outflow graft, percutaneous power cable, pump speed controller, and direct-current power supply. The single moving part is the impeller located in the center of the titanium housing. Electromagnetic forces rotate the impeller, which consists of an electromagnet suspended by two ceramic bearings. All blood-contacting surfaces are made of smooth titanium. The pump operates at 8000 to 12,000 rpm and can generate flows up to 8 L/min. This pump is particularly suited to “off-pump” implantation as described in Techniques of Operation.

Figure 22-11  MicroMed-DeBakey ventricular assist device.

Figure 22-12  Jarvik 2000 heart pump.

Figure 22-13  CorAide ventricular assist device.
HeartWare

The HeartWare LVAD (HeartWare Ltd., Sydney, Australia) is a miniaturized centrifugal flow pump that sits entirely within the pericardial cavity (Fig. 22-16). A unique feature is the left ventricular apical inflow cannula, which is an integral part of the pump. The device weighs only 145 g but can generate flows up to 10 L/min. An apical sewing ring attaches to the left ventricular apex and allows adjustment of the inflow cannula orientation. Impeller blades are held in place by a hybrid magnetic and hydrodynamic bearing system.

Total Artificial Heart

The major advantage of the total artificial heart (TAH) over VADs is the provision for biventricular support with an implantable device. (The only currently available implantable separate right and left VAD system is the Thoratec IVAD system [see previous section].) The major disadvantage of the TAH is the necessity of removing the native heart, which removes the option of recovery. The second major disadvantage of current iterations is the space requirement for the device, such that only patients with a BSA of about 1.7 m² or greater are suitable.

The two TAH devices currently available for clinical use are the SynCardia CardioWest C-70 TAH and the AbioCor TAH. Both pumps replace the native ventricles and all four valves in the orthotopic position.

SynCardia Total Artificial Heart

The SynCardia TAH (SynCardia Systems Inc., Tucson, Ariz.) is a pneumatic pulsatile pump in which a rigid spherical outer housing around each artificial ventricle supports a seamless blood-contacting segmented polyurethane diaphragm, two intermediate diaphragms, and an air diaphragm (Fig. 22-17). Two Medtronic 27-mm inflow valves and two Medtronic 25-mm outflow valves provide unidirectional flow. The full ejection volume of each ventricle is 70 mL per beat, and the TAH typically generates a cardiac output of 7 to 8 L/min. The atrial components are sewn to the native atrial cuffs, and the atrioventricular and ventricular outflow graft connections are via “quick snap” connectors. The external console consists of one primary and one secondary pneumatic driver, air tanks,
rapid initiation of CPB in the event of bleeding or acute cardiac decompensation during sternotomy.

A pulmonary artery catheter is routinely advised to assess the response of pulmonary artery pressure to pharmacologic interventions and device implantation. Continuous measurement of pulmonary artery and central venous (or right atrial) pressures provides critical information in determining the need for inhaled nitric oxide and/or biventricular support.

Intraoperative transesophageal echocardiography (TEE) is necessary during MCS implants for assessment of biventricular function, evaluation of aortic insufficiency and presence of a patent foramen ovale, identification of intracardiac and aortic air bubbles during implantation and subsequent de-airing maneuvers, and assessment of inflow cannula position within the left ventricle.

Prior to sternotomy, formal discussions occur with anesthesia and echocardiography colleagues regarding the pulmonary artery and central venous pressures (CVP) and interventions to optimize right ventricular function, the presence and severity of aortic insufficiency and any need to address the aortic valve surgically (see Special Issues in Mechanical Circulatory Support), the presence or absence of intraventricular thrombus, and the presence of a patent foramen ovale (which if present has to be surgically closed to prevent postimplant arterial desaturation).

Prior to initiating CPB, any pockets necessary for device implantation are developed. If an intracorporeal device that requires an intraabdominal pocket is planned, the abdominal cavity is opened and a porous PTFE membrane is implanted to isolate the pump from the intraabdominal contents and allow drainage of blood around the pump through the porous membrane into the peritoneal cavity. In creating space for the left ventricular inflow cannula, leftward dissection along the diaphragm must extend far enough to allow proper alignment of the cannula within the left ventricular cavity.
Insufficient leftward dissection (often requiring entry into the left pleural space) will result in inadequate leftward positioning of the inflow cannula (particularly with a markedly enlarged heart and leftward displacement of the apex) such that the inflow portion points against that lateral wall rather than into the central portion of the left ventricular cavity, producing chronic partial inflow obstruction.

CPB is established with ascending aorta and right atrial cannulation (unless emergent femoral cannulation is required). After initiation of CPB, the heart is maintained in a continuously beating state without cardioplegic arrest unless additional cardiac procedures are needed. Strong suction is maintained on the aortic needle vent and continuous surveillance by TEE is important for detection of any air in the ascending aorta. The left ventricular apex is displaced, and an opening is created in the left ventricle for insertion of the apical cannula. For most devices, creation of the hole is facilitated by a special coring instrument. The left ventricle is inspected for presence of any thrombus, which if present is removed.

The apical cannula for some devices is inserted directly into the left ventricular apex, and for others, an inflow collar is first sutured to the left ventricular apex and the apical cannula is inserted through the collar. Interrupted 2-0 sutures are recommended, often with an additional purse string of polypropylene for improved hemostasis.

The pump is then completely assembled, including the outflow graft, while maintaining the heart in a filled state to avoid trapping of air in the left ventricle. The apical inflow cannula is inserted and secured during continuous TEE surveillance of the ascending aorta for air. Surgical glue is often placed around the insertion site for added hemostasis. With the heart and pump filled with blood, the operating table is rotated away from the surgeon, and the pump is de-aired to allow residual air in the pump to collect in the outflow graft and be eliminated. When no further residual intercardiac air is identified by TEE, the outflow graft is measured to an appropriate length, trimmed, and clamped proximally. An end-to-side anastomosis is then constructed to the exteriorized right lateral aspect of the ascending aorta, usually with continuous 4.0 polypropylene suture. This suture line is particularly hemostatic if constructed in two layers, the first layer being a continuous horizontal mattress suture followed by a second standard layer. The drive line is brought out through a long subcutaneous tunnel, usually in the right upper quadrant. Specific care must be taken to avoid inadvertent passage of the drive line through the intraperitoneal space.

Appropriate inotropic support is initiated to optimize right ventricular function, with or without the addition of inhaled nitric oxide. The driveline and its connecting tubing is passed off the surgical field and connected to the pump console. With the outflow graft clamped (initially fully, then partially) near its connection to the aorta, standard de-airing procedures are carried out under TEE guidance, with needle vents both in the outflow graft and the ascending aorta.

Full pumping is established, and CPB is discontinued with continued surveillance by TEE for air and right ventricular function. Surveillance of right ventricular function is particularly important during the first 10 to 15 minutes after discontinuation of CPB and during protamine administration.

Prior to sternal closure, the outflow graft and apical cannulation site should be covered with bovine pericardium or PTFE patches to facilitate safe sternotomy and dissection at the time of cardiac transplantation.

**Intracorporeal Continuous Flow Left Ventricular Assist Device**

Implantation of continuous flow devices follows the same general surgical plan as for pulsatile devices, with a few notable differences. Because the pumps are smaller than most pulsatile devices, the pump pocket requires either no additional dissection or limited dissection at the level of the diaphragm on the left side to allow the pump to sit in a position that does not compromise the inflow cannula position. When the usual de-airing procedure has been completed and CPB discontinued, close surveillance of right ventricular function by TEE, right atrial pressures, and direct observation is of critical importance. Because rotary pumps of either axial or centrifugal design will continue pumping at the set speed, sudden right ventricular failure can limit blood return to the left ventricle to such a degree that air is sucked in around the inflow cannula and can potentially cause a major air embolism. This contrasts with pulsatile pumps, which either fill completely before emptying (auto mode) or can eject blood from a partially filled sac (fixed-rate mode), which greatly reduces the risk of air entrapment.

In the event of sudden, severe right ventricular failure early post bypass with a continuous flow pump, left atrial or pulmonary artery diastolic pressure should be carefully observed for rapid fall, and pump speed should then be rapidly decreased while observing for aortic air by TEE. If air is seen in the ascending aorta, the outflow graft must be clamped and CPB rapidly reestablished when heparinization is adequate.

Implantation of continuous flow pumps without CPB have been described, particularly for the Jarvik 2000 axial flow pump. The silicone polyester sewing cuff is attached to the apex of the beating left ventricle with pledgeted sutures. With the patient in Trendelenburg position to avoid air entrapment, a coring knife is used to create a suitable incision within the sewing cuff. The pump is rapidly inserted and secured with cotton tape around the cuff and pump housing. The outflow graft can be anastomosed to either the ascending or descending thoracic aorta. Frazier and colleagues have described transdiaphragmatic pump placement through a subcostal extrathoracic approach.

Replacement of failing pulsatile LVADs with continuous flow pumps requires special comment. Currently, the most common indication for pump exchange is bearing wear causing pump failure of the HeartMate XVE 18 to 24 months post implant (see “Pulsatile Ventricular Assist Devices” under Durable Circulatory Support Devices). Catheters are placed in the femoral artery and vein to allow rapid percutaneous cannulation for CPB in the event of uncontrolled bleeding. A repeat sternotomy is recommended for optimal access to both the inflow cannula and outflow graft. The apical sewing cuff and collar from the XVE is retained for simplified insertion of the apical cannula of the HeartMate II pump. The smaller HeartMate II outflow graft is connected directly to the larger residual outflow graft with a beveled anastomosis. Device de-airing is accomplished as usual. If a PTFE membrane was used in the XVE pocket, it should be removed to minimize the presence of foreign bodies around the new pump.
Paracorporeal Ventricular Assist Devices

Implantation of paracorporeal devices follows the same general procedure as for intracorporeal pumps, with the exception that the inflow and outflow cannulae are passed through subcutaneous tunnels following implantation and then connected to the pump itself. Specific protocols are followed for de-airing individual pumps via direct portals, or aspiration techniques of the pump itself following connection to the outflow graft. When biventricular support is needed, the LVAD is generally implanted first. The right ventricular device can receive inflow from either the right ventricle or right atrium. The position of skin exit for right and left ventricular inflow and outflow cannulae on the anterior abdomen must be carefully planned to allow appropriate spacing of the cannulae.

Total Artificial Heart

The technique for implantation of the SynCardia TAH has been described in detail by Copeland and colleagues. Before systemic heparinization, the arterial outflow conduits are appropriately preclotted, and drivelines are tunneled and brought out under the left costal margin. The left-sided ventricular driveline is positioned approximately 5 cm below the costal margin in the midclavicular line. The right ventricular driveline is brought through the skin about 5 cm medial to the left driveline. Both ventricles are then covered with a surgical towel and placed on the left chest until implantation.

CPB is established and the aorta cross-clamped. The recipient heart is excised on the ventricular side of the arterioventricular (AV) groove, leaving a small rim of ventricular muscle. The great vessels are divided just above the aortic and pulmonary valves (Fig. 22-19). The mitral and tricuspid valve leaflets are excised and the chordae trimmed. The coronary sinus ostium in the right atrium is oversewn to prevent backflow of blood to the AV groove.

A “neopericardium” is constructed out of three 15-× 20-cm sheets of expanded polytetrafluoroethylene (ePTFE). The first sheet of ePTFE is sutured to the pericardial reflection as posteriorly as possible at the level of the superior vena cava, inferior vena cava, and pulmonary veins on the right side (without injuring the phrenic nerve); the second sheet is sutured anterior to the left pulmonary veins on the left side; and the third sheet is placed to cover the entire diaphragmatic reflection. The three ePTFE sheets are later folded over the artificial ventricles after completion of the implantation.

The outer rims of the left and right atrial cuffs, which consist of approximately 1 cm of ventricular muscle and fat in the AV groove, are buttressed circumferentially with 1-cm-wide strips of Teflon felt to reinforce the anastomoses between the atrial cuffs and the quick connect and provide maximal hemostasis. The atrial quick connects are trimmed to 6 mm from the connectors, turned inside out, and anastomosed to the atrial cuff (first left, then right), using 3-0 polypropylene. The suture line includes the felt strip–strengthened free ventricular wall and the interventricular septum, taking care to achieve a maximally hemostatic suture line. After completion of both anastomoses, the quick connect are everted back to normal configuration, and biological glue is applied to the suture lines.

The outflow conduits from each artificial ventricle are cut to an appropriate length, determined by briefly placing the artificial ventricles in the mediastinum. The entire length of the pulmonary artery is preserved and anastomosed to the conduit with 4-0 polypropylene. The aortic anastomosis is similarly constructed. All suture lines are tested for hemostasis using a plastic tester device with saline via a three-way stopcock.

The ventricular connections to the quick connects are facilitated by grasping each side of the quick connect with a large clamp while pushing in the device. To avoid conduit angulation, the left ventricular outflow should be as close as possible to the native aorta. Orientation of the ventricle and the outflow mount is fixed by the atrial connection. Prior to completing the aortic connection, the pump and conduit are filled with saline. The right atrial inflow quick connect and the right arterial conduit are attached to the right artificial ventricle similarly. The right side is filled by partially releasing the inferior vena cava tape, completing device implantation (Fig. 22-20).

The patient is placed in steep Trendelenburg, and the aortic cross-clamp is removed with the ascending aorta vented. With the CardioWest TAH pumping at 40 beats/min, vigorous de-airing is completed under TEE guidance. The TAH pumping rate is then increased and CPB discontinued while maintaining a CVP of 12 to 15 mmHg. Cardiac output from the CardioWest TAH is usually about 7 to 8 L/min at this point. After obtaining meticulous hemostasis, the previously secured ePTFE “neopericardium” is closed over

Figure 22-19  Ventricular rim with AV valves and chordae excised. Great vessels are transected just above sinotubular junction. (Redrawn from Copeland and colleagues.)

---

PART IV Other Cardiac Conditions
details and principles of implantation are similar to the SynCardia device, with the following notable features. Because the device has no external driveline, a slight caudal extension of the incision facilitates placement of the transcutaneous energy transfer coils anterior to the pectoral muscle fascia prior to heparinization. Following median sternotomy, dissection for placement of the internal battery and controller is performed in either the preperitoneal space or deep to the rectus abdominis muscle.

After initiation of CPB and aortic cross-clamping, the right and left ventricles are excised just below the AV groove to allow for anastomosis of the atrial cuffs at the level of the anuli after excision of the mitral and tricuspid valves. The left atrial appendage is ligated and the coronary sinus and any patent foramen ovale oversewn. The left, and subsequently right, atrial cuff is trimmed to an appropriate diameter and anastomosed to the native atrium at the level of the anulus, using continuous 4-0 polypropylene reinforced with felt strips. A leak-testing device is used to check each anastomosis. A cast model of the AbioCor unit is placed in the mediastinum to determine the appropriate length and orientation of the outflow grafts. The grafts are sewn end-to-end to the great vessels (4-0 polypropylene), with the aortic outflow graft placed anterior to the pulmonary artery graft (Fig. 22-22).

The pumping unit is placed in the mediastinum, and the TAH anteriorly. A rectangular piece of ePTFE is passed around the proximal aorta and secured. During chest closure, special attention is focused on device output and TEE monitoring of inferior vena caval and left pulmonary venous flows.

The technique for implantation of the AbioCor TAH has been described in detail by Dowling and colleagues. The
Antiplatelet Therapy

The mainstay of antiplatelet activity is aspirin (acetylsalicylic acid [ASA]). Aspirin irreversibly inhibits cyclooxygenase, an enzyme responsible for conversion of arachidonic acid to prostaglandin and eventually thromboxane A\textsubscript{2}, which promotes platelet aggregation. Effectiveness of aspirin therapy can be monitored by the in vitro platelet aggregation response to arachidonic acid.\textsuperscript{W3} The antithromboembolic effect of aspirin does not increase with dosages greater than about 325 mg/day, and there is probably no advantage for doses greater than 160 mg/day.\textsuperscript{W3} The ADP pathway for induction of platelet activation is not inhibited by aspirin, and ADP receptors play a central role in platelet activation secondary to shear stress.\textsuperscript{S3}

Clopidogrel irreversibly inhibits platelet activation via ADP receptors on the platelet surface. Dipyridamole inhibits platelet aggregation through a different mechanism. Specifically, dipyridamole inhibits the uptake of adenosine into platelets and endothelial cells, effectively increasing local adenosine concentration. The excess adenosine stimulates platelet adenylate cyclase, which increases platelet cyclic adenosine monophosphate (cAMP) levels, inhibiting platelet aggregation response to ADP, collagen, and platelet-activation factor.

Anticoagulation for Continuous Flow Pumps

The anticoagulation of all currently available rotary pumps includes warfarin and antiplatelet therapy (usually with aspirin). Initial anticoagulation with heparin is recommended in some protocols, though others have successfully avoided heparin without identifiable thromboembolic effects. A simplified anticoagulation protocol employs clopidogrel, aspirin 325 mg twice daily, and warfarin beginning the day after implantation. Clopidogrel is continued until the INR exceeds 2.0, after which warfarin is adjusted to maintain an INR of 2.0 to 3.0.

Anticoagulation for the Total Artificial Heart

Specific protocols have been developed for the SynCardia and AbioCor TAHs.\textsuperscript{C5, K6} Warfarin and antiplatelet agents are routinely combined with additional monitoring by thromboelastography and platelet aggregation studies.

Blood Pressure Management with Continuous Flow Pumps

Although pulsatile flow can usually be detected by direct arterial line monitoring in the early postimplant period, ambulatory blood pressure cannot be reliably measured with a standard blood pressure cuff or with automatic blood pressure devices. The normal Korotkoff sounds are typically absent with the minimal pulsation of continuous flow pumps. The most reliable estimate of mean or systolic blood pressure (depending on degree of pulsatility) is use of a Doppler device over the radial artery while gradually deflating a standard blood pressure cuff. Monitoring outpatient blood pressure with continuous flow pumps is important because of the occasional development of severe hypertension (possibly related to abnormal autonomic deregulation), which, if undetected and untreated, can result in a major intracerebral bleeding event.

**Figure 22-23** The AbioCor total artificial heart in its final position after complete de-airing and occlusion of side ports of outflow grafts. (Redrawn from Copeland and colleagues.\textsuperscript{S3})
Ventricular Suction

When pump speed in a rotary pump exceeds the ability of the left ventricle to supply a continuous inflow of blood into the inlet cannula, the resultant rapid decrease in size of the ventricular chamber can result in cavitary collapse around the inlet cannula, which impedes entrance of blood and creates a “suction event.” The result is a sudden decrease in pump flow. Ventricular suction is remedied by decreasing pump speed. The HeartMate II device detects sudden changes in pump flow by a change in pulsatility index (a measure of flow pulse through the pump described by the relationship: pulse index = [maximum flow − minimum flow] / mean flow). Sudden drops in pulsatility index and a decrease in pump flow indicates a likely suction event. The HeartMate II device incorporates a suction detection algorithm in which pump speed automatically reduces to 9000 rpm if a sudden change in pump flow pulsatility is detected, after which the pump speed slowly returns to the set speed. Observation of this phenomenon indicates the need to reduce the set pump speed.

Pump Thrombus in Continuous Flow Pumps

If thrombus develops on the pump rotor, an abnormal increase in power is required to maintain impeller speed. The increase in power consumption causes an inaccurately high estimate of pump flow and a decrease in pulsatility index caused by a reduction in cyclic power consumption (because continuously high power consumption is caused by the rotor drag induced by thrombus). In contrast, inlet obstruction (secondary to inlet cannula misalignment or thrombus on the inlet cannula orifice), or outflow obstruction (such as kinking of the outflow graft or anastomotic narrowing) produces a decrease in power consumption along with decreased pump flow and pulsatility index. The diagnosis of inflow or outflow obstruction can be aided by echocardiographic imaging, which may reveal a dilated left ventricle, which is not improved by increasing pump speed.

Pump Stoppage of Continuous Flow Pumps

In contrast to pulsatile devices (in which a hand-pumping device is usually available), continuous flow pumps carry no manual option to maintain forward pump flow in the event of pump stoppage. The physiologic sequelae of pump stoppage are discussed in “Continuous Flow Ventricular Assist Devices.”

When pump stoppage occurs, most commonly resulting from damage to the driveline, rapid decompensation and death are common secondary to a combination of severe reduction in cardiac output and a variable degree of “pump/aortic” insufficiency due to the absence of valves. If the patient is viable, emergency transport to an experienced MCS center is mandatory while cardiac output is maximized with inotropic support. Upon hospital arrival, a surgical team should be ready for emergency device exchange. An echocardiogram is necessary to evaluate for possible intracavitary left ventricular thrombus. If no thrombus is identified and soldering of damaged electrical wiring is an option, full heparinization followed by device restart (with the small possibility of thromboembolic stroke) may provide a more favorable risk/benefit ratio than emergency reoperation for pump exchange.

RESULTS

Survival

Survival and adverse events following MCSD implant are reported and analyzed in the Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) supported by the National Heart, Lung and Blood Institute (NHLBI). Among isolated LVADs approved by the FDA for use in the United States, the 12- and 24-month survival are 74% and 55% (Fig. 22-24). The requirement for biventricular support confers a significantly worse prognosis (Fig. 22-25).

![Figure 22-24](https://example.com/f22_24.png)

**Figure 22-24** Actuarial and parametric survival for 1092 patients from Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) database, undergoing primary left ventricular assist device (LVAD) implant. Patients are censored at transplant or device explant for recovery. Dashed lines represent 70% confidence limits. Hazard function (instantaneous risk of death) is depicted by lower curve.

![Figure 22-25](https://example.com/f22_25.png)

**Figure 22-25** Actuarial survival by device type from Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) database (n = 1420). Patients are censored at time of transplantation or device explant for recovery. Error bars represent 70% confidence intervals. Key: Bi-VAD, Biventricular assist device; LVAD, left ventricular assist device; RVAD, right ventricular assist device; TAH, total artificial heart.
Major causes of death among LVAD patients differ according to interval post implant. The most frequent cause of death during the first 30 days is cardiac failure, followed by multiorgan failure and stroke (Table 22-2). After the first month, infection is the major cause of mortality. The hazard function for death in the current era (see Fig. 22-24) has a rapidly falling early phase that merges with a gradually increasing phase at about 6 months. Risk factors for death after LVAD implant include older patient age, indicators of more advanced right heart failure, cardiogenic shock at implant, and pulsatile (vs. continuous flow) pumps (Table 22-3).

Major Adverse Events

Neurologic Events

The most devastating early complication is severe neurologic injury, usually caused by embolization of particulate matter or air. Air embolization constitutes a greater risk after device implant than during other forms of cardiac surgery. In addition to the potential for air trapping in the left atrium or left ventricle, the pump itself adds a major source of air. Even if the pump is adequately de-aired, negative pressures generated by a blood pump can suck air in through porous conduits or around cannulation sites if the left ventricle is severely underfilled. Specific maneuvers to prevent this complication include:

1. Continuous TEE monitoring of the left atrium, left ventricle, and aortic root during the terminal phases of CPB and for 10 to 15 minutes after discontinuation of bypass
2. Thorough de-airing of the pump with hand pumping (for some pulsatile devices) or short bursts of power to the pump (for some pulsatile devices and most rotary pumps)
3. Appropriate support and observation of right ventricular function after bypass to avoid sudden drops in right ventricular output to the LVAD
4. Minimizing the use of vacuum pressures until the chest is closed

The potential for thromboembolic events during and after CPB can be greatly reduced by careful examination of the left ventricular cavity by TEE prior to implant, and direct inspection of the left ventricular cavity during implantation of the inflow cannula.

Later neurologic events are generally categorized as either hemorrhagic or thromboembolic. With the exception of the HeartMate XVE (see earlier section) all other pulsatile and rotary pumps currently employed are considered inherently thrombogenic. Neutralizing this complication requires detailed analysis of thromboembolic events and a better understanding of the role of the device itself, the patient’s underlying medical condition, and the selection and management of specific anticoagulation regimens.

A relationship between clinical infections and subsequent thromboembolic strokes following MCSD implant has been observed in multiple centers, but a causal relationship and potential mechanisms such as activation of inflammatory mediators with procoagulant effect remain unproven.

Alterations in the underlying coagulation system that are not identified by the INR, partial thromboplastin time (PTT), and platelet count (see “The Coagulation System” under Biological Barriers) may contribute to development of hemorrhage or thromboembolic strokes post MCSD. The

Chapter 22 Mechanical Circulatory Support

Other Adverse Events

The overall profile of adverse events in the current era is detailed in Table 22-4, separated by type of pump technology. Continuous flow pumps are currently associated with a major reduction in device malfunction and infection compared with pulsatile pumps during the first 6 months post implant.

K8

SPECIAL ISSUES IN MECHANICAL CIRCULATORY SUPPORT

Emergence of Continuous Flow Technology

The current preference for continuous flow technology as bridge-to-transplant therapy is reflected by data from INTERMACS, in which more than 85% of primary LVAD implants in the current era are continuous flow technology (Fig. 22-28). Survival data to date indicate a significant advantage with continuous flow technology (Fig. 22-29).

Decisions Regarding Biventricular Support

When the severity of right ventricular failure is such that isolated left ventricular support will leave the patient with excessive chronic elevation of right atrial pressure (generally

imperfection of standard coagulation monitoring has prompted greater application of more detailed analyses of the coagulation system using thromboelastography and platelet aggregation studies.

Infection

Major pump-related infections involve either the pump pocket or the driveline at the exit site. Overall freedom from major infection among 420 patients in the INTERMACS database is depicted in Fig. 22-26. In the REMATCH trial of the HeartMate XVE pulsatile LVAD, infections, including driveline and other device-related infections, were the leading cause of death. As experience with devices has evolved, the frequency of pump infections has progressively declined. Placement of larger pulsatile pumps in an intraperitoneal pocket using a porous PTFE sheet has reduced the risk of pocket infections. Smaller rotary pumps rarely develop pocket infections, particularly those that are totally intrapericardial.

Driveline infections continue to plague long-term circulatory support and will undoubtedly be an ongoing limitation until totally implantable systems are available. The most important maneuver to minimize late development of exit site infections appears to be total immobilization of the driveline at the exit site, preferably using a double stabilization technique (Fig. 22-27) to minimize transmitted driveline tension or movement at the exit site. Other advances such as novel applications of biofilm technology, instillation of biosubstances to promote tissue ingrowth around the driveline, and the potential use of muscle flaps around the driveline offer promise in reducing pump-related infections.

Gastrointestinal Bleeding

Rarely, bleeding from intestinal arteriovenous malformations (present in 10% of normal adults) is observed with continuous flow pumps (rotary devices). This complication has also been reported in patients with aortic stenosis.

From Kirklin and colleagues.28

bWith current reporting, identification of hypertension with continuous flow pumps is unreliable.

Figure 22-28  Bar graph depicting number of implants for each 6-month interval since the beginning of Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) prospective data collection, divided between pulsatile pumps (blue) and continuous flow pumps (red). Note that initial bar includes some additional patients implanted between June 23 and July 1, 2006, and that patients implanted between January 1 and March 31, 2009 are not included in this depiction.

Figure 22-29  Actuarial survival following primary left ventricular assist device (LVAD) implant with an initial strategy of either bridge-to-transplant (BTT) or bridge-to-candidacy (BTC) strategy, stratified by pulsatile vs. continuous flow pumps (Interagency Registry for Mechanically Assisted Circulatory Support [INTERMACS], n = 1092).
20 mmHg or higher), the likelihood is great that organ function will be importantly compromised secondary to chronic venous congestion, and/or left ventricular filling will be inadequate (secondary to inadequate right ventricular output) to provide effective LVAD flow. However, the advantages of biventricular support must be balanced against reduced success in bridging to transplantation with BVAD therapy compared with isolated LVAD support (see Fig. 22-25). A possible exception to this strategy is use of the TAH for bridging or permanent therapy.

With current implantable pulsatile or continuous flow pumps (with the exception of the TAH), the addition of right ventricular support requires a paracorporeal device. If the device cannot be successfully removed during initial hospitalization, the longer-term (outpatient) quality of life is dramatically reduced.

Although considerable variability exists in protocols at individual institutions, biventricular support should be considered if, despite appropriate doses of right ventricular inotropic support, there continues to be very poor right ventricular function (as judged by echocardiography), and signs of right ventricular failure persist (CVP in excess of 18 mmHg, ascites, and/or peripheral edema). In the operating room following implantation of an LVAD, the addition of right ventricular support should be considered if CVP persists at a level above about 19 mmHg, and cardiac output (LVAD output) is depressed despite administration of nitric oxide and suitable right ventricular inotropic support.

Given the distinctly inferior survival and postimplant quality of life when biventricular device support is required, a major therapeutic priority in advanced heart failure management should focus on referral for MCS before the advent of advanced right ventricular failure.

Aortic Insufficiency

Aortic insufficiency decreases pump efficiency by creating a loop of flow between the LVAD and the native left ventricle. Therefore, native aortic insufficiency should be recognized. In the presence of grade 3/5 or greater aortic insufficiency, specific management of the aortic valve is advisable. Mild degrees of aortic insufficiency frequently progress following LVAD implant, in part related to abnormally high radial force against the closed aortic valve secondary to high pressure (pulsatile pumps) or flow (rotary pumps) entering the ascending aorta above the valve. A variety of methods to surgically treat aortic insufficiency have been employed, but a useful technique is to fix the midpoints of the aortic leaflets together with one or more pledgeted sutures.

Myocardial Recovery

The potential for myocardial recovery days, months, or even years after MCS implant is the ideal goal of any implant that does not result in cardiac replacement. Although sufficient myocardial recovery to allow successful device explant is the desired goal, successful explant of durable long-term devices has to date been uncommon.

Extensive studies have characterized the histologic and molecular changes of chronic myocardial damage sufficient to produce terminal heart failure. Myocyte hypertrophy and interstitial fibrosis, and decreased contractile function define the phenomenon of cardiac remodeling and characterize the failing myocardium. The cellular markers of cardiac remodeling signal myocyte hypertrophy, fibrosis, and abnormal expression of specific genes that characterize the failing myocardium. These cellular and molecular abnormalities are associated with left ventricular enlargement, increase in left ventricular mass, and systolic/diastolic dysfunction. Increases in collagen content are associated with diastolic dysfunction.

In the presence of prolonged cardiac unloading with an LVAD, myocyte size and myocardial collagen content and collagen production (fibrosis) generally decline. Expression of proinflammatory cytokines—particularly tumor necrosis factor α (TNF-α), IL-6, and IL-8—is associated with cardiac enlargement and heart failure. Chronic ventricular unloading with an LVAD is associated with a reduction in expression of these cytokines. Thus, reversal of the proinflammatory state of the failing myocardium may play an important role in restoring more normal structure and function by interrupting the cycle of inflammation, necrosis, and fibrosis.

Dystrophin is a structural protein that contributes to normal contractility, likely through support of the cardiomyocyte membrane. In the failing heart, abnormal dystrophin activity can be partially normalized with chronic VAD therapy.

On an anatomic and functional level, chronic LVAD support generally results in reduction in left ventricular mass as well as left ventricular end-systolic and end-diastolic volume. Frequently there is improvement in left ventricular ejection fraction.

Available evidence suggests that in the present of chronic cardiomyopathy, prolonged unloading with an LVAD frequently induces recovery of cellular and molecular markers of cardiac remodeling, occasionally produces improvement in ejection fraction and other hemodynamic and structural parameters, yet rarely restores sufficient function to allow successful LVAD removal.

Considerable experience is accumulating with surviving patients suffering from chronic heart failure who have undergone device removal for myocardial improvement/recovery, with reported 5-year survival as high as 78%. It remains to be determined whether specific device type (pulsatile vs. continuous flow), pumping strategy (complete vs. incomplete unloading), or the addition of specific pharmacologic therapies during support (e.g., the β-agonist clenbuterol) will increase the likelihood of sufficient recovery for successful explantation.

The expectation for recovery in the setting of acute heart failure due to recent-onset nonischemic cardiomyopathy or acute myocarditis is much more favorable. Even among patients with acute myocarditis who present in cardiogenic shock and require emergent mechanical support, the natural history is usually one of progressive improvement. Such patients should be managed with the expectation that recovery and explantation will be likely, rather than proceeding with early cardiac transplantation.

Mechanical Circulatory Support as Permanent Therapy for Advanced Heart Failure

With FDA approval of the HeartMate XVE for long-term “destination therapy” (DT), widespread application of continuous and pulsatile pumps for long-term therapy in Europe,
and multiple ongoing clinical trials of continuous flow pumps as DT in the United States, the application of permanent MCS is evolving toward a larger population of advanced heart failure patients. Currently, permanent therapy is reserved for patients with refractory or recurrent class IV heart failure who are ineligible for heart transplantation.\(^{92}\)

The NHLBI-sponsored INTERMACS database has categorized subsets of class IV heart failure to better reflect current indications for device therapy. The distribution of DT patients by INTERMACS level is depicted in Table 22-5.\(^{58}\)

With the demonstration of improved survival (see Fig. 22-29) and device durability (see Table 22-4) with continuous flow pumps, greater application of MCS as long-term therapy for advanced heart failure is expected. Specific guidelines for application of device therapy for transplant-ineligible patients in INTERMACS levels 1 to 6 (subsets of NYHA class IV) await further prospective studies.

### PEDIATRIC CIRCULATORY SUPPORT

Limitations in access to cardiac transplantation for infants and children with advanced heart failure has provided a potent stimulus for development of MCS systems suitable for small patients. During the past decade, application to small children of pumps designed for adults has generated poor survival.

A multi-institutional analysis by Blume and colleagues\(^{87}\) examined the use of MCS in pediatric patients in the decade from 1993 to 2003. Although mortality during MCS support progressively decreased during the decade (8% mortality prior to transplant after 2000), the inadequacy of mechanical support systems for smaller patients is apparent by stratifying outcome according to age at implant (Fig. 22-30). Mortality during support in patients younger than 10 years of age (and especially in small children and infants) exceeded 60%. During this era, support for infants and small children was basically limited to extracorporeal membrane oxygenator (ECMO) support.

### Paracorporeal Support

Although the Thoratec paracorporeal PVAD is primarily designed for adults, it has been widely applied to the pediatric age group. Pediatric and adolescent PVAD support has been reported in over 150 patients.\(^{162}\) Approximately 50% of the patients have required biventricular support, with the vast majority of patients suffering from cardiomyopathy or acute myocarditis. The major adverse events with this device in the pediatric population are thromboembolism and hemorrhage, which were more common than among adult patients. The higher incidence of thromboembolic neurologic complications in older children and small adolescents with this device likely relates to the low pump rate (and resultant increase in stasis) when the 65-mL pump is applied to smaller patients.

Reproducible effective bridging of infants and children to transplantation requires availability of a variety of pump sizes suitable for the anticipated cardiac output. Paracorporeal volume displacement pumps are particularly prone to thrombus formation when either pump speed is low (≤50 beats per minute) or when there is consistent incomplete filling of the blood chamber.

To address the challenge of providing mechanical support in small patients, the Berlin Heart EXCOR (Berlin, Germany) was developed to include multiple pump sizes. The Berlin Heart EXCOR is a paracorporeal system with an electropneumatic drive system. Pediatric blood pumps are available in

important elevation of left atrial (and potentially pulmonary arterial) pressure.

**Anticoagulation**
Following implantation of the Berlin Heart standard administration of clotting factors can be employed to achieve hemostasis, with the exception that platelet transfusion should be avoided when possible because of the associated risk of sensitization and subsequent development of anti-HLA antibodies that could affect donor matching. When bleeding and chest tube drainage are minimal, initiation of heparin infusion is recommended, although some protocols avoid heparin altogether. Warfarin therapy is guided by INR (2.5-3.5). Some centers substitute chronic heparin therapy for warfarin in small infants. ASA and dipyridamole (or clopidogrel) are initiated within the first few days. Twice-weekly monitoring with thromboelastography is recommended to assess overall anticoagulation effectiveness, and specific testing of platelet function is advisable to determine adequacy of blockade of the arachidonic acid pathway (by ASA) and the ADP pathway (by clopidogrel).

**Neurologic Events**
Intracerebral hemorrhage and thromboembolic episodes are the major causes of morbidity and mortality during pump support. Specific time-related risk of these events is not precisely documented, but the incidence of serious neurologic events during support is estimated at 7% to 8%.

**EXCOR Pediatric Experience**
The German Heart Institute reported an experience of 68 pediatric patients supported between 1992 and 2005.
Since 1999, approximately 60% of patients received isolated left ventricular support, with about 40% requiring biventricular implants. The maximum duration of support was 420 days, with 73% of patients surviving to transplantation or recovery with device explantation. Major causes of mortality were multi-organ failure, sepsis, stroke, and hemorrhage. In North America, 80 patients were supported between 2000 and 2007, with the smallest patient being 3.0 kg and 15 days of age. The longest support was 234 days, with 55% of patients undergoing cardiac transplantation, 13% weaned from the device for recovery, and 25% mortality during device support. The Berlin EXCOR is currently approved for clinical use in Europe and the United States.

**MicroMed-DeBakey VAD Child**

The MicroMed-DeBakey VAD Child is a pediatric axial flow pump of the same basic design as the adult MicroMed pump (see “Continuous Flow Ventricular Assist Devices” under Durable Circulatory Support Devices). Basic design differences include a shorter inflow apical cannula (2.5 cm), an inflow tube angle of 140 degrees, and a shorter outflow protector sleeve (2.6 inches). These design alterations allow the pump to lie at a more acute angle with less lateral space required in the child or adolescent (Fig. 22-33). Current accepted criteria for this pediatric axial flow pump include (1) bridge-to-transplant therapy, (2) patients aged 6 to 16 years, (3) refractory NYHA class IV symptoms with inotrope requirement, and (4) BSA of at least 0.7 m².
Emerging Devices

With the clear need for more effective miniaturized systems for technical circulatory support in infants and small children, the NHLBI has funded research for the development of five unique pediatric pumps: two magnetically suspended continuous flow pumps, an axial-flow apically implanted device, a pulsatile flow device, and a compact integrated pediatric cardiopulmonary assist system (Fig. 22-34). None of these devices has currently entered clinical trials.

## Section I: Chronic Constrictive Pericarditis

### Definition
Chronic constrictive pericarditis is a chronic inflammatory process that involves both fibrous and serous layers of the pericardium, leading to pericardial thickening and compression (constriction) of the ventricles. The resultant impairment in diastolic filling reduces cardiac function.

### Historical Note
It is said that Galen in AD 160 described cicatricial thickening of the pericardium in an animal and surmised that the same condition might occur in humans. The first formal account of the condition in humans was apparently that of Lower, who described both acute and chronic constrictive pericarditis in 1669. Other early descriptions were those by Bonetus in 1679 and Vieussens in 1715. Lancisi apparently understood the pathology of the condition; in 1728 he described at autopsy a patient with a small heart encased by a thick adherent pericardium in association with marked swelling of the abdomen and jugular veins.

### Postpericardiectomy Syndrome
As a result of the observations of Morgagni in 1760 and Laennec in 1819 that pericardial adhesions were rarely associated with symptoms, little attention was paid to the possible clinical significance of chronic pericarditis for nearly a century because of ignorance of the difference between adhesive pericarditis and constrictive pericarditis. The early literature contains only four reports (Cheevers, 1842; Greisinger, 1856; Wilks, 1870; Kussmaul, 1873), largely ignored, stressing that chronic constrictive pericarditis could be clinically important.

Interest was refocused on the condition by Pick’s report in 1896 of three patients with chronic constrictive pericarditis whose clinical course had been thought in life to be due to cirrhosis of the liver. About that time, surgeons were becoming more expert and aggressive, and Weill in 1895 and Delorme in 1889 suggested that pericardectomy be used to treat this condition. Brauer in 1902 suggested removing the bony precordium as a method of relief. Apparently, the first operation directed against chronic constrictive pericarditis was carried out by Halloopeau. Both Rehn and Sauerbruck in Germany performed a successful partial pericardectomy in 1913. In 1926, Schmieden and Fischer in Germany reported a series of successful cases, as did Churchill in 1929 from Massachusetts General Hospital and Beck in 1931 from Cleveland. Surgical experience was expanded by Harrington and Barnes at the Mayo Clinic and by Heuer and Stewart at New York Hospital. By 1941, Blalock and Burwell reported surgical treatment of 28 patients.

Animal experiments began to clarify some of the perplexing problems that persisted despite the advent of surgical treatment. In 1929, Beck reproduced the syndrome by injecting Dakin solution into the pericardial cavity of dogs. He demonstrated that simple obliteration of the pericardial cavity by adhesions did not produce the syndrome; only a thick, dense scar around the heart did so, thus solving the riddle of 100 years earlier. He then demonstrated in animals that the syndrome could be relieved by pericardectomy. He also demonstrated experimentally several efficient methods of controlling the hemorrhage that could develop from the surface of the heart during the dissection required to relieve chronic constrictive pericarditis. The pathogenesis was then further elucidated by the cardiac catheterization studies of Sawyer and colleagues and by the ingenious experiments of Isaacs and colleagues. These studies led directly to development of better diagnostic and surgical methods.

MORPHOLOGY

Normally, the potential space between inner and outer layers of the visceral pericardium contains a thin layer of fluid. A demonstrable amount of fluid normally accumulates only over the atrioventricular junctions. This has provoked controversy about the pressures normally present between the fibrous pericardium and the inner layer of the visceral pericardium (epicardium).

As chronic constrictive pericarditis develops, the fibrous parietal pericardium and both layers of the visceral pericardium are involved to some extent, but details of the pathologic process vary. If the two layers of the visceral pericardium remain separate, the pericardial space contains variable amounts of fluid, often with extensive and sometimes hemorrhagic fibrinous deposits on both surfaces. This entire fibrous and fluid mass can be constricting to the heart. When the process is far advanced, the two layers of visceral pericardium thicken and fuse, and along with the fibrous pericardium, encase the heart in a thick, solid, fibrous, and often calcified envelope that is adherent to the myocardium.

In addition, cardiac muscle fiber atrophy occurs in many cases. Atrophy may appear relatively early in the course of the disease. Myocardial fibrosis also complicates late stages of chronic constrictive pericarditis.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Pathophysiology of Cardiac Compression

Cardiac compression occurs in chronic constrictive pericarditis, but is also a feature of acute cardiac tamponade and effusive constrictive pericardial disease, a condition characterized by pericardial thickening and variable amounts of fluid in the pericardial space.

Normal

Pericardial pressure is subatmospheric under normal circumstances, similar to intrapleural pressure. Both intrapericardial and intrapleural pressures become more negative during inspiration. There are small fluctuations of intrapericardial pressure related to the cardiac cycle, and the transpericardial pressure (pericardial minus pleural pressure) is highest at end-diastole, the period of largest ventricular volume. Pericardial pressure rises as ventricular volume is increased beyond normal limits by the rapid infusion of fluid. Under such circumstances the effects of pericardial restraining are predominant on the right ventricle.

Pressure-volume relationships and stress-strain characteristics of the normal pericardium are such that there is little increase in intrapericardial pressure when a small amount of fluid is placed intrapericardially. With rapid addition of more fluid, the pressure slope rises progressively. At this stage, adding small amounts of fluid causes a large increase in intrapericardial pressure, and conversely, removing small amounts causes a large decrease in intrapericardial pressure (the rationale of pericardiocentesis in acute pericardial tamponade). Furthermore, because of pericardial hysteresis, intrapericardial pressure at a given volume during fluid removal is lower than during addition of fluid.

Intrapericardial events—normal and abnormal—affect both cardiac filling and cardiac output. Such events are reflected in phasic and overall atrial and venous pressures. The effect on systemic venous pressure is of particular importance because it is easily observed in the jugular venous pressure. Normally, the inferior and superior vena cava pressures exceed atmospheric pressure by only a few millimeters of mercury (mmHg). The jugular venous (and caval) pulse consists sequentially of three positive upward waves and two downward movements. First is the a wave, generated by atrial systole. The c wave follows, caused by displacement of the tricuspid valvar apparatus toward the right atrium during isovolumic ventricular systole. A negative x descent is next, generated in part by descent of the closed tricuspid valve apparatus at the beginning of ventricular ejection and in part by decreased intrapericardial pressure resulting from reduced ventricular volume as the ventricle ejects. A positive y wave is then generated by passive filling of the right atrium from
the cavae and coronary sinus. Finally, a negative y descent occurs as blood flows rapidly from right atrium to right ventricle.

**Acute Cardiac Tamponade**

Rapid increase in intrapericardial fluid, usually blood, produces acute cardiac tamponade. Intrapericardial pressure may rise as high as 20 to 30 mmHg. Such a pressure would be incompatible with life if it were not for reflex venoconstriction, catecholamine release, and the immediate retention of sodium and water by the kidneys as part of the total body response to reduced cardiac output. As a result, venous pressure rises to the level of intrapericardial pressure, and cardiac output is maintained, although usually at a reduced level. This process has led to one definition of cardiac tamponade as a condition in which right atrial and systemic venous pressure are determined by elevated intrapericardial pressure. 

When intrapericardial pressure first rises, it tends to exceed left as well as right atrial pressure, and in patients who survive, both left and right atrial pressures rise in response to the neurohumoral compensatory mechanisms mentioned earlier. At this stage, right and left atrial pressures, right and left ventricular diastolic pressures, pulmonary artery diastolic pressure, and pulmonary artery wedge pressure are identical to intrapericardial pressure. Untreated, the patient dies when cardiac output continues to decrease despite compensatory mechanisms.

In this classic setting of acute cardiac tamponade, the heart is small and quiet, venous pressure is elevated, and systemic arterial blood pressure is depressed—a group of signs known as the *Beck triad*. Elevation of venous pressure may be mild, or it may reach 20 mmHg or more. Jugular venous wave forms are altered because the tamponade effect is least during ventricular ejection, when ventricular volume is smallest. No cardiac filling occurs during diastole, and thus there is no y descent. All filling occurs during systole, so the x descent is preserved and exaggerated.

Unless hypotension is extreme, the condition is also characterized by *pulsus paradoxus*, an inspiratory decrease in arterial systolic blood pressure exceeding 10 mmHg during quiet respiration. The mechanism underlying pulsus paradoxus in acute cardiac tamponade is complex. During inspiration, caval flow into the right atrium increases, just as in the normal situation; in fact, the percentage of increase is greater than normal. The resultant increase in right heart volume raises intrapericardial pressure still further, and pericardial transmural (intrapericardial minus intrapleural) pressure rises. Left ventricular volume is decreased as the ventricular septum is displaced leftward by the increased right ventricular volume. Left ventricular inflow is diminished because the somewhat decreased right ventricular output is easily accommodated by the expanding lung blood volume during inspiration, with less transmitial flow. These phenomena result in decreased left ventricular stroke volume and thus diminished arterial blood pressure. Another contributor to pulsus paradoxus is delay in passage of the increased caval flow of early inspiration to the left ventricle, so that by the time it has occurred, respiration has generally shifted to the expiratory phase. Also, the inspiratory decrease in intrathoracic pressure tends to decrease aortic and arterial pressure, and inspiration tends directly to decrease left ventricular contraction.

**Chronic Constrictive Pericarditis**

Basic pathophysiology of chronic constrictive pericarditis has been debated for more than half a century. By 1949, Holman and Willett concluded that constriction of the caval orifices and atria was important in its pathogenesis and for this reason adopted the median sternotomy approach for its surgical correction. In 1951, Burwell concluded from cardiac catheterization study that both right and left ventricular function were impaired and constriction of caval orifices or atria played no role. In 1952, Isaacs and colleagues showed in dogs that a change in the pressure-volume curves of the two ventricles resulted from experimentally produced constrictive pericarditis, and this was the fundamental pathophysiologic change associated with the disease (Fig. 23-1). These investigators also demonstrated during development of the constriction an increase in right and left ventricular diastolic pressure and a decrease in stroke volume. In their experimental animals, a small increase in volume resulted in a considerable increase in end-diastolic pressure. These studies indicated that lack of ventricular diastolic distensibility, and thus inability to generate an adequate preload (see “Ventricular Preload” under Cardiac Output and Its Determinants in Section I of Chapter 5), was a characteristic of hearts with chronic constrictive pericarditis. These considerations influenced Scannell and colleagues to adopt a left anterolateral thoracotomy as their surgical approach of choice by 1952.

A number of features of clinical cases of chronic constrictive pericarditis derive from these basic abnormalities of diastolic function. Ventricular filling is impaired and ventricular stroke volume reduced as a result of decreased compliance of the fused cardiac and pericardial mass. Phasic aspects of ventricular filling are also altered. For a brief period in early diastole, ventricular filling is rapid. However, the limit of
ventricular distensibility is reached rapidly, and the right ventricular pressure pulse displays an early diastolic dip and then a high diastolic plateau (square root sign). There is nearly complete diastolic ventricular filling during the first 50 milliseconds of diastole.\textsuperscript{61}

Systemic venous pressures are correspondingly abnormal; mean venous pressure is elevated. The \( x \) descent is steep and deep, corresponding to the beginning of ejection. The \( y \) descent is also steep and deep, corresponding to the early diastolic dip of right ventricular pressure. This differs from events during acute cardiac tamponade, in which the \( y \) descent is absent. The normal inspiratory increase in vena caval flow and decrease in pressure is diminished and often absent.

Pulsus paradoxus is said to be infrequent in chronic constrictive pericarditis, in contrast to the situation with acute cardiac tamponade. However, frequency of its recognition is influenced by cardiac rhythm; it is usually present when there is sinus rhythm, but impossible to detect when there is atrial fibrillation (a frequent accompaniment of chronic constrictive pericarditis).

Ventricular end-diastolic volumes are small in this disease, as are end-systolic volumes and stroke index. Rate of increase of left ventricular systolic pressure and ejection fraction are not altered.\textsuperscript{15} Thus, systolic left ventricular function under these circumstances is normal, but this does not necessarily indicate normal contractility.

**Effusive Constrictive Pericardial Disease**

Although seen in a number of settings, effusive pericardial disease is common in nephrogenic pericarditis.\textsuperscript{182} In this condition, increased volume of pericardial fluid produces the characteristic clinical picture of acute cardiac tamponade, with absence of a \( y \) descent and a preserved and prominent \( x \) descent in the jugular venous pulse. However, because of coexisting pericardial thickening, aspiration of pericardial fluid does not return the situation to normal. Rather, the thickened pericardium begins to restrain the heart, but only after the rapid filling phase of the ventricles is over. Thus, the \( y \) descent is again present and is prominent, occurring during the time the right atrium is in free communication with the right ventricle through the open tricuspid valve and simultaneously with the early diastolic dip of ventricular pressure. In effusive constrictive pericardial disease, after the fluid is removed, there is no respiratory variation in the right atrial and venous pressures, just as in constrictive pericarditis.

**Etiology**

In most patients the etiology of chronic constrictive pericarditis is not known. McCaughan and colleagues were able to identify a specific etiologic factor in only 27% of their patients, and Blake and colleagues in only 34%.\textsuperscript{87,114}

In about 10% of cases, documented acute pericarditis precedes development of chronic constrictive pericarditis. Prior to its effective treatment, tuberculosis was the etiology of chronic constrictive pericarditis in up to 17% of cases.\textsuperscript{114,27} Currently, a prominent cause is mediastinal radiation for malignant disease.\textsuperscript{510} Rheumatoid disease and sarcoidosis occasionally are causes. Trauma is another uncommon cause, with hemopericardium usually present as the precursor of pericardial thickening and constriction.\textsuperscript{66,66}

Cardiac surgery can be followed by constrictive pericarditis, but this is uncommon, probably occurring in less than 5% of patients.\textsuperscript{3,114} It may be more common after coronary artery bypass grafting than after other operations.\textsuperscript{3} The interval between the original cardiac operation and development of evidence of pericardial constriction is highly variable, ranging from 1 month to nearly 10 years.\textsuperscript{3} Mean interval is about 2 years.\textsuperscript{3}

**Clinical Presentation**

Classically, symptoms of chronic constrictive pericarditis are delayed for several years after the clinical or subclinical episode of acute pericarditis. The interval may, however, be as short as 3 to 4 weeks in those rare instances in which pericarditis develops after cardiac surgery, or 4 to 12 months after trauma or acute nonspecific pericarditis.

Initial symptoms may be only fatigue with or without modest effort breathlessness, and neck vein distention may be noticed. Insidiously, however, hepatomegaly and ascites develop, initially with or without peripheral edema. Even within the context of such evidence of appreciable fluid retention, breathlessness may occur only on exertion and not at rest; although in severe cases there may be orthopnea. Paroxysmal nocturnal dyspnea occurs infrequently.\textsuperscript{114}

**Clinical Findings**

When constriction is not severe, clinical findings may be limited to modest but persistent elevation of jugular venous pressure and slight liver enlargement with or without intermittent ankle edema. As constriction increases, there is a progressive increase in venous pressure and hepatomegaly, with eventual development of persistent peripheral edema, ascites, and pleural effusion. Venous pressure fails to decline during inspiration (Kussmaul sign), but this is not specific, in that the same findings may accompany right ventricular failure, restrictive myocardial disease, or tricuspid valve stenosis.\textsuperscript{117} By this stage, pulsus paradoxus is to be expected if sinus rhythm persists, and pulse pressure often is reduced. The apex beat is usually not palpable, but there is often systolic retraction in the left parasternal region. This retraction may be followed by a visible and palpable forward thrust extending toward the expected site of the cardiac apex. This impulse, which results from forceful ventricular filling with the onset of diastole, may be mistaken for the apex beat and used to argue against the existence of pericardial constriction. Rapid ventricular filling in early diastole is also associated with an unusually early, often loud, third heart sound that is sometimes referred to as a pericardial knock, but usually there are no murmurs.

As in other forms of heart failure, salt and water retention are present. Anand and colleagues found important increases of total body water, extracellular volume, plasma volume, and exchangeable sodium in their study of patients with proven constrictive pericarditis.\textsuperscript{114} However, renal plasma flow was only moderately decreased, and glomerular filtration rate was normal. Norepinephrine, renin activity, aldosterone, and cortisol were also increased, as was plasma atrial natriuretic hormone, although not to levels usually seen in other heart failure syndromes. The ratio of left atrial to aortic diameter measured by echocardiography was only minimally increased, indicating that in constrictive pericarditis, the atria are
Laboratory Investigation

Protein-losing enteropathy occurs in some patients with chronic constrictive pericarditis who develop ascites and hepatomegaly. They may have severe hypoproteinemia, with depression of albumin and gamma globulin, and an increased rate of leakage of plasma protein into the gastrointestinal tract. This syndrome also develops after other conditions that chronically elevate inferior or superior vena caval pressure, such as the Fontan operation and atrial switch operations with inferior vena cava obstruction (see “Protein-Losing Enteropathy” under Results in Section IV of Chapter 41, and “Superior Vena Cava Obstruction” and “Inferior Vena Cava Obstruction” under Special Situations and Controversies in Chapter 52).

Chest Radiography

The chest radiograph may be unremarkable, although about one third of patients show moderate to marked enlargement of the cardiac silhouette. Pericardial calcification is evident in about 40%, and radiologic evidence of compression in about 60%.

Electrocardiography

The electrocardiogram (ECG) is usually abnormal, with nonspecific ST-segment and T-wave changes in 90% of cases. In about 40% of patients with surgically verified chronic constrictive pericarditis, the QRS complexes have low voltage, and an atrial arrhythmia is present in 30%.

Imaging Studies

Two-Dimensional Echocardiography

Although extraordinarily useful in evaluating accumulations of pericardial fluid, two-dimensional (2D) echocardiography is less specific in diagnosing chronic constrictive pericarditis. It can, however, be helpful in studying patients with restrictive cardiac disease in general and reflects hemodynamic-respiratory interactions. Specifically, with inspiration, the right ventricle fills normally, but the left ventricle is inadequately filled because of both leftward septal movement and reservoir function of the lungs. Doppler interrogation shows diminished transmitral velocities. These are due partly to increased left ventricular afterload, negative intrathoracic pressure during inspiration, and systemic vasoconstriction associated with low cardiac output.

Computed Tomography

Computed tomography (CT) can identify thickened pericardium and distinguish this from pericardial effusion. However, anatomic findings on CT study have little diagnostic importance unless the physiologic phenomena of restriction to ventricular diastolic filling are demonstrated.

Oren and colleagues, using CT, demonstrated that the abnormally rapid early diastolic filling of the left ventricle characteristic of constrictive physiology, coupled with a measured pericardial thickness greater than or equal to 10 mm, can distinguish constrictive from normal or restrictive physiology.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) also can provide measurements of pericardial thickness and depict characteristic right atrial dilatation and right ventricular compression.

Masui and colleagues found the sensitivity, specificity, and accuracy of MRI in diagnosis of constrictive pericarditis to be 88%, 100%, and 93%, respectively.

Cardiac Catheterization

Characteristically, end-diastolic pressures are elevated and equal in the right atrium, pulmonary artery, and left atrium; this is the hallmark of chronic constrictive pericardial disease. In the report by McCaughan and colleagues, such findings were obtained in all patients coming to catheterization.

Intraventricular pressure pulse contours characteristically demonstrate an early rapid fall in diastolic pressure in the right ventricle, followed by a rapid rise to an elevated diastolic plateau (square root sign). Left ventricular pressure pulse usually has a similar contour.

Mean right atrial pressure fails to decrease normally during inspiration, or it may actually rise slightly. There is a transient increase in pulmonary blood volume and a slight reduction in right ventricular afterload, resulting in a fall in pulmonary arterial and right ventricular systolic pressure and a decline in pulmonary venous pressure and left ventricular diastolic pressure as well.

Vaitkus and Kussmaul identified the predictive accuracy of three different hemodynamic criteria for differentiating constrictive from restrictive disease (Table 23-1): (1) equalization of right and left ventricular end-diastolic pressure favors constriction; (2) constriction is associated with more modest elevation of right ventricular systolic pressure (≤50 mmHg); in restriction, it exceeds that amount; (3) in constriction, right and left ventricular end-diastolic pressure usually is greater than one third of right ventricular systolic pressure;

in restriction, the ratio is characteristically less than one-third.\textsuperscript{61}

When hemodynamic studies are equivocal, rapid infusion (in 6 to 8 minutes) of 1000 mL of normal saline solution produces diagnostic features of occult chronic constrictive pericardial disease.\textsuperscript{81,82} These features include not only striking elevations of filling pressures but also development of typical pressure pulse morphologic characteristics of constriction, loss or reversal of the respiratory variation of right atrial pressure, and precise diastolic equilibration of cardiac pressures.

Endomyocardial Biopsy

When diagnosis is unclear, myocardial biopsy may be useful. Normal myocardium, nonspecific changes (e.g., from irradiation), or myocarditis on biopsy must be considered nondiagnostic, because they may be present with either restrictive or constrictive disease.\textsuperscript{83} Finding amyloid disease is diagnostic of a restrictive etiology.

Minor Thoracotomy

Despite the studies mentioned previously, distinguishing between chronic constrictive pericarditis and restrictive cardiomyopathy can remain difficult, and a minor thoracotomy may be useful in a few circumstances.\textsuperscript{84} A small left anterior thoracotomy incision placed in the line of the formal anterolateral incision that would be used for pericardectomy is made, and the pericardium is exposed through the interspace and biopsied. If the pathologic diagnosis is chronic constrictive pericarditis, the incision is extended and a formal pericardectomy performed. If no pericardial pathologic condition is found, diagnosis favors restrictive cardiomyopathy, and operation is terminated as a minor procedure. If recurring pericardial effusion is found with a more or less normal pericardium, wide removal of the pericardium can be easily accomplished with slight extension of the incision.

\textbf{NATURAL HISTORY}

Knowledge of the natural history of surgically untreated patients with chronic constrictive pericarditis is incomplete. The interval between an etiologic event and onset of clinical evidence of constriction varies between a few months and many years. Factors that determine rate of progression of the disease and its symptoms are unknown. Atrial fibrillation commonly occurs at some stage and can result in sudden deterioration in circulatory status.

Somerville has estimated that once signs and symptoms of chronic constrictive pericarditis develop, a semi-invalid life can be led over an interval of 5 to 15 more years.\textsuperscript{85} When the clinical syndrome includes ascites, progression is more rapid, particularly in children.\textsuperscript{86}

\textbf{TECHNIQUE OF OPERATION}

Because patients with chronic constrictive pericarditis coming to operation are often seriously ill, an arterial catheter is inserted into the radial artery for pressure recording, in addition to usual preparations in the operating room. A central venous pressure line and often a pulmonary arterial catheter are also inserted.

Approach may be through a left anterolateral thoracotomy or a median sternotomy.

\textbf{Left Anterolateral Thoracotomy Approach}

The patient is positioned supine, with a roll beneath the left scapula. The left hand is secured beneath the left buttock, with the elbow padded and positioned on the left side of the table (Fig. 23-2, A). A curving left anterolateral skin incision is made beneath the breast anteriorly and more laterally over the fifth interspace. Incision is carried through the pectoralis major anteriorly, and the fifth interspace is opened. The interspace incision is extended well anteriorly. The internal thoracic vessels can be ligated and divided and the fifth costal cartilage disconnected from the sternum if exposure is inadequate. The rib spreader is inserted and the interspace incision extended laterally with scissors as the spreader is gradually opened.

The left phrenic nerve is identified and freed from the pericardium if possible. Occasionally the nerve is mobilized with a narrow strip of pericardium to avoid injury. The pericardium is incised through an area of minimal calcification posterolaterally if possible, over what is presumed to be left ventricle (Fig. 23-2, B). On occasion, this initial incision through the abnormal pericardium takes the dissection immediately onto the myocardium; in other cases, it enters a fluid-filled space (see “\textbf{Morphology}” earlier in this section).

When a space is entered, the initial longitudinal incision is carried anteriorly and posteriorly from its superior and inferior extremities. The anterior pericardial flap is dissected as far as the right atrioventricular groove, beneath the elevated thymus and prepericardial fat, and resected (Fig. 23-2, C). The posterior flap is dissected far posteriorly and excised. Dissection must be carried superiorly onto the pulmonary trunk, because failure to relieve pericardial bands across it can result in postoperative gradients and severe right ventricular hypertention.\textsuperscript{87} The piece of pericardium left inferiorly is dissected off the diaphragm except in the area of the central fibrous tendon, from which it often cannot be removed. Fibrous plaques adherent to the epicardium are then dissected off through the entire area of resection. If the epicardium is thin and relatively normal, it need not be disturbed. If it is thickened, it must be removed either in its entirety or in a sufficient number of areas to allow more normal diastolic filling of the ventricles. Failure to do this severely compromises results of operation.\textsuperscript{88}

If no pericardial space is found, the entire longitudinal incision and its anterior and posterior extensions are made only through the fibrous pericardium. Then the incision is deepened in an area that seems to be over myocardium rather than over the interventricular or atrioventricular groove. Slowly and carefully, the posterior flap is dissected off the left ventricular myocardium. At first, this dissection is done only in areas in which it proceeds reasonably well, leaving the epicardium on the myocardium wherever it is thin and normal. When dissection in this plane is not possible, such as in an area of calcification or dense scarring, islands of calcification and scarring may be left attached to the myocardium but separated from other areas. Dissection moves to the anterior pericardial flap whenever progress ceases posteriorly and vice versa. Particular care is necessary when dissection passes across the interventricular groove containing the coronary vessels; here, islands of calcific plaque may need to be left in place.
Dissection is carried just across the atrioventricular groove and onto the atria. It is important to be certain that all constrictions in the atrioventricular groove are removed, because they can result in gradients between atrium and ventricle. No special effort is made to free the venae cavae or cavoatrial junctions, because constriction does not occur in these areas. When dissection is complete, the pericardial flaps, as well as the diaphragmatic portion of the pericardium, are excised (Fig. 23-2, D).

If a pulmonary arterial catheter is not placed, a polyvinyl catheter can be inserted into the left atrium via the appendage or left pulmonary veins to monitor pressure and assist in postoperative care. Two pleural drainage catheters are inserted, the tip of one being placed posteriorly and inferiorly and that of the other anteriorly and superiorly. The interspace incision is closed with heavy pericostal and perichondrial absorbable sutures, and the muscle layers are closed with continuous absorbable sutures. The skin is closed with a continuous subcuticular suture.

**Median Sternotomy Approach**

The median sternotomy approach may be used with or without cardiopulmonary bypass (CPB). In either event, the sternum is divided in the usual manner (see “Incision” in Section III of Chapter 2). The pericardium is opened vertically anteriorly. Often it is necessary to use a knife for this maneuver, and particular care must be taken when the plane between the thickened (visceral) pericardium and the myocardium is reached. The pericardial flaps are then dissected laterally, superiorly and inferiorly, as described in preceding text. To the right, dissection passes across the atrioventricular groove and proceeds across the anterior and lateral walls of the right atrium, as long as the cleavage plane there is readily
C, Flaps have been dissected back, completely liberating both left and right ventricles, leaving where necessary small calcific plaques in situ. First portion of pulmonary trunk has been completely unroofed. D, Appearance at end of procedure. Thickened pericardium has been removed from diaphragm.
found. If it is not, this portion of thickened pericardium can be left in situ. In the former instance, the pericardial flap is excised about 1 to 2 cm anterior to the right phrenic nerve. To the left, dissection proceeds across the front of the ventricles and then over the lateral left ventricular wall. This pericardial flap is excised about 1 cm in front of the left phrenic nerve. Dissection continues posterior to the pericardial nerve but in the plane between myocardium and epicardium until the entire left ventricle is freed (up to the atrioventricular groove posteriorly and over the diaphragm inferiorly). It is usually possible to remove the thickened, often calcified, outer pericardial layer, because there is generally a cleavage plane between this and the overlying thickened pleura containing the pericardic nerve. The same is usually true of the thickened pericardial tissue inferiorly overlying the diaphragm. Operation is completed as described earlier.

The need for CPB is debatable. However, if CPB is anticipated, the obvious approach is median sternotomy. The improved exposure afforded by CPB must be balanced against the probability of increased blood loss. When CPB is used, it may be most convenient to use the femoral vessels for both venous and arterial cannulation (see “Cardiopulmonary Bypass Established by Peripheral Cannulation” under Special Situations and Controversies in Section III of Chapter 2). Then, after CPB has been established at 34°C to 37°C, the thickened pericardium can be incised and dissection accomplished.

Choice of Surgical Approach

The main advantage of the left anterolateral approach is the excellent exposure afforded for complete liberation of the left ventricle and complete removal of the diseased pericardium over it, including its diaphragmatic surface. The main advantage of median sternotomy is the ease with which the incision is made and the improved exposure obtained for removing pericardium from the right ventricle. It is a better approach when CPB is used, although CPB can be used with the anterolateral approach by cannulating the femoral vessels (see “Cardiopulmonary Bypass Established by Peripheral Cannulation” under Special Situations and Controversies in Section III of Chapter 2). Although there are proponents of near-routine use of CPB for pericardectomy, there is no clear evidence that this improves outcomes after operation. One proposed advantage, is the ability to liberate the cavoatrial junction and to remove the pericardium over the right atrium, although the benefit of this is controversial.

Complementary Techniques

A high-speed Burr or ultrasonic dissector may help to define the epicardial layer and dissect the adherent calcified pericardium away from the myocardium. Complete resection of all thickened and constrictive epicardium is as important for achieving a good result as complete removal of the parietal pericardium. However, in some patients (particularly those with postoperative or postirradiation constriction), it is impossible to develop a consistent plane of dissection. Usually that plane is apparent by encountering dark pink myocardium, the surface of which expands into the pericardial incision and contracts vigorously. In cases in which the epicardial peel is exceptionally adherent, a cross-hatching “waffle” procedure described by Heimbecker and colleagues or multiple incisions of the peel (turtle cage operation) allow myocardial expansion and restoration of adequate hemodynamics.

SPECIAL FEATURES OF POSTOPERATIVE CARE

Postoperative care is given as described in Chapter 5. Low cardiac output early postoperatively occurs commonly in patients who have advanced disability, fluid retention, and ascites preoperatively. Low cardiac output may require maintaining left atrial pressure at a relatively high level (15 mmHg or more) and using catecholamine infusions for 12 to 48 hours. Intraaortic balloon pulsation is effective in these patients when cardiac output is low and unresponsive to other measures.

RESULTS

Survival

Early (Hospital) Death

Hospital mortality after pericardectomy for chronic constrictive pericarditis does not approach zero even in the current era. In an earlier era, early (hospital) mortality was 10% to 15%. More recently, it has been about 5%. Nataf and colleagues reported 2% to 3% operative mortality in 84 patients operated upon between 1979 and 1989 using a median sternotomy. Others have reported similar results.

Time-Related Survival

Patients operated on for chronic constrictive pericarditis have a time-related survival that is less than, or in favorable cases similar to, that of an age-gender-ethnicity–matched population (Fig. 23-3). Survival, including hospital deaths, at 1, 5, 10, and 20 years is about 90%, 75%, 65%, and 55%, respectively.
Chapter 23 Pericardial Disease

Factors in the early phase after operation. Preoperative NYHA functional class is also a risk factor for death late after operation (see Fig. 23-4). Correspondingly, high right ventricular end-diastolic pressure preoperatively has been a risk factor (Fig. 23-5). Moderate to severe tricuspid regurgitation is also associated with increased early mortality.

Previous radiation therapy over the chest is an important risk factor for unfavorable results and a higher time-related prevalence of death than otherwise occurs (Fig. 23-6). Mode of Death

About 75% of postoperative in-hospital deaths occur from acute or subacute cardiac failure. Postoperative hemorrhage and respiratory failure are other modes of early death.

Only about 5% of patients continue to have chronic heart failure after recovery from a satisfactory pericardectomy. Such patients have usually had long-standing symptoms (Fig. 23-4) or were older at operation.

Incremental Risk Factors for Death

Preoperative functional status is a powerful risk factor for death in the early hazard phase after operation. Thus, early risk approaches zero for patients in New York Heart Association (NYHA) functional class I or II preoperatively, 10% (CL 8%-14%) for those in NYHA class III, and 46% (CL 29%-64%) for those in NYHA class IV. Related to this is the fact that ascites and peripheral edema, usually associated with preoperative NYHA class IV, have been identified as risk factors in the early phase after operation.

Surgical approach—that is, left anterolateral thoracotomy or median sternotomy with or without CPB—has not affected outcome beyond what could be due to chance alone (Fig. 23-7).

Section II  Chronic Effusive Pericarditis

DEFINITION

Chronic effusive pericarditis is a condition in which an inflammatory reaction of the pericardium stimulates accumulation of appreciable amounts of pericardial fluid. The fluid itself may be an indication for therapeutic intervention, or, coupled with loss of compliance of the pericardium, it may provoke the syndrome of pericardial constriction.

HISTORICAL NOTE

Chronic effusive pericarditis is more common currently than in earlier eras because of improved therapy and thus longer survival of patients with malignant disease, and because of the appreciable number of patients whose lives are prolonged by long-term dialysis for end-stage renal disease.

MORPHOLOGY

Chronic effusive pericarditis is usually of the so-called bread-and-butter type, with dense strands of fibrin bridging the space between the layers of the visceral pericardium. Both the visceral and parietal layers may be thickened and adherent to one another, and the entire area may be hemorrhagic. Pericardial fluid may occupy the entire pericardial space or may be loculated into several areas.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Pathophysiology

Rarely, acute cardiac tamponade develops in patients with chronic effusive pericarditis. More commonly, fluid accumulates sufficiently slowly that this does not occur. Instead, the patient presents with signs and symptoms of effusive constrictionary pericardial disease (see “Pathophysiology of Cardiac Compression” in Section I for the pathophysiology of this and other types of cardiac compression).

Etiology

Although precursors of chronic effusive pericarditis (e.g., advanced renal disease, dialysis, malignant disease, trauma) are recognized, precise etiologic mechanisms are not known (except in cases of frank pericardial involvement by malignant disease or collagen vascular disease). It was once believed that accumulation of pericardial fluid in patients with chronic renal failure was related to serum creatinine levels or degree of nitrogen retention, but this is not the case.

Chronic effusive pericarditis that develops during dialysis, and particularly during hemodialysis rather than peritoneal dialysis, is more refractory to medical treatment than that which develops from chronic renal disease itself. This syndrome appears more likely to develop in young women than in men. Infection was once thought to

Figure 23-8  Preoperative and late postoperative New York Heart Association (NYHA) functional class in 141 patients undergoing pericardectomy for chronic constrictive pericarditis. (Data from McCaughan and colleagues.)

Hemodynamic Results

Virtually all patients with a good result have normal resting hemodynamic characteristics after adequate surgical treatment of chronic constrictive pericarditis. During exercise, 10% to 20% may show mild elevation of pulmonary artery pressure or failure to increase cardiac output. When considerable amounts of thickened pericardium are left over the ventricles, hemodynamic improvement is less complete.

Functional Status

Most patients have a good long-term result from pericardectomy for chronic constrictive pericarditis, with nearly all in NYHA class I or II (Fig. 23-8).

Reoperation

Only a small percentage of patients (~2%) require reoperation.

INDICATIONS FOR OPERATION

Diagnosis of chronic constrictive pericarditis is, in general, an indication for operation. When physiologic effects of constriction are minimal, and particularly when other serious disease is present, operation may be delayed until more marked signs and symptoms appear.

Occasional patients are seen with fatigue, dyspnea, and chest pain, but without the characteristic clinical and laboratory features of chronic constrictive pericarditis. When diagnosis of pericardial constriction is made by rapid volume expansion in the catheterization laboratory (see “Clinical Features and Diagnostic Criteria” earlier in this section), pericardectomy is indicated, because symptomatic and long-term results are good under these circumstances.

Because of unfortunate results in patients whose chronic constrictive pericarditis is the result of previous radiation therapy, operation is advisable only when symptoms are advanced and there is near certainty that the cause of the symptoms is cardiac constriction by the pericardium.
be responsible for chronic effusive pericarditis, but this occurs rarely.45

Acute nonpurulent pericarditis often becomes a chronically recurring disease, which sometimes develops into chronic effusive pericarditis.

Symptoms
Onset of pericarditis may be heralded by chest pain—from mild to excruciating—and may be difficult or impossible to distinguish from angina. Some patients present with fever, leukocytosis, and a pericardial friction rub, but have little pain. A few patients present with evidence of acute cardiac tamponade.

Signs
The most striking abnormality on physical examination is gross elevation of jugular venous pulse. The characteristically absent y descent and preserved x descent are found in the jugular venous pulse wave. A pericardial friction rub may or may not be audible. Arterial blood pressure may be depressed, and pulsus paradoxus may be present.

Chest Radiography
An enlarged and globular cardiac silhouette on the chest radiograph supports diagnosis.

Electrocardiography
When nephrogenic or other forms of effusive pericarditis are acute, characteristically there is widespread ST-segment elevation.518,822 Later, the ECG may be normal or, if the disease becomes chronic, typical ECG features of chronic constrictive pericarditis may evolve.

Echocardiography
For patients with chronic effusive pericarditis, 2D echocardiography is a highly useful diagnostic modality. Not only can the diagnosis be made with this technique, but also aspiration of the pericardium can be made precisely and effectively by concomitant observation of the pericardial space.

NATURAL HISTORY
Development of chronic effusive pericarditis in patients with malignant disease is unpredictable unless there is malignant involvement of the pericardium. Nephrogenic pericarditis develops in about 15% of patients on chronic hemodialysis. It has a tendency to occur early in the course of dialysis.52

The natural history of this complication without intervention is unknown. Presumably, some patients with considerable effusion die with acute cardiac tamponade; in others, chronic constrictive pericarditis develops and follows its natural history.

TECHNIQUE OF OPERATION
Pericardiocentesis

The cardiologist generally performs pericardiocentesis in the cardiac catheterization laboratory, under hemodynamic and electrocardiographic control, after localizing the fluid by echocardiography. Either the subxiphoid or apical route is used, depending on location of the fluid. Previously, morbidity associated with this method was considerable. However, Callahan and colleagues have found pericardiocentesis directed by 2D echocardiography to be safe.43 Allen and colleagues compared percutaneous catheter drainage with subxiphoid pericardiotomy for treatment of pericardial effusion.43 Subxiphoid pericardiostomy had no operative deaths (0%; CL 0%-2.0%) and 1 complication (1.1%; CL 0.1%-3.6%) among 94 patients. Percutaneous catheter drainage resulted in 1 death (4%; CL 0.6%-14%) and 4 complications (17%; CL 9%-29%) among 23 patients (P < .005). The authors concluded that catheter drainage was suitable only for patients with hemodynamic instability.

Subxiphoid Pericardial Window
Either local anesthesia, conscious sedation, or general anesthesia may be used. A vertical midline incision about 4 cm in length is made over the xiphoid process and upper abdomen. The linea alba is divided, and the xiphoid is removed or retracted upwardly with the distal sternum. The diaphragm is dissected away from the undersurface of the sternum and xiphoid, fat is removed from over the pericardium, and the pericardium is opened under direct vision. All fluid is aspirated, and loculations may be broken up gently with the tip of a suction device. A large pericardial window as possible is made by excision of pericardium. Percardial tissue and fluid are sent for bacteriologic and histologic study. A drain is inserted and placed on 10- to 20-mmHg suction and the wound is loosely closed. Generally, the tube is left for several days and then removed.

Percutaneous Balloon Pericardiotomy
Percutaneous balloon pericardiotomy involves use of a percutaneous balloon–dilating catheter to create a nonsurgical pericardial window. Under local anesthesia, a needle is introduced via the subxiphoid approach, followed by a guidewire and dilator. Some fluid is removed, and radiographic contrast is injected into the pericardial space. A dilating balloon is placed so as to straddle the pericardial border. The balloon is inflated to create a window, and the remaining fluid is drained. Ziskind and colleagues reported that this procedure was successful in 46 of 50 patients (92%; CL 86%-96%) treated for tamponade or large effusion.21

Pericardial Window via Left Anterolateral Approach
A small left anterolateral incision is made, similar to the anterior portion of the incision described for treatment of chronic constrictive pericarditis. A simple pericardial window is created, usually anterior to the phrenic nerve. After evacuation of fluid, posterolateral and anterior chest tubes are brought out from the left pleural space through lower intercostal stab wounds. The incision is closed.
These operations can be performed through a standard left anterolateral incision or median sternotomy (see Technique of Operation in Section I).

RESULTS

These procedures can be curative when applied to chronic effusive pericarditis of unknown etiology. In this circumstance, however, use of a pericardial window is less effective than subtotal or complete removal of the pericardium.\(^1\),\(^5\),\(^6\),\(^7\)

When operation is done for palliation of an underlying malignant disease, long-term survival is considerably less than in patients with benign disease. However, relief of symptoms is generally excellent, although about 10% of such patients have recurrent effusions or late pericardial constriction.\(^8\)

Usually, such patients have been treated by a pericardial window; when the recurrence is symptomatic, subtotal or complete pericardectomy is indicated.\(^9\)

INDICATIONS FOR OPERATION

When symptoms are important and persist despite 7 to 10 days of intensive medical treatment, or when acute pericardial tamponade develops, operation is indicated. Under most circumstances a pericardial window is indicated, and the subxiphoid approach is chosen because of its greater simplicity and equal effectiveness compared with a window created through the transthoracic route.\(^1\) When a satisfactory result is not obtained, or when chronic effusive pericarditis recurs or constriction develops, subtotal or total pericardectomy is indicated.

Section III Other Types of Pericarditis

PURULENT PERICARDITIS

Intractable purulent pericarditis is uncommon in the current era. It is most commonly caused by *Staphylococcus aureus*, less often by *Haemophilus influenzae*. When it occurs and the pericardial abscess is not loculated, pericardiocentesis with 2D echocardiographic control is usually the initial treatment.\(^9\) Unless the process subsides rapidly after one or two aspirations, more adequate drainage is required. This can be accomplished with a tube through the subxiphoid approach (see Technique of Operation in Section II).\(^2\)

Majid and Omar reported 12 cases with 1 death (8%; CL 1%-26%).\(^1\) In children with staphylococcal pericarditis accompanied by symptoms of fever, respiratory difficulty, or tamponade, urgent pericardectomy and drainage are indicated.

TUBERCULOUS PERICARDITIS

In developed countries, tuberculosis occurs uncommonly, and tuberculous pericarditis occurs in only about 1% of patients in whom tuberculosis develops.\(^1\),\(^3\),\(^4\),\(^7\) In earlier times, mortality among patients with tuberculous pericarditis was as high as 40%.\(^8\)

When the amount of pericardial fluid is moderate and examination by 2D echocardiography shows little pericardial thickening, medical therapy alone is appropriate. When effusions are persistent after medical therapy with or without periodic aspirations under echocardiographic control, when the pericardium becomes thickened, or when signs of pericardial constriction develop, either because of the fluid or a cicatricial process in the pericardium itself, operation is indicated. Optimal procedures and their sequencing are the same as those described for chronic effusive pericarditis in Section II. If chronic constrictive pericarditis develops, then a full pericardectomy is indicated (see Technique of Operation in Section I).

CONGENITAL ABSENCE OF PERICARDIUM

Congenital absence of the pericardium may be partial or (less often) complete. In most instances the defects occur on the left side. Most patients are asymptomatic, but symptoms may develop because of herniation of cardiac tissue, either spontaneously or following a surgical procedure.\(^c\),\(^d\),\(^e\)

According to van Son and colleagues, in patients with partial left defects, chest radiography may show prominence of the left hilum or pulmonary trunk caused by herniation of the left atrial appendage through the defect.\(^2\) Echocardiography, MRI, and CT are useful in confirming the diagnosis.\(^c\),\(^d\),\(^e\),\(^f\) Complete absence of the left pericardium may be characterized by leftward displacement of the heart and aortic knob, a long prominent pulmonary artery, and a flattened left cardiac silhouette. Pericardial defects are rarely of clinical importance, although moderate-size defects may produce cardiac strangulation.\(^1\),\(^3\),\(^4\)

Most are discovered during cardiac surgery, and usually the only treatment is pericardiostomy by longitudinal extension of the existing defect to relieve tension at the defect and prevent herniation.

POSTPERICARDIOTOMY SYNDROME

Postpericardiotomy syndrome is an inflammatory pericarditis occurring in 10% to 40% of patients following cardiac surgery.\(^9\) It develops days to several months after surgery and is accompanied by pleuritic chest pain, low-grade fever, and pericardial friction rub on auscultation. Uncommonly, it progresses to chronic constrictive pericarditis. The Task Force on the Diagnosis and Management of Pericardial Diseases of the European Society of Cardiology lists colchicine as a class IIa indication for acute pericarditis. A randomized double-blind multicenter placebo-controlled Italian clinical trial has been completed to test the safety and efficiency of colchicine in preventing postpericardiotomy syndrome. Patients were randomized to 1 mg colchicine twice daily on day 1 and 0.5 mg twice daily for a month in those weighing 70 kg or more, and half that amount in those weighing less than 70 kg, versus a placebo. Postpericardiotomy syndrome within the subsequent 12 months was 8.9% vs. 21% \((P = .002\), respectively, and disease-related hospitalizations were 0.6% vs. 5.0% \((P = .02\), respectively. Gastrointestinal side effects were higher in the colchicine group \((8.9% vs. 5.0%, P = .2\). In symptomatic patients, the pain and effusions can
often be relieved by bed rest and aspirin or nonsteroidal anti-inflammatory drugs (ibuprofen, indomethacin). Although symptoms can also be resolved with corticosteroids (prednisone), their use should be avoided whenever possible because of the side effects.

## Acute Traumatic Aortic Disruption

### Definition

Acute Traumatic Aortic Disruption refers to the tearing or ripping of the inner layer of the aorta, which is a major blood vessel carrying blood from the heart to the rest of the body. This condition can be life-threatening if not treated promptly.

### Historical Note

The incidence of acute traumatic aortic disruption has increased due to improvements in road safety and injury management, but it remains a rare but severe condition.

DEFINITION
Acute traumatic aortic disruption is rupture of all or part of the aortic wall, usually occurring as a result of blunt trauma. A theoretical sequence of injury involves initial rupture of the intimal and medial layers. After a period of unpredictable duration, rupture of the adventitial layer occurs. Patients are considered to have acute disruption when it occurs within 14 days of injury. Chronic traumatic aortic disruptions and posttraumatic aneurysms (pseudoaneurysms) are discussed in Chapter 26. Paraplegia as a complication of aortic surgery, and grafts used to replace or exclude the aorta, are also discussed in this chapter.

HISTORICAL NOTE
Although the lethal nature of acute traumatic aortic disruption had been recognized for centuries and was noted by Strassmann in 1947, data supporting lethality of traumatic disruption and temporal relationships between trauma and subsequent death were delineated by Parmley and colleagues in 1958. The first report of successful repair of traumatic disruption of the thoracic aorta apparently was by Dshanelidze in 1923 (cited by Clarke and colleagues). In 1957, Gerbode and colleagues reported successful repair of such an injury, as did Klassen and colleagues in 1958 (according to Passaro and Pace and Vasko and colleagues). In 1998, Kato and colleagues at Stanford University reported successful treatment of three patients with acute traumatic aortic disruption using endovascular stent-grafts constructed from modified Z stents covered with woven polyester or expanded polytetrafluoroethylene (PTFE) graft material and deployed through a delivery sheath from a peripheral artery.

MORPHOLOGY
Upper Descending Thoracic Aorta
Traumatic aortic disruptions occur most commonly in the upper descending thoracic aorta at or near the aortic isthmus. In the study of Parmley and colleagues, 45% of disruptions occurred at this site. In a more recent multicenter study by the American Association for the Surgery of Trauma (AAST) reported by Demetriades and colleagues, 82 (74%) of 110 acute aortic injuries occurred in this location. Occasionally, the disruption may occur at the origin of the left subclavian artery and extend proximally to involve the distal portion of the aortic arch.

A traditional view has been that with abrupt deceleration of the thorax, such as occurs in a high-speed vehicular accident in which the body is thrown against a near-stationary object, the ligamentum arteriosum and intercostal arteries anchor the upper descending thoracic aorta to the thorax, as do the thoracic exits of the brachiocephalic vessels. These structures decelerate with the thorax, but the distal end of the aortic arch and most proximal part of the descending thoracic aorta continue to move forward. Aortic disruption tends to develop at the interface between these two areas, although the sum of the forces involved and directions of their effects are complex. The force needed to produce rupture is equivalent to an intravascular pressure of 2500 mmHg.

There are other theories regarding the mechanism of blunt aortic injury (Fig. 24-1). Aortic rupture from a sudden increase in intraabdominal pressure may explain the association between blunt aortic injury and diaphragmatic rupture. A “water-hammer” effect, which involves simultaneous occlusion of the aorta and a sudden elevation in blood pressure, and the “osseous pinch” effect from entrapment of the aorta between the anterior chest wall and the vertebral column have also been postulated. Most injuries probably involve a combination of forces.

Disruption can be complete, including aortic adventitia and mediastinal pleura. If the deceleration forces are less severe, the mediastinal pleura and the adventitia are spared. With lower initial velocity or less rapid deceleration, the mediastinal pleura and adventitia remain intact, while a fracture develops in a portion of the circumference of the aorta, usually posteriorly.

If the person survives the immediate post-disruption period, the periaortic hematoma begins to liquefy about 2 weeks after the traumatic event. It is gradually absorbed or evacuated into the aorta, and a false aneurysm (pseudoaneurysm) develops. The false aneurysm may remain stable for a long period and even calcify, but it can enlarge and rupture.

Ascending Aorta
Disruption of the ascending aorta is uncommon (10% of isolated cases of disruption without other major visceral injuries reported by Parmley and colleagues and 3.6% [4 of 111 patients] reported by Demetriades and colleagues). Again, the mechanism is sudden deceleration, which is apt to be severe in unrestrained drivers who strike the steering wheel. Cammack and colleagues showed that vertical forces of deceleration tend to lead to rupture of the ascending aorta and arch, and horizontal forces to rupture of the descending aorta. Disruption occurs most commonly in the distal portion of the ascending aorta, near the origin of the brachiocephalic trunk. Less commonly, it is in the proximal portion of the ascending aorta. As in the upper descending thoracic aorta, disruption may be complete or partial.

Other Sites
Disruptions can occur in the lower thoracic aorta (often in association with spinal fractures) and in the aortic arch and abdominal aorta.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA
Pathophysiology
When complete disruption occurs that includes the investing mediastinal pleura or pericardium, hemorrhage is free and exsanguinating, and death occurs instantly or within a few minutes. When the tear involves all layers of the aortic wall but the mediastinal pleura remains intact, a large amount of blood escapes into the retropleural tissues, and signs and symptoms of hemorrhagic shock appear. Usually under such circumstances, some blood or plasma passes through the mediastinal pleura to produce a left hemotorax or pleural fluid collection. When the adventitia of the aorta remains essentially intact, a smaller extravasation of blood occurs, and the mediastinal hematoma is less extensive. The aortic
Theories of blunt aortic injury. Many blunt aortic injuries probably involve a combination of forces, including stretching, shearing, torsion, a “water-hammer effect” (which involves simultaneous occlusion of the aorta and a sudden elevation in blood pressure), and the “osseous pinch” effect from entrapment of the aorta between the anterior chest wall and vertebral column. (From Neschis and colleagues.\textsuperscript{1})

Clinical Features

Persons with acute traumatic aortic disruptions frequently have other severe injuries, including liver and spleen lacerations with intraabdominal hemorrhage, and head injuries. Such injuries have their own clinical features and diagnostic criteria that may affect management of the aortic disruption (see Indications for Operation later in this chapter).

Those who survive to reach the hospital may be in profound hemorrhagic shock if a large mediastinal extravasation has occurred or if there has been extensive intraabdominal or extremity bleeding. Some patients, however, are hemodynamically stable after initial resuscitative measures, and a few show no signs of hemodynamic instability. In such patients, upper body hypertension is common.\textsuperscript{2} Some patients in whom other trauma is not severe complain of interscapular back pain, but pain is generally not a major part of the presentation.

Evidence of impaired blood flow beyond the disruption is uncommon. However, a small number of patients with acute disruption of the descending thoracic aorta who reach the hospital alive have paraplegia or paraparesis (2.6%; CL 2.2%-3.0%, of the 1742 patients in the meta-analysis of von Oppell and colleagues\textsuperscript{3}). Rarely, patients have severe lower body and leg ischemia.

Diagnostic Imaging

Chest Radiography

The chest radiograph is usually abnormal, but with variable findings. There may be opacification of the left hemothorax and rightward shift of the mediastinum resulting from massive collection of fluid in the left pleural space. These features are not diagnostic of aortic disruption, because bleeding after trauma may come from intercostal or pulmonary vessels, cardiac and pericardial rupture, or traumatic rupture of the left hemidiaphragm with intrathoracic splenic rupture.

Commonly the radiograph shows only diffuse upper mediastinal widening (Fig. 24-2), which in the setting of a severe injury strongly suggests upper descending aortic disruption. However, rightward shift of the trachea, blurring of the normally sharp outline of the upper descending thoracic aorta, and opacification of the usually clear space between it and the pulmonary trunk may be evident; all these findings suggest aortic disruption.\textsuperscript{4}

Computed Tomography

Computed tomography (CT) has been evaluated as a screening examination to detect aortic injury in patients with blunt chest trauma.\textsuperscript{5} In the early years of its use, time required to perform the study (60-70 minutes) in patients who often were severely injured, low sensitivity and positive predictive value, and lack of demonstrated cost effectiveness limited its utility.\textsuperscript{6} It is, however, essential for managing patients with...
associated head trauma and for assessing presence of intra-abdominal and retroperitoneal injuries.

Now, helical CT of the thorax can be performed more rapidly than conventional CT, and its sensitivity for detecting blunt aortic injury equals that of aortography (discussed later). In trauma centers, it is currently the most widely used technique to diagnose traumatic aortic disruption. Findings indicative of aortic disruption include extravasation of contrast, intimal flaps, mural thrombus, paraaortic hematoma, wall thickening, pseudoaneurysm, and pseudocoarctation (Fig. 24-3). Advantages of helical CT over other imaging techniques include its wide availability, speed of performance, sensitivity, and relatively low cost.

**Figure 24-2** Chest radiograph 6 hours after a high-speed automobile accident. Upper mediastinal shadow is abnormally wide, and outlines of distal aortic arch and upper descending thoracic aorta are blurred.

**Figure 24-3** Computed tomographic axial (A) and three-dimensional (B) images of a posttraumatic pseudoaneurysm of the aortic isthmus. The aortic disruption (small arrow), periaortic hematoma (asterisk), and a large pleural effusion (large arrow) are shown. (From Botta and colleagues.)

**Transesophageal Echocardiography**

Transesophageal echocardiography (TEE) is a highly effective method for imaging the proximal ascending aorta, distal aortic arch, and descending thoracic aorta. Its characteristic finding is presence of a mural flap (Fig. 24-4). Two studies comparing TEE with aortography or with findings at operation or autopsy in 101 and 32 patients, respectively, have demonstrated a sensitivity of 91% and 100% and a specificity of 100% and 98%, respectively. A more recent prospective comparison of TEE to helical CT demonstrated a sensitivity, specificity, negative predictive value, and positive predictive value of 93%, 100%, 99%, and 100%, respectively, for TEE, compared with 73%, 100%, 95%, and 100% for helical CT. TEE can be performed with minimal risk in the emergency room, intensive care unit, or operating room and can be carried out simultaneously with other diagnostic or therapeutic procedures. It requires less than 30 minutes to complete and provides, in addition to images of the aorta, information about ventricular function and wall motion. It can detect presence of cardiac valvar lesions and pericardial fluid. A limitation is that the distal ascending aorta and brachiocephalic trunk cannot be imaged clearly because of interposition of the column of air in the distal trachea and right bronchus between the probe in the esophagus and the aorta. Thus, presence of a tear in these locations cannot be excluded. In centers with extensive experience, TEE can be used as the primary diagnostic imaging technique in patients with blunt chest trauma.

**Aortography**

Until recently, aortography has been the definitive diagnostic study for acute aortic disruption (Fig. 24-5), the imaging modality against which all subsequently developed imaging techniques have been compared. Its specificity approaches 100%, and prevalence of false positives and false negatives is low. The procedure is associated with some risk, is time consuming, and requires a skilled interventional radiology team. Up to 90% of studies performed to determine presence of aortic disruption are negative.
With increasing use of CT as the primary diagnostic imaging study, aortography is being used less frequently. In a multicenter study by the AAST, it was used to screen for traumatic aortic disruption in only 8.3% of 193 patients treated during a 26-month interval in 2005-2007, as compared with 87% of 274 patients treated during a 30-month interval in 1994 to 1996.\(^4\)

**Magnetic Resonance Imaging**

Magnetic resonance imaging (MRI) provides excellent images of vascular structures in the thoracic aorta and provides diagnostic accuracy similar to aortography.\(^3\) Its use in the acute trauma patient is limited because of the confining nature of the scanners and the time required to obtain images.

### NATURAL HISTORY

Risk of death, generally from massive intrathoracic hemorrhage, is greatest immediately after the injury. As time passes, the instantaneous risk of death (hazard function) decreases, but the patient remains at risk of death from hemorrhagic shock over the next several days (Fig. 24-6). Shock may be secondary either to initial blood loss into a large mediastinal hematoma or to renewed bleeding into the adventitia and mediastinal pleura as arterial blood pressure rises after the initial period of hypotension.\(^1\) Probability of survival for at least 4 hours after the accident is not improved with certainty by rapid transport from accident scene to hospital.\(^15\) About 40% to 50% of persons die within 48 hours of the traumatic event.\(^18\)

Instantaneous risk of death in surgically untreated patients begins to level off about 7 days after injury (see Fig. 24-6). Most patients who survive this long without treatment survive much longer. However, a low constant risk of death from hemorrhage persists because of propensity of the false aneurysm (see **Morphology** earlier in this chapter) to rupture even years later.\(^6\) It has been estimated that even after 10 years, 20% of patients with this type of traumatic false aneurysm will die of rupture within the subsequent 5 years.\(^35,69\)

### TECHNIQUE OF OPERATION

**Preoperative Management**

When a presumptive diagnosis of acute traumatic aortic disruption or other major vascular injury is made based on an abnormal chest radiograph, hemodynamic monitoring and medical therapy are instituted before diagnostic imaging (CT, TEE, or aortography) is performed. In hemodynamically...
stable patients, medical therapy should include intravenous infusion of a vasodilator (usually sodium nitroprusside) to avoid hypertension, limitation of intravenous fluid infusion once the systolic arterial blood pressure exceeds 90 to 100 mmHg, and administration of a \( \beta \)-adrenergic antagonist when heart rate exceeds 80 to 90 beats/min. This therapy should be continued while diagnostic studies and any surgical procedures, if indicated, are performed.

Repair of Acute Traumatic Aortic Disruption of Upper Descending Thoracic Aorta

Operative Strategies

Open operative repair has been the standard surgical treatment of traumatic aortic disruption of the descending thoracic aorta for more than 50 years. Development and recent widespread availability of endovascular stent-grafts have dramatically altered management. The first patients with traumatic aortic disruption of the descending thoracic aorta treated this way were reported by Kato and colleagues in 1997. The technique is now widely used in trauma centers throughout the world. A prospective multicenter study by the AAST reported by Demetriades and colleagues compared the methods of definitive repair of traumatic aortic disruption in two time intervals: 1994-1996 (274 patients, 50 participating centers) and 2005-2007 (193 patients, 18 participating centers) (Table 24-1). In the latter interval, 65% of patients were treated with stent-grafts. Although there are no randomized trials comparing endovascular stent-grafting with open repair, ease of insertion, reduced operative time, and reduction in major postoperative complications are attractive features of the technique that have led to increasing use.

Open Repair

Spinal cord ischemic injury resulting in paraplegia or paraparesis is a devastating complication of surgical repair, and the optimal technique for avoiding injury to the spinal cord during open repair remains arguable (see detailed discussion in “Paraplegia after Aortic Clamping” under Special Situations and Controversies later in this chapter). In their meta-analysis, von Oppell and colleagues noted that the mean number of patients with acute traumatic aortic disruption admitted to any unspecified center was 2.6 per year (range 0.2-10.7 patients). The centers in most of the reports (39 of 60 with data suitable for analysis) treated fewer than this mean number of patients per year. Thus, annual experience with this condition is limited in all but a few centers. With simple aortic clamping, von Oppell and colleagues found that the earliest reported case of paraplegia occurred after a clamp time of 24 minutes; if clamp time extended to 34 minutes, cumulative risk of paraplegia increased to 18%. At 60 minutes, risk approached 80%, and at 120 minutes, 100%. In contrast, when distal aortic perfusion was used, the earliest paraplegia occurred after a clamp time of 34 minutes, and risk of

\]
paraplegia at 120 minutes was approximately 18% \( (P < .0001) \) (Fig. 24-7).

A comparable protective effect of distal aortic perfusion was demonstrated in a subsequent meta-analysis by Jahromi and colleagues and in a single institution by Katz and colleagues. Taken together, these findings strongly suggest that distal aortic perfusion, achieved either by partial cardio-pulmonary bypass (CPB) and mild hypothermia or by left atrial–to–distal arterial bypass, should be used for most patients with acute traumatic aortic disruption undergoing open repair. Simple aortic clamping should be reserved for patients in whom anticipated clamp time is less than 20 to 25 minutes (although this is not always predictable) and for patients with life-threatening hemorrhage.

An arterial catheter is inserted in the patient’s right arm to monitor blood pressure; nasopharyngeal and bladder or rectal thermistors are placed for temperature measurement. If not already in place, a Swan-Ganz catheter is inserted for measurement of pulmonary artery pressure and cardiac output. A double-lumen endotracheal tube is inserted whenever possible. At least one large-bore needle must be securely in position in a peripheral vein. The patient is placed in a right lateral decubitus position, but with hips rolled back toward a supine position so that the left femoral vessels are accessible (Fig. 24-8, A [inset]). Facilities are organized for aspirating shed blood from the thorax in a sterile manner, washing and compacting red blood cells, and rapidly returning them to the patient.

A left posterolateral incision is made, and the thorax is entered through either the fourth intercostal space or the bed of the resected fifth rib. The rib spreader is positioned and opened in stages over several minutes, and the opening into the thorax anteriorly and posteriorly is lengthened with scissors. As soon as the rib spreader has been partially opened, unclotted blood and clots are removed from the thorax, taking great care not to exacerbate the bleeding by disturbing the mediastinal hematoma. Usually there is no active bleeding into the pleural space (persons with such bleeding usually have not survived to this point), but if it is occurring, immediate control is obtained by digital pressure.

Once the rib spreader has been positioned, the lung is covered with a moist laparotomy pad and retracted anteriorly with a malleable retractor held by an assistant. The mediastinal pleura is still undisturbed, and at this point a decision is made about the technique that will be used for spinal cord protection during aortic clamping (see previous text and "Paraplegia after Aortic Clamping" under Special Situations and Controversies later in this chapter).

A synthetic aortic tube graft is then selected (see “Grafts for Use in Aortic Surgery” under Special Situations and Controversies later in this chapter), as are clamps for aortic control. A few stay sutures are placed along the mediastinum behind the hilum of the lung and held anteriorly by clamps, which replace the malleable retractor.

The mediastinal pleura is opened adjacent to the hematoma at three points: (1) over the mid-descending thoracic aorta, (2) over the aortic arch, and (3) over the left subclavian artery (see Fig. 24-8, A-B). Dissection is carried around the aorta and subclavian artery at these three sites so that clamps can be placed. Tapes can be placed around the vessels, but they are not necessary and generally should be avoided. If accessible, the vagus nerve—identified as it descends over the aorta—is protected. When the hematoma is small and general condition of the patient is good, dissection is carried along the anterior surface of the aorta toward the hematoma from below, and down the aortic arch and the subclavian artery from above. The aortic arch is usually dissected circumferentially between the left carotid and left subclavian arteries (see Fig. 24-8, B).

When the hematoma is extensive or the hemodynamic state is unstable, dissection is not performed until the clamps are in place. When this dissection has been accomplished, clamps are placed in a preliminary manner, one across the aortic arch between the left carotid and left subclavian arteries, one across the subclavian artery, and one on the descending thoracic aorta (Fig. 24-8, C). With this maneuver, reasonable control of bleeding can be established, although there may be bleeding retrogradely into the aorta from intercostal arteries above the distal aortic clamp. After the clamps are placed, dissection is carried toward the hematoma from the distal clamp, and this clamp is expeditiously moved proximally as far as possible to allow blood from the distal aorta to perfuse as many intercostal arteries as possible. The surgeon must recognize that clamping the distal aortic arch rather than aorta beyond the left subclavian artery causes a greater increase in left ventricular afterload and also decreases collateral flow to the lower body and spinal cord from the left subclavian artery. Thus, whenever possible, the clamps on the arch and left subclavian artery should be replaced with one on the aorta just beyond the left subclavian artery (Fig. 24-8, D).

Dissection now continues toward the site of disruption, staying in the periaortic tissue plane (see Fig. 24-8, C). At some point the hematoma is entered, and blood and clot are evacuated rapidly. Usually there will be some bleeding into the field from the intercostal arteries between the disruption...
and distal clamp. This blood should be aspirated through a system that returns blood to the patient. Alternatively, the bleeding intercostal arteries can be occluded with bulldog clamps (see Fig. 24-8, D). They should not be ligated or oversewn (see “Paraplegia after Aortic Clamping” under Special Situations and Controversies later in this chapter); the aorta can often be tailored to preserve their origins.

When disruption involves only part of the circumference of the aorta, direct repair can often be made with interrupted pledged evverting mattress sutures or a simple whip stitch of 4-0 or 5-0 polypropylene (Fig. 24-8, E). Although Fontan and colleagues report being always able to make a direct repair with partial or complete disruption, this method is considered advisable only if the tissues are of good quality. Otherwise, a segment of the tube graft already selected is anastomosed to the two ends of the aorta using a 4-0 or 5-0 polypropylene suture (Fig. 24-8, F-G). The distal clamp is released, anastomotic bleeding between the sutures is secured with fine interrupted sutures, and the proximal clamp is slowly removed. Disruptions that involve the middle or lower descending thoracic aorta are repaired in a similar fashion after obtaining proximal and distal control of the aorta.
Incisions in mediastinal pleura

Figure 24-8, cont’d  C, Dissection is continued around the aorta and left subclavian artery in these locations, and clamps are placed first on the proximal aorta between the left carotid and left subclavian artery then on the left subclavian artery, and finally on the distal aorta. Pleura over mediastinal hematoma is incised, and hematoma is removed. D, Aortic clamps are repositioned, wherever possible, to locations just above and below area of disruption to permit perfusion of subclavian artery and as many pairs of intercostal arteries as possible. Bleeding from intercostal arteries closest to the aortic tear is controlled with bulldog clamps. E, If tear is incomplete, aorta can be repaired by direct suture.

For patients in shock resulting from massive intra-thoracic hemorrhage, full cardiopulmonary bypass and hypothermic circulatory arrest permits salvage of the shed blood in the pleural space and mediastinum and eliminates the need for mediastinal dissection of placement of clamps proximal and distal to the aortic tear. Kawahito and Adachi utilized this technique in 10 patients with hemorrhagic shock and major associated injuries. Nine of the patients were discharged from the hospital without complications.

After repair is completed and any devices used for distal aortic perfusion have been removed, as much of the mediastinal pleura as possible is closed over the operative site. One intercostal drainage catheter is positioned posteriorly and inferiorly in the chest cavity, and another anteriorly and superiorly. The incision is closed after making certain the lung has been reexpanded and the catheters are attached to a suction apparatus.

Endovascular Stent-Grafting

Endovascular stent-grafting should be performed under general anesthesia in a standard cardiovascular operating
room with a C-arm fluoroscopy unit, or in a “hybrid” operating room with a fluoroscopy unit designed for endovascular surgery. The operating team must be prepared to convert to an open procedure if necessary, and a cardiopulmonary perfusion team should be available on standby.

Access to the aorta is established through a common femoral, external iliac, or common iliac artery. If the common femoral artery is large enough to admit the sheath necessary for deployment of the endovascular stent-graft (EVSG), the procedure can be performed percutaneously or through a small incision in the groin area. If the femoral artery is not of suitable size, access is obtained through a small extraperitoneal incision in a lower quadrant of the abdominal wall to expose the external or common iliac artery. An 8- or 10-mm segment of collagen- or gelatin-impregnated polyester graft is sutured end-to-side to the artery and is used as a conduit through which the graft is deployed. Only low-dose heparinization (2500-5000 units) is required.

Appropriate flexible guidewires are advanced under fluoroscopic guidance into the ascending aorta, and the sheath through which the EVSG will be inserted is passed over the guidewire and positioned in the abdominal aorta. The diameter of the aorta proximal and distal to the site of the tear is determined from a previously obtained CT angiogram (or alternatively, using TEE or intravascular ultrasound), and the appropriate-sized EVSG is selected. The diameter of the graft is 10% to 15% greater than the diameter of the aorta. In general, 2 cm of aorta proximal and distal to the site of disruption is essential for proper sealing of the graft. This may require covering the orifice of the left subclavian artery. Length of the graft should only be long enough to ensure an adequate seal, thus avoiding unnecessary coverage of adjacent intercostal arteries. Once the graft is deployed, angiography or CT imaging is performed to assess adequacy of the seal and to be certain that the left carotid artery has not been compromised (Fig. 24-9). If the left subclavian artery is

Figure 24-8, cont’d  F-G, In most cases, a woven polyester tube graft is sutured to proximal and then distal aorta.

Figure 24-9  Same patient as in Fig. 24-3. After deploying an endovascular stent-graft, the disrupted aorta is excluded (A), and flow to the left subclavian artery has been preserved (B). (From Botta and colleagues.812)
covered and there is evidence postoperatively of compromised circulation to the left arm, a left carotid–to–left subclavian artery bypass graft with simultaneous embolization of the proximal left subclavian artery, or left subclavian artery transposition to left carotid artery, should be performed.

After satisfactory deployment of the EVSG has been confirmed, the sheath and guidewires are removed, and the artery through which they were inserted is repaired with a 5-0 or 6-0 polypropylene suture. If a graft was used for access, it is excised, leaving a small remnant attached to the artery that is oversewn with a 5-0 or 6-0 polypropylene suture.

Repair of Acute Traumatic Disruption of Ascending Aorta

When the ascending aorta is disrupted, preparations are made for standard CPB as the patient is being transferred to the operating room (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2).

In the operating room, the usual peripheral and monitoring devices are placed. After the patient is anesthetized and intubated, one member of the surgical team performs a median sternotomy while another exposes a common femoral artery and vein in the groin. The pericardium is opened just enough to expose the right atrial appendage. No dissection should be performed in the region of the hematoma. If there is active bleeding, control is obtained with digital pressure.

The patient is heparinized and the femoral artery cannula is advanced. A single right atrial venous cannula is placed (see Cardiopulmonary Bypass Established by Peripheral Cannulation in Section III of Chapter 2) and CPB established. If the right atrium is not accessible, a long cannula is inserted from a common femoral vein (preferably the right) and positioned with its tip in the middle of the right atrium. Body temperature is reduced by cooling the perfusate (see “Technique in Adults” in Section IV of Chapter 2). As this is being done, the thymus gland is divided, the pericardium is opened more widely, and the pericardial reflection is carefully dissected away from the hematoma over the distal portion of the ascending aorta. If massive hemorrhage occurs, perfusion flow is reduced to 0.5 L · min⁻¹ · m⁻² until enough of the aorta can be dissected to place an aortic occlusion clamp beyond the site of disruption. If the tear does not involve the brachiocephalic trunk, this clamp is placed just proximal to its origin from the aorta, although the clamp may have to be angled so that it excludes more of the undersurface of the aortic arch. Once this clamp is positioned, full CPB flow may be resumed and perfusate temperature stabilized at 28°C to 32°C.

After this clamp has been placed, the aorta is opened and cardioplegic solution is administered directly into the ostia of the coronary arteries using perfusion cannulae (see “Perfusion of Individual Coronary Arteries” in Chapter 3). Alternatively, or as an adjunctive measure, cardioplegic solution can be infused retrogradely into the coronary sinus (see “Technique of Retrograde Infusion” in Chapter 3). A venting catheter is placed into the left ventricle, either through a purse-string suture in the right superior pulmonary vein or through the opened aorta.

The area of disruption is dissected carefully. Usually there has been sufficient damage to the aorta that a tube graft is required for reconstruction of aortic continuity (see “Grafts for Use in Aortic Surgery” under Special Situations and Controversies later in this chapter). Repair is made by the technique described for graft interposition for descending thoracic aortic disruptions (see previous text). After the anastomosis is completed, the clamp on the aorta is released. Aortic root reperfusion is begun, and the remainder of the procedure is completed (see “De-airing the Heart” in Section III of Chapter 2).

If the disruption clearly involves the brachiocephalic trunk or aortic arch, or if it is unclear whether the brachiocephalic trunk is involved, no dissection or manipulation of the aorta and hematoma is begun until the patient has been cooled by the perfusate to a nasopharyngeal temperature below 18°C. Then, with the patient in moderate Trendelenburg position, CPB is discontinued, an aortic clamp is placed across the uninvolved proximal portion of the aorta, cardioplegic solution is administered through a previously placed aortic infusion cannula, and the aorta is opened at the area of disruption without placing a clamp distally. Repair is accomplished by the technique used to repair aortic arch aneurysms (see “Replacement of Aortic Arch” under Technique of Operation in Chapter 26). When disruption involves the origin of the brachiocephalic trunk or left carotid artery, the damaged segment is resected and an appropriately sized collagen- or gelatin-impregnated woven polyester graft is sutured to the normal artery distally and to the aortic arch proximally, or to the graft that has replaced the aortic arch and ascending aorta.

SPECIAL FEATURES OF POSTOPERATIVE CARE

Postoperative care is that usually given after other major cardiovascular operations (see Chapter 5). Many patients have systemic hypertension early postoperatively, and particular care is taken to control it. Associated injuries are managed appropriately.

RESULTS

Survival

Early (Hospital) Death

Many patients who would otherwise have died survive after repair of acute traumatic aortic disruption, but the proportion surviving varies according to the particular circumstances. Associated severe injuries decrease probability of survival. Paradoxically, rapid transport systems between accident site and hospital, although giving the patient a potentially better chance to survive, may actually decrease the proportion of surgical survivors, because more severely injured patients reach the hospital.

Open Operation VonOppell and colleagues performed a meta-analysis of 88 articles published in English between 1972 and 1992 related to surgical management of acute aortic disruption in which sufficient information was available to permit estimation of mortality and prevalence of paraplegia. Of 1742 patients who reached the hospital alive, 179 (10%) died before surgical intervention. An additional 61 patients (3.5%) exsanguinated despite emergency thoracotomy for profound hemodynamic deterioration. Ten patients were managed without operation. Intraoperative deaths occurred in 111 patients (6.7%), and an additional 201 patients (11.5%) died in the postoperative period. Thus,
overall mortality for patients who arrived at the hospital alive was 32% \( (\text{Table 24-2}) \). Of 1492 patients who reached the operating room in a presumably stable hemodynamic state, mortality was 21%. This mortality ranged from 0% to 54% in individual institutions.

In a more recent analysis, Demetriades and colleagues reported a 24% early mortality rate among 68 patients treated between 2005 and 2007 in 18 trauma centers. In a meta-analysis of 17 retrospective cohort studies from 2003 to 2007 involving 369 patients treated with open repair, 30-day mortality was 20% (72 patients; CL 17%-22%). It ranged from 0% to 50% in individual centers.

**Endovascular Stent-Grafting** In the study of Demetriades and colleagues noted previously, early mortality for 125 patients treated concurrently by EVSG was 7.2% (9 patients; CL 4.9%-10%). In the meta-analysis of 17 retrospective cohort studies by Xenos and colleagues, 30-day mortality for 220 patients treated concurrently by EVSG was 7.9% (18 patients; CL 6.1%-10.0%). It ranged from 0% to 25% in individual centers.

*Modified from von Oppell and colleagues. Represents 96% of 1492 patients reaching operating room in stable condition.
Includes patients with shunting from the ascending aorta and left ventricle.
Includes patients with heparinless partial bypass with centrifugal pump, cardiopulmonary bypass with oxygenator, and heparinless femoral vein to femoral artery bypass without oxygenator.

**Time-Related Survival**

Long-term survival of patients discharged after open repair is excellent. Long-term results after EVSG are unknown.

**Modes of Death**

Most deaths occur in the postoperative period (see Table 24-2). Principal modes of intraoperative death are hemorrhagic shock and cardiac failure. Modes of postoperative death are central nervous system injury and organ failure (lung, kidney, liver).

**Risk Factors for Premature Death**

A higher Injury Severity Score (ISS) and older age appear to be important risk factors for increased hospital mortality. Surgical technique is not a risk factor for hospital mortality.

**Paraplegia**

The proportion of patients who develop paraplegia or paraparesis after open surgical repair is variable. In the meta-analysis of von Oppell and colleagues, new paraplegia occurred in 9.9% (CL 9.1%-10.8%) of the 1492 patients who reached the operating room (see Table 24-2). Prevalence of paraplegia varied according to the operative technique used (Table 24-3). The highest prevalence (19%) was associated with use of simple aortic clamping; lowest prevalence (2.3%) was associated with “active shunting,” defined as augmentation of distal perfusion by CPB with an oxygenator and full CPB, by a centrifugal pump and no heparin, or by femoral vein to femoral artery bypass without an oxygenator or heparin. Prevalence with “passive shunting” (no augmentation of distal perfusion) was 11% (P < .0001 compared with “active shunting”). Categorization of surgical technique employed was possible in 96% of the 1492 patients. The high prevalence of paraplegia in the simple aortic clamping group was associated with the lowest weighted average clamp time (32 minutes; range 13-62 minutes) (see Table 24-3 and “Paraplegia after Aortic Clamping” under Special Situations and Controversies later in this chapter). In the meta-analysis of Jahromi and colleagues of 618 patients from 20 reports published between 1966 and 2000, a lower prevalence of paraplegia was observed among patients in whom left heart bypass (0 of 84 [0%; CL 0%-2.3%]; odds ratio 6.4; P = .07) or partial CPB (5 of 227 [2%; CL 1.2%-3.7%]; odds ratio 3.4;
Prevalence of paraplegia after EVSG is lower than that after open repair. In the study of the AAST, paraplegia occurred in 1 (0.8%) of 125 patients treated by EVSG between 2005 and 2007. In the meta-analysis of 17 retrospective cohort studies of 215 patients treated by EVSG from 2003-2007 and with data suitable for analysis, paraplegia/paraparesis occurred in 1 patient (0.5%).

### INDICATIONS FOR OPERATION

Immediate surgical repair of acute traumatic aortic disruption is indicated for patients with massive hemothorax or signs of impending rupture. Among patients in whom the hematoma is contained within the mediastinum, immediate repair is usually indicated unless there are severe coexisting injuries that require medical or surgical management. Several studies have demonstrated that mortality from rupture among patients who reach the hospital alive and who have a contained rupture is low (approximately 5%). Thus, injuries that may be more immediately life threatening (e.g., intraabdominal or intracranial hemorrhage, severe pulmonary or myocardial contusion, extensive fractures) should be treated before repair of the aortic disruption.

When diagnosis is made more than several days after injury, operation is usually advisable, but unless the hematoma is large or there is evidence of active bleeding, operation can be performed urgently or electively rather than emergently. In the interim, arterial hypertension and tachycardia should be treated with sodium nitroprusside and β-adrenergic blockade. Frequent monitoring of the thoracic aorta with CT scanning or MRI is essential during this interval.

After about 14 days, management is similar to that for chronic thoracic aortic aneurysm (see “Special Features of Postoperative Care” in Chapter 26).

### SPECIAL SITUATIONS AND CONTROVERSIES

#### Choice of Operative Procedure

As noted, EVSG has replaced open operation as the most commonly performed intervention for acute traumatic aortic disruption. It is associated with lower early mortality and a lower occurrence of paraplegia. Other advantages over open repair include avoidance of thoracotomy, aortic clamping, and left heart bypass or CPB.

However, endovascular treatment requires expeditious imaging, personnel trained in endovascular procedures, and availability of endografts of variable sizes. Currently in the United States, treatment of acute traumatic aortic disruption with an endograft is an off-label use of the device. Because the aortas of younger individuals are smaller than those of patients with aneurysms, for which these devices were initially designed, oversizing has been associated with collapse of the stent-graft. Other complications unique to EVSG include endoleaks, component migration, stent fractures, injury to the arteries used for access, and cerebral or left upper-extremity ischemic events resulting from coverage of the left subclavian and left carotid arteries. In the study by the AAST, prevalence of device-related complications among 125 patients was 20% (CL 16%-24%).

### Long-term results of EVSG are unknown. The thoracic aorta becomes ectatic and tortuous with aging, so there is a theoretical risk of graft dislodgement over time. A study of proximal aortic diameters using CT imaging following endovascular repair of blunt thoracic aortic injury in 17 patients followed for at least one year, demonstrated a significant increase in the rate of dilatation at the level of the aortic isthmus when compared with the aorta distal to the end of the endograft (0.83 mm/yr vs. 0.47 mm/yr, P=0.025). Long-term performance and mechanical properties of currently used grafts are unknown. Frequent imaging, currently with CT, is recommended and may be necessary for the life of the patient. Cost of this imaging and the associated risk of excessive radiation are not insignificant.

All these factors must be taken into consideration when deciding on the method of operative management for individual patients. Until additional information becomes available, a selective strategy, treating young patients with limited associated injuries by open operation and older patients with comorbid conditions or those with extensive associated injuries by EVSG, may be advisable.

#### Paraplegia after Aortic Clamping

Paraplegia or paraparesis can develop as a result of ischemia of the spinal cord after operations in which the distal aortic arch, descending thoracic aorta, or thoracoabdominal aorta is temporarily clamped. It usually develops immediately, but occasionally onset is delayed for several hours or days.

### Risk Factors

#### Duration of Aortic Clamping

When the aorta is clamped just beyond the left subclavian artery under more or less normothermic conditions, probability of developing paraplegia or paraparesis is directly related to duration of clamping. In humans, this probability is essentially zero when duration is less than 15 minutes. In patients with acute traumatic aortic disruption, the probability approaches 100% when duration is 1 hour or longer. Use of moderate or profound systemic hypothermia has been associated with lower prevalence of spinal cord ischemia after operations on the descending thoracic and thoracoabdominal aorta compared with operations performed at normothermia. Use of profound systemic hypothermia (<20°C) permits extension of the duration of aortic occlusion and spinal cord ischemia to more than 100 minutes without an increase in prevalence of paraplegia or paraparesis (Fig. 24-10). Selective cooling of the spinal cord by infusion of cold (4°C) saline into the epidural space to achieve cerebrospinal fluid (CSF) temperatures of 24°C to 28°C has been associated with lower prevalence of spinal cord ischemic injury following

\[ P = .02 \text{ was used when compared with simple aortic clamping (14 of 194 [7.2%; CI 5.3%-9.7%]).} \]

Lettinga-van de Poll and colleagues of 284 patients treated in 62 centers up until January 2006, procedure-related complications occurred in 41 patients (14%; CI 12%-17%). Need for repeat intervention is also a concern.
repair of thoracoabdominal aortic aneurysm with the simple aortic clamping technique than observed without cooling in otherwise comparable patients.\textsuperscript{61}

**Level of Aortic Clamping** When a clamp is placed for 60 minutes on the abdominal aorta beyond the origin of the renal arteries (about the level of L2), paraplegia or paraparesis occurs in less than 0.1% of cases.\textsuperscript{66} When a clamp is placed at the level of the diaphragm for 60 minutes, paraplegia or paraparesis develops in about 10% of patients.\textsuperscript{514} As already discussed, when the proximal clamp is on the aorta just beyond the origin of the left subclavian artery for 60 minutes in patients with acute traumatic aortic disruption, more than 80% develop clinical evidence of spinal cord ischemic injury.

Evidence from experimental studies indicates that clamping of the left subclavian artery and the thoracic aorta just beyond the origin of the left subclavian artery further increases risk of paraplegia or paraparesis.\textsuperscript{66,91} This is because the left subclavian artery gives origin to the left vertebral artery, which joins with the right vertebral artery to form the anterior spinal artery.

When two clamps are placed across the thoracic aorta, the distance between them is related directly to probability of paraplegia, at least in experimental animals.\textsuperscript{98,91} This implies that as the distance between the clamps is increased, more of the intercostal arteries, and thus the spinal arteries, are excluded from the collateral circulation coming from the proximal and distal aorta.

**Variability in Blood Supply of Spinal Cord** The anterior spinal artery is formed at the level of the medulla by spinal artery branches from each of the vertebral arteries. As the anterior spinal artery passes down the spinal cord, it is connected to a variable number of radicular arteries (usually five to eight) that are formed from spinal branches of the intercostal and lumbar arterial branches of the descending thoracic and abdominal aorta.\textsuperscript{67,510,562} (Fig. 24-11). A particularly large radicular artery is present in most humans (the arteria radicularis magna, or artery of Adamkiewicz). It arises from the T5 (fifth thoracic vertebral level) to the T8 level in 15% of people, T9 to T12 in 75%, L1 to L2 (lumbar level) in 8%, L3 in 1.4%, and L4 to L5 in 0.2%.\textsuperscript{13,97} Its ligation in pigs usually results in paraplegia or paralysis.\textsuperscript{92} Clamping the aorta distal to the origin of this large artery probably imposes only a small risk of paraplegia or paraparesis, whereas clamping proximal to it imposes a considerable risk. In the latter situation, perfusion of the distal aorta may provide adequate protection of the lumbar spinal cord if perfusion pressures are adequate. If the segment of aorta that contains this or other large radicular arteries is resected or excluded, or if the artery is ligated, there is considerable probability of paraplegia or paraparesis.\textsuperscript{66,92} In this circumstance, reimplantation of the critical intercostal artery or arteries is advisable.

**Variability in Collateral Circulation to Spinal Cord** When collateral circulation around the part of the aorta exteriorized by a pair of aortic clamps is well developed, as in most patients undergoing operation for aortic coarctation, the aorta can probably be clamped safely at that level for a long interval. However, some patients with coarctation have incomplete collateral circulation and greater likelihood of developing paraplegia.\textsuperscript{514} (see “Collateral Circulation” under Morphology in Section I of Chapter 48).

Patients coming to operation for chronic degenerative descending thoracic or thoracoabdominal aneurysm frequently have little or no flow through some of the intercostal or lumbar arteries because of previous progressive occlusion of the origins of these arteries from the aorta. This usually

\begin{figure}
\centering
\includegraphics[width=\textwidth]{figure24-10.png}
\caption{Figure 24-10 Risk of paraplegia or paraparesis according to duration of spinal cord ischemia in 60 patients undergoing resection and graft replacement of the descending thoracic aorta using hypothermic (under 20°C) cardiopulmonary bypass and intervals of circulatory arrest. Duration of spinal cord ischemia was defined as time between onset of circulatory arrest or aortic clamping and establishment of antegrade flow to intercostal and lumbar arteries below the T6 interspace. Dashed lines enclose 70% confidence intervals. \textit{P} value relates to association between ischemic time and probability of developing paraplegia or paraparesis. (Modified from Kouchoukos and colleagues.\textsuperscript{65})}
\end{figure}

\begin{figure}
\centering
\includegraphics[width=\textwidth]{figure24-11.png}
\caption{Figure 24-11 Summary of findings of the blood supply to the spinal cord in eight human cadaver dissections. Sizes are mean sizes for these arteries when distended under pressure with blood. Level of origin of the arteries may vary in any one person; however, the diagram summarizes the most commonly identified sites of origin. Key: ARM, Arteria radicularis magna; C, cervical; L, lumbar; µ, microns; T, thoracic. (From Svensson and Crawford.\textsuperscript{93})}
\end{figure}
chronic process is infrequently associated with paraplegia because of concomitant development of collateral circulation. The collateral circulation, when well developed, may be sufficient to permit aortic occlusion without ischemic injury to the spinal cord.\textsuperscript{2,2,3} However, it can also be precarious and sensitive to even minor fluctuations in arterial pressure, cardiac output, and intraspinal pressure during and early after graft replacement of the diseased aortic segment.

**Intraspinal Pressure** An increase in intraspinal pressure, which can occur following occlusion of the descending thoracic aorta, is believed to increase spinal cord ischemia and thus the probability of paraplegia.\textsuperscript{54,58,56} Presumably, increased intraspinal pressure compresses the delicate spinal arteries sufficiently to reduce blood flow through them. In theory, increase in pressure, reflected by increase in the measured intrathecal pressure, reduces spinal cord perfusion pressure (defined as distal aortic pressure minus CSF pressure). Increased venous pressure may result following occlusion of the thoracic aorta and may also increase CSF pressure, thus reducing spinal cord perfusion pressure.\textsuperscript{59}

**Upper Body Blood Pressure** Reduction of upper body blood pressure when the thoracic aorta is clamped decreases flow (through collaterals) to the lower body and reduces spinal cord collateral flow. Thus, upper body hypotension during aortic clamping increases the probability of paraplegia.\textsuperscript{51}

**Methods to Minimize Spinal Cord Injury**
Generally, aortic operations should be performed in a manner that recognizes the risk factors for paraplegia while accomplishing an effective procedure with minimal blood loss and injury to various organs. At times, difficult situations may force compromises:

- A double-lumen endotracheal tube should be used whenever possible to permit optimal exposure in the left hemithorax.
- If the aorta is clamped without distal perfusion, upper body blood pressure should be maintained above normal values. Cardiac function should be monitored carefully.
- The proximal aortic clamp should be placed beyond the left subclavian artery whenever possible and as far distally on the aorta as possible.
- The more distal of a pair of clamps should be positioned as close to the distal extent of the disruption as possible.
- Operation should be planned and performed to minimize duration of aortic occlusion.
- Hemostasis should be accurate to avoid hypotension after removal of the clamps.

**Whole-Body Hypothermia during Simple Aortic Clamping** Hypothermia clearly prolongs the safe ischemic time for the spinal cord, just as it does for all other organs\textsuperscript{36} (see Section I of Chapter 2). This was demonstrated more than 50 years ago by Hufnagel and Gross,\textsuperscript{52} later by Beattie and colleagues,\textsuperscript{51} and reaffirmed by the elegant experimental study of Pontius and colleagues.\textsuperscript{59} The studies of these three groups indicate that the spinal cord can recover normal function after aortic occlusion for 60 minutes at a whole-body temperature of 30°C.

Hypothermia to a nasopharyngeal temperature of 30°C to 32°C can be achieved simply. In neonates and infants, operation is performed with the patient on a cooling and heating pad and with operating room temperature about 16°C (60°F) during thoracotomy. If at the time of aortic clamping, the patient’s temperature has not reached 32°C to 33°C, additional cooling is obtained by 5 to 10 minutes of ice water lavage of the left pleural space. Even in adults, such lavage is effective in reducing body temperature 2°C to 3°C within 5 to 10 minutes. In neonates and small infants, rewarming after the clamps are removed is easily accomplished with the pad (now heating rather than cooling) and by raising room temperature. The rewarming process is slower in larger patients but can be facilitated by use of a warming blanket placed over the lower abdomen and legs.

Cooling to 30°C or lower without extracorporeal support usually requires formal surface cooling, which is cumbersome and time consuming in large patients. It is generally inadvisable for operations on the descending thoracic and thoracoabdominal aorta.

**Perfusion of Distal Aorta during Aortic Clamping** When a pair of aortic clamps are applied close together to the most proximal part of the descending thoracic aorta (e.g., in operations for acute traumatic aortic disruption), perfusion of the distal aorta by any one of a number of methods minimizes spinal cord ischemia and development of paraplegia.\textsuperscript{1,2,3} This was demonstrated by Stranahan and colleagues in 1954 by use of an external shunt.\textsuperscript{57} However, distal aortic perfusion prevents paraplegia only if the short segment of aorta exteriorized by the clamps does not give origin to critical radicular arteries, which can occur following occlusion of the descending thoracic aorta.\textsuperscript{1,2,3} The experimental studies of Connolly and colleagues and Laschinger and colleagues\textsuperscript{22,1,1,3} support the concept that managing acute traumatic aortic disruption by perfusing the distal aorta while a pair of aortic clamps is on the upper descending thoracic aorta neutralizes the incremental risk of longer clamp times on probability of paraplegia (see “Variability in Blood Supply of Spinal Cord” earlier in this chapter). If the critical arteries originate from the exteriorized segment and the aortic clamps remain in position for a considerable period, perfusion of the distal aorta cannot be expected to afford complete protection to the spinal cord consistently.

The study by Katz and colleagues\textsuperscript{55} and the meta-analyses of von Oppell and colleagues\textsuperscript{59} and Jahromi and colleagues\textsuperscript{52} support the concept that managing acute traumatic aortic disruption by perfusing the distal aorta while a pair of aortic clamps is on the upper descending thoracic aorta neutralizes the incremental risk of longer clamp times on probability of paraplegia (see Fig. 24-7). Other studies also support this concept by showing that distal aortic perfusion restores spinal cord blood flow, maintains spinal cord function, and restores function temporarily lost by a brief period of inadequate perfusion of the distal aorta.\textsuperscript{22,1,1,3} The experimental studies of Connolly and colleagues and Laschinger and colleagues\textsuperscript{22,1,1,3} suggest that distal aortic perfusion needs to be about 60 to 70 mmHg or more to provide low probability of paraplegia and high probability of adequate lower-body organ function during and after an operation performed at normothermia (=37°C).\textsuperscript{51,1,3}

**Reattachment of Intercostal and Lumbar Arteries** During resection of a segment of the thoracic or upper abdominal aorta from which arteries critical to spinal cord blood flow emerge, perfusion of the intercostal and lumbar arteries seems logical, as does their reattachment to the aorta as part of the reconstruction. One way of accomplishing reconstruction of spinal cord blood flow is tailoring the resection and graft so that most of the posterior wall of the aorta, from which origins of the lower intercostal and lumbar arteries arise, is preserved (see Fig. 25-11, D in Chapter 25). The graft is cut obliquely at one end for an appropriate end-to-end anastomosis. Another method is creation of an oval
opening in the graft and anastomosis of the opening to the aortic wall around the origin of critical intercostal and lumbar arteries (see Fig. 26-18, F-G in Chapter 26).

The importance of reattaching intercostal and lumbar arteries in preventing spinal cord ischemic injury and the resulting paralysis remains controversial. Several groups have reported a low prevalence of neurologic deficits after resection and graft replacement of extensive thoracoabdominal aortic aneurysms without reattaching any intercostal or lumbar arteries.\textsuperscript{1,11,88} However, emerging consensus is that, at least for extensive thoracoabdominal aortic aneurysms that require prolonged periods of aortic occlusion—particularly those resulting from aortic dissection where large numbers of intercostal and lumbar arteries may be patent—reattachment of patent lower intercostal (below the T6 or T7 level) and upper lumbar arteries reduces the prevalence of postoperative neurologic deficits.\textsuperscript{1,11,13,89-93}

**DRAINAGE OF CEREBROSPINAL FLUID** In experimental studies, reducing intraspinal pressure by drainage of CSF is associated with reduced prevalence of paraplegia.\textsuperscript{88,94} In some clinical studies, the protective effect of CSF drainage has not been conclusively demonstrated when comparable groups of patients (randomized and nonrandomized) are evaluated.\textsuperscript{11,100}

In three clinical studies and in a randomized trial, use of CSF drainage in combination with other adjuncts such as distal aortic perfusion, intravenous infusion of naloxone, an endorphin (opiate) receptor antagonist, and epidural cooling has been associated with reduced prevalence of lower-extremity neurologic deficits compared with historical controls.\textsuperscript{1,11,14,52}

**LOCALIZED COOLING OF SPINAL CORD DURING AORTIC CLAMPING** Experimental studies by Colles and colleagues\textsuperscript{99} and Colon and colleagues\textsuperscript{97} have shown that infusing cold crystalloid solution or blood into an isolated segment of the descending aorta provides protection against paraplegia for an occlusion period of 30 to 45 minutes. Berguer and colleagues\textsuperscript{85} and Wissell and colleagues\textsuperscript{83} demonstrated the protective effect of irrigating the subarachnoid space with cold (5°C) saline solution during an occlusion interval of 45 minutes in dogs, and Marsala and colleagues\textsuperscript{44} showed similar protection with cold irrigation of the epidural space. Clinical experience with these techniques is limited. Fehrenbacher and colleagues have used infusion of 8°C to 10°C crystalloid solution containing heparin, mannitol, and methylprednisolone into isolated segments of the lower thoracic and upper abdominal aorta before implanting the intercostal and lumbar arteries contained in these segments into an aortic graft.\textsuperscript{55}

Normothermic left heart bypass and segmental clamping of the aorta were also used to minimize duration of spinal cord ischemia. Paraplegia occurred in 1 (4.3%; CL 0.2%-17%) of 23 patients with extensive thoracoabdominal aortic aneurysms. Cambria and colleagues infused 4°C normal saline solution into the epidural space of 70 patients with descending thoracic or thoracoabdominal aortic aneurysms.\textsuperscript{11} Simple aortic clamping was used in all but one patient. Two patients (2.9%; CL 0.6%-8%) developed lower-extremity neurologic deficits. In their extended experience with this technique for repairing thoracoabdominal aortic aneurysms, spinal cord ischemic injury (paraplegia or paraparesis) occurred in 11% (CL 8.2%-13%; 19 of 180 patients) in whom epidural cooling was used, and in 20% (CL 15%-25%; 18 of 91 patients) in whom it was not used ($P = .04$).\textsuperscript{87}

**MONITORING SOMatosensory and Motor Evoked Potentials** In patients undergoing resection of thoracoabdominal aortic aneurysms, Cunningham and colleagues demonstrated that after occluding the proximal descending thoracic aorta, responses monitored in the cerebral cortex after stimulation of the posterior tibial nerve demonstrated an increased latency and decreased amplitude within 3 to 4 minutes.\textsuperscript{123} Responses disappeared after 5 to 10 minutes and returned 8 to 9 minutes after unclamping the aorta. Mizrahi and Crawford demonstrated similar changes within 10 minutes after occluding the aorta in 13 patients and observed rapid reversal of these changes after restoration of flow in the aorta.\textsuperscript{99}

Although monitoring of somatosensory evoked potentials appears to be a sensitive method to detect spinal cord ischemia and impending paralysis, the technique has several limitations. Because the potentials are conducted through the posterior (sensory) column of the spinal cord and not the anterior (motor) column, ischemia and resulting paraplegia may occur despite recording normal impulses. General anesthetics, changes in temperature, drugs, hypoxia, hypotension, and ischemia of peripheral nerves that occurs following aortic occlusion may affect sensitivity of recorded impulses.\textsuperscript{122}

Direct stimulation of the spinal cord rather than a peripheral nerve appears to increase sensitivity of the technique.\textsuperscript{67,84}

Monitoring somatosensory evoked potentials in patients during operations on the descending thoracic and thoracoabdominal aorta alone or in conjunction with other adjuncts that may reduce the risk of spinal cord ischemic injury (e.g., distal perfusion, hypothermia, CSF drainage, reimplanting intercostal or lumbar arteries) has not consistently reduced the prevalence of paraplegia.\textsuperscript{11,13,22,23,67,83}

Achouh and colleagues have shown that monitoring these potentials is a poor screening tool for development of a neurologic deficit.\textsuperscript{11} Among 444 patients undergoing thoracoabdominal or descending thoracic aortic repair, they observed a sensitivity of 62% and a specificity of 81% for the technique. The negative predictive value, however, was 99%, indicating a low event probability in the absence of changes in the evoked potentials.

Monitoring motor evoked potentials may be a more accurate method to detect spinal cord ischemia intraoperatively.\textsuperscript{22,14,51,6} Clinical experience with this technique is limited.\textsuperscript{71,87,93} Monitoring these potentials appears to have a strong negative predictive value for immediate neurologic deficit, similar to that for somatosensory evoked potentials.\textsuperscript{11,87}

However, use of the technique has not been shown to substantially reduce or eliminate the occurrence of spinal cord ischemic injury in patients with extensive repairs of the thoracoabdominal aorta, and the positive predictive value is low.\textsuperscript{71,87}

**PHARMACOLOGIC INTERVENTIONS** Many pharmacologic agents have been evaluated for their neuroprotective effects in experimental studies of spinal cord ischemia (Box 24-1). Few have been extensively evaluated in humans, however. Thiopental and methylprednisolone are widely used clinically for protection of the brain and spinal cord during operations requiring circulatory arrest and clamping of the descending thoracic aorta.\textsuperscript{99} Naloxone has been used in humans in combination with CSF drainage during operations on the thoracoabdominal aorta, and a low prevalence of spinal cord ischemic injury was observed.\textsuperscript{11} Intrathecal administration of papaverine, a potent vasodilator, has also been associated with reduced prevalence of paraplegia in a small series of patients.\textsuperscript{518}

As the pathophysiology of spinal cord ischemic injury is more clearly elucidated, it is likely that pharmacologic
agents will be used more frequently as adjuncts to the other interventions described in the preceding text during thoracic aorta operations that involve interrupting blood flow to the spinal cord.\textsuperscript{62,64,65} Methods for Perfusing the Distal Aorta during Aortic Clamping

A wide variety of techniques have been used to perfuse the distal aorta during operations that involve clamping the descending thoracic aorta.

Left Atrial–to–Femoral Artery Bypass As the left thoracotomy is being made, with the patient in a right lateral decubitus position and the left leg fully extended, the left common femoral artery is exposed. After thoracotomy and before addressing the aortic patholgy, the pericardium is opened anterior to the phrenic nerve. A purse-string suture is placed around the base of the left atrial appendage. After a full dose of heparin, or after a reduced dose of 100 to 150 units \(\cdot\) kg\(^{-1}\) (1-1.5 mg \(\cdot\) kg\(^{-1}\)), or after no heparinization,\textsuperscript{61,63} a standard femoral arterial cannula (see “Cardiopulmonary Bypass Established by Peripheral Cannulation” in Section III of Chapter 2) is inserted into the femoral artery (or an aortic cannula can be inserted into the distal descending thoracic aorta) and a 28F, 30F, or 32F venous cannula is inserted into the left atrium through the appendage. Alternatively, a 28F cannula, which is usually sufficiently large, can be inserted into the left inferior pulmonary vein extrapericardially.\textsuperscript{12} The cannulae are connected to each other through a vortex pump (see “Temporary Ventricular Assistance” in Section I of Chapter 5) using standard or heparin-covered tubing. Bypass is then commenced at a flow of about 1.5 L \(\cdot\) min\(^{-1}\) \(\cdot\) m\(^2\) (in adults). During bypass, mean pulmonary artery pressure should be maintained above 18 to 20 mmHg to avoid pumping excessive blood from the atrium to the distal aorta, which may result in inadequate perfusion of the proximal aorta and hypotension. Blood volume must also be maintained at appropriate levels by infusing blood and fluids to avoid hypotension.

Decannulation is effected as soon as the aortic clamps are removed. If heparin was used, protamine is administered in an appropriate dose (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2). Left atrial–to–femoral artery bypass has been shown to provide better postoperative lower-body organ function than passive shunts,\textsuperscript{65,66} and there is increasing evidence that when carefully implemented, it is associated with a lower prevalence of spinal cord ischemic injury and renal dysfunction than when distal perfusion is not used, particularly when aortic occlusion time exceeds 40 minutes.\textsuperscript{51,69,70,71,72,73,74,75,76} Maintaining distal perfusion with this technique also reduces need for vasodilating agents during aortic clamping and reduces prevalence of hypotension and acidosis after unclamping.\textsuperscript{31}

Aortic-Aortic Shunting Aortic-aortic shunting is a passive process (unless a pump is interposed\textsuperscript{69}) in which arterial pressure above the aortic clamp drives blood through the shunt into the distal aorta. A full or half dose of heparin may be given, or none at all. A 9-mm Gott heparin-bonded shunt may be used,\textsuperscript{69} or a simple shunt constructed from standard perfusion tubing and cannulae. Proximally, the shunt is inserted through a purse-string suture into the aortic arch or ascending aorta (which can at times be difficult), or into the apex of the left ventricle. The distal end of the shunt is similarly inserted into the descending thoracic aorta. Alternatively, the shunt may be extended and connected to a cannula placed in the femoral artery. The shunt is opened as soon as the aorta is clamped. Flow through the shunt should be monitored, either with a flow probe incorporated into the shunt or by measuring arterial pressure distal to the lower aortic clamp.\textsuperscript{69} After removing the aortic clamps, decannulation is effected in a standard manner, and protamine may be given if heparin has been administered.

Hemodynamic state during aortic clamping and lower-body organ function postoperatively are better with this method (and with left atrial to femoral artery bypass) than with simple aortic clamping.\textsuperscript{61,64,65,10} Flows between 1100 and 4900 mL \(\cdot\) min\(^{-1}\) (mean 2500 mL \(\cdot\) min\(^{-1}\)) have been measured in patients having resection of descending thoracic aorta aneurysms.\textsuperscript{69} Shunt flow is dependent on proximal aortic pressure and resistance in the arterial compartment distal to the lower aortic clamp. Reducing pressure in the proximal aorta with nitroprusside may be necessary to avoid cardiac failure. A zero prevalence of lower-extremity neurologic deficits (0%; CL 0%-0.5%) has been reported by Verdant and colleagues, who used this technique in 866 patients with aneurysms confined to the descending thoracic aorta.\textsuperscript{72}

When CPB is conducted at normothermia or mild hypothermia (>32°C), the heart continues to beat, so some pulmonary blood flow continues and CPB is only partial for the upper body. For the lower body, supplied by that part of the aorta distal to the lower aortic clamp, CPB is complete. A pulmonary arterial pressure monitoring catheter should be in place, and if left heart decompression is inadequate, a venting catheter can be placed in the pulmonary artery or left inferior pulmonary vein. When conducted at hypothermia, either as continuous perfusion or in preparation for hypothermic circulatory arrest, CPB is usually total because the heart becomes ineffective as lowering of body temperature proceeds.

Use of hypothermic circulatory arrest for aortic surgery using a lateral approach began in 1964 and was used only sporadically during the next 20 years. High prevalence of pulmonary complications was reported by Crawford and colleagues in 1987. With increasing experience, prevalence of pulmonary and other major complications has been reduced.

Currently available information indicates that this technique has an important place in aortic surgery, particularly when extensive operations are required and when clamping of the proximal descending thoracic aorta cannot be safely accomplished. It is of particular value in patients who require resection of the entire descending thoracic and most or all of the abdominal aorta. The combination of CPB, using femoral cannulation, hypothermic circulatory arrest, implanting patent lower intercostal and upper lumbar arteries into the graft, and early insertion of a second arterial cannula into the graft after the proximal anastomosis has been

Thoracoabdominal incision can be established effectively in most patients using the femoral artery and vein (see “Cardiopulmonary Bypass Established by Peripheral Cannulation” in Section III of Chapter 2). Special long catheters are required for adequate venous drainage (Fig. 24-13). The tip of such a catheter can be positioned accurately in the mid-right atrium using TEE.
completed allows perfusion of the heart and head vessels as the more distal parts of operation are being completed935,12,13 (see Fig. 26-19 in Chapter 26).

Grafts for Use in Aortic Surgery

Type
Through the years, PTFE and polyester grafts (knitted or woven and of various weaves), autologous and bovine pericardium, and allograft aorta and pulmonary trunk have been used to augment or replace a portion of the systemic or pulmonary arterial pathway. Although this discussion will focus on grafts for aortic replacement, it is relevant to pulmonary arterial replacement and to patches used in these locations and inside the ventricles and atria.

Issues related to graft type include ease of handling, compliance, durability, hemostatic properties, and thickness and adherence of the neointima that develops. Autologous pericardium, either untreated or immersed in 0.6% glutaraldehyde for 5 to 30 minutes (the advantages of which remain arguable), is easy to handle and suture. It is compliant, durable (although sometimes given to stretching or contracting), and impervious to blood. It is extremely useful as a patch graft. Tube grafts fashioned from pericardium are no longer used for aortic replacement. In neonates and young infants, allograft aorta is ideal for augmenting the aorta, as is allograft pulmonary artery; both are useful as extracardiac conduits to the pulmonary arteries. They are also used in the sinutubular portion of the ascending aorta. The wall of the aortic allograft calcifies (pulmonary allograft wall does so to a lesser degree), but it functions well for a number of years (see “Isolated Aortic Valve Replacement” and “Replacement of Aortic Valve and Ascending Aorta, En Bloc” under Technique of Operation in Chapter 12 as well as Technique of Operation in Section II of Chapter 38).

Intracardiac patches need not be impervious to blood immediately after insertion, and thus the Sauvage knitted polyester patch (see Chapter 35, footnote 4) works well.

Contoured patches are more conveniently cut from tube grafts, and double-velour woven polyester grafts (see later) are easily handled, compliant, and durable. They may be backed by pericardium (autologous or bovine) if the patch is large and must be immediately hemostatic. PTFE is entirely satisfactory for patches and small tube grafts, and is generally impervious to blood. However, it is susceptible to kinking, and bleeding through suture holes may be persistent.

When a patch or tube graft forms part of the wall of a blood vessel or the heart in a heparinized patient, demands for hemostasis are stringent. A number of solutions to this problem have become available. Knitted polyester grafts with a baseline water permeability of about 2000 mL·cm⁻²·min⁻¹ have enjoyed favor in the past because of ease of handling and development of a thinner and more adherent neointima after insertion than is the case with woven grafts.12,13 In heparinized patients, untreated knitted polyester grafts, which permit massive hemorrhage through the graft, are unsuitable for use for any external vascular surface. Newer types of woven polyester grafts are as soft and easy to handle and sew as knitted grafts and are more impervious to blood. Bovine pericardium is an excellent patch material for the aorta, major systemic arteries, and the pulmonary artery. Its handling characteristics and ready availability make it an optimal substitute. It can also be used as a tube graft in the pulmonary arterial circulation.

Preclotting of Synthetic Grafts
A number of useful methods of preclotting grafts can be used in heparinized patients. In one, preclotting is obtained by aspirating about 50 mL of the nonheparinized patient’s blood from the heart or aorta, clamping one end of the graft and stretching it and injecting the blood into the other end under as high a pressure as can be generated. As the blood exudes from the graft, it is collected in a small pan, and after the first injection is completed, the blood is reaspirated from the pan and again injected under high pressure. This process is continued until most of the blood has clotted. Before the graft is inserted, the clots are aspirated or wiped from the interior (not rinsed out with saline solution), and the device is ready for use.

A second method involves autoclaving the graft.12,12 The general technique of autoclaving as part of the preclotting process was suggested by Betha and Recemtsma, who soaked grafts in heparinized whole blood before autoclaving. Alternatively, 5% albumin, concentrated serum albumin, plasma, or platelet-rich plasma can be applied to the graft prior to autoclaving.

Various preclotting techniques affect inner-surface thrombogenicity of polyester grafts and their tendency toward thromboembolism. According to experimental studies in dogs by Gloviczki and colleagues, with low-porosity polyester woven grafts, the area of desirable thrombus-free surface was greatest when the graft was not preclotted or when it was preclotted with blood in the standard manner.13 Among autoclaved grafts, those soaked with platelet-rich plasma rather than blood had the most thrombus-free surface, and this was correlated with the lowest prevalence of thromboembolism. Albumin alone and platelet-free plasma were not tested.

Grafts Treated Before Packaging
The convenience of grafts that are ready for insertion without further treatment after removal from the package is evident.12 Woven and knitted grafts impregnated with albumin, collagen, or gelatin are now commercially available. In experimental and clinical studies, these grafts demonstrate less transinterstitial bleeding than preclotted grafts. Woven grafts appear to be preferable to knitted grafts in fully heparinized patients who require replacement of segments of the thoracic aorta.

Endografts
The initial thoracic endovascular stent-grafts used clinically were hand-made from polyester or PTFE aortic grafts covered with modified Z stents.13 Several commercially manufactured endografts approved by the U.S. Food and Drug Administration for treating descending thoracic aortic aneurysms are currently available. They have undergone numerous modifications in construction as clinical experience has increased. The currently available grafts are constructed from self-expanding nitinol or stainless steel stents that are sutured to the outer surface of thin PTFE or polyester grafts. They are available in various diameters and lengths and incorporate different systems for anchoring the grafts to the aortic wall. Long-term durability of these grafts is unknown.

DEFINITION

Acute aortic dissection is an event of sudden onset in which blood leaves the normal aortic lumen through a usually discrete point of exit (intimal tear) and rapidly dissects inner from outer layers of the media to produce a false lumen. However, dissection of the media can occur in the absence of an intimal tear. Patients are considered to have an acute dissection when the process is less than 14 days old, and a chronic dissection thereafter (see “Chronic Aortic Dissection” under Morphology and Morphogenesis in Chapter 26).

HISTORICAL NOTE

Aortic dissection was recognized in the 16th century, but knowledge of many of its aspects was incomplete and confused. D6 Laennec introduced the term dissecting aneurysm in 1819. Shennan’s 1934 treatise was a landmark in developing knowledge of this entity, documenting among other things its seriousness. D11 Surgical treatment began in the mid-1930s. Early operations were indirect, consisting of creating a distal internal femorotomy (reentry passage) between true and false lumens or attempting to restore circulation directly to major branches sheared off by the dissection. D13, S10 With failure of these methods, surgical attention turned to the tendency of the false lumen to rupture, and efforts were directed by Paulin and James in 1948 to wrapping the area of dissection and by Johns in 1953 to suturing the rupture. D13, S26

Modern treatment of aortic dissection is a contribution of DeBakey, who in 1955 reported the successful outcome of an operation performed in 1954 in which the aeurysmal descending thoracic aorta resulting from dilatation of the false lumen was resected, entry into the false lumen distally oversewn, and end-to-end anastomosis performed. D6 Subsequently, DeBakey and colleagues devised a classification of aortic dissection that is widely used today (see “Morphology” later in this chapter). D8 The first successful repair of chronic ascending aortic dissection with aortic regurgitation was reported in 1962 by Spencer and Blake in a patient with chronic dissection, although the procedure was proposed by Bahnson and Spencer in 1960. B4, S19 Spencer and Blake carried out the operation that is currently widely used, including suspension of aortic valve commissures. The first successful repair of acute ascending aortic dissection with aortic regurgitation was reported by Morris and colleagues in Houston in 1963. M13 Moderate aortic regurgitation persisted postoperatively, and 15 years later the regurgitation was severe, with moderate heart failure. Aortography showed a persisting double lumen that extended distally to the aortic bifurcation. Aortic valve replacement was performed in 1977. L6 The patient continued to be well in 1989 (Morris GC: personal communication, 1989). Further successful surgical experiences with acute dissection of the ascending aorta were reported by DeBakey and colleagues in 1964. D7 In 1965, Wheat and colleagues demonstrated the possibility of improving management of acute aortic dissection by medical measures directed at controlling arterial hypertension while maintaining adequate organ perfusion. W4

Technological improvements in cardiopulmonary bypass (CPB) circuitry and in synthetic replacements for the involved aortic segments have contributed to improved outcomes following surgical treatment of acute aortic dissection. Use of hypothermic circulatory arrest, described initially by Barnard and Schrire and by Borst and colleagues in the early 1960s to treat aneurysms and other conditions involving the aortic arch, and applied systematically by Griep and colleagues in a series of patients described in 1975, permitted extension of operative procedures into the aortic arch. B7, B21, G10 In 1982, Livesay and colleagues described a technique for open distal anastomosis in treating both ascending aortic aneurysms and dissections, a technique that is now widely used. D1, L3 Use of gelatin-resorcinol-formaldehyde (GRF) glue to strengthen the disrupted layers of the aorta before they are approximated and sutured directly or to an aortic graft was described in 1979 by Guilmet and colleagues in France. G12 It is extensively used in Europe and in other parts of the world but is not approved for use in the United States. BioGlue, an albumin and glutaraldehyde-based adhesive, has been approved for this purpose in the United States by the U.S. Food and Drug Administration (FDA). Kato and colleagues in Tsu, Japan, and Dake and colleagues at Stanford University introduced endovascular stent-grafting initially to manage vascular ischemic complications of acute aortic dissection, then to exclude the primary tear in the descending thoracic aorta. The combined experience of these two groups was reported in The New England Journal of Medicine, which focused not only on early mortality and morbidity, but also specifically on the fate of the false lumen 5 to 28 months after stent-grafting. D2

MORPHOLOGY

Morphologic Substrates

In many patients in whom an aortic dissection develops, the aortic wall shows only changes commensurate with patient age. D3, H6, L5, S7, S22 Thus, it appears that once blood enters the aortic media, cleavage of concentric elastic lamellar plates can occur in even an essentially normal aorta; this event permits rapid and extensive dissection. Dissection usually proceeds distally but may also extend proximally.

Medial degeneration (cystic medial necrosis) of the aorta of a greater degree than is normal for age is present in about 20% of patients with acute aortic dissection and may predispose to dissection. L5, S28 Rarely, aortitis is a predisposing factor. H5

Marfan syndrome is an important morphologic substrate for acute aortic dissection, and acute dissection develops in 20% to 40% of patients with this syndrome. H5, B9, S96 In fact, aortic root dissection and rupture and chronic aortic regurgitation are the primary causes of death in these patients. N5, M14 Many patients with Marfan syndrome and aortic dissection exhibit no medial degeneration; therefore, this syndrome appears to be, per se, a risk factor for acute dissection. I5

Defective synthesis of fibrillin, a glycoprotein that is an important component of elastic tissue in the medial layer of the aorta, has been demonstrated in patients with Marfan syndrome. T10, S3 The genetic defect of Marfan syndrome and the fibrillin gene have been mapped to the same region in the long arm of chromosome 15. K1, M1 Turner, Noonan, vascular Ehlers-Danlos, and Loew-Dietz syndromes are other genetic disorders associated with aortic dissection.

1Manufactured by Cryolife Inc., 1655 Roberts Blvd. NW, Kennesaw, GA 30144.
A genetic basis of nonsyndromic familial thoracic aortic aneurysm and dissection has recently been defined. A genetic basis of nonsyndromic familial thoracic aortic aneurysm and dissection has recently been defined. **Anuloectasia** without Marfan syndrome is present in some patients in whom acute dissection of the ascending aorta develops. It is important to recognize anuloectasia when it coexists, because aortic root replacement rather than cusp resection is indicated (see “Indications for Operation, Selection of Technique, and Choice of Device” in Chapter 12).

A bicuspid aortic valve is frequently associated with acute aortic dissection. Larson and Edwards, in the study of Larson and Edwards, the process of acute dissection occurred nine times as frequently in patients with bicuspid as in those with tricuspid aortic valves. There may be a higher prevalence of congenital abnormalities of the aortic wall in patients with bicuspid than in those with tricuspid valves.

A dilated ascending aorta (>5.0-5.5 cm) occurring in combination with anuloectasia (with or without Marfan syndrome), with a bicuspid aortic valve, or with previous aortic valve replacement is associated with increased risk of aortic dissection. The role of arteriosclerosis in development of acute aortic dissection has been debated. It is probably not a predisposing lesion, although occasionally an intimal tear may develop in a penetrating arteriosclerotic ulcer, resulting in dissection of the media.

Aortic coarctation is associated with acute dissection, but this is likely due to systemic arterial hypertension, an important risk factor for developing acute aortic dissection. Bicuspid aortic valve and an abnormal ascending aorta, frequently present in patients with coarctation, may also be contributing factors.

The role of pregnancy in genesis of acute aortic dissection is unresolved. Closed chest trauma may rarely result in true aortic dissection, as may aortic cannulation and aortic clamping during operations employing CPB.

Intramural hematoma may be a precursor of aortic dissection. It likely results from rupture of vasa vasorum and may, in its initial stages, exist in the absence of an intimal tear (see text that follows).

**Intimal Tear**

Controversy exists as to whether an intimal tear is consistently present in acute aortic dissection and, thus, whether an intimal tear is a requisite for dissection. One point of view is that rupture of aortic vasa vasorum is the inciting event and that it initiates an intramural hemorrhage and subsequent dissection. This hypothesis is supported by studies of the role of intramural hematoma as a precursor of aortic dissection and by intraoperative and postmortem observations of aortic dissection without the presence of an intimal tear. However, Larson and Edwards found an intimal tear in each of 158 specimens personally examined, supporting the hypothesis of the primacy of an intimal tear, a view held by Murray and Edwards and by Roberts. The intimal tear develops commonly in the ascending aorta but also in the upper descending aorta just beyond the origin of the left subclavian artery. In the latter instance, dissection usually proceeds only distally (antegrade) but may extend proximally (retrograde) as far as the ascending aorta. Proximal dissection occurred in 48% (CL 29%-47%) of autopsied cases studied by Larson and Edwards. The intimal tear originates in the aortic arch in about 10% to 20% of patients and dissection is both retrograde into the ascending aorta and antegrade into the descending thoracic aorta. Rarely, the intimal tear is low in the descending thoracic or abdominal aorta.

**Dissection**

When medial dissection occurs, the walls of any of the branches of the aorta may be involved with the dissection, may be sheared off from the lumen and occluded by the dissecting media and intima, may stay in communication with the aorta but only by the false lumen, or may be uninvolved. Extension of dissection into the branch wall is more common in large arteries such as the brachiocephalic, carotid, subclavian, and renal than in smaller ones. Dissection more frequently involves the left rather than right iliac artery. Extent and nature of involvement of the branches, including coronary and iliac arteries, is an important determinant of the clinical syndrome with which the patient presents.

**False Lumen**

The false lumen develops in the outer half of the aortic media; as a consequence, its external wall is thinner than the internal wall (dissecting membrane). The false lumen usually involves half to two thirds of the circumference of the aorta and rarely the entire circumference. Although the false lumen may be contained initially by the thin outer layer of media and adventitia, it often ruptures into the pericardium, the pleural space (usually the left), or less commonly, the abdomen. Even when initial rupture does not occur, blood from the false lumen may extravasate through weak areas of media and adventitia to form a mediastinal or pericardial hematoma.

Usually, the false lumen gradually enlarges as time passes, producing a marked increase in wall thickness and size of involved portions of the aorta. In many instances, aortic enlargement in the acute stage is diffuse and does not reach aneurysmal proportions. In the ensuing years, the thin outer wall of the false aneurysm tends to weaken, the lumen tends to become aneurysmal, and eventually rupture may occur. The false lumen may become partially or totally thrombosed.

**Types of Aortic Dissection**

Two classifications of aortic dissection are widely used (Fig. 25-1): DeBakey and Stanford (Box 25-1). DeBakey type I or Stanford type A dissection, the intimal tear is usually located in the anterior wall of the proximal portion of the ascending aorta. Occasionally it is in the aortic arch and less commonly in the descending aorta distal to the left subclavian artery. Aortic valve regurgitation and myocordial infarction (MI) may result from extension of the dissection into the most proximal portion of the ascending aorta and the aortic root. In DeBakey type II dissection, only the ascending aorta is involved, and dissection terminates proximal to the brachiocephalic artery. This type may be found incidentally during operations for ascending aortic aneurysms. In DeBakey type III or Stanford type B dissection, the dissecting hematoma may involve only the descending thoracic aorta (DeBakey type IIIa), but most commonly extends into the abdominal aorta and occasionally into the iliac arteries (DeBakey type IIIb). It may also extend proximally into the aortic arch and the ascending aorta. In these types, the
**Box 25-1 Classification of Aortic Dissection**

**DeBakey Classification**
- Type I. Intimal tear usually originates in the proximal ascending aorta and dissection involves ascending aorta, arch, and variable lengths of descending thoracic and abdominal aorta.
- Type II. Dissection is confined to ascending aorta.
- Type III. Dissection may be confined to descending thoracic aorta (type IIIa) or may extend into the abdominal aorta and iliac arteries (type IIIb). Dissection may also extend proximally to involve the arch and the ascending aorta.

**Stanford Classification**
- Type A. All cases in which ascending aorta is involved by dissection, with or without involvement of the arch and descending thoracic aorta.
- Type B. Cases in which only descending thoracic aorta is involved; however, occasionally, dissections originating in the descending thoracic aorta extend proximally (retrograde) to include the aortic arch but not the ascending aorta, and others originating in the aortic arch remain localized or extend distally (antegrade) without involving the ascending aorta; in this text these are included in type B.

intimal tear is usually located just distal to the left subclavian artery. The proportion of patients with the various types of dissection depends on the nature of the series reported. In the large surgical series of DeBakey and colleagues, which contained both acute and chronic dissections, type I and type II dissections comprised about 35% of cases. In other clinical and autopsy series, acute dissections involved the ascending aorta in 62% to 85% of cases.

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

**Hemodynamic State**

*Sudden death* may be the presenting feature, occurring shortly after onset of dissection, with free rupture of the false lumen through the thin outer wall into the pericardial, pleural, or peritoneal space. Sudden death can also follow shearing off of the coronary arteries from their aortic origins.

Alternatively, the presentation may be *hypovolemic shock* of varying degree. It may be the immediate result of acute dissection with loss of a considerable amount of blood from the false lumen into periaortic tissues and spaces. It may also result from development of acute aortic regurgitation when the dissection shears off the aortic attachment of valve commissures, which occurs in 35% to 60% of patients with acute dissection involving the ascending aorta. It may also be the result of acute cardiac tamponade after the site of rupture into the pericardium has temporarily sealed off. As time passes after the acute event, often with some improvement in arterial hypotension, further extravasation of blood can occur from the false lumen into periaortic tissues or spaces, leading to further hypovolemia and a worsening hemodynamic state.

In some patients, the *hemodynamic state is good* after the immediate event, and acute extravasation from the false lumen or rupture of the lumen may not occur for hours, days, or years, if at all. In a few patients, acute dissection results in *no symptoms* and passes unnoticed.

**Demographics and Syndromes**

Most patients (80%-90%) presenting with acute aortic dissection are age 60 or older and have a history of arterial hypertension. Severe acute arterial hypertension, such as occurs in weight lifters, appears to predispose to acute dissection, particularly of the ascending aorta. Use of cocaine, which induces hypertension and vasoconstriction, has also been associated with acute aortic dissection. Patients with acute dissection involving the ascending aorta tend to be younger than those with more distal dissections; thus, the mean age of patients with ascending aortic dissections in the experience of Fann and colleagues was 56 ± 14 years (range 15-85 years), whereas that of patients with involvement of only the descending aorta and beyond was 64 ± 13 years (range 32-86 years). Some patients have evidence of Marfan syndrome; in others, dissection develops during pregnancy. A few have a history of coarctation or its repair or previous aortic valve
surgery (see Morphology earlier in this chapter). Occasionally, acute aortic dissection occurs in patients with Turner, Noonan, vascular Ehlers-Danlos, and Loeys-Dietz syndromes. In patients with these syndromes, dissection develops at a younger age, generally during the third or fourth decade of life. In them, and in younger persons in general, there is likely to be no history of hypertension, and dissection usually originates in the ascending aorta. Patients with nonsyndromic familial thoracic aortic aneurysm and dissection present at a younger age than patients with sporadic (non-genetically mediated) disease, but are older than patients with Marfan or Loeys-Dietz syndrome.

Symptoms and Signs

Although dissection may be painless and at times unknown to the patient, most patients experience sudden severe pain at the moment of dissection and a feeling of impending death. The pain is often interscapular, but it may be precordial and radiate into the neck or arms. It is at times difficult to distinguish from angina pectoris. Once acute dissection occurs, symptoms and signs can be produced by occlusion of a major vessel. Arch vessel occlusion causes stroke in 5% to 10% of patients with type I dissection. One leg (more commonly the left than right) may suddenly become numb, pale, and pulseless as dissection occludes the iliac artery or aortic bifurcation. Occasionally, the same process causes pulses to diminish or disappear in an upper extremity. Uncommonly (2%-5% of patients), paraplegia suddenly develops as intercostal arteries are separated from the aortic lumen by dissection. Oliguria or anuria may appear with occlusion of the aortic origin of the renal arteries.

Chest Radiography

The chest radiograph frequently exhibits widening of the mediastinal shadow, particularly in its upper part and toward the left in DeBakey types I and III dissections. There may be cardiomegaly secondary to pericardial effusion or signs of pleural effusion, particularly in the left hemithorax. The aortic shadow is frequently prominent. However, as a diagnostic test, chest radiography is inadequately sensitive to definitively exclude the presence of aortic dissection in all but the lowest-risk patients. Sensitivity is lower for pathology confined to the ascending aorta than for disease involving distal aortic segments.

Imaging Studies

Echocardiography

Transesophageal echocardiography (TEE) with Doppler color flow imaging is emerging as the most useful and accurate diagnostic technique. It is distinctly superior to transthoracic echocardiography (TTE) and can be performed relatively rapidly with minimal morbidity. When TEE was compared with aortography or with findings at operation or autopsy, its sensitivity and specificity for type A dissection ranged from 88% to 100% and from 86% to 100%, respectively, and for type B dissection from 98% to 100% and from 96% to 100%, respectively. In addition to identifying the dissecting membrane (Fig. 25-2, A), TEE can identify pericardial fluid, evidence for pericardial tamponade, aortic regurgitation, involvement of proximal coronary arteries in the dissection process (Fig. 25-2, B), and wall motion abnormalities of right and left ventricles.

TTE may be useful in critically ill patients to establish a diagnosis rapidly. However, absence of positive findings does not preclude the presence of an acute dissection, and other diagnostic studies become necessary.

Computed Tomography

Computed tomography (CT) with use of contrast material is useful for diagnosing and delineating acute aortic dissection. It produces excellent images with relatively short scanning times (Fig. 25-3). Because CT scanning equipment
is available in emergency departments of most hospitals, CT is the most widely used diagnostic technique for aortic dissection. Advantages include ability to image the entire aorta including lumen, wall, and periaortic regions; identify anatomic variants and branch vessel involvement; and distinguish between the various acute aortic syndromes (intramural hematoma, penetrating arteriosclerotic ulcer, and acute aortic dissection). Electrocardiographic-gated techniques have made it possible to generate motion-free images of the aortic root and coronary arteries. Reports using new-generation multidetector helical CT scanners have noted sensitivities of up to 100% and specificities of 98% to 99%. In comparative studies, however, CT has lower sensitivity and specificity than either TEE or magnetic resonance imaging (MRI) (see later). Dissection may be obscured by complete thrombosis of one lumen or similar opacification in both true and false lumens. Location of entry site and presence of aortic regurgitation cannot always be accurately determined. The technique requires use of contrast medium for accurate delineation of aortic pathology and may be contraindicated in patients with allergies to contrast agents or with renal insufficiency.

Magnetic Resonance Imaging
MRI is emerging as a premier imaging method for diagnosing diseases of the thoracic aorta, including acute aortic dissection. It does not require use of contrast medium. In some situations, a single study can provide information similar to that obtained from a combination of echocardiography, CT, and aortography, with high sensitivity and specificity. It provides superb imaging of both ascending and descending thoracic aortic dissections and can accurately identify sites of entry and thrombus formation (Fig. 25-4). MR angiography (MRA) using gadolinium, a contrast agent, further enhances its utility. Disadvantages of MRI compared with CT and TEE include a longer time to complete the study, greater cost, inaccessibility to patients who are connected to ventilators and monitoring devices, and limited availability.

Aortography
Despite advances in noninvasive and minimally invasive techniques for diagnosing acute aortic dissection, aortography remains an important and highly accurate method for establishing the diagnosis. It is the benchmark against which other diagnostic studies are measured. The false lumen can be visualized, as can at times the intimal tear (Fig. 25-5). It provides accurate information about branch artery involvement and presence of aortic valve regurgitation. It is an essential component of interventional procedures to treat acute aortic dissection, such as fenestration and endovascular stent-grafting (see “Special Situations and Controversies” later). Disadvantages of aortography compared with other diagnostic methods include need for arterial access and introduction of wires and catheters into the aorta, potential for false-negative results if the false lumen is thrombosed, risk of allergic reactions to contrast medium, and renal failure in patients with impaired renal function.

In the International Registry of Acute Aortic Dissection (IRAD), which included 618 patients with acute aortic dissection who had imaging studies between January 1996 and December 1999, the order for which the imaging studies were performed was known in 604 patients (98%). Among these, CT was performed first in 379 (63%), TEE in 192 (32%), aortography in 24 (4%), and MRI in 9 (1%). Among the 396 patients with a second study, TEE was performed in 229 (58%), CT in 68 (17%), aortography in 61 (15%), and MRI in 38 (10%). Data from the IRAD centers demonstrated a high diagnostic sensitivity for all four imaging modalities. However, false-negative CT, TEE, and aortography studies were frequent, so diagnosis of acute aortic dissection could not be confidently excluded on the basis of negative findings of a single test. The authors strongly recommended a second imaging study if the initial diagnostic test did not identify aortic dissection when the diagnosis was suspected clinically.
Chapter 25 Acute Aortic Dissection

25%–39%) patients analyzed by Weiss and colleagues. Thus, thrombolytic therapy can be safely administered to patients with ST-segment elevation and no physical signs of aortic dissection without need for further diagnostic studies. Additional studies may be indicated before thrombolytic agents are given to patients with ST-segment depression or other ECG evidence of myocardial ischemia.

Several serum markers have been investigated for their utility in diagnosing acute aortic dissection and differentiating it from other conditions associated with acute onset of chest pain, such as MI and pulmonary embolism. D-dimer, a degradation product of cross-linked fibrin in thrombus, is sensitive for ongoing intravascular thrombosis. It is highly elevated in patients with acute aortic dissection, with a sensitivity in pooled studies of 94% (95% CL, 91%-96%).

Using 64-slice CT scanners, it is possible to establish or exclude a diagnosis of acute aortic dissection, acute pulmonary embolism, and obstructive coronary artery disease (the so-called triple rule-out CT), and this diagnostic study is being used with increasing frequency.

Coronary Angiography

Selective coronary angiography to identify coronary artery involvement in acute ascending aortic dissection is not usually indicated, because this can be determined by TEE preoperatively or intraoperatively (see Fig. 25-2, B) and by direct examination of the coronary arteries after the aorta has been opened. Use of coronary angiography to detect arteriosclerotic coronary artery disease in patients who are to undergo surgical treatment of acute ascending aortic dissection is arguable (see Special Situations and Controversies later in this chapter).

Differential Diagnosis

Symptoms associated with acute aortic dissection can mimic those of acute MI. The electrocardiogram (ECG) may demonstrate myocardial ischemia, and serum creatine kinase may be elevated. Because thrombolytic therapy is frequently administered to patients with acute MI and ST-segment abnormalities, thrombolytic agents might be administered to patients with acute aortic dissection with potentially disastrous results. ST-segment elevation occurs rarely in acute aortic dissection; however, ST-segment depression occurs more commonly and was noted in 16 of 50 (32%; CL 25%-39%) patients analyzed by Weiss and colleagues. Thus, thrombolytic therapy can be safely administered to patients with ST-segment elevation and no physical signs of aortic dissection without need for further diagnostic studies. Additional studies may be indicated before thrombolytic agents are given to patients with ST-segment depression or other ECG evidence of myocardial ischemia.

Several serum markers have been investigated for their utility in diagnosing acute aortic dissection and differentiating it from other conditions associated with acute onset of chest pain, such as MI and pulmonary embolism. D-dimer, a degradation product of cross-linked fibrin in thrombus, is sensitive for ongoing intravascular thrombosis. It is highly elevated in patients with acute aortic dissection, with a sensitivity in pooled studies of 94% (95% CL, 91%-96%).

The lower specificity (40%-100%) in the pooled studies is not of sufficient magnitude to exclude the diagnosis, however, and in general, other diagnostic studies are required. Using 64-slice CT scanners, it is possible to establish or exclude a diagnosis of acute aortic dissection, acute pulmonary embolism, and obstructive coronary artery disease (the so-called triple rule-out CT), and this diagnostic study is being used with increasing frequency.
NATURAL HISTORY

Acute aortic dissection is a serious event, and the natural history of patients who have sustained it is related primarily to type and extent of the dissection and to the nature and severity of complications that may follow.

Survival

Information about survival of nonsurgically treated patients is sparse, but some general inferences may be drawn. Between 40% and 90% of patients survive 24 hours or more after the dissection, but this generalization ignores the well-established difference in prognosis between type A and type B dissections (Fig. 25-6, A). The hazard function for death also appears to be different in these two types of dissection (Fig. 25-6, B). Type B has a rapidly declining early hazard phase, a constant phase, and a rising late hazard phase beginning about 2 years after dissection; type A dissection has a rapidly declining early hazard phase and only a constant phase thereafter.

Involvement of the ascending aorta or aortic arch is, then, a risk factor for early death in patients with acute dissection.

Modes of Death

Most patients who die acutely succumb from false lumen rupture with hemopericardium, hemomediastinum, or hemothorax. Deaths later in the early period after dissection can result from delayed rupture or organ dysfunction secondary to arterial occlusions.

Course after Surviving Acute Aortic Dissection

Patients surviving acute dissection continue to be at greater risk of dying than the general population. This is because the false lumen generally persists (see Morphology [earlier] and Results [later]), usually and gradually becomes aneurysmal, and may rupture months or years after the acute episode. Also, a new dissection (redissection) may occur in a previously uninvolved portion of the wall of the aorta and present new risks.

TECHNIQUE OF OPERATION

Purpose of Surgical Treatment

Operation for acute aortic dissection is performed to prevent death from cardiac tamponade or exsanguination by excising and repairing or replacing areas of actual or impending rupture and, wherever possible, restoring blood flow to branches of the aorta that have been occluded by the dissection. Operation does not remove the entire false lumen in most patients. To this extent, operation is palliative rather than curative. Another purpose of operation when dissection involves the ascending aorta is to correct acutely developed or chronic coexisting aortic valve regurgitation. Resuspending detached commissures or replacing the aortic valve may be necessary. Replacing the aortic root may be required in some instances, and this is accomplished with a composite graft, an aortic allograft, or a stentless xenograft.

Repair of Acute DeBakey Type I or II (Type A) Dissection

General Considerations

Usual preparations are made for operations in which CPB is used (see Sections III and IV in Chapter 2). Pressures are monitored in the right radial artery and in the femoral artery opposite the cannulation site to promptly detect obstruction to retrograde flow within the aortic arch after CPB is established. Doppler sonography of the extracranial carotid arteries and monitoring of cerebral oxygen saturation are useful techniques for detecting compromised blood flow in brachiocephalic arteries.

The common femoral artery with the most normal pulse is exposed through a small vertical or oblique incision in the inguinal fold. If dissection is present upon opening it, the lumen in which blood is flowing should be cannulated. This may be either the false or the true lumen. In some cases,
effective retrograde arterial perfusion may not be possible, because the aorta becomes obstructed (see “Malperfusion Syndromes” later under Special Situations and Controversies). In this situation, provisions should be made for antegrade aortic perfusion through the ascending aorta, aortic arch, or apex of the left ventricle, or for perfusion of an axillary artery or the opposite femoral artery (see “Cardiopulmonary Bypass Established by Peripheral Cannulation” under Special Situations and Controversies in Section III of Chapter 2).  

If it is necessary to establish CPB urgently, the right common femoral vein should be used because the long venous cannula can be more easily positioned in the right atrium from the right side.

After median sternotomy, the pericardium is incised and stay sutures placed. The often hemorrhagic ascending aorta is not disturbed at this point (Fig. 25-7, A). If dissection is confined to the ascending aorta (DeBakey type II) and hypothermic circulatory arrest is not needed, a single two-stage

---

**Figure 25-7** Repair of acute DeBakey type I or II (type A) aortic dissection.  

A, Dashed line indicates proposed line of incision into dissected and often hemorrhagic ascending aorta. B, After cardiopulmonary bypass is established, aorta is clamped proximal to origin of brachiocephalic artery. After incising outer layer of aorta, origin of intimal tear is often visualized just distal to aortic valve. Cardioplegic solution is infused directly into coronary arteries whenever possible for optimal myocardial management.  

C, Aortic wall is transected circumferentially 4 to 5 mm above level of aortic commissures.

D. Pledgeted, double-armed, polypropylene sutures are placed across each detached commissure and through outer layer of aorta, and are tied over a second pledget. Inset: Gelatin-resorcinol-formaldehyde or other glue may be used to obliterate false lumen. E, Disrupted layers of aorta are approximated between strips of polytetrafluoroethylene (PTFE) felt or pericardium and are secured with multiple polypropylene mattress sutures.

In Section III of Chapter 2). A balloon-tipped catheter is placed into the coronary sinus through a purse-string suture in the right atrium for delivery of retrograde cardioplegia (see “Technique of Retrograde Infusion” in Chapter 3).

Limited dissection is carried out, carefully separating the ascending aorta from the pulmonary trunk proximal to the origin of the brachiocephalic artery, and the aorta is clamped at this point after transiently reducing CPB flow to a low level \( (0.5 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}) \). Whenever possible, the clamp should be placed several centimeters proximal to the brachiocephalic artery to avoid further injury and fragmentation of the aorta at a site where an anastomosis to a graft may be performed. A longitudinal incision is made in the ascending aorta extending to, but not into, the noncoronary sinus (Fig. 25-7, B). This incision often enters into the false lumen, which is
This cuff is sutured to a prepared woven polyester graft using a continuous polypropylene suture. Note that cut ends of layers of aorta extend beyond bolster. 

With DeBakey type II dissection, intact ascending aorta beyond dissection is completely transected and sutured to distal end of aortic graft with a continuous polypropylene suture incorporating a strip of PTFE felt or pericardium.

Completed procedure. A pledgeted polypropylene suture is used to seal site of insertion of a needle vent for aspiration of air.

Figure 25-7, cont’d
usually anterior and to the right of the true lumen. If clot is present in the false lumen, it is carefully removed. The dissecting membrane is incised, and retraction sutures are placed in the aortic wall. Cardioplegic solution is promptly infused into the coronary ostia. Retrograde cardioplegia should be administered if the coronary ostia are compromised by the dissection (see “Methods of Myocardial Management during Cardiac Surgery” in Chapter 3). Cardioplegic solution is infused every 12 to 15 minutes. External cooling of the ventricles with topical slush or a cooling jacket may also be used. The interior of the ascending aorta is examined and the aortic wall transected circumferentially 4 to 5 mm above the level of the aortic commissures (Fig. 25-7, C).

Management of Aortic Root

Repair of Disrupted but Nonectatic Aortic Root If one or more aortic valve cusps have been separated from the outer aortic wall by the dissecting hematoma with consequent cusp prolapse, a pledgeted 4-0 double-armed polypropylene mattress suture is placed across each affected commissure and through the outer layer of the aorta, and is tied over a second felt pledget (Fig. 25-7, D). The coronary arteries are carefully examined, and if dissection extends to one or both ostia but the coronary artery is intact, divided layers of the aorta surrounding the ostium are approximated with pledgeted 4-0 polypropylene sutures. Aortic wall surrounding the involved coronary artery is mobilized, and these sutures are tied on the outside of the aorta. If dissection completely surrounds a coronary ostium, a 3- to 4-mm button of both layers of the aorta surrounding the ostium is excised, and the divided layers are approximated with a 5-0 or 6-0 running polypropylene suture. This button can be attached to the ascending aortic graft or to an interposed segment of saphenous vein or 8-mm collagen- or gelatin-impregnated woven or knitted polyester graft (see “Ascending Aorta Replacement” under Technique of Operation in Chapter 26).

If dissection extends into the coronary artery, most commonly the right, repair may be possible. Alternatively, an interposition or bypass graft of saphenous vein or polyester is sutured to the unininvolved artery beyond the dissection in an end-to-end or end-to-side fashion, and the proximal end is anastomosed to the ascending aortic graft. If the end-to-side technique is used, the coronary artery is ligated proximal to the anastomosis. Disrupted layers of the aorta are approximated using 4- to 5-mm strips of polytetrafluoroethylene (PTFE) felt placed in the lumen and outside the aorta. This is accomplished with multiple mattress sutures of 4-0 or 5-0 polypropylene (Fig. 25-7, E).

Alternatively, strips of autologous or bovine pericardium may be used. This cuff, containing the two strips of felt (or pericardium) and the two layers of the aorta, is sutured to a collagen- or gelatin-impregnated woven polyester graft with a continuous 3-0 or 4-0 polypropylene suture (Fig. 25-7, F). Occasionally, use of 5-0 polypropylene suture may be indicated because of thinness and friability of aortic tissue. Diameter of the graft should be 10% to 15% smaller than the diameter of the aortic anulus to ensure adequate coaptation of the aortic cusps. The separated layers of the aorta can also be approximated using GRF or other glue (see Fig. 25-7, D, inset).

Replacement of Structurally Abnormal or Diseased Aortic Valve Occasionally, resuspension of the aortic valve is inadequate and replacement is necessary. The aortic valve may also require replacement if it is structurally abnormal. If the aortic root is not dilated, the aortic valve is excised and replaced (see “Replacement of Aortic Valve and Ascending Aorta, En Bloc” under Technique of Operation in Chapter 12). Dissected layers of the aorta in the region of the coronary sinuses and the coronary ostia are managed as described earlier under “Repair of Disrupted but Nonectatic Aortic Root.” The ascending aortic graft is sutured to the reinforced cuff of aorta at or just above the level of the aortic commissures, as shown in Fig. 25-7, F.

Management of Ectatic Aortic Root In patients with preexisting dilatation of the aortic sinuses and sinutubular junction, combined replacement of the aortic valve, aortic sinuses, and ascending aorta is the preferred method of treatment. These abnormalities are frequently encountered in patients with Marfan syndrome but may also be present in patients without this condition. Replacement with a composite graft containing a mechanical valve and a polyester tube graft is the most widely used technique. Conduits containing xenograft valves may be used in elderly patients or those in whom long-term anticoagulant therapy is contraindicated or inadvisable. Aortic root allografts and pulmonary root autografts can also be used. Valve-sparing procedures in combination with reconfiguration of the aortic root are only rarely indicated in patients with acute aortic dissection, because these operations are lengthy and complex. Such procedures are described under “Repair of Aortic Valve Regurgitation Caused by Aortic Dilatation or Aneurysm” in Chapter 12.

Occasionally, aortic root replacement may be advisable in the absence of ectatic aortic sinuses when there is marked disruption of layers of the aorta in this area. The aortic anulus is generally unaffected by the dissection and provides a secure area for attaching a composite graft or an aortic allograft. The coronary arteries are repaired, if necessary, and attached to the graft directly or to interposed segments of saphenous vein or polyester grafts.

DeBakey Type II Dissection

In these infrequent cases, dissection is confined to the ascending aorta, and the distal graft-to-aorta anastomosis is made to undissected aortic tissue. If dissection involves only the proximal ascending aorta, the aortic clamp is placed just proximal to the origin of the brachiocephalic artery (Fig. 25-7, G). The aorta is completely transected and sutured to the aortic graft with a continuous 3-0 or 4-0 polypropylene suture incorporating a strip of PTFE felt (see Fig. 25-7, G-H).

The interposition method of graft insertion is preferred for replacing the ascending aorta. Use of collagen- or gelatin-impregnated polyester grafts, fine suture (4-0 or 5-0 polypropylene), strips of PTFE felt or pericardium (see Fig. 25-7, G), and biological glue has substantially reduced severity of bleeding through graft interstices and from anastomotic suture lines. The older graft inclusion technique favored by some surgeons (see “Historical Note” in Chapter 26) is not recommended, because hemostasis and approximation of dissected layers of the aorta may be less secure, and because wrapping the aorta around the graft to reduce bleeding through graft interstices is no longer necessary.

Intraluminal sutureless prostheses have been used to treat both acute and chronic dissections of the ascending aorta. Woven polyester grafts of varying lengths with
a felt-covered metal spool at each end are available for this.\textsuperscript{2} Cloth tapes are placed around the aorta proximal and distal to the incision in the ascending aorta. After the aorta is clamped distally and opened longitudinally, the device is inserted into the aorta and is secured with the tapes, which are tied over the grooves in the proximal and distal spools. Obstruction of orifices of the coronary arteries and brachiocephalic artery must be avoided. The aorta can be sutured over the graft to minimize bleeding. Complications with these prostheses include dislodgment or buckling, pressure gradients when the prostheses buckle or are too small, and erosion of the aortic wall. The authors have observed all of these complications, as have others.\textsuperscript{8,12} For these reasons, intraluminal prostheses have a limited role in treating acute ascending aortic dissection. Occasionally, end-to-end anastomosis of the ascending aorta is possible after resecting the area containing the aortic tear.\textsuperscript{13}

As repair of whatever type is being completed, suction on the intracardiac venting catheter is discontinued, and the venous line is partially occluded to fill the heart with blood and evacuate air. The lungs are temporarily inflated to assist in this maneuver. Anastomosis of the aortic graft to the distal ascending aorta is completed, and a venting catheter or needle is inserted through a small stab incision in the graft guarded by a pledgeted mattress suture. With suction on the vent, the aortic clamp is opened briefly to remove any remaining air and reapplied. Infusion of warm blood cardioplegia retrogradely through the coronary sinus or controlled aortic root reperfusion can be performed at this time (see “Methods of Myocardial Management during Cardiac Surgery” in Chapter 3). When this is completed, suction is placed on the aortic vent, and the aortic clamp is released and may be reapplied to the aortic graft distal to the vent in a partially occluding position. Standard de-airing procedures are carried out (see “De-airing the Heart” in Section III of Chapter 2). CPB is then discontinued. TEE can be used to assist in evacuating air from the cardiac chambers and to assess competency of the aortic valve or valve substitute.\textsuperscript{24} Operation is completed in the usual manner.

\textit{DeBakey Type I Dissection}

When it is known from preoperative diagnostic studies or intraoperative TEE that dissection involves the distal ascending aorta, aortic arch, and remainder of the thoracic aorta, provisions are made for hypothermic circulatory arrest. An open technique for performing the distal aortic anastomosis is recommended because it provides the opportunity for directly inspecting the aortic arch and proximal descending thoracic aorta and permits distal anastomosis of the aorta to the aortic graft to be made at the most appropriate level.

If retrograde brain perfusion is to be used (for alternative methods, see “Brain Protection during Operations on the Aortic Arch” under Special Situations and Controversies in Chapter 26), separate cannulae are placed in the superior and inferior venae cavae and are connected to venous return tubing of the pump-oxygenator. Tapes are placed around both venae cavae but are not secured. Cannulating the femoral artery and placing left-heart venting and retrograde cardioplegia catheters are performed as described earlier under “General Considerations.”

\textsuperscript{2}Maquet Inc., 45 Barbour Pond Drive, Wayne, NJ 07470.
Figure 25-8 Repair of acute DeBakey type I (type A) aortic dissection. A, After circulatory arrest is established, aortic clamp is removed and aorta is completely transected proximal to origin of brachiocephalic artery. Disrupted layers of aorta are approximated between strips of polytetrafluoroethylene (PTFE) felt or pericardium and secured with multiple polypropylene mattress sutures. B, This cuff is sutured to a prepared woven polyester graft using a continuous polypropylene suture. C, After infusing cold blood into superior vena cava and briefly restoring retrograde arterial flow (arrows) (see "Brain Protection during Operations on the Aortic Arch" under Special Situations and Controversies in Chapter 26), proximal end of graft is elevated and gently massaged to evacuate air.

Malperfusion of brachiocephalic vessels and may reduce flow in the false lumen, thus reducing the possibility of late aneurysmal changes in the remaining aorta. The remaining steps in managing the proximal extent of the dissection and discontinuing CPB are completed as described earlier for DeBakey type II dissection. After removing the cannula in the aortic graft, the purse-string suture is secured (Fig. 25-8, E). If a sidearm graft was used for arterial return, it is suture-ligated as close to the aortic graft as possible and the remaining portion excised.

If it is necessary to include the aortic arch in the repair, the incision already made in the ascending aorta is extended into the arch and, if necessary, into the upper descending thoracic aorta to just beyond the origin of the left subclavian artery (Fig. 25-9, A). If an intimal tear is present in the arch, is located beneath the origins of the brachiocephalic arteries, and does not involve them or extend into the descending thoracic aorta, the aorta is transected obliquely beneath the brachiocephalic arteries (Fig. 25-9, B). The area containing the tear is excised. Disrupted layers of aorta are approximated between strips of PTFE felt or pericardium using mattress sutures of 4-0 polypropylene as previously described (Fig. 25-9, C). A prepared polyester graft of appropriate size is cut obliquely with a wire cautery and is sutured to the aortic cuff with 3-0 or 4-0 polypropylene suture (see Fig. 25-9, C). If the bevel created in the aorta at the level of transection is short, the graft is sutured so that it is vertically aligned with respect to the aortic arch (Fig. 25-9, C-D). If the aortic bevel is long, the graft is beveled in the reverse direction and sutured in a more horizontal position (see Fig. 25-9, D, inset).

As this anastomosis is being completed, cold oxygenated blood is infused into the superior vena cava as previously described, and air is evacuated from the brachiocephalic arteries and distal aorta. A cannula connected to the arterial return line of the pump-oxygenator is inserted into the graft close to the suture line and is secured with a purse-string suture. Alternatively, an aortic graft containing a sidearm can be used as previously described. Air is evacuated from the graft, the graft clamped proximal to the cannula (Fig. 25-9, E), and the procedure completed as previously described.

If the inner layer of the aorta is disrupted over the entire length of the aortic arch or if the arch has ruptured or is aneurysmal, replacing the entire arch is indicated. After the aorta has been incised, the phrenic and vagus nerves are dissected free from the anterior surface of the arch. The aorta is transected distal to the origin of the left subclavian artery. If dissection is present at this level, the disrupted layers of the aorta are approximated with strips of PTFE felt or pericardium. A prepared polyester graft is sutured to the distal aortic
Figure 25-8, cont’d  D. A perfusion cannula that has been attached to the arterial return tubing from the pump-oxygenator is inserted into aortic graft through a purse-string suture, and antegrade perfusion is reestablished (arrows). A soft-jawed clamp is placed on the graft. Graft is then anastomosed to proximal prepared aortic cuff with a continuous polypropylene suture. E. Completed procedure. Aortic cannula is removed and a pledgeted polypropylene suture used to seal this site and site of insertion of needle vent for aspirating air.

Figure 25-9  Repair of acute DeBakey type I (type A) aortic dissection when aortic arch is included in repair. A. Dashed line indicates line of incision that is extended onto anterior surface of aortic arch. B. Dashed line indicates site of transection of aorta when the aortic tear does not involve distal aortic arch or origins of brachiocephalic arteries and inner layer of aorta is intact in these areas. 

Continued
cuff with a 3-0 or 4-0 polypropylene suture (Fig. 25-10, A). After this anastomosis is completed, the graft is temporarily clamped, and retrograde aortic perfusion is established briefly to detect leaks in the anastomotic suture line. These are repaired with mattress sutures of 3-0 or 4-0 polypropylene. Alternatively, a ringed intraluminal prosthesis can be inserted into the true lumen of the descending thoracic aorta and secured with tapes, which are tied over a strip of PTFE felt.

A full-thickness elliptical incision is made in the aorta surrounding the origins of the brachiocephalic arteries (see Fig. 25-10, A). If dissection is present, the layers of the aorta are approximated between strips of PTFE felt or pericardium. An opening is made in the aortic graft opposite the aortic cuff with a wire cautery, and the cuff is sutured to the graft with a continuous 3-0 or 4-0 polypropylene suture (Fig. 25-10, B). As this suture line is being completed, cold oxygenated blood is infused retrogradely into the superior vena caval cannula to evacuate air from the brachiocephalic vessels. The open end of the graft is elevated to assist in evacuating air. A purse-string suture is placed in the graft beneath the brachiocephalic arteries, and an aortic cannula attached to the arterial return tubing is inserted into the graft through a small incision. Alternatively, as noted previously, an 8- or 10-mm polyester graft that is attached to the aortic graft and positioned beneath the anastomosis to the brachiocephalic arteries can be used for arterial return. A soft-jawed clamp is placed across the graft just proximal to the brachiocephalic artery. Antegrade flow is established and rewarming begun (Fig. 25-10, C). The remainder of the procedure is completed as described earlier.

If dissection extends into the brachiocephalic arteries and there are no intimal tears, disrupted layers of aorta adjacent to these arteries are approximated as described earlier and sutured to the aortic graft. If intimal tears are present in these arteries, they are transected, and the disrupted layers are
injury is a serious complication following descending thoracic clamping, distal aortic perfusion is routinely employed (see "Methods for Perfusing the Distal Aorta during Aortic Clamping" under Special Situations and Controversies in Chapter 24). If only a short segment of the proximal descending thoracic aorta requires replacement, left atrial–to–femoral artery bypass or partial CPB can be used. If the distal aortic arch requires replacement, or if extensive resection of the descending thoracic or thoracoabdominal aorta is necessary, full CPB with profound hypothermia (with or without circulatory arrest) is preferred.

Replacement of Descending Thoracic Aorta

After positioning the patient in the lateral decubitus position with the pelvis rotated posteriorly to allow access to the left femoral vessels, a posterolateral thoracotomy incision is made and the pleural cavity entered through the bed of the fifth rib, which

Figure 25-10 Repair of acute DeBakey type I (type A) aortic dissection when replacing entire aortic arch is necessary (see Indications for Operation in text). A, Aorta is completely transected distal to origin of left subclavian artery. Disrupted layers of aorta are approximated with strips of polytetrafluoroethylene (PTFE) felt or pericardium. A full-thickness elliptical incision is made in aorta surrounding origins of brachiocephalic arteries. If aorta is dissected in this area, disrupted layers are approximated with strips of PTFE felt or pericardium. A prepared polyester graft is sutured to distal aortic cuff with a continuous polypropylene suture. B, An opening is made into aortic graft with a wire cautery corresponding to size of aortic cuff surrounding the brachiocephalic arteries. Graft is sutured to aortic cuff with a continuous polypropylene suture. C, After evacuating air from the distal aorta and brachiocephalic arteries (see Fig. 25-8, C), aorta is clamped, a perfusion cannula attached to arterial return tubing from pump-oxygenator is inserted into the aortic graft through a purse-string suture, and antegrade perfusion is reestablished. Procedure is completed as shown in Fig. 25-8, D and E.
can be retracted or resected. This incision provides adequate exposure of the distal aortic arch and proximal two thirds of the descending thoracic aorta. If exposure of the more distal thoracic aorta is required, the incision can be extended anteriorly, dividing the cartilage at the costal arch; alternatively, a separate incision through a lower interspace can be made using the same skin incision. After placing a retractor, the left lung is collapsed and retracted anteriorly. Often there is an extensive mediastinal hematoma, and the mediastinal pleura is incised only where clamps are to be placed (Fig. 25-11, A; see also Fig. 24-8, A-D, in Chapter 24). Distal aortic perfusion is then established.

Whenever possible, control of the proximal aorta should be obtained at a level proximal to the origin of the disease, which is usually located just distal to the origin of the left subclavian artery. This is achieved by placing a clamp on the distal aortic arch between the left carotid and left subclavian arteries. The mediastinal pleura is opened in this area, and the aorta is circumferentially freed from surrounding tissue. The left subclavian artery is also freed from adjacent tissue near its origin. Intraoperative TEE and epiaortic scanning as well as preoperative CT or MRI can be used to detect presence of retrograde dissection in this area.

If placing clamps in these areas is inadvisable, total CPB with hypothermic circulatory arrest is used, and anastomosis of the aortic graft to the proximal aorta is performed using an open technique (see “Technique Using Hypothermic Circulatory Arrest” under Technique of Operation in Chapter 26). The vagus nerve is identified and protected (see Fig. 25-11, A-D). The site for clamping the distal aorta is identified, the mediastinal pleura is incised in this area, and the aorta is freed from surrounding tissue. Every effort should be made to limit resection to as short a segment of the upper descending thoracic aorta as possible to minimize risk of spinal cord ischemic injury. Clamps are then placed on the aorta between the left carotid and left subclavian arteries, on the left subclavian artery, and on the descending aorta just distal to the proposed area of resection (see Fig. 25-11, A).

The aorta is opened longitudinally (Fig. 25-11, B), thrombus removed from the false lumen, and the true lumen entered. Orifices of any bronchial arteries and of the intercostal arteries above the level of the sixth intercostal space are suture-ligated. Intercostal arteries below this level should be preserved and can be temporarily occluded with bulldog clamps if necessary. The aorta is completely transected below the origin of the left subclavian artery. The recurrent laryngeal nerve should be identified and protected. The aortic cuff below the proximal aortic clamp is carefully examined. If no dissection is present, this cuff is sutured to a prepared polyester tube graft of appropriate size using a continuous 3-0 or 4-0 polypropylene suture, incorporating a small cuff of PTFE felt that is placed on the external surface of the aorta (Fig. 25-11, C). If the layers of the aorta are separated in this area, they are approximated between strips of PTFE felt, and the resulting cuff is sutured to the aortic graft using the technique shown in Fig. 25-8, A and B. (If an intimal tear is present and extends proximally beyond the aortic clamp into the aortic arch, an alternative procedure is used as described in text that follows.) The completed suture line can be tested by placing a soft-jawed clamp on the graft and temporarily releasing the clamp on the proximal aorta. Bleeding sites on the suture line can be controlled with interrupted sutures.

The appropriate site for transection of the aorta above the distal clamp is selected. If this is above the level of the sixth intercostal space, the dissected layers are approximated between strips of PTFE felt using mattress sutures (Fig. 25-11, D). This cuff is sutured to the aortic graft with a continuous 3-0 or 4-0 polypropylene suture. If the site of transection is below the sixth intercostal space, the aorta is divided obliquely whenever possible to preserve lower intercostal arteries, and the cuff containing the strip of PTFE felt is sutured to the aortic graft. If it is necessary to transect the

**Figure 25-11** Repair of acute DeBakey type III (type B) aortic dissection. A, Aorta is approached through a left posterolateral thoracotomy incision, and preparations are made for distal perfusion and protection of spinal cord (see “Methods to Minimize Spinal Cord Injury” under Special Situations and Controversies in Chapter 24). Clamps are placed on aorta between left carotid and left subclavian arteries, on left subclavian artery, and on the descending aorta just distal to proposed area of resection. Dashed line indicates site of incision. B, Aorta is opened and true and false lumens identified. Bulldog clamps are placed on exposed intercostal arteries.
Chapter 25  Acute Aortic Dissection

Polyester graft

C, Aorta is completely transected below origin of left subclavian artery. If layers of aorta are separated in this area, they are approximated between strips of polytetrafluoroethylene (PTFE) felt or pericardium (see Fig. 25-8, A and B). Aortic cuff is sutured to a prepared polyester graft with a continuous polypropylene suture. D, Appropriate site for transection of distal aorta is selected. Dissected layers are approximated between strips of PTFE felt or pericardium, and aortic cuff is sutured to distal end of aortic graft. E, If aorta must be transected at or above level of left subclavian artery, the aortic graft is sutured to the aorta at this level, and transected subclavian artery is sutured to the aortic graft directly or to a prepared, interposed 8- or 10-mm polyester graft using a continuous polypropylene suture.

Figure 25-11, cont’d  C, Aorta is completely transected below origin of left subclavian artery. If layers of aorta are separated in this area, they are approximated between strips of polytetrafluoroethylene (PTFE) felt or pericardium (see Fig. 25-8, A and B). Aortic cuff is sutured to a prepared polyester graft with a continuous polypropylene suture. D, Appropriate site for transection of distal aorta is selected. Dissected layers are approximated between strips of PTFE felt or pericardium, and aortic cuff is sutured to distal end of aortic graft. E, If aorta must be transected at or above level of left subclavian artery, the aortic graft is sutured to the aorta at this level, and transected subclavian artery is sutured to the aortic graft directly or to a prepared, interposed 8- or 10-mm polyester graft using a continuous polypropylene suture.

If it is necessary to transect the aorta proximally at or above the level of the left subclavian artery, the aortic graft is sutured to the aorta at this level using the technique previously described, and the transected subclavian artery is sutured to the aortic graft directly or with an interposed prepared 8- or 10-mm polyester graft using 4-0 or 5-0 polypropylene suture (Fig. 25-11, E).

After the distal anastomosis is completed, the distal aortic clamp is removed and air evacuated from the graft using an 18-gauge needle. Proximal clamps are removed, and if no major bleeding points are identified, CPB is discontinued. Cannulae used for distal perfusion are removed, heparin is neutralized with protamine, and the femoral vessels are

descending aorta below the level of the eighth or ninth intercostal space, intercostal arteries between the level of transection and the sixth intercostal space are isolated with a full-thickness cuff of aorta using the electrocautery, and this button of aorta is sutured to an opening in the graft with a continuous 4-0 polypropylene suture (see Fig. 26-18, F in Chapter 26). Alternatively, a separate prepared polyester graft can be sutured to the cuff of aorta surrounding the intercostal arteries. This graft is then sutured to an opening in the aortic graft with 5-0 polypropylene. If the aortic tissue surrounding the intercostal arteries is too friable to support sutures, these arteries are suture-ligated. Anastomosis of the graft to the distal aorta is completed as described previously.
Involvement of Aortic Arch  Occasionally, a DeBakey type III dissection extends retrogradely, involving the aortic arch and even the ascending aorta. If arch involvement is recognized preoperatively or intraoperatively, hypothermic CPB and circulatory arrest are used (see “Technique Using Hypothermic Circulatory Arrest” in Chapter 26). During cooling, the left phrenic and vagus nerves are identified and protected. After the desired temperature has been reached, the patient is placed in the head-down position, a clamp is placed on the aorta near the site selected for the distal anastomosis, and circulation is arrested.

The aorta is opened anteriorly distal to the origin of the left subclavian artery, and the incision is extended proximally beneath the origins of the brachiocephalic arteries. The site for the anastomosis must be proximal to the site of any intimal tears or rupture, although separation of layers of the aorta may be present. The aorta is completely transected, divided layers of the aorta are approximated with strips of PTFE felt or pericardium, and a prepared aortic graft containing a 10-mm sidearm is sutured to this cuff as described previously. Most often, the aorta can be transected obliquely beneath the origins of the brachiocephalic arteries so that only a single anastomosis is required.

Rarely, separate anastomoses to the aorta proximal to the origins of the brachiocephalic arteries and to a cuff of aorta surrounding these arteries are necessary. Once these anastomoses are completed, the sidearm of the aortic graft is attached to a second arterial line from the pump-oxygenator. After evacuation of air, flow is established through the aortic graft as well as through the femoral arterial cannula to assist in evacuating air from the upper body. Once this has been accomplished, a clamp is placed on the graft just distal to the sidearm, and CPB is reestablished (see Fig. 26-19, D-E in Chapter 26). Anastomosis of the graft to the distal aorta is completed as described earlier under “Replacement of Descending Thoracic Aorta.”

If dissection extends more proximally to involve the ascending aorta and the false lumen is not thrombosed or there is evidence for hemopericardium, the aorta should be approached through a midline sternotomy. The technique is described earlier under “DeBakey Type I Dissection.” The area of the aorta containing the intimal tear in the descending thoracic aorta may not be accessible with this anterior approach. In this situation, exposure of the proximal one third to one half of the descending thoracic aorta can be achieved by transverse extension of the midline sternotomy incision into the left third intercostal space, retracting the left lung anteriorly and inferiorly. If involvement of the ascending aorta with dissection is determined after a left thoracotomy has been performed, the thoracotomy can be extended anteriorly, and the sternum divided transversely at this level to facilitate exposure.

Involvement of Thoracoabdominal Aorta  Extension of operation to the thoracoabdominal aorta is indicated when rupture of this segment of the aorta has occurred or is imminent and when there is evidence for malperfusion of distal organs. This is only rarely necessary. Techniques for replacement of the thoracoabdominal aorta are discussed under “Thoracoabdominal Aorta Replacement” in Chapter 26.

Repair of Intraoperative Aortic Dissection  Intraoperative dissection of the ascending aorta is an infrequent complication of cardiac operations that require use of CPB. In two large series of patients operated on between 1980 and 1990, intraoperative dissection recognized intraoperatively or early postoperatively occurred in about 0.5% of patients. It is also a recognized complication of off-pump coronary artery bypass grafting (CABG), occurring in up to 1% of patients. Actual prevalence is likely higher, because diagnosis is not made perioperatively in all patients, and because some patients present late after operation with evidence for dissection that likely occurred intraoperatively. If unrecognized, this complication is associated with substantial mortality. Prompt diagnosis and surgical treatment are essential for survival.

Intraoperative aortic dissection should be suspected when a subadventitial or intramural hematoma develops in the ascending aorta, particularly in association with excessive bleeding from suture lines or needle holes. TEE and epiaortic ultrasonographic imaging are especially useful in establishing presence and extent of the dissection. Dissection originates most commonly at sites of partial or complete aortic clamping and aortic cannulation, and less frequently at sites of proximal anastomoses to venous or arterial bypass grafts and of needle venting.

Disrupted layers of aorta must be approximated and the false lumen, if present, obliterated. If dissection is localized to a small part of the aorta, such as the site of a venting or cardioplegia needle, it can be repaired by plicating the aorta using mattress sutures placed over strips of PTFE felt to exclude the area of dissection. This type of repair should be performed at a low level of aortic pressure to avoid tension on the suture line and possible extension of the dissection. This is best accomplished with the patient on CPB. Clamping the aorta with a partially occluding clamp surrounding the area of the tear should be avoided.

If the tear occurs at the anastomotic site of a bypass graft, the graft should be relocated to another area of the aorta or anastomosed to an adjacent graft. After the aorta is clamped in a nondissected area, divided layers of the aorta are approximated, usually with strips of PTFE felt or pericardium placed inside and outside the aorta. If dissection is not circumferential, the defect can be repaired with a patch of polyester or pericardium. If dissection is more extensive or extends beyond the ascending aorta, as is often the case when it originates from the aortic clamp or aortic cannulation site, resection and graft replacement of the ascending aorta are usually required. When dissection originates at the aortic cannulation site, the cannula is removed, and a common femoral artery exposed and cannulated. Unless dissection is confined to the proximal two thirds of the ascending aorta, aortic clamping should be avoided and preparations made for hypothermic circulatory arrest. Repair is accomplished using the techniques described earlier under “Repair of Acute DeBakey Type I or II (Type A) Dissection.”

SPECIAL FEATURES OF POSTOPERATIVE CARE  Early postoperatively, standard protocols are used (see Chapter 5). Control of hypertension is particularly important because hypertension predisposes the patient to excessive bleeding and early redissection or rupture of the residual false
lumen. Because malperfusion of major branches of the aorta may occur or become apparent postoperatively (see Special Situations and Controversies later), peripheral pulses and organ function should be monitored frequently.

Periodic evaluation following surgical repair or medical management of acute aortic dissection is mandatory. Stringent control of arterial hypertension is essential and is accomplished with calcium channel blocking agents, β-adrenergic blocking agents, and angiotensin-converting enzyme inhibitors used singly or in combination. β-Adrenergic blocking agents reduce rate of dilatation of the aorta and development of aortic complications in patients with Marfan syndrome and thus may provide an additional protective effect in patients with acute aortic dissection.514

Long-term follow-up is also necessary to detect false lumen enlargement and development of aneurysms that may require surgical treatment to prevent rupture. Currently, contrast-enhanced CT is the most widely used and cost-effective diagnostic study for evaluating the dissected aorta postoperatively. It provides accurate measurement of aortic diameter at various levels. MRI provides similar information, but is presently less readily available and more expensive than CT. Aortography may be indicated if additional surgery is contemplated or if compromise of branch vessels is suspected. TTE may be used to assess competency of the aortic valve after its resuspension as well as the size of the ascending aorta. TEE provides this information as well as information regarding flow and thrombosis in the false lumen. A protocol proposed by Borst and colleagues for follow-up of patients with aortic dissection is shown in Table 25-1.518 Patients with Marfan syndrome should be examined at 6- to 12-month intervals for the duration of their lives. Follow-up examinations are best performed by cardiovascular specialists who are knowledgeable about the sequelae and complications of aortic dissection.

### RESULTS

#### Acute Dissection Involving Ascending Aorta (DeBakey Types I and II)

**Early (Hospital) Death**

Hospital mortality for heterogeneous groups of patients undergoing repair for various types of acute dissection of the ascending aorta has been 5% to 33%,85,B11,B12,C7,F5,G1,G4,G5,G11,M14,N2,O4,T4,Y4,Y7,Z1 A report by IRAD, established in 1996 and consisting of 18 large international referral centers, assessed the current presentation, management, and outcomes of patients with acute aortic dissection; hospital mortality was 25% among 526 patients (CL 23%-27%) with acute type A aortic dissection treated surgically between January 1, 1996, and December 31, 2001.74

**Time-Related Survival**

In the study of Crawford and colleagues of a heterogeneous group of patients undergoing repair of acute ascending aortic dissection, 1-month, and 1-, 5-, 10-, and 15-year survival was 79%, 66%, 46%, 46%, and 37%, respectively (Fig. 25-12, A).57 The hazard function for death had a rapidly declining early phase and a constant phase (see Fig. 25-12, B). Among 174 patients treated by the Stanford group and followed up to 30 years, 1-, 5-, 10-, and 15-year survival was 67%, 55%, 37%, and 24%, respectively.38

**Modes of Death**

In earlier years, hemorrhage and acute cardiac failure were the principal modes of death early after operation. In more recent experience, which reflects improved perioperative management, brain injury and malperfusion syndromes have emerged as important contributors to early death. B11,G1,G5,G11 Cardiac failure, MI, and stroke are other common modes of early death.37 Approximately 20% to 30% of late deaths are related to aortic rupture or new dissection. C9,F5,17

**Incremental Risk Factors for Premature Death**

**Acuity** The event of acute dissection itself is the dominant patient-specific risk factor, as is need for preoperative resuscitation. C7,G5 Predissection functional class (New York Heart Association class) of the patient was a surprisingly weak risk factor, which interacts with extent of operation to become more powerful when the arch is included in repair (Fig. 25-13).67 However, Sabik and colleagues, who combined acute and chronic dissections and used both analysis of interactions with dissection acuity and propensity score adjustment (see “Clinical Studies with Nonrandomly Assigned Treatment” in Section I of Chapter 6), concluded that it was hemodynamic state rather than acuity of dissection that was the risk factor for early mortality.51 In the IRAD study, preoperative shock or cardiac tamponade was an independent predictor of operative mortality.74

**Location of Dissection** Five-year survival is appreciably better for patients with DeBakey type II as compared with DeBakey type I ascending aortic dissection (87% vs. 56%, respectively). G4

**Comorbidity** In the IRAD study, age 70 years or older was a risk factor for hospital mortality.74 Older age was a risk...
factor for late-phase risk in the studies by Sabik and colleagues and Zierer and colleagues. In the IRAD study, previous aortic valve replacement and preoperative limb ischemia were risk factors for premature death. Presence of diabetes is a risk factor, as is preoperative renal insufficiency. Procedural Risk Factors Earlier date of operation is a predictor of early death in some series (Fig. 25-14), reflecting the major improvements in technique and perioperative management not seen in other series. Failure to include the area of the intimal tear has not been, with any certainty, a risk factor for death early or late after repair. Inclusion of the arch in the repair is a risk factor for death within 30 days and late after operation in some series (see Fig. 25-14) but not in others. Sabik and colleagues found that need to use a composite graft technique was a risk factor.

Concomitant CABG, particularly when performed in conjunction with extended operations, was a risk factor for death in the experience of Crawford and colleagues and Zierer and colleagues. In the IRAD study, previous aortic valve replacement and preoperative limb ischemia were risk factors for premature death. Presence of diabetes is a risk factor, as is preoperative renal insufficiency. those involving the aortic arch and proximal descending thoracic aorta. Among operative survivors, aneurysmal dilatation of the remaining dissected aorta occurs in up to 50% to 60% within 10 years, and up to 25% require reoperation (see later section on “Reoperation”). Risk factors for aneurysmal dilatation include patent or wide false lumen, larger aortic diameter early after repair, Marfan syndrome, hypertension, younger age, and male sex. In the study of Park and colleagues, shrinkage of the false lumen occurred in 36 (29%) of 122 patients with serial CT imaging who were followed a mean of 34 months. Shrinkage occurred in 23 of 24 patients (96%) who had thrombosed and narrow false lumens in the thoracic aorta.

Redissection

Redissection (i.e., new aortic dissection in a different part of the aortic wall) may develop years after surgical or medical treatment of an acute aortic dissection. Marfan syndrome is believed to increase the probability of redissection.

Aortic Valve Competence after Commissural Resuspension

Successful resuspension of the aortic valve, rather than replacement, does not increase risk of operation in patients with acute aortic dissection and aortic regurgitation. Furthermore, in most patients, the aortic valve is competent or shows only mild regurgitation after this procedure. Late reoperation and valve replacement occur infrequently. Meng and colleagues reported 55 of 60 patients (92%; CL 86%-95%) in a collected series to be free of the need for valve replacement 2 to 10 years later, virtually the same as that reported by Borst and colleagues, Fann and colleagues, Jex and colleagues, and Sabik and colleagues. Among 123 patients with acute type A dissection treated at Stanford University who had resuspension of the aortic valve (n = 82), composite graft replacement (n = 21), or separate valve and ascending aortic replacement (n = 20), actuarial freedom estimates for reoperation on the aortic valve at 6 years were 94% ± 4%, 100% ± 2%, and 88% ± 12%, respectively (P = NS). A new dissection proximal to the ascending aortic graft or development of a sinus of Valsalva aneurysm late postoperatively predisposes patients to developing important aortic valve regurgitation that may require reoperation.

Reoperation

Need for reoperation is relatively common. It is required most often for enlarging aneurysms of the false lumen but also for a new dissection, false aneurysms at the original suture lines, sinus of Valsalva aneurysms, or aortic valve regurgitation (described in the preceding text). In the experience from Stanford with 174 patients with acute type A dissections, 30 patients (17%; CL 14%-20%) required reoperation. Freedom from reoperation at 1, 5, 10, and 15 years was 94%, 83%, 65%, and 65%, respectively. In the multivariable analysis, younger age was the only risk factor predicting a higher likelihood of reoperation over time. Similar prevalence of reoperation has been observed by other groups. However, Sabik and colleagues reported 5- and 10-year freedom from reoperation of 91% and 85%, with a rate of 2% per year after the first 3 months. Freedom from reoperation for distal false-lumen aneurysm only, in the series of Crawford and colleagues, is shown in Fig. 25-15. Kirsch and colleagues identified severe preoperative aortic regurgitation as the only risk factor for proximal reoperation. Reoperation is required with greater frequency in patients with Marfan syndrome. Other important risk factors for reoperation include patent false lumen, large initial aortic diameter distal to the repair, hypertension, and non-resection of the primary tear.

Surgical Techniques to Reduce the Frequency of Late Aneurysm Formation and Reoperation

Total Aortic Arch Replacement

Total aortic arch replacement at the time of repair of acute DeBakey type I (type A) aortic dissection has been performed in experienced surgical centers and has been accomplished without increasing the risk of operation in selected patients. It has been proposed as a mechanism to promote thrombosis of the distal false lumen and reduce the frequency of late aneurysm formation and reoperation. Extended follow-up, however, has not conclusively demonstrated that this procedure improves survival or reduces frequency of reoperation.

Elephant Trunk Technique

Addition of an elephant trunk to ascending aorta and total arch replacement has been proposed as a method to ensure a more secure distal aortic anastomosis and to promote thrombosis of the false lumen in the descending thoracic and abdominal aorta. This can be accomplished with either a polyester graft (see section on Elephant Trunk Technique in Chapter 26) or an endovascular stent-graft inserted through the open aortic arch (Fig. 25-16). The putative advantages of an elephant trunk include promoting thrombosis of the false lumen, reducing the frequency of subsequent operations for aneurysm formation of the residual dissected aorta, and simplifying any subsequent operative procedure on the distal aorta. In contrast to a polyester elephant trunk, use of a stent-graft permits fixation of the distal end of the elephant trunk to the aortic wall. Thrombosis of the false lumen surrounding the elephant trunk has been demonstrated in a high percentage of patients undergoing either technique (Fig. 25-17). Thrombosis of the more distal thoracic and abdominal aorta, however, has not consistently occurred. It has not been conclusively demonstrated in a large series of patients undergoing either procedure.
demonstrated that the frequency of reoperations on the remaining dissected aorta has been reduced. Unique complications of extending the aortic graft into the descending thoracic aorta include paraplegia/paraparesis, creation of a new dissection by the stents of the endovascular graft, endoleak, and compression or collapse of the graft, creating important obstruction to aortic flow.

Functional Status
Most patients return to their predissection functional status after surgical repair of the acute dissection.

Acute Dissection Involving Descending Thoracic Aorta

Early (Hospital) Death
When operation is performed as a routine for acute dissections involving the descending aorta, early mortality can be as low as 10%. However, in most centers, operation is commonly performed in patients with specific indications (see Indications for Operation later) such as a failed initial course of medical treatment, and for them, early mortality has ranged from 28% to 49%. An IRAD study, independent predictors of early death following surgical treatment in 82 patients were age older than 70 years (odds ratio 4.3; CL 2.4-7.9) and preoperative shock/hypotension (odds ratio 6.0; CL 2.6-14.0).

Time-Related Survival
Time-related survival following operation appears to be similar to that of patients with acute dissection involving the ascending aorta. In the Stanford University experience, 1-, 5-, 10-, and 15-year survival for 46 patients with acute type B dissections was 56%, 48%, 29%, and 11%, respectively. In a more recent IRAD study of patients treated surgically and discharged alive, 3-year survival was 83% ± 19%.

Morbidity
Paralysis of the lower extremities and renal failure are more frequent postoperative complications following operations on the descending aorta than on the ascending aorta.

INDICATIONS FOR OPERATION

Acute Dissection Involving Ascending Aorta (DeBakey Types I and II)

When dissection involves the ascending aorta with or without involvement of the proximal portion of the aortic arch, immediate operation is indicated. This policy is the result of comparison of the natural history (see Fig. 25-6) with results of surgical treatment (see Figs. 25-12 and 25-18) and the knowledge that rupture or fatal cardiac tamponade is likely to occur. Contraindications are markedly advanced age and frailty, severe incurable disease such as malignancy or chronic dementia, and evidence of irreversible brain injury. Stroke occurring as a result of dissection is a risk factor for death after operation, but among survivors, symptoms and signs of stroke may resolve considerably. Thus, a new stroke is not necessarily a contraindication to operation. MI induced by the dissection, coma, paraplegia, renal failure, and ischemia of the extremities and abdominal viscera are
not contraindications to operation. These complications may disappear or improve following repair of the aorta, or they may be surgically treated at the time of or after the aortic procedure.

The aortic arch should be included in repair when the intimal tear is located in the arch, the inner layer of the aorta is fragmented, the outer wall of the aorta is tenuous or aneurysmal, or rupture of the arch has occurred. Although replacement of all or, more commonly, a part of the arch to eliminate the site of the intimal tear is arguable, it should usually be performed, because prevalence of late reoperation is greater when the site of the intimal tear is not resected, and because recent experience with resection of the aortic arch in the setting of acute dissection is associated with acceptable operative risk. Replacement of the arch may also be advisable in patients with acute ascending aortic dissection when the tear is located in the proximal descending thoracic aorta.

Acute Dissection Involving Descending Thoracic Aorta (DeBakey Type III)

Whereas indications for operation for acute aortic dissections involving the ascending aorta are fairly well standardized, those for acute dissections involving the descending aorta are not. When only the descending thoracic aorta is involved in acute dissection, with or without involvement of the abdominal aorta and iliac vessels, and there have been no clinically evident complications of the acute dissection, medical treatment is indicated. This plan is supported by comparisons of results in comparable patients treated medically vs. surgically, which show no differences. With medical treatment only, approximately 90% of selected patients survive for 30 days (Fig. 25-18) and 80% survive at least 1 year after acute dissection. Medical treatment is directed toward maintaining normal (not elevated) arterial blood pressure with sodium nitroprusside, reducing force of left ventricular ejection with β-adrenergic receptor blockade, and maintaining good urine flow and good overall subsystem function.

When initial medical treatment results in survival without important complications, close patient follow-up after hospital discharge is essential. This need is emphasized by the experience of Wheat and colleagues and of McFarland and colleagues, who found that 50% of such patients die during the subsequent 3 to 5 years. Follow-up is conducted to obtain the same information, and for the same reasons as required after surgical treatment (see Special Features of Postoperative Care earlier in this chapter).

Complications occurring in patients with acute aortic dissection involving only the descending thoracic and abdominal aorta require immediate surgical treatment by open operation, endovascular grafting, or interventional procedures to manage malperfusion (see “Malperfusion” and “Endovascular Grafts” later under Special Situations and Controversies). These include aortic rupture; dissection superimposed upon a preexisting aneurysm; rapid expansion of aortic diameter; ischemia of limbs, visceral organs, or kidneys; progression of dissection; uncontrolled hypertension; intractable pain despite medical therapy; and extensive hemothorax. Marfan syndrome is considered by some to be an indication for early operation because of poorer results with medical therapy.

Paraplegia occurring as an isolated complication is not an indication for intervention, because recovery of spinal cord function following repair of aortic dissection does not commonly occur. However, neither is it a contraindication to operation, because relief of distal ischemia, particularly when femoral pulses are absent, may result in return of sensory and motor function. Although there are no absolute contraindications to operative treatment, mortality may be prohibitively high in very elderly patients and those with comorbid conditions such as ischemic heart disease, pulmonary disease, and extensive arteriosclerosis.

**SPECIAL SITUATIONS AND CONTROVERSIES**

**Malperfusion Syndromes**

Major branches of the aorta are commonly involved in dissection, and the presenting clinical picture may be influenced by symptoms that result from ischemia of one or more affected organs. Thus, patients may present with myocardial ischemia, stroke, paralysis of the lower extremities, symptoms and signs of acute abdomen, renal failure, or ischemia of the extremities. In the large autopsy study of Hirst and colleagues, dissection was observed in the carotid arteries in 28%; in the celiac, mesenteric, or renal arteries in 28%; in the iliac and femoral arteries in 26%; in the subclavian arteries in 14%; in the coronary arteries in 7%; and in the spinal arteries in 1.8% of cases.

In large clinical studies of aortic dissection, symptomatic malperfusion of the major aortic branches was present in 15% to 33% of patients. Malperfusion and ischemia can result from compression of the true lumen of the aorta by the expanding false lumen, extension of the dissection into the branch artery with compression of the true lumen, intussusception of the inner wall of the aorta into a branch artery, or occlusion of a branch vessel by a flap of dissected aorta. Managing malperfusion of the coronary arteries during repair of acute dissection involving the ascending aorta was discussed earlier under “Repair of Disrupted but Nonectatic Aortic Root.” If malperfusion of the brachiocephalic arteries
is detected after establishing CPB using the femoral artery or after placing a clamp on the ascending aorta, urgently establishing antegrade flow in the ascending aorta is indicated. This can be accomplished by direct cannulation of the ascending aorta or aortic arch guided by TEE, or by cannulating the left ventricular apex or right axillary artery.\textsuperscript{B20,R10,S22}

Occasionally, extraanatomic bypass grafts to the carotid or subclavian arteries may be necessary to correct persisting malperfusion after repair of ascending aortic dissection. In most cases of acute ascending aortic dissection, graft replacement of the ascending aorta will correct malperfusion syndromes of visceral, renal, and lower extremity arteries, and this should be expeditiously performed.\textsuperscript{F4,G2} If ischemia persists, fenestration of the dissecting membrane or direct revascularization of the occluded arteries may be necessary.\textsuperscript{G2} In patients with acute descending aortic dissection, fenestration or direct revascularization procedures may be indicated to relieve ischemia when other indications to resect and replace a segment of the descending thoracic aorta are not present.\textsuperscript{G6} Alternatively, these procedures can be performed using endovascular techniques.\textsuperscript{C2,K6,L1,P5,W1}

Endovascular Grafts

Endovascular grafts have been used to treat acute complicated DeBakey type I (type A) and DeBakey type III (type B) aortic dissections when the primary intimal tear is located in the descending thoracic aorta.\textsuperscript{D2,K3,K4,P1} Use of an endovascular stent-graft eliminates need for thoracotomy and for clamping the thoracic aorta. Other putative advantages of endovascular repair include restoration of true lumen flow with closure of the primary tear, thrombosis of the false lumen, restoration of flow to distal organs and lower extremities, and lower early mortality than reported for open repair. Results of endografting from recently reported series and from a single meta-analysis are shown in Table 25-2. Early mortality appears to be lower than for open repair, although no randomized trials comparing the two forms of therapy for complicated descending thoracic aortic dissection have been reported. Conversion to open operation has been infrequent (0.6% among the 942 patients [CL 0.4%-1.0%] included in the meta-analysis of Parker and Golledge\textsuperscript{P3}).

The complications of aortic rupture, stroke, spinal cord ischemic injury (paralysis or paraparesis), and renal failure have not been eliminated, and adjunctive procedures to manage endoleaks and persisting malperfusion are often required (see Table 25-2). Type A aortic dissection following endovascular repair occurred in 2% of patients (18 of 918; CL 1.5%-2.6%) in the meta-analysis of Parker and Golledge.\textsuperscript{P3} Complete thrombosis of the false lumen has not been consistently observed.\textsuperscript{C6,K7,R10,S24}

A randomized multicenter trial comparing endovascular stent-grafting with medical therapy for patients with uncomplicated acute type B aortic dissection who were randomized 2 weeks after onset of symptoms was performed by the INvestigation of STEnt-grafts in Aortic Dissection (INSTEAD) group.\textsuperscript{N6} There was no difference in 30-day mortality between the two groups. One-year survival was 91% in the stent-graft group and 97% in the medically treated group (\(P = .16\)).\textsuperscript{C6} Follow-up from one of the earliest series of patients with acute type B dissection treated with endovascular stent-grafts by Palma and colleagues\textsuperscript{P3} demonstrated that at a mean of 36 ± 28 months, late mortality was 18%; subsequent endovascular grafting was required in 6 of 28 patients (21%); and late failure, defined as sudden or aortic-related death, surgical conversion, or reintervention, occurred in 12 patients (43%).\textsuperscript{A3}

Detecting and Managing Coexisting Coronary Artery Disease

With increased use of CT and TEE to diagnose acute ascending aortic dissection, routinely performing preoperative angiography, including coronary angiography, has been questioned.\textsuperscript{G1,K9,R3} Rizzo and colleagues suggest that rapid noninvasive diagnosis and avoidance of routine angiography appear to improve survival by expediting surgical intervention and thus decreasing risk of aortic rupture.\textsuperscript{R3} In contrast, Creswell and colleagues documented the presence of arteriosclerotic coronary artery disease (>50% stenosis) in 8 of 23 patients (35%; CL 25%-45%) with acute ascending aortic

dissection. Four of these patients with the most severe disease had CABG at the time of repair of acute dissection, and all survived the operative procedure. Mean age of the four patients was 73 years, whereas age of the entire cohort of patients with acute dissection was 59 years. These observations suggest that coronary angiography and CABG, when indicated, should be considered for hemodynamically stable patients with a known history of coronary artery disease, previous CABG, or acute changes on preoperative ECGs.

Use of Biological Glues to Reduce Bleeding and Obliterate the False Lumen

GRF and other biological glues have been used in an attempt to reduce bleeding during operations for acute aortic dissection. Although several groups have reported satisfactory early outcomes with use of GRF and other glues with low mortality and reduced bleeding, no prospective or randomized trials have been reported. In contrast to the findings of Bachet and colleagues, Goossens and colleagues did not observe a reduction in hospital mortality or need for reoperation for bleeding following introduction of GRF glue. Although several groups have reported satisfactory early outcomes with use of GRF and other glues with low mortality and reduced bleeding, no prospective or randomized trials have been reported. Biological glues have also been used to facilitate reconstruction of the aortic root by obliterating the false lumen and reinforcing the aortic layers.

Although initial results have been satisfactory, need for reoperation for aortic root dissection and for aortic regurgitation attributed to use of various glues has been observed in several centers.

DEFINITION

This chapter considers true aortic aneurysm, false aortic aneurysm, chronic aortic dissection, penetrating arteriosclerotic ulcer, intramural hematoma, and diffuse arteriosclerotic disease. Methods for protecting the brain during operations on the aortic arch are also discussed.

True aortic aneurysm is a permanent localized dilatation of the aorta, of a diameter 50% or greater than normal, contained by walls that although attenuated, have all layers of the normal wall.15 False aortic aneurysm is a localized dilatation whose wall consists of adventitia, some or all of the media, and compressed periaortic tissue. Chronic aortic dissection is a separation for more than 14 days of the outer from the inner layer of the media, caused by blood leaving the normal aortic channel through a point of exit (intimal tear). Penetrating arteriosclerotic ulcer is an arteriosclerotic lesion that penetrates the internal elastic lamina of the aortic wall. Intramural hematoma is an extravasation of blood into the aortic wall, commonly in the absence of an intimal disruption. Diffuse arteriosclerotic disease is sessile, mobile, or pedunculated atheroma involving lipid deposition in large areas of the intimal layer of the aorta.

HISTORICAL NOTE

An important contribution to modern aneurysm surgery was made by Rudolph Matas in New Orleans in 1902 when he described the basic maneuver of “getting inside the aeurysm” with minimal external dissection and after obtaining control of the artery above and below the aneurysm.37 Interestingly, this basic maneuver was ignored as aortic aneurysm surgery began to develop, and in early work with abdominal aortic aneurysms at the Mayo Clinic, the aneurysm was dissected away from surrounding tissues, often with a long and difficult operation and considerable hemorrhage from lumbar arteries.9,21 DeBakey and Cooley described this same tedious method in their classic paper of 1953.37 Javid and colleagues in 1962 and Crecel in 1966 are generally credited with reintroducing the technique of working within the aneurysm.33,12 However, DeBakey and colleagues in Houston had reintroduced this concept into abdominal aortic aneurysm surgery by 1958.48 The inclusion technique of sewing the graft in place from within the aneurysm is an embodiment of this concept.43

Throughout the first half of the 20th century, sporadic attempts were made to treat aortic aneurysms, almost all in the abdominal aorta. Treatment was by proximal partial or complete ligation of the aorta. Results were generally unsatisfactory.11,12 Various other palliative procedures had also been used unsuccessfully. In 1950, Estes at the Mayo Clinic published a classic paper that demonstrated the poor prognosis of patients with abdominal aortic aneurysms, only 50% of whom survived 3 years after diagnosis, with two thirds of the deaths attributable to aneurysmal rupture.12 In response to that study, the Mayo Clinic began a surgical approach to this condition in 1951, and in 1953 reported the results of aneurysm reinforcement and the tedious operation of aortoplasty and complete wrapping with fascia lata.10 In 1952, Schafer and Hardin in Kansas City reported resection and grafting with an aortic allograft of an abdominal aortic aneurysm, only to have the patient die of numerous complications 28 days after operation.59 In that same year, Dubost and colleagues, working in Paris, reported the first successful case of aortic resection for aneurysm and restoration of blood vessel continuity (in their case, an abdominal aortic aneurysm that was approached retroperitoneally and replaced by a preserved aortic allograft).22 In 1953, reports of similar successes came from DeBakey and Cooley in Houston and from the Mayo Clinic.47,66,10 Aortic allograft banks were subsequently established in some centers to provide aortic replacement grafts.47,48,20,26

In 1944, Alexander and Byron successfully resected a thoracic aortic aneurysm secondary to coarctation, although without restoration of aortic continuity.85 Aortic allografts were developed in 1948 by Gross and colleagues in Boston to replace resected aortic segments.47,48,26 On May 24, 1948, they resected a coarctation in a 7-year-old boy, restoring aortic continuity with an aortic allograft. When the clamps were released, the distal vasculature dilated, and the patient became hypotensive and died. This led to a recommendation to slowly release the clamps following repair of aortic coarctation.47,48 They performed four more allograft replacements of the aorta for coarctation in 1948, five in 1949, and eight in 1950, including the first frozen and irradiated graft, which functioned for at least 30 years (Dr. Robert Replogle, personal communication, July 19, 2002). In 1950, Swan and colleagues also reported successful clinical use of allografts for treating complex coarctations, including those with aneurysms.31 Adopting this technique, Lam and Aram in 1951 reported resection and allograft replacement of a descending thoracic aortic aneurysm in an adult.4,5 Prophetically, paraparesis developed in their patient, who died 6 weeks after operation of empyema. About this time, Bahnsen reported successful management of a saccular aneurysm of the descending thoracic aorta by lateral resection and aortorrhaphy.52 In 1953, DeBakey and Cooley reported the first successful application of resection and grafting to a descending thoracic aortic aneurysm.58

Ascending aortic aneurysms were also approached surgically before the advent of cardiopulmonary bypass (CPB). In 1952, Cooley and DeBakey reported removal of sacciform ascending aortic aneurysms by lateral resection and aortorrhaphy, as did Bahnsen and Johnston and colleagues in 1953.52,8,9 In 1956, Cooley and DeBakey reported the first successful modern operation for ascending aortic aneurysm, consisting of resecting the ascending aorta and grafting with an aortic allograft, with the aid of CPB.52,8,9 Wheat and colleagues then reported successful simultaneous but separate replacement of the ascending aorta and aortic valve with implantation of the coronary ostia into the graft.56 Bentall and De Bono in 1968 and Edwards and Kerr in 1970 reported accomplishing this replacement with a composite valve and polyester tube graft.8,9 Wheat and colleagues subsequently demonstrated long-term patency of their anastomoses between grafts and coronary ostia.56

Aneurysms of the arch of the aorta presented a more difficult surgical challenge. By 1952, Cooley and DeBakey had removed some sacciform aneurysms in this portion of the aorta by lateral resection, as had Bahnsen by 1953.52,8,9 The next year, DeBakey and Cooley reported successful resection of the distal aortic arch and replacement by a graft for an aneurysm that had resulted from acute traumatic aortic transection.58 The case is of interest in that the patient’s temperature was reduced to 28°C by surface cooling before thoracotomy. The aorta was clamped proximal to the left
subclavian artery (which was also individually clamped) for 1 hour, and paraplegia did not develop (see “Paraplegia” under Special Situations and Controversies in Chapter 24 for the significance of this finding). In 1955, Cooley and colleagues reported unsuccessful resection of an aneurysm of the entire aortic arch, using the cumbersome method of temporary shunts without CPB, as did Stranahan and colleagues in a 15-hour operation in 1955 and Creech and colleagues in 1956. In 1957, DeBakey and colleagues reported the first successful repair of an aortic arch aneurysm using CPB and allograft replacement.

Thoracoabdominal aneurysms also presented difficult surgical challenges, not only because of the magnitude of the operation but also the propensity of patients to develop renal and spinal cord dysfunction after repair. In 1952 during Bahnsen’s pioneering work with aneurysms of the aorta, he successfully repaired a saccular thoracoabdominal aneurysm by lateral resection and aortorrhaphy. Ellis and colleagues at the Mayo Clinic first reported repair of such an aneurysm involving a visceral artery (in their case, the renal artery) by resection and grafting in 1955. Etheredge and colleagues reported successful repair of a more complex thoracoabdominal aneurysm including the celiac axis and superior mesenteric artery in the same year. In 1956, DeBakey and colleagues reported successful repair of such an aneurysm involving all the visceral arteries (celiac, superior mesenteric, and both renal). Subsequently, they devised the technique of permanent aortic bypass with a synthetic graft and visceral arterial reattachment to appropriately located side-arm grafts, and in 1965 they reported 26% mortality among 42 patients. Crawford and colleagues modified and simplified the operation by applying the inclusion technique, reducing hospital mortality to 8% by 1978.

During this developmental phase, there was controversy about the lethality of thoracic aortic aneurysms. Some reports indicated that patients with thoracic aneurysms fared better than those with abdominal aneurysms. In 1964, Joyce and colleagues established that this was not the case. A series of technical improvements evolved into many of the techniques currently used for surgical treatment of thoracic aortic aneurysms. Even after successful repair of aneurysms of the arch had been accomplished using CPB, methods remained complex, often involving separate cannulation of the brachiocephalic arteries. In 1964, Bosr and colleagues reported repair of a traumatic aneurysm of the distal portion of the aortic arch through a left thoracotomy, using CPB to produce profound hypothermia and performing the repair during an interval of circulatory arrest.

In 1975, Griep and colleagues established the value of profoundly hypothermic circulatory arrest for resecting and grafting of more proximal and more extensive aneurysms of the aortic arch. Among the technical improvements was use of a single anastomosis between an oval opening in the graft and the aortic wall around all three brachiocephalic arteries in replacing aortic arch aneurysms, reported by Bloodwell and colleagues in 1968 and by Pearce and colleagues the following year. Later, Ott and colleagues reported tailoring the arch resection and graft so that a single distal anastomosis could be made. Crawford and Saleh applied the inclusion technique to arch aneurysms, working entirely within the aneurysm and wrapping the graft with aneurysm wall.

Technical improvements have also been made in the aortic replacement devices required for treating aortic aneurysms and dissections. Soon the search for synthetic aortic substitutes was revived despite the unsuccessful pioneering efforts of Carrel and others. The first satisfactory synthetic aortic substitute was a fabric tube made of polyvinyl chloride cloth, and the first clinical application of this device was reported by Blakemore and Voorhees in New York City in 1954. Shumaker and King in Indianapolis also used these fabric tubes for aortic replacement in the same year. For the next several years, surgeons autoclaved and used fabric grafts made on the sewing machines of wives and friends, with generally good results. Intensive study of prosthetic grafts was quickly undertaken by several groups, and in 1955, Deterling and Bhonslay reported that polyester was the best material then available for aortic replacement. Knitted and woven grafts of various types, mostly polyester, have been widely used since then. Subsequent development of polyester grafts impregnated with collagen, gelatin, or albumin has resulted in a substantial reduction in blood loss through the grafts (particularly in fully heparinized patients), a major cause of postoperative morbidity (see “Grafts for Use in Aortic Surgery” under Special Situations and Controversies in Chapter 24.)

Stent-grafting of descending thoracic aortic aneurysms was introduced by Duke and colleagues at Stanford University in the early 1990s using custom-designed grafts. Since then, a number of commercially developed grafts have become available for clinical use.

MORPHOLOGY AND MORPHOGENESIS

Classification

Diseases of the thoracic aorta that are amenable to surgical treatment are listed in Box 26-1. Acute traumatic aortic transection and acute ascending and descending aortic dissection are discussed in Chapters 24 and 25.

Aneurysm

Aneurysm is the most common condition of the thoracic aorta that requires surgical treatment. This category includes congenital or developmental, degenerative, chronic traumatic, inflammatory, infectious, mechanical, and anastomotic aneurysms.

Congenital or Developmental

Marfan syndrome is an autosomal dominant disorder resulting from mutations in the FBN1 gene that lead to defective synthesis of the glycoprotein fibrillin (a component of elastic tissue in the medial layer of the aorta). The aorta becomes aneurysmal as a result of a reduced number of microfibrils in this layer. The dilated aortic segments are prone to rupture or dissection.

Loeys-Dietz syndrome is an autosomal dominant aortic aneurysm disorder with involvement of other systems. It results from mutations in either the transforming growth factor receptor type I or II (TGFBR1 or TGFBR2) genes. The majority of patients have aortic root aneurysms that result in aortic dissection. These patients also develop aneurysms of other vessels.

Ehlers-Danlos syndrome comprises a group of heterogeneous conditions characterized by various defects in the synthesis of type III collagen. Development of aneurysms is
uncommon, but rupture or dissection of the aorta or other arteries (often abdominal) can occur as a catastrophic event. Tissue fragility and poor healing can complicate surgical treatment.\textsuperscript{512} Ehlers-Danlos type IV (vascular form) is generally sporadic, but when familial is usually an autosomal dominant disorder.

Other genetically mediated conditions associated with aneurysm development and aortic dissection include Turner syndrome, Beals syndrome (contractural arachnodactyly), Noonan syndrome, autosomal dominant polygenic disease, and the nonvascular form of Ehlers-Danlos syndrome.\textsuperscript{A5,I4,M18,S12,W3}

Degenerative Cystic medial degeneration is the most frequent pathologic condition that results in aneurysms of the ascending aorta.\textsuperscript{515} Characteristic features are fragmentation and loss of elastic tissue and loss of smooth muscle cells. Inflammation and apoptosis may be components of this process as well.\textsuperscript{517} Enlargement is usually confined to the proximal portion of the ascending aorta. Dilatation of the sinuses of Valsalva and aortic anulus (anulooaortic ectasia) may result in aortic regurgitation. (See “Anulooaortic Ectasia” under Morphology in Chapter 12 for discussion of this entity in patients with aortic valve regurgitation.)

Degenerative aneurysms, often associated with arteriosclerosis of the aorta, are the most frequently occurring aneurysms of the thoracic and abdominal aorta and most commonly involve the descending thoracic or thoracoabdominal segments.\textsuperscript{C41,C56} Abnormal proteolysis, presence of elastolytic serum enzymes, and deficiencies of collagen and elastin have been implicated as factors contributing to development of these aneurysms.\textsuperscript{B21,B24,C4,N2,R2} Although atheromatous changes are frequently present in and around such aneurysms, the causative role of arteriosclerosis in their development is not clearly established.\textsuperscript{C41,E11,J5}

**Chronic Posttraumatic** Aneurysms resulting from blunt trauma most frequently involve the proximal descending thoracic aorta and may present many years after the acute injury. When neither death nor operation follows the acute transection, disruption of at least part of the aortic circumference, usually at the level of the ligamentum arteriosum, results in extravasation of blood into the periaortic tissues (see Chapter 24). This blood may remain in communication with the aorta and form a pulsating hematoma that is contained by aortic adventitia or the mediastinal tissues. The resulting false aneurysm may enlarge and rupture from increased wall stress (Laplace law). Chronic posttraumatic aneurysms represent a small percentage of patients with aneurysms of the thoracic aorta.

**Inflammatory** Patients with Takayasu arteritis, Behçet disease, Kawasaki disease, and giant cell arteritis may develop aneurysms of the thoracic aorta that require surgical treatment.\textsuperscript{A6,A14,D1,E15,I1,I2,K11,T1,W4} Other inflammatory disorders, such as ankylosing spondylitis, psoriatic arthritis, polyarteritis nodosa, and Reiter syndrome, may result in dilatation of the aortic root and aortic valve regurgitation that require surgical intervention.\textsuperscript{I2}

**Infected** Primary infected (mycotic) aneurysms of the thoracic aorta are rare. A frequent cause is direct deposition of circulating bacteria in a diseased, arteriosclerotic, or traumatized aortic intima following an episode of endocarditis or infection of an aortic jet lesion.\textsuperscript{F3,G4} Infection of intraluminal clot in a preexisting degenerative aneurysm may occur after an episode of bacteremia or other infectious process.\textsuperscript{C10} Organisms can also infect previously inserted prosthetic grafts, causing false aneurysms. Other risk factors for development of infected aneurysm include congenital cardiac or vascular defects, trauma, and impaired immunity.\textsuperscript{B22,G4,G16} \textit{Staphylococcus aureus} is the most frequent causative organism, followed by \textit{Staphylococcus epidermidis}, \textit{Salmonella}, and \textit{Streptococcus} species.\textsuperscript{B22,C10,M24,G10} Infected aneurysms may be multifocal.

**Mechanical** Aneurysmal changes can occur in the aorta distal to stenotic aortic valves and aortic coarctation and proximal to arteriovenous fistulae. Dilatation of the ascending aorta in patients with a bicuspid aortic valve and of the descending thoracic aorta in patients with aortic coarctation is more likely the result of structural abnormalities of the aortic wall rather than turbulent flow produced by the stenotic lesions.\textsuperscript{I10}

**Anastomotic** Aneurysms (usually of the false type) can develop at the site of aorta-to-aorta or aorta-to-graft anastomoses.

**False Aneurysm** False aneurysms are most commonly associated with trauma, infection, and previous operations on the aorta.

**Chronic Aortic Dissection** Morphologic features of acute aortic dissection, including classification, are discussed in Chapter 25. When the false lumen persists after an acute aortic dissection, as it usually
does, its outer wall, consisting of the outer layer of the media and the adventitia, has a tendency to weaken and enlarge. A saccular or fusiform aneurysm may result. Chronic aortic dissection with persisting false lumen is a common substrate for development of chronic thoracic or thoracoabdominal aneurysms.

**Penetrating Arteriosclerotic Ulcer**

Arteriosclerotic lesions involving the intimal layer of the aorta may ulcerate and penetrate the internal elastic lamina of the aortic wall (Fig. 26-1). Penetrating arteriosclerotic ulcers occur most commonly in the descending thoracic aorta.\(^{220,244}\) They can result in separation of the layers of the media and formation of intramural hematoma.\(^{315,317}\) Saccular and fusiform aneurysms may develop, and dissection, rupture, and embolization can occur.

**Intramural Hematoma**

Intramural hematoma can occur in the absence of an intimal tear and may result in dissection\(^{14,26,81}\) (Figs. 26-2 and 26-3). Rupture of an arteriosclerotic plaque and spontaneous rupture of vasa vasora have been postulated as mechanisms for development of the hematoma.\(^{26}\)

**Diffuse Arteriosclerotic Disease**

Sessile, mobile, or pedunculated atheroma is an important risk factor for stroke after operations that require cannulating and clamping the ascending aorta or aortic arch\(^{214,24,91,92}\) (Fig. 26-4). Severe arteriosclerosis of the ascending aorta, aortic arch, and descending thoracic aorta is also an important cause of embolic stroke and embolization to the abdominal organs and lower extremities in patients who do not undergo cardiac or thoracic surgical procedures.\(^{49,93}\) In some situations, the latter condition is amenable to surgical treatment.\(^{233,98,332}\)

**Prevalence**

During the first half of the 20th century, thoracic aneurysms were far more common than abdominal aneurysms because of the predominance of syphilitic aneurysms. In 1952, the ratio of thoracic to abdominal aortic aneurysms was 2:1 in autopsy studies.\(^{315}\) By 1964, this ratio had declined to less than 1:1, primarily as a result of the decline in syphilitic aneurysms.\(^{46}\) In a study from England and Wales that examined mortality statistics, the number of deaths resulting from thoracic aneurysms increased 17% between 1974 and 1984.\(^{55}\) This increase was substantially less than that for abdominal aneurysms (53%).

Prevalence of thoracic and thoracoabdominal aortic aneurysms is difficult to determine because of underreporting of these aneurysms in mortality statistics.\(^{63}\) Between 1958 and 1985 in Malmo, Sweden, which has a stable urban population and an autopsy prevalence of 83%, thoracic aortic aneurysms were found in 489 per 100,000 autopsies in men and 437 per 100,000 autopsies in women.\(^{823}\) Prevalence of asymptomatic thoracic aneurysms was about 400 per 100,000 autopsies in 65-year-olds and about 670 per 100,000 autopsies in 80-year-olds. In a study by Bickerstaff and colleagues in Rochester, Minnesota, the prevalence of thoracic aneurysms between 1951 and 1980 was 5.9 per 100,000 population per year.\(^{811}\) In a subsequent study from the same institution, prevalence of thoracic aneurysms between 1980 and 1994 had increased to 10.4 per 100,000 population per year.\(^{316}\) A study of the entire population of Sweden by Olsson and colleagues\(^{37}\) from 1987 to 2002 found the prevalence of thoracic aortic disease (nonruptured or ruptured thoracic aneurysm, acute or chronic aortic dissection) to be 10.7 per
100,000 per year for men and 7.1 per 100,000 per year for women in 1987. By 2002, the prevalence had increased to 16.3 per 100,000 per year for men and 9.1 per 100,000 per year for women. The number of operations on the thoracic aorta increased sevenfold over this interval for men and 15-fold for women.

Penetrating arteriosclerotic ulcer and intramural aortic hematoma without an intimal tear are being diagnosed with increasing frequency, primarily because of aging of the population and more frequent use of imaging techniques such as computed tomography (CT) and magnetic resonance imaging (MRI). Among older patients who undergo cardiac surgical procedures, moderate or severe arteriosclerosis of the ascending aorta and aortic arch is present in approximately 15% to 20% of those older than 50 years and 33% of those 80 years of age or older.\textsuperscript{92}

**Location**

The true anatomic distribution of thoracic aortic aneurysms is not known with certainty. In 72 individuals with aneurysms, Bickerstaff and colleagues found that 37 (51%) involved the ascending aorta, 8 (11%) the aortic arch, and 27 (38%) the descending thoracic aorta.\textsuperscript{811} The cause was aortic dissection in 53%, degenerative disease in 29%, aortitis in 8%, cystic medial necrosis in 6%, and syphilis in 4%. Svensjo and colleagues found that thoracoabdominal aneurysms made up 5% of asymptomatic thoracic aneurysms.\textsuperscript{823}

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

**Symptoms**

Many patients with thoracic aortic aneurysms are asymptomatic at presentation, and the aneurysms are detected during testing for other disorders. Symptoms relating to the aneurysm usually develop later in the course of enlargement of the aorta and result from impingement of the aneurysm on
adjacent structures. Patients with aneurysms involving the ascending aorta associated with dilatation of the aortic anulus frequently present with symptoms referable to the aortic regurgitation that develops as a result of progressive aortic enlargement. Patients with aneurysms of the aortic arch may present with pain in the neck and jaw. Hoarseness results from stretching of the left recurrent laryngeal nerve, stridor from compression of the trachea, dysphagia from impingement on the lumen of the esophagus, dyspnea from compression of the lung parenchyma, and plethora and edema from compression of the superior vena cava. Patients with aneurysms of the descending thoracic aorta may report pain in the interscapular area or left-sided pleuritic pain. Aneurysms of the thoracoabdominal aorta may be associated with back pain, abdominal pain, and pain in the left shoulder resulting from irritation of the left hemidiaphragm.

Acute onset of severe pain in the anterior part of the chest or neck or between the shoulders is the typical presenting symptom of acute aortic dissection, although it may occur with rupture or sudden expansion of a chronic dissecting or nondissecting aneurysm (see Chapter 25). Acute chest pain may also result from a nondissecting intramural hematoma of the aorta or erosion of a penetrating arteriosclerotic ulcer into the surrounding tissues. Stroke or evidence of ischemia of the kidneys, abdominal viscera, and lower extremities may result from embolization of atheroma or thrombus from a severely arteriosclerotic aorta.

Signs
Direct physical signs of the presence of a thoracic aortic aneurysm are uncommon. In earlier times, a pulsating mass of the anterior chest was the first evidence of a syphilitic aneurysm of the ascending aorta; rarely, such an aneurysm eroded the sternum and ruptured, resulting in fatal hemorrhage. Signs of aortic regurgitation (bounding peripheral pulses, an aortic diastolic murmur) may be present in patients with large ascending aortic aneurysms that involve the aortic sinuses. A pulsatile mass in the upper abdomen may be present in patients with thoracoabdominal aortic aneurysms. Evidence for embolization of atheroma or thrombus from an aneurysm or from a severely arteriosclerotic aorta to the lower extremities (blue toe syndrome) may occasionally be the first indication of severe aortic disease.

Diagnostic Techniques
Chest Radiography
Findings on the chest radiograph may be diagnostic of a thoracic aortic aneurysm. Ascending aortic aneurysms produce a convex shadow to the right of the cardiac silhouette (Fig. 26-5), those of the arch an anterior and left-sided shadow (Fig. 26-6), and those of the descending aorta a shadow to the left and posteriorly (Fig. 26-7). However, approximately 17% of patients with documented aneurysms or dissections have no abnormalities on chest radiography.\(^{K3}\) Pooling data place the sensitivity of detecting a widened mediastinum or abnormal aortic contour in patients with aortic dissection at 64% and 71%, respectively.\(^ {K3}\) Substantial enlargement of the ascending aorta may be confined to the retrosternal area, so that the aortic silhouette appears normal. Aneurysms that involve the ascending aorta and aortic arch cannot always be differentiated from tumors or other masses.\(^ {C11,E1}\)

Computed Tomography
CT is the most widely used noninvasive technique for diagnosing thoracic aortic disease. It provides information about size, location, and extent of disease (Fig. 26-8). It is of particular value in documenting the growth rate of aneurysms, determining timing of operative intervention in asymptomatic patients, and evaluating patients postoperatively.\(^ {D5,G14,H11,T3}\) It is useful in identifying anatomic variants and branch vessel involvement, and provides three-dimensional (3D) data (Fig. 26-9). Because approximately 25% of patients have aneurysms in more than one area of the aorta, both the thoracic and the abdominal aorta should be examined.\(^ {B1,P10}\) CT is also useful for detecting intramural hematoma (see Fig. 26-2) and penetrating arteriosclerotic ulcers, and for determining severity and extent of thickening of the aortic wall in patients with severe aortic arteriosclerosis.\(^ {L11,C20,L14,N6}\) It is of particular value in diagnosing thoracic aortic dissection.\(^ {C37,P7}\) The principal disadvantage of CT is that it requires use of contrast medium for precise delineation of aortic disease, which may be contraindicated in patients with allergies to contrast agents or with renal insufficiency.

Radiation-induced malignancy in patients with thoracic aortic disease who require periodic CT imaging is a concern. Techniques to reduce radiation exposure (e.g., appropriate shielding, radiation dose reduction and management, algorithms to improve system efficiency) have been implemented to minimize this risk.\(^ {M10}\)

Magnetic Resonance Imaging
MRI is emerging as a premier imaging method for diagnosing diseases of the thoracic and thoracoabdominal aorta.\(^ {L11,M17}\) Standard techniques do not require contrast agents (Fig. 26-10, A). In certain applications, a single study can provide
information similar to that obtained from a combination of echocardiography, CT, and angiography. It provides excellent imaging of aortic dissections and can accurately identify thrombus formation and sites of entry.\textsuperscript{N4,N5} It can also differentiate periaortic hematoma from thrombosis of a false aneurysm. Breath-holding and 3D magnetic resonance angiography permit examination of the entire thoracic aorta, its major branches, the pericardium, the aortic valve, and the contractile pattern of the left ventricle.\textsuperscript{H5} Contrast-enhanced, time-resolved, 3D magnetic resonance angiography using agents such as gadolinium provide excellent images of the aorta and its major branches, comparable with those obtained by conventional aortography (Fig. 26-10, B).

Compared with CT, current disadvantages of MRI include a longer time to complete the study, greater cost, inaccessibility to patients who are connected to ventilators
and monitoring devices, contraindication in patients with metallic implants, pacemakers, and defibrillators, and limited availability. Use of MRI with a contrast agent (gadolinium compounds) is associated with a risk of nephrogenic systemic sclerosis.

**Transesophageal Echocardiography**

Transesophageal echocardiography (TEE) with Doppler color flow imaging is being used with increasing frequency for diagnosing thoracic aortic disease and caring for patients who undergo operations on the thoracic aorta. It is superior to transthoracic echocardiography for these purposes. It can be performed rapidly, with minimal morbidity, and has emerged as the most useful and accurate technique for diagnosing acute aortic dissection (see Chapter 25).

Before and during operations on the thoracic aorta, TEE is invaluable for assessing presence of arteriosclerosis, including mobile or pedunculated atheroma in the thoracic aorta, hemopericardium, malperfusion, competency of the aortic valve before CPB is established, and adequacy of reparative procedures on the valve. It also provides information about ventricular function and function of the mitral and tricuspid valves.

Disadvantages of TEE include lack of availability at small centers and during off hours, need for sedation, and occasionally endotracheal intubation.
Aortography
Aortography can be performed in patients who are to undergo elective operations on the thoracic aorta. It provides information about location of aneurysms, particularly in relation to major branches of the aorta in the chest and upper abdomen (Fig. 26-11). It also defines areas of relatively normal aorta proximal and distal to aneurysms. It can detect presence of aortic regurgitation. Selective injections of the coronary, brachiocephalic, visceral, and renal arteries provide important information that permits more accurate assessment of operative risk and may demonstrate need for modifications in operative technique.\(^{C8,3}\)

A disadvantage of aortography is that the size of large aneurysms may be underestimated because of the presence of thrombus. Other disadvantages include risk of allergic reactions after injection of contrast medium and risk of renal failure in patients with impaired renal function.\(^{N5}\) Multidetector CT has largely replaced angiography for anatomic studies that are required for treating and monitoring aortic disease.\(^{B5}\)

Epiaortic Ultrasonography
Intraoperative epiaortic ultrasound imaging of the ascending and descending thoracic aorta is useful for detecting arteriosclerosis. Presence of severe arteriosclerosis, including mobile or pedunculated atheroma, may necessitate alterations in surgical technique to avoid embolization of atheromatous debris to the brain and other organs during cardiac and thoracic aortic operations (see Fig. 26-4, A). Epiaortic imaging is more accurate than palpation of the aorta and, in comparative studies, more accurate than TEE for detecting atheromatous disease in the ascending aorta.\(^{D6, N8}\)

Preoperative Evaluation
Because myocardial infarction, respiratory failure, renal failure, and stroke are the principal causes of mortality and morbidity after operations on the thoracic aorta, preoperative assessment of the function of these organ systems is essential.\(^{K2,8,7, S7}\)

Cardiac Function
Because of the high prevalence of ischemic heart disease in older individuals, particularly those with degenerative aneurysms, assessment of cardiac function is necessary when elective operation is contemplated, especially for those with a history of myocardial infarction or angina pectoris and those older than 50 years. Patients with symptoms or electrocardiographic (ECG) changes indicative of myocardial ischemia should undergo stress testing and coronary angiography when indicated. Patients with valvar heart disease are evaluated with echocardiography and cardiac catheterization. Clinically important coronary artery disease should be treated with percutaneous catheter interventional techniques or bypass grafting, and valvar heart disease by valve repair or replacement before or, in some cases, at the time of the procedure on the thoracic aorta.

Pulmonary Function
History of smoking and presence of chronic pulmonary disease are important predictors of respiratory failure, and they are frequently present in patients who require operations on the descending thoracic and thoracoabdominal aorta.\(^{C2, K23, S7}\) Pulmonary function tests should be performed in patients with these risk factors. Spirometric tests and arterial blood gas analysis should be performed in patients with chronic pulmonary disease.\(^{C2}\) If reversible restrictive disease or excessive sputum production is present, antibiotics and bronchodilators should be administered preoperatively. Cessation of smoking is advisable.
Rupture is often preceded by symptoms. Bickerstaff and colleagues reported that once symptoms developed, the mean time to rupture was 2 years.111 Medical treatment is of limited value in managing thoracic aneurysms. Control of systemic hypertension, when present, is important to reduce wall stress even though no clear correlation between expansion rate of thoracic aneurysms and presence of hypertension has been demonstrated.154 Hypertension is a risk factor for aortic enlargement and need for reoperation after repair of type A aortic dissection, however.21 Administration of β-adrenergic blocking agents decreases progression of aortic dilatation in Marfan syndrome patients and may slow the rate of aortic dilatation in those with chronic aortic dissection in the absence of this syndrome.13 Angiotensin receptor blockers and angiotensin-converting enzyme inhibitors may slow the growth rate of aneurysms in patients with Marfan syndrome.226 Whether these agents can similarly affect other diseases of the aorta is unknown. Although statin therapy has been associated with decreased long-term mortality in patients with abdominal aortic aneurysms, no similar effect has been observed in patients with thoracic aneurysms.138 No prospective trials have demonstrated a beneficial effect of cessation of smoking on rates of progression of thoracic aortic disease.

Other Conditions

The natural history of penetrating arteriosclerotic ulcers is variable. In the largest reported series, the majority of ulcers detected by CT imaging were not associated with symptoms and remained stable or regressed.155,221 A small percentage progressively enlarged, with formation of saccular aneurysms. Intramural hematoma, dissection, embolization, and rupture can also occur.134,221

Intramural hematoma is a dynamic entity that may regress, expand, or progress to aortic dissection. Its natural history varies according to location of the hematoma in the thoracic

---

**Figure 26-12** Survival of patients with thoracic aortic aneurysms (TAA; n = 57), thoracoabdominal aortic aneurysms (T-AAA; n = 53), and abdominal aortic aneurysms (AAA; n = 60) who did not undergo operative treatment. (From Perko and colleagues.96)
aorta and geographic location. A higher prevalence of dissection and death has been observed among patients with hematomas in the ascending aorta and arch than in those with hematomas in the descending aorta.52,57,58 The experience from Asia suggests more frequent resolution of the hematomas with conservative management than that reported from Western countries.56

Patients with severe arteriosclerotic plaques (>4 mm in thickness) involving the ascending aorta and aortic arch have a high prevalence of atheromatous emboli in the cerebral circulation.81,14 These emboli are probably a major cause of cerebral infarction.10,18,14 Patients with severe ascending aortic arteriosclerosis are at risk for embolization and stroke after manipulation of the ascending aorta during coronary artery bypass grafting and other cardiac surgical procedures.14,75,91,92 When severe atheromatous disease is present in the distal aortic arch and descending thoracic aorta, embolization to the visceral, renal, and peripheral arteries may occur.

Among patients with the conditions just described, death due to coexisting cardiovascular disease is common.

**TECHNIQUE OF OPERATION**

**Preparations for Thoracic and Thoracoabdominal Aortic Surgery**

After anesthesia induction, venous access is obtained with a large-bore central catheter and several large peripheral catheters. A radial arterial catheter is inserted for monitoring blood pressure and withdrawing blood samples. This is placed in the left radial artery in patients with ascending aortic and proximal arch disease, and in the right radial artery in patients with descending thoracic or thoracoabdominal aortic disease. If chronic aortic dissection is present and the potential for malperfusion exists (see “Malperfusion Syndromes” under Special Situations and Controversies in Chapter 25), a second arterial catheter is placed in a femoral artery or the opposite radial artery. If entrance into the left chest after a median sternotomy is anticipated, or if a lateral thoracotomy or thoracoabdominal incision is used, a double-lumen endotracheal tube is inserted. Alternatively, an occlusive balloon can be placed through a single-lumen endotracheal tube. Leads II and V5 of the ECG are continuously monitored. A pulmonary artery catheter is placed to measure pulmonary artery pressure, oxygen saturation, and cardiac output. Thermistor probes are placed for measuring nasopharyngeal and bladder temperature. If an interval of hypothermic circulatory arrest is planned, electroencephalographic monitoring is also necessary, and monitoring of cerebral oxygen saturation is advisable. Cerebrospinal fluid drainage is performed in patients with extensive descending thoracic aortic disease and thoracoabdominal aneurysms.84 TEE is performed intraoperatively to assess function of the cardiac valves, size of the aorta, and type and extent of aortic disease, and to monitor myocardial function.82,83

**Ascending Aorta Replacement**

**Aneurysm**

The aneurysmal segment of the ascending aorta is excised and replaced with a tube graft. When the aortic valve is diseased and requires repair or replacement, the techniques are those described under Technique of Operation in Chapter 12. A full median sternotomy or a partial upper sternotomy is used. If the aneurysm does not involve the distal ascending aorta or proximal aortic arch, these sites can be used for cannulation (Fig. 26-13, A). If this is not possible, the common femoral artery or axillary artery may be used for arterial return from the pump-oxygenator.51 A single two-stage venous cannula is inserted into the right atrium. After CPB is established, a venting catheter is inserted through the right superior pulmonary vein, although this is not always necessary. A balloon-tipped catheter is inserted into the right atrium and positioned in the coronary sinus for delivery of retrograde cardioplegia (see Fig. 26-13, A). Moderate hemodilution (hematocrit 20%-30%) and moderate systemic hypothermia (28°C-32°C) are used.

A standard approach involves replacing the ascending aorta from the level of the aortic commissures to just proximal to the brachiocephalic artery. The aorta is clamped proximal to the origin of the brachiocephalic artery. Cardioplegic solution is administered into the aortic segment proximal to the aortic clamp if there is no aortic regurgitation. Alternatively, it can be infused directly into the coronary arteries after the aorta is incised (see Chapter 3).

The aorta is completely transected just proximal to the aortic clamp and just above the commissures of the aortic valve (Fig. 26-13, B). A collagen- or gelatin-impregnated (prepared) woven polyester tube graft of appropriate size is sutured to the distal aorta with a continuous 3-0 or 4-0 polypropylene suture incorporating a 4- to 5-mm strip of polytetrafluoroethylene (PTFE) felt (Fig. 26-13, C). Use of the PTFE felt is not essential, but is of value in minimizing blood loss when the aorta is thin. If aortic valve replacement or repair is necessary, this is performed (Fig. 26-13, D and E). The aortic graft is then cut to the appropriate length and sutured to the proximal aorta with a 3-0 or 4-0 polypropylene suture incorporating a strip of PTFE felt (Fig. 26-13, F). If there is appreciable cephalad displacement of the ostium of the right coronary artery, an opening is created in the graft with a wire cautery, the artery is detached from the aorta with a cuff of aortic tissue and sutured to the graft with a 4-0 or 5-0 polypropylene suture incorporating a small strip of PTFE felt.

As the proximal aortic suture line is being completed, suction on the intracardiac vent is discontinued, warm blood cardioplegic solution is administered through the coronary sinus catheter, and CPB flow is reduced to permit filling of the heart and the aortic graft with blood. The lungs are temporarily inflated to facilitate removal of air. A venting needle or catheter is inserted into the graft through a small stab incision and secured with a pledged suture and a tourniquet (Fig. 26-13, F). After the suture line is completed, controlled aortic root reperfusion can be performed (see “Methods of Myocardial Management during Cardiac Surgery” in Chapter 3). Standard de-airing procedures are carried out, CPB is discontinued, and the cannulae are removed (Fig. 26-13, G).

If coronary artery disease that requires bypass grafting is present, anastomoses of grafts to the coronary arteries are performed after infusion of cardioplegic solution. During rewarming, the proximal ends of the bypass grafts are sutured to the aortic graft with 5-0 or 6-0 polypropylene suture after openings in the graft are made with a wire cautery (Fig. 26-13, H).
Other Conditions
Penetrating arteriosclerotic ulcers that result in formation of saccular or fusiform aneurysms in the ascending aorta are treated by resecting the involved segment and replacing it with a polyester graft using the technique described in the preceding text. Managing patients with intramural hematoma involving the ascending aorta is similar to managing patients with ascending aortic dissection (see “Repair of Acute DeBakey Type I or II [Type A] Dissection” in Chapter 25). Severe diffuse arteriosclerosis or mobile atheroma involving the ascending aorta that is encountered during coronary artery bypass grafting or valve replacement can be managed by resection and graft replacement or by endarterectomy. Surgical management of mycotic aneurysms, false aneurysms, and infected grafts is discussed under Special Situations and Controversies later in this chapter.

Figure 26-13  Ascending aorta replacement. A, After cardiopulmonary bypass is established and venting and cardioplegia catheters have been inserted, aorta is clamped just proximal to origin of brachiocephalic artery. B, Aorta is transected just proximal to aortic clamp and just above commissures of aortic valve.
Alternative to Replacement

Resection of a portion of the dilated ascending aorta and closure of the aortotomy longitudinally, with or without external reinforcement (usually with a synthetic graft), is an alternative to resection and graft replacement when the aorta is less than 6 cm in diameter. Rupture of the aorta following aortoplasty has been reported both with and without external reinforcement. B4,D16,R4 Atrophy of the aortic wall beneath an external wrap has also been observed. B4,N1

Aortic Arch Replacement

Although aortic disease can be confined to the aortic arch (segment of the thoracic aorta that extends from the proximal origin of the brachiocephalic artery to the distal origin of the
left subclavian artery), most aneurysms in this area are associated with aneurysmal disease of the ascending aorta or the adjacent descending thoracic aorta. In rare circumstances, the aneurysm may be localized to a discrete area of the arch with a small opening into the aneurysm from the aortic lumen. Excising the aneurysm and closing the defect in the aortic wall with a synthetic patch may be possible.

Hypothermic circulatory arrest is the most widely used technique for protecting the brain during operations on the aortic arch. The technique is described in “Clinical Methodology of Hypothermic Circulatory Arrest” in Section IV of Chapter 2. Alternative techniques are discussed in “Brain Protection during Operations on the Aortic Arch” under Special Situations and Controversies later in this chapter.

Figure 26-13, cont’d  
E, Aortic valve is replaced when necessary with a mechanical or biological valve. F, Aortic graft is cut to appropriate length and sutured to proximal aorta with continuous 3-0 or 4-0 polypropylene suture incorporating a strip of PTFE felt.
Because of the increased risk of dislodging and embolizing atheromatous material from retrograde perfusion associated with femoral artery cannulation, axillary artery cannulation is used with increasing frequency for operations that involve the aortic arch. Alternative sites for establishing return of arterial blood from the pump-oxygenator include the ascending aorta, brachiocephalic artery, and carotid artery. Separate cannulae are placed in the superior and inferior venae cavae for venous return to the CPB circuit (Fig. 26-14, A). Cooling is initiated immediately after CPB is established, and a venting catheter is inserted into the left ventricle through the right superior pulmonary vein. A balloon-tipped catheter is inserted in the right atrium and positioned in the coronary sinus for delivery of retrograde cardioplegia. The superior vena cava is encircled with a tape that is secured around the cava and the cannula with a tourniquet (see Fig. 26-14, A). The ascending aorta is clamped if possible, and if the aortic valve is competent, cardioplegic solution is infused into the aortic root. If the aortic root is opened, cardioplegic solution can be infused directly into the coronary arteries. If coronary artery bypass grafting is required, anastomoses of grafts to the coronary arteries are performed during cooling.

Nasopharyngeal, bladder, and perfusate temperatures are continuously monitored. Temperature gradients between the water bath of the heat exchanger in the CPB circuit and the blood, and between the blood and the tissues, are maintained below 12°C. Hematocrit is maintained between 15% and 20%. During cooling, methylprednisolone (7 mg · kg⁻¹) and...
Figure 26-14  Partial replacement of aortic arch. A, After separate cannulation of superior and inferior venae cavae (SVC, IVC) and placement of venting and cardioplegia catheters, superior vena cava is encircled with a tape. Dashed line indicates line of incision in ascending aorta and aortic arch. B, If only proximal arch replacement is necessary, aorta is transected obliquely beneath brachiocephalic vessels. Dashed line indicates line of incision.

Continued
Prepared polyester graft is cut at appropriate angle with a wire cautery. If bevel of aorta is relatively short, graft is sutured to aorta so that it is aligned vertically with respect to aortic arch, using 3-0 or 4-0 polypropylene suture incorporating a strip of polytetrafluoroethylene felt. If aortic bevel is long, graft is beveled in reverse direction and sutured to aorta in a more horizontal position (inset).

Figure 26-14, cont'd

Thiopental (10-15 mg · kg$^{-1}$) are administered to enhance the neuroprotective effect of hypothermia.$^{12,12}$ Mannitol (0.3-0.4 g · kg$^{-1}$) and furosemide (20-60 mg) are infused to preserve renal function.$^{35}$

Continuous electroencephalographic monitoring is used, and the head is packed in ice. Because hyperglycemia is associated with an increased prevalence of central nervous system dysfunction following hypothermic circulatory arrest, blood glucose levels are monitored, and insulin is administered intravenously to maintain the blood glucose level below 140 mg · dL$^{-1}$.$^{18}$

When nasopharyngeal temperature reaches 12°C to 14°C, bladder temperature reaches 15°C to 18°C, and the electroencephalogram becomes isoelectric, circulatory arrest can be
The patient is placed in Trendelenburg position, the superior vena caval cannula is occluded (to distend the venous system of the upper body so that air will not be sucked into the brachiocephalic arteries when the aorta is opened), and perfusion from the CPB circuit is discontinued. From 20% to 25% of the patient’s calculated blood volume is withdrawn from the venous line into the reservoir of the oxygenator. The clamp is removed from the ascending aorta. If hypothermic circulatory arrest is the sole means of brain protection (in addition to the agents noted previously), no clamps are placed on the distal aorta or brachiocephalic arteries.

After circulatory arrest is established, the ascending aorta is opened (dashed line, Fig. 26-14, A) and the incision is extended beneath the brachiocephalic arteries. The extent of aortic disease is assessed (Fig. 26-14, B). Aneurysms of the aortic arch vary in size and extent, and techniques of repair vary.

**Partial Arch Replacement**

If the aneurysm involves only the proximal portion of the arch (often the disease is contiguous with disease in the ascending aorta), a single anastomosis between the tube graft and the distal aorta can be performed by beveling the incision in the aorta beneath the brachiocephalic arteries (see Fig. 26-14, B). A prepared polyester graft of appropriate size is correspondingly beveled and sutured to the distal aorta with a continuous 3-0 or 4-0 polypropylene suture incorporating a 3- to 4-mm strip of PTFE felt (Fig. 26-14, C and D). As the suture line is being completed on the anterior aspect, a shunt from the arterial line of the perfusion circuit is opened to the venous line, the inferior vena caval cannula is occluded with a clamp, and cold (18°C-20°C) oxygenated blood is infused into the superior vena caval cannula at a flow rate of 350 to 500 mL · min⁻¹ (Fig. 26-14, E). The jugular venous pressure is monitored and should not exceed 30 to 35 mm Hg. Flow is continued until the suture line is completed. This maneuver removes air and particulate matter from the brachiocephalic arteries. Flow through the arterial line from the pump-oxygenator (femoral or axillary) is reestablished, and air is evacuated from the distal aorta. The aortic graft is gently massaged to facilitate evacuating any remaining air, a clamp is placed across the graft close to the brachiocephalic artery, and CPB is reestablished (Fig. 26-14, F). If the femoral artery has been cannulated, dislodging atheromatous debris into the lumen of the aorta is a concern. Therefore, a perfusion cannula is inserted into the aortic graft through a stab wound and secured, the arterial line from the pump-oxygenator is disconnected from the femoral artery cannula and connected to this cannula, air is evacuated from the graft, the clamp is applied, and flow is established in the antegrade direction. This maneuver substantially reduces the possibility of embolizing atheromatous debris into the brachiocephalic arteries and embolic stroke.

Rewarming is accomplished using temperature gradients of 12°C or less between the water bath of the heat exchanger and the blood, and between the blood and the tissues. The perfusate flow is gradually increased to a maximum of 2.4 to 2.6 L · min⁻¹ · m⁻². During rewarming, the aortic graft is anastomosed to the proximal ascending aorta. If aortic valve or aortic root replacement is required, it is performed at this time (see Fig. 26-13, D and E). If coronary artery bypass grafting has been performed, the grafts are sutured to the aortic graft (see Fig. 26-13, H). Procedures for evacuating air and reperfusing the myocardium are identical to those described previously under “Ascending Aorta Replacement.” When bladder temperature reaches 36°C, CPB is discontinued and the cannulae are removed.

**Total Arch Replacement**

If the aneurysm involves the entire aortic arch, the aorta is completely transected distal to the left subclavian artery. During cooling, the left phrenic and left vagus nerves are identified and protected by gentle dissection away from the anterior and posterior surface of the aorta. A prepared polyester graft is sutured to the ascending aorta with a 3-0 or 4-0 continuous polypropylene suture incorporating a strip of PTFE felt (Fig. 26-15, A). If chronic dissection is present, a portion of the septum between the true and false lumens of the descending thoracic aorta is excised and the graft sutured circumferentially to the outer wall of the aorta. This permits antegrade perfusion of both lumens. The origins of the

---

**Figure 26-14, cont’d**

**E.** Cold oxygenated blood from pump-oxygenator is infused into superior vena cava to remove air and particulate matter from brachiocephalic arteries. If femoral artery has been cannulated, flow from pump-oxygenator is also initiated to evacuate air from distal aorta. **F.** Aortic graft is clamped, and cardiopulmonary bypass is reestablished.
Figure 26-15  Total aortic arch replacement. A, After circulatory arrest is established, aorta is transected distal to left subclavian artery (LSA). Aortic graft is sutured to descending thoracic aorta (DTA) with continuous 3-0 or 4-0 polypropylene suture incorporating a strip of polytetrafluoroethylene (PTFE) felt. Origins of brachiocephalic arteries are separated from diseased aorta with a small cuff of aortic tissue. B, Aortic graft is placed under tension, and an oval segment is excised with a wire cautery. Graft is sutured to cuff of aorta with continuous 3-0 or 4-0 polypropylene suture incorporating a strip of PTFE felt. Alternatively, the three brachiocephalic arteries can be individually transected, and separate prepared polyester grafts can be sutured to the arteries and to openings in aortic graft (inset).
brachiocephalic arteries are separated from the aneurysm with a small cuff of aortic tissue (see Fig. 26-15, A). If the layers of the aorta are separated in this area as a result of dissection, they are approximated. The graft is placed under tension, and an oval segment corresponding to the size of the aortic cuff is excised with a wire cautery. The graft is sutured to the cuff of aorta with a continuous 3-0 or 4-0 polypropylene suture incorporating a strip of PTFE felt (Fig. 26-15, B). Alternatively, the three brachiocephalic arteries can be individually transected, and separate polyester grafts can be sutured to these arteries and to openings in the aortic graft (see Fig. 26-15, B [inset]). Commercially prepared aortic grafts containing presewn branches are available and eliminate the need for the graft-to-graft anastomoses shown in the Fig. 26-15 inset. As the single suture line or the last branch anastomosis is being completed, retrograde brain perfusion is initiated, and the procedure is completed as described in the preceding text on partial arch replacement (Fig. 26-15, C-D).

If a prolonged period of circulatory arrest is contemplated, the brachiocephalic arteries can be perfused directly or they can be separately clamped, with perfusion of the brain occurring from the cannulated axillary artery (see “Antegrade Brain Perfusion” under Special Situations and Controversies later in this chapter).

**Elephant Trunk Technique**

When the aneurysm involves more than just the very proximal descending thoracic aorta, a two-stage procedure may be considered. Borst and colleagues introduced a useful technique for performing the first stage, the “elephant trunk” procedure. An important modification was introduced by Crawford and colleagues, whose technique is shown in Fig. 26-16. After establishing hypothermic circulatory arrest, the aorta is completely transected just beyond the origin of the left subclavian artery, and a cuff of aorta is fashioned around the brachiocephalic arteries (Fig. 26-16, A). The left phrenic and left vagus nerves are identified and protected. A polyester tube graft slightly smaller in diameter than the transected aorta is selected. Its length should be 5 to 8 cm (the length of the segment that will be positioned in the descending thoracic aorta) plus an amount sufficient for attachment to the aortic arch and to part or all of the ascending aorta. A stay suture is placed at the proximal (ascending aortic) end of the graft and secured with a clamp (Fig. 26-16, B). The proximal end of the graft is then inverted into the distal 5- to 8-cm segment that will be positioned in the descending thoracic aorta (see Fig. 26-16, B). The entire graft is inserted into the descending thoracic aorta (Fig. 26-16, C). The stay suture permits easy withdrawal of the inverted segment after anastomosis of the graft to the transected aorta is completed. If chronic dissection is present in the descending thoracic aorta, the septum between the true and false lumens is excised to permit full expansion of the segment of graft that will remain in the descending thoracic aorta. This segment of graft is kept relatively short to avoid compromising the lower intercostal arteries and development of paraplegia or paraparesis. The aorta is sutured to the double-layer edge of the aortic graft with a continuous 3-0 polypropylene suture. If the aorta is thin or dissected, this suture line can be reinforced with a strip of PTFE felt placed around the outside of the aorta (see Fig. 26-16, C). The invaginated portion of the graft is then...
withdrawn from the descending thoracic aorta by traction on the stay suture (Fig. 26-16, D). The procedure is then completed as just described under “Total Arch Replacement.” It is essential that aortic flow be reestablished in the antegrade direction following the interval of circulatory arrest to avoid malperfusion of the brachiocephalic and coronary arteries. This can result from resumption of retrograde aortic flow from the femoral artery cannula and compression of the elephant trunk. For this reason, an aortic cannula is inserted into the aortic graft beneath the anastomosis to the brachiocephalic arteries and connected to the arterial line of the pump-oxygenator. Alternatively, an 8- or 10-mm prepared graft can be sutured to the aortic graft and connected to the arterial line. Use of the right axillary artery for arterial return obviates the need for these maneuvers.

Arch First Technique
In some situations, a staged procedure may not be feasible or safe. Extensive thoracic aortic disease, particularly when there is marked (>4.5 cm) dilatation of the aorta just distal
Entire graft is positioned into DTA, and aorta is sutured to doubled-over edge of aortic graft with continuous 3-0 polypropylene suture incorporating a strip of polytetrafluoroethylene felt. Invaginated portion of graft is then withdrawn from DTA by traction on stay suture. Procedure is completed as shown in Fig. 26-15, B through D. It is necessary, however, to reestablish aortic flow in antegrade direction to avoid compression of the elephant trunk and malperfusion of brachiocephalic and coronary arteries (see text).

Key: BR, Brachiocephalic artery; LCA, left carotid artery.
intercostal space, combined with anastomosis of the graft to the brachiocephalic arteries first, facilitates exposure and minimizes duration of circulatory arrest. This approach also permits satisfactory exposure of the aortic root and provides access to the mitral valve and coronary arteries.\(^{21,16,87}\) It may be of particular value in patients with chronic type A aortic dissection who require reoperation.\(^{21,22}\)

After inserting the appropriate monitoring devices and cannulae for vascular access and a double-lumen endotracheal tube, the patient is placed in the supine position with the left hemithorax rotated 20 to 30 degrees to the right. The right arm is secured around the head, and the left arm is positioned over the head (Fig. 26-17, A [inset]). Bilateral submammary anterior thoracotomy incisions are made in the fourth intercostal space, with the left incision extending laterally to the midaxillary line and the right to the anterior axillary line. The left lung is collapsed. Both internal thoracic vascular pedicles are ligated and divided, and the sternum is divided transversely. The pericardium is incised over the aorta and over the right atrium, but only enough to permit separate cannulation of the superior and inferior venae cavae, insertion of a venting catheter through the right superior pulmonary vein, and placement of a cannula in the coronary sinus for delivery of cardioplegic solution (see Fig. 26-17, A). A tape is placed around the superior vena cava. Arterial return is established through a common femoral artery or the right axillary artery.

CPB is established, and cooling is initiated. Exposure of the ascending aorta, aortic arch, and descending thoracic aorta is obtained. Left phrenic and left vagus nerves are identified and protected (Fig. 26-17, B). The left inferior pulmonary ligament is divided. When the heart fibrillates, the ascending aorta is clamped. If there is no aortic regurgitation, cardioplegic solution is administered through a needle into the aortic root at 12- to 15-minute intervals. If clamping of the aorta is not possible, retrograde cardioplegia is used; it is administered as soon as the ascending aorta is opened after circulatory arrest has been established, and every 12 to 15 minutes thereafter. This may be supplemented by direct perfusion of the coronary arteries. When coronary artery bypass grafting is required, distal anastomoses are performed during cooling. Aortic valve or aortic root replacement or reconstruction can be performed at this time, if indicated. Circulatory arrest is established when the appropriate temperatures are reached and the electroencephalogram becomes isoelectric (see “Aortic Arch Replacement”). The patient’s head is packed in ice and placed in a dependent position. The tape around the superior vena cava is secured, the superior vena cava cannula is clamped to distend the veins of the upper body and avoid suctioning of air into the opened aorta, and 20% to 25% of the calculated blood volume of the patient is drained from the inferior vena cava cannula into the venous reservoir of the bypass circuit. A clamp is placed on the distal descending thoracic aorta to minimize blood loss into the operative field when the aorta is opened and to permit perfusion of the lower body and lower intercostal arteries.

The ascending aorta is incised and transected proximally. Origins of the brachiocephalic arteries are separated from the aneurysm with a small cuff of aortic tissue. The descending aorta is incised distal to the arch (see Fig. 26-17, B). A prepared tube graft to which a 10-mm limb is attached is passed into the opened arch beneath the pedicle containing the left phrenic and vagus nerves, and into the opened descending aorta (Fig. 26-17, C). The 10-mm graft is positioned opposite the site where anastomosis of the aortic graft to the brachiocephalic arteries will be performed. An opening is made in the aortic graft with a wire cautery at the site of the arch vessels, and the cuff of aorta surrounding them is sutured to the graft (see Fig. 26-17, C). All aortic anastomoses are constructed with a continuous 3-0 or 4-0 polypropylene suture buttressed with a strip of PTFE felt.

As anastomosis to the arch vessels is being completed, cold (18°C-20°C) oxygenated blood is infused into the superior vena cava cannula to evacuate air and atheromatous debris (see “Partial Arch Replacement”). The aortic graft is clamped just distal to the arch anastomosis with a long, straight atraumatic vascular clamp, and the proximal portion of the graft is allowed to fill with blood. A second arterial line from the pump-oxygenator is attached to the 10-mm graft, and flow is initiated to evacuate air from the proximal segment of the graft. If the axillary artery was used for arterial return, flow is initiated through this vessel rather than the 10-mm graft. Retrograde perfusion through the superior vena cava cannula is discontinued, and the aortic graft is clamped proximal to the aortic arch with a large straight or angled vascular clamp. Antegrade perfusion into the brachiocephalic arteries is then established at a flow of 800 to 1200 mL · min\(^{-1}\) at a temperature of 20°C (Fig. 26-17, D).

An alternative technique involves use of a branched graft and separate suture of the three brachiocephalic arteries to branches of the graft (see Fig. 26-15, B [inset]). Right axillary artery perfusion is used, and after establishing circulatory arrest, the three arteries are transected at their origins from the aorta. They are flushed by a brief period of perfusion from the axillary artery to evacuate air and are occluded separately with clamps. Flow to the brain is established through the axillary artery (10-15 mL · kg\(^{-1}\) · min\(^{-1}\) at a temperature of 20°C to 22°C. The brachiocephalic arteries are then sequentially attached to the branches of the aortic graft, beginning with the left subclavian artery. When these anastomoses are completed, the aortic graft is clamped just distal to the left subclavian branch, the clamps on the brachiocephalic arteries are released, and after evacuation of air from the aortic graft, it is clamped just proximal to the brachiocephalic artery. Flow to the brain is then established in the antegrade direction through the three brachiocephalic arteries.

During hypothermic low flow to the upper body with either of the techniques described in the previous text, the distal clamp on the descending aorta is removed and the aorta is transected at the appropriate level (see Fig. 26-17, D). The aorta is beveled whenever possible to preserve the origins of the intercostal arteries below the sixth intercostal space. In the presence of chronic dissection, a large segment of the septum between the true and false lumens is removed to permit perfusion of both. The graft is cut to the appropriate length and sutured to the distal aorta (see Fig. 26-17, D and E). As this anastomosis is being completed, perfusion through the femoral arterial line (if present) is initiated to remove air and debris. After the anastomosis is completed, air is removed from the graft through several puncture holes created by an 18-gauge needle. The clamp on the aortic graft distal to the left subclavian artery is released, flow from the femoral arterial line is discontinued, and antegrade flow is established through the 10-mm graft or the axillary artery (see Fig. 26-17, E). Rewarming is begun at this time. The excluded, patent upper intercostal and bronchial arteries are ligated.
Figure 26-17  Arch first technique. A, [Inset] Patient is positioned supine with left chest elevated 20 to 30 degrees. Chest cavity is entered through a bilateral anterior thoracotomy incision in fourth intercostal space (dashed line). Bicaval cannulation is used, and superior vena cava (SVC) is encircled with a tape. Left phrenic and vagus nerves are mobilized and protected. B, After circulatory arrest is established, clamp is placed on proximal ascending aorta and distal descending aorta to minimize blood loss. Ascending aorta is incised and resected, and a cuff of aortic tissue containing brachiocephalic arteries is prepared.

Continued
Opening is made in aortic graft, and aortic tissue surrounding brachiocephalic arteries is sutured to graft with a continuous 3-0 or 4-0 polypropylene suture buttressed with a strip of polytetrafluoroethylene felt. A 10-mm prepared graft has been sutured to aortic graft opposite brachiocephalic arteries. After completing retrograde brain perfusion (see text) and evacuating air from brachiocephalic arteries and aortic graft, clamps are placed on graft just proximal and distal to arch anastomosis, and antegrade perfusion of arch vessels with cold blood is initiated. Clamp on distal descending aorta is removed, and open anastomosis of graft to distal descending aorta is performed.

The proximal end of the aortic graft is sutured to the ascending aorta or to an existing ascending aortic graft (see Fig. 26-17, E). Aortic valve or aortic root replacement, if indicated, can be completed during this time. If saphenous vein bypass grafts were placed, they are anastomosed to the aortic graft. The remaining clamp on the aortic graft is removed, and a needle vent is placed in the proximal portion of the graft and connected to suction. Procedures for reperfusion of the myocardium and evacuation of air are identical to those described under “Replacement of the Ascending
the top of the nonresected fifth rib. If the entire descending thoracic aorta is involved, a longer incision is made, curving slightly inferiorly at the anterior portion, and the pleural space is entered through the top of the nonresected sixth rib. Exposure can be enhanced by dividing the sixth rib or the fifth rib posteriorly. If the distal clamp must be placed at or near the diaphragm, a second entrance into the pleural space can be made through the top of the bed of the nonresected eighth rib. Alternatively, the costal margin can be divided. This will substantially enlarge the single opening into the chest, exposing the entire descending thoracic aorta.

The procedure varies according to location and extent of aortic disease. A limited dissection is performed around the aorta just proximal and distal to the diseased segment to permit placement of clamps. If the aortic disease begins at or
Figure 26-18 Descending thoracic aorta replacement. 

A, Patient is positioned in right lateral decubitus position with left hip rotated posteriorly to permit access to left femoral artery and vein. Left pleural space is entered through fourth or fifth intercostal space (dashed line). 

B, Left femoral artery (LFA) is cannulated. If femoral vein–to–femoral artery bypass is used, left femoral vein (LFV) is also cannulated. If left heart bypass is used, femoral artery and left atrial appendage or left inferior pulmonary vein are cannulated. Clamps are placed on aorta proximal and distal to site of entry into aneurysm. 

C, Aorta is opened between clamps and transected proximally (dashed line).
near the origin of the left subclavian artery, mobilizing the aortic arch between origins of the left common carotid and left subclavian arteries is required. The parietal pleura is incised between the left phrenic and left vagus nerves, and the aorta is isolated circumferentially. The left vagus and left recurrent laryngeal nerves are identified and protected. Access to the more proximal aorta can be improved by opening the pericardium, particularly if an aortic cannula is to be inserted proximal to the clamp site. Appropriate clamps are selected. The segment of aorta that is replaced should be no longer than necessary to avoid sacrificing patent intercostal arteries.

A suitable technique for protecting the spinal cord during aortic clamping is selected and implemented (see “Paraplegia after Aortic Clamping” under Special Situations and Controversies in Chapter 24). A prepared polyester tube graft of the proper size is chosen. The proximal aortic clamp and, when necessary, a left subclavian arterial clamp are placed (Fig. 26-18, B). When distal aortic perfusion is used, the distal aortic clamp is initially placed as close as possible to the
If intercostal arteries below sixth or seventh intercostal space are patent, they are excised from aorta along with a small cuff of aortic tissue, using a wire cautery (inset). Opening is made in graft, and aortic cuff is sutured to graft with continuous 3-0 or 4-0 polypropylene suture. Clamp on graft is repositioned below intercostal pedicle to permit perfusion of intercostal arteries. Graft is sutured to aorta with continuous 3-0 or 4-0 polypropylene suture buttressed with a strip of PTFE felt. Key: BR, Brachiocephalic artery; LCA, left carotid artery; LSA, left subclavian artery.

Figure 26-18, cont’d.
proximal clamp to permit perfusion of as many of the intercostal arteries as possible. The aorta is opened between the clamps and is transected proximally (Fig. 26-18, C). The patent intercostal and bronchial arteries in the aortic segment that will be excluded are ligated (Fig. 26-18, D). The graft is sutured to the proximal aorta with a continuous 3-0 or 4-0 polypropylene suture buttressed with a strip of PTFE felt. If the left subclavian artery has been occluded, the proximal aortic clamp is repositioned onto the aortic graft to permit early perfusion of the left subclavian artery (Fig. 26-18, E). After this anastomosis is completed, the distal clamp can be repositioned at a lower level if necessary, and the aorta opened longitudinally. Location and patency of intercostal arteries, particularly those below the sixth or seventh intercostal space, are determined. The distal aorta is transected obliquely whenever possible, to permit preservation of the lower patent intercostal arteries. The aortic graft is beveled appropriately and sutured to the aorta. If an oblique incision is not possible, the lower intercostal arteries are detached from the aorta with a small, full-thickness cuff of adjacent aorta using the electrocautery (Fig. 26-18, F). The aortic graft is stretched, and a segment opposite the intercostal artery pedicle is excised with a wire cautery. The aortic cuff is sutured to the graft with a continuous 3-0 or 4-0 polypropylene suture. The graft is flushed to remove air by removing the proximal clamp. This clamp is then repositioned below the pedicle to permit perfusion of the intercostal arteries (Fig. 26-18, G). The distal aorta is transected at the appropriate level, and the graft is sutured to the aorta with a continuous 3-0 or 4-0 polypropylene suture buttressed with a strip of PTFE felt. If distal perfusion is used, the distal aortic clamp is briefly removed to assist in evacuating air from the graft and to assess integrity of the anastomosis. Distal flow is then discontinued.

If partial or total CPB is used, it is discontinued, protamine is administered, and the central and peripheral cannulae are removed. Two intercostal drainage catheters are placed, one posteriorly and inferiorly and one anteriorly at the apex of the pleural cavity. The incision is closed.

If the location and severity of aortic disease are such that clamps cannot be safely placed on the aorta, particularly in the area of the distal aortic arch, the procedure is performed using hypothermic CPB and circulatory arrest without placing clamps on the proximal aorta (see “Technique Using Hypothermic Circulatory Arrest” in later text).

**Thoracoabdominal Aorta Replacement**

After standard preparations are completed, the patient is positioned in the right lateral decubitus position. The shoulders are positioned almost perpendicular to the operating table. The hips are rotated posteriorly at about 45 degrees from the table (Fig. 26-19, A). A thoracoabdominal incision is made, usually through the fifth or sixth intercostal space, entering the pleural cavity through the top of the bed of the lower rib. After dividing the costal margin, the incision is extended obliquely across the abdominal wall, and the muscles are divided to the level of the rectus abdominis fascia. The diaphragm is incised radially to the level of the aortic hiatus or circumferentially 2 to 3 cm from the chest wall. In some cases, it is possible to enlarge the aortic hiatus circumferentially and obtain sufficient exposure of the upper abdominal aorta so that division of the diaphragm is not necessary. The peritoneum is incised in the left gutter, and stomach, intestines, spleen, and left kidney are retracted anteriorly and to the right.

Because of the prevalence and clinical importance of paralysis of the lower extremities (paraplegia or paraparesis) following operations on the thoracoabdominal aorta, distal perfusion with some degree of systemic hypothermia (passive or induced), or regional hypothermia of the spinal cord induced by irrigation of the epidural space, is employed. Drainage of cerebrospinal fluid is also used (see “Paraplegia after Aortic Clamping” in Chapter 24).

**Technique Using Hypothermic Circulatory Arrest**

For purposes of illustration, the technique for thoracoabdominal aorta replacement using hypothermic CPB and circulatory arrest for protection of the spinal cord and the abdominal organs is shown in Fig. 26-19. The left common femoral artery and vein are exposed through an oblique or vertical incision in the groin crease. Heparin is administered, and a long 28F, 30F, or 32F cannula is inserted into the femoral vein over a guidewire system and positioned in the center of the right atrium. TEE is used to facilitate proper placement. With cannulae of these sizes and use of vacuum-assisted venous drainage, flows of 2.0 to 2.4 L · min⁻¹ · m⁻² can be easily achieved. If flow is limited, the pericardium is incised anterior and parallel to the left phrenic nerve and a second 28F or 30F angled cannula is inserted into the pulmonary trunk through a purse-string suture. The tip of the cannula is passed retrogradely through the pulmonary valve and positioned in the right ventricle. Unless there is severe atherosclerosis of the common femoral or external iliac artery, or if an abdominal aortic aneurysm is present, the femoral artery is cannulated with a 20F or 22F cannula. If this is not possible, the descending thoracic aorta, left subclavian artery, or left axillary artery can be used.

CPB is established immediately after the chest is entered, and perfusion cooling is initiated. Methylprednisolone (7 mg · kg⁻¹) and thiopental (10−15 mg · kg⁻¹) are administered to protect the central nervous system. No other adjuncts for spinal cord protection are used. During cooling, the abdominal portion of the incision is completed. The left lung is collapsed and gently retracted to minimize manipulation and injury. The left vagus and left recurrent laryngeal nerves are identified and protected. When the heart fibrillates, a venting catheter is inserted into the left inferior pulmonary vein for decompression (Fig. 26-19, B). If the vein is not accessible, the catheter is placed into the left ventricle through a stab wound near the apex. The aorta proximal to the diseased segment is not clamped, and no form of cardioplegia is used.

Preparations for circulatory arrest are made as described under “Aortic Arch Replacement.” Circulatory arrest is established after the patient is placed in Trendelenburg position and the venting catheter in the left heart has been occluded to prevent suction of air into the heart and proximal aorta. No clamps are placed on the proximal aorta. The aorta distal to the diseased segment is clamped. If a clamp cannot be safely placed on the distal aorta, it is opened and occluded with a balloon catheter. This is done to permit later perfusion of the iliac and hypogastric arteries, which may be important sources of blood flow to the lower spinal cord. The aorta is opened and transected proximal to the diseased segment (see Fig. 26-19, B). A prepared tube graft is selected and sutured to the proximal aorta with a continuous 3-0 or 4-0
Figure 26-19  Thoracoabdominal aorta replacement. A, Patient is positioned in right lateral decubitus position. Shoulders are positioned perpendicular to operating table, and hips rotated posteriorly to 45-degree angle. Left pleural space is entered through fifth or sixth intercostal space. Incision is extended obliquely across costal margin toward umbilicus (dashed line). Oblique muscles of abdomen are divided to level of rectus fascia, and peritoneal cavity is entered. Diaphragm is divided, peritoneum in left gutter is incised vertically, and abdominal viscera and left kidney are retracted anteriorly and to the right (see text). B, Technique employing hypothermic cardiopulmonary bypass and circulatory arrest. (See text for details.) Left femoral artery and vein (LFA, LFV) are cannulated, and a venting catheter is placed in left inferior pulmonary vein. After circulatory arrest is established, clamp is placed on lower thoracic aorta (if possible) to minimize blood loss. No clamps are placed on aorta proximal to diseased segment. Aorta is opened and transected proximally.

Polypropylene suture buttressed with a strip of PTFE felt (Fig. 26-19, C). When this anastomosis is completed, an aortic perfusion cannula or a 10-mm prepared polyester graft that has been attached to the aortic graft is connected to a second arterial line from the pump-oxygenator adjacent to the anastomosis. With the patient’s head in a dependent position, cold oxygenated (18°C-20°C) blood is infused retrogradely through the venous line until all air is evacuated from the brachiocephalic arteries and aortic arch. The aortic graft is clamped just distal to the proximal arterial line and flow into the upper and lower aorta (through the femoral artery) is established (Fig. 26-19, D). If the time of circulatory arrest is short (<20-25 minutes), it can be extended briefly so that the aorta can be widely opened to clearly identify patent lower intercostal and lumbar arteries and the origins of the visceral and renal arteries.

After flow through the upper and lower circuits has been established, 35% of the total arterial flow is directed through
C, Aortic graft, to which a 10-mm prepared polyester graft is attached, is sutured to aorta with continuous 3-0 or 4-0 polypropylene suture buttressed with a strip of polytetrafluoroethylene (PTFE) felt. Patent bronchial and intercostal arteries above sixth intercostal space are ligated. D, After evacuating air from circulation of upper body (see text), clamp is placed on graft just distal to the 10-mm graft, and flow into upper aorta is established. Lower aortic clamp is repositioned below segment of aorta to be resected, and flow into femoral arterial cannula is initiated.

Figure 26-19, cont’d  C, Aortic graft, to which a 10-mm prepared polyester graft is attached, is sutured to aorta with continuous 3-0 or 4-0 polypropylene suture buttressed with a strip of polytetrafluoroethylene (PTFE) felt. Continued

the upper arterial line and 65% through the lower line. The temperature of the perfusate is adjusted to maintain the nasopharyngeal temperature between 18°C and 20°C, and total flow is maintained between 750 and 1500 mL · min⁻¹ · m⁻². Drainage through the left heart vent is reestablished. During the period of hypothermic low flow, the intercostal and lumbar arteries that will be attached to the graft are isolated within a full-thickness cuff or cuffs of aorta that are excised from the diseased aortic segment with a cautery (Fig. 26-19, E). All patent intercostal and lumbar arteries below the sixth intercostal space should be attached to the graft if possible. A segment of graft opposite these arteries is excised with a wire cautery, and the rim of aortic tissue surrounding the arteries is sutured to the graft with a continuous 3-0 or 4-0 polypropylene suture (see Fig. 26-19, E and F). The aortic clamp is repositioned below the intercostal artery–to-graft anastomoses, air is evacuated from the graft with a needle vent, and flow to the intercostal arteries is established (see Fig. 26-19, F). Rewarming is begun at this time, and flow is gradually increased to the precooling level.

Anastomoses to the visceral and renal arteries are then completed. This can be accomplished using a cuff of aorta (see Fig. 26-19, F) or by suturing the arteries individually to the graft. Interposition of segments of polyester grafts between the aortic graft and these arteries may be necessary, particularly in patients with Marfan syndrome.¹²⁰,K¹² When these anastomoses are completed, the aortic clamp is repositioned below the level of the renal arteries, and anastomosis to the distal aorta is completed (Fig. 26-19, G).
With hypothermic low flow established above and below isolated aortic segment, intercostal and lumbar arteries that will be attached to graft are isolated with full-thickness cuff of aorta. This cuff is sutured to graft with continuous 3-0 or 4-0 polypropylene suture. Clamp on graft is repositioned below intercostal pedicle to permit perfusing intercostal arteries. Full-thickness cuff of aortic tissue surrounding celiac, superior mesenteric, and renal arteries is excised from aorta with a cautery, and cuff is sutured to graft with continuous 3-0 or 4-0 polypropylene suture. Clamp on graft is repositioned on aorta below renal arteries, and graft is sutured to distal aorta with 3-0 or 4-0 polypropylene suture buttressed with a strip of PTFE felt.

Figure 26-19, cont’d
During cooling, the heart spontaneously fibrillates and becomes quiescent; during rewarming, spontaneous defibrillation occurs in most patients when the nasopharyngeal temperature reaches 26°C to 28°C. The venting catheter is then removed. CPB is discontinued when the bladder temperature reaches 36°C. Peripheral cannulae are removed, protamine is administered, and hemostasis is obtained. A drain connected to suction is placed in the retroperitoneal space, and intercostal drainage catheters (two or three) are placed in the left pleural space. Edges of the divided diaphragm are approximated, and the incision is closed.

**Technique Using Left Heart Bypass**

A widely used alternative technique is left heart bypass (left atrium to left femoral artery) and mild (32°C–33°C) permissive hypothermia. The common femoral artery and the left atrium (or alternatively, the left inferior or superior pulmonary vein) are cannulated and partial cardiac bypass established using an in-line centrifugal pump. Bypass flows are adjusted to maintain a mean arterial pressure in the lower circulation of 60 to 70 mmHg while normal arterial pressure and central venous pressure are maintained in the upper circulation. Flows between 750 and 1500 mL · min⁻¹ · m⁻² are generally required. The aorta is clamped proximal to the diseased aortic segment, and a second clamp is placed on the descending aorta in the midportion. This maneuver maintains perfusion of the lower intercostal arteries, kidneys, abdominal organs, and lower extremities. As the operation proceeds, the distal aortic clamp is sequentially moved to lower positions to maintain distal perfusion. If distal clamping is not possible, separate balloon-tipped perfusion catheters can be introduced into the celiac, superior mesenteric, and renal arteries and connected to a cannula from the perfusion circuit to provide oxygenated blood to these organs. The procedure is then completed as shown in Fig. 26-19, E through G.

**SPECIAL FEATURES OF POSTOPERATIVE CARE**

Patients who have undergone thoracic or thoracoabdominal aorta replacement receive the same care given to patients after major cardiac operations (see Chapter 5). Particular attention is paid to maintaining adequate ventricular preload by volume infusions. Amount of chest drainage is closely monitored, and the usual rules for reentry (see “Treatment of Bleeding” in Chapter 5) are observed because major bleeding can occur, and it is a risk factor for developing other complications.

When the procedure has been performed through a left thoracotomy or thoracoabdominal incision, pulmonary complications are more likely to develop than after a median sternotomy. Thus, close attention to pulmonary subsystem management is mandatory (see Chapter 5 for details). Because renal blood flow is often reduced or absent for a time during and early after repair, renal function must also be carefully monitored early postoperatively. Managing renal dysfunction and renal failure is discussed in Chapter 5.

Although most patients in whom paraplegia or paraparesis develops after operations on the descending thoracic or thoracoabdominal aorta have evidence of ischemic injury upon awakening from anesthesia, this complication sometimes develops later postoperatively. Prompt initiation of cerebrospinal fluid drainage may, in some instances, reverse the neurologic deficit, and if a drain is not already in place, it should be inserted when signs of spinal cord ischemia develop postoperatively. Avoiding prolonged periods of hypotension is also essential to ensure optimal spinal cord perfusion.

Because additional aortic disease frequently develops in patients who have had operations on the thoracic aorta, perioperative evaluation is an important feature of their postoperative care. This should be performed at 4- to 6-month intervals in the first postoperative year, and semiannually or annually thereafter. Two-dimensional echocardiography is useful for examining the aortic root and proximal ascending aorta. CT or MRI is required to accurately assess the aortic arch and descending thoracic aorta. Ultrasonography can be used to evaluate the abdominal aorta.

**RESULTS**

**Survival**

**Early (Hospital) Death**

**Ascending Aorta**

Early (hospital) mortality after elective repair of chronic ascending aortic disease in heterogeneous groups of patients ranges from 0% to 9%. Most patients in these series had aneurysms of the ascending aorta resulting from aortic medial degenerative disease and had concomitant aortic valve replacement, either as a separate procedure or using a composite graft. These series also included patients with Marfan syndrome and patients who had partial resection of the aortic arch with hypothermic circulatory arrest. Use of hypothermic circulatory arrest is not a risk factor for increased mortality among such patients. Resection of the ascending aorta for severe diffuse arteriosclerosis or calcification, usually performed in conjunction with coronary artery bypass grafting or aortic valve replacement, is associated with higher early mortality and morbidity. These procedures usually require hypothermic circulatory arrest. Endarterectomy is preferred by some groups for managing the severely calcified ascending aorta and has similar early mortality.

**Aortic Arch**

Early mortality after elective repair of aortic disease that involves the arch is higher, ranging from 5% to about 20%. This is related in part to greater complexity of the operative procedures compared with operations on the ascending aorta, and to higher prevalence of neurologic injury, which is associated with increased mortality. In general, resection of the entire or distal aortic arch is associated with higher mortality than operations involving only the proximal aortic arch (Table 26-1).

Data from Svensson and colleagues. Key: CL, 70% confidence limits.
In all the mentioned categories, emergency operation for rupture or acute dissection is associated with substantially higher early mortality.

### Time-Related Survival

#### Ascending Aorta

Among heterogeneous groups of patients, survival after ascending aorta replacement, usually in combination with aortic valve replacement, is approximately 70% at 5 years and 50% to 60% at 10 years (Fig. 26-20). In a collaborative study from 10 centers, excellent results were obtained for patients with Marfan syndrome. Five-year survival for elective repair was 86%, and 10-year survival was 80% (Fig. 26-21). Survival was lower for patients who required urgent or emergency operation.

#### Thoracoabdominal Aorta

With increasing experience, and with use of adjuncts such as distal aortic perfusion and hypothermia, early mortality for elective operations is approximately 3% to 15% (Table 26-2).

#### Descending Thoracic Aorta

When aortic disease is confined to the descending thoracic aorta, early mortality for elective procedures with currently used techniques is 4% to 10% (Table 26-2).
employing hypothermic CPB and circulatory arrest in 151 patients, 5- and 10-year survival was 71% and 45%, respectively. Survival was less favorable for patients with degenerative aneurysms than for those with nondegenerative aneurysms (Fig. 26-26).

Thoracoabdominal Aorta In one of the largest series of patients with surgical repair of thoracoabdominal aortic disease ($n = 1509$) reported by Svensson and colleagues in 1993, $S_{27}$ survival was 60% at 5 years and 32% at 10 years (Fig. 26-27). In a series of 1220 patients treated more recently reported by Coselli and colleagues, $C_{35}$ survival was 74% at 5 years (Fig. 26-28). As noted previously with descending thoracic aortic aneurysms, survival among patients with degenerative thoracoabdominal aortic aneurysms was substantially lower than for those with nondegenerative aneurysms ($K_{33}$) (Fig. 26-29).

Modes of Death

Myocardial failure and infarction, hemorrhage, neurologic dysfunction, and multiple system organ failure are common
operation are due to rupture of an anastomotic false aneurysm.

Incremental Risk Factors for Premature Death after Repair

Patient-Specific Risk Factors

Location of aneurysm on the aortic arch or thoracoabdominal aorta poses greater risks for early death than location on the ascending or descending thoracic aorta. Among patients with thoracoabdominal aortic disease, operations for extent II disease as defined by Crawford and colleagues (Fig. 26-30) are associated with increased risk compared with extent I or III (see Tables 26-3 and 26-4). These risks are related importantly to brain and spinal cord ischemic injuries, which occur more often after operations in these regions. Improved techniques of brain and spinal cord protection may ultimately neutralize these risks.

Older age and coexisting coronary arterial, renal, and pulmonary disease are associated with increased early and late death. Emergency operation for rupture of a thoracic or thoracoabdominal aortic aneurysm increases risk.

Diagnostic and Procedural Risk Factors

Although improved outcomes in recent years can be attributed to changes in preoperative, intraoperative, and postoperative management, the specific improvements that are responsible are difficult to quantify. They include a clearer understanding of the natural history of diseases of the thoracic aorta, improved diagnostic studies, increased knowledge of the determinants of operative risk, and critical analyses of early and long-term results.

Improved techniques for brain protection have reduced the risk of operations on the aortic arch. Increased use of distal perfusion and other adjuncts has substantially reduced spinal cord ischemic injury and death after operations on the descending thoracic and thoracoabdominal aorta. Availability of prepared grafts that are impervious to blood and improved methods for minimizing intraoperative and postoperative blood loss have also contributed to the improved outcomes.

Institutional Risk Factors

In institutions properly prepared for complex aortic surgical procedures, risks of repair are lower than in other institutions.

Complications

Brain Injury

Brain injury is an important complication of operations on the thoracic aorta, particularly those that involve the aortic arch. In a study of 183 patients following operations on the thoracic aorta in which hypothermic circulatory arrest was used, Ergin and colleagues identified two types of neurologic injury: (1) temporary neurologic dysfunction (agitation, lethargy, obtundation, disorientation, psychosis, choreoathetoid movements, and seizures) and (2) stroke. Temporary neurologic dysfunction occurred in 19% of patients and was correlated with duration of circulatory arrest and older age. Stroke was attributed to embolism and occurred in 11% of patients. Strokes correlated with older age, operations on the aortic arch, and presence of descending thoracic

aneurysms that contained thrombus or atheroma. Improved methods of brain protection during operations on the aortic arch, including retrograde brain perfusion, avoidance of prolonged (>50-60 minutes) circulatory arrest, and antegrade cerebral perfusion are associated with lower occurrence of both temporary and permanent neurologic dysfunction.

Spinal Cord Injury
Paraplegia and paraparesis can occur after operations on the descending thoracic and thoracoabdominal aorta. Because of its clinical importance, preventing spinal cord ischemic injury is paramount (see “Paraplegia after Aortic Clamping” under Special Situations and Controversies in Chapter 24). Although considerable experience has been reported with the technique of simple aortic clamping, principally by Crawford and colleagues, there is emerging consensus that distal perfusion with some degree of systemic hypothermia (passive or induced), or regional hypothermia of the spinal cord induced by irrigation of the epidural space, reduces occurrence of spinal cord ischemic injury. Drainage of cerebrospinal fluid has also been associated with reduced occurrence of spinal cord ischemic injury.

Renal Dysfunction and Failure
Renal dysfunction can occur following operations on the descending thoracic and thoracoabdominal aorta. Because of variability of the criteria that are used to define it, the true prevalence is difficult to determine. Postoperative renal failure managed with dialysis occurs in 1% to 5% of patients having operations on the descending thoracic aorta and in 5% to 15% of those requiring replacement of the thoracoabdominal aorta. Preoperative renal dysfunction, as evidenced by elevated creatinine, is a predictor of postoperative renal failure when simple aortic clamping or normothermic distal perfusion is used for operations on the thoracoabdominal aorta.

Pulmonary Dysfunction
Pulmonary dysfunction of sufficient severity to require prolonged (>48-72 hours) mechanical ventilatory support occurs in 20% to 30% of patients undergoing repair of thoracic and thoracoabdominal aneurysms in which a lateral incision is used. Occurrence of this complication appears to be independent of operative technique (simple aortic clamping, distal perfusion, hypothermic circulatory arrest, epidural cooling). Incremental risk factors for prolonged ventilatory support after operations on the thoracoabdominal aorta include older age, division of the diaphragm, duration of aortic clamping, number of packed red blood cell units transfused, and current smoking.

Reoperation
Late reoperation is necessary in a substantial number of patients, particularly when there has been a previous aortic dissection or when Marfan syndrome is present. Thus, as in the case of acute aortic dissection (see Chapter 25), periodic evaluation with aortic imaging of patients following operations on the thoracic and thoracoabdominal aorta is essential.

INDICATIONS FOR OPERATION
Ascending Aorta
Patients with symptoms attributable to chronic aneurysm of the ascending aorta should, in general, have prompt surgical treatment whether the symptoms are from enlargement of
the aneurysm or from aortic valve regurgitation. Patients with cystic medial degenerative disease should undergo elective replacement of the ascending aorta and the aortic sinuses when the greatest diameter of the aorta exceeds 5.0 to 5.5 cm. If substantial aortic valve regurgitation is present, operation may be advisable before the aorta reaches this diameter. Surgical repair of the dilated aortic root or ascending aorta in patients with Marfan syndrome is usually performed at a threshold of 5.0 cm because of the greater tendency for aortic dissection at a smaller diameter. Rapid growth of the aneurysm (>0.5 cm · year⁻¹), family history of aortic dissection, and presence of moderate to severe aortic regurgitation are indications for operation at a smaller diameter. For patients with Loeps-Dietz syndrome or a confirmed TGFB1 or TGFB2 gene mutation, repair should be considered at a diameter of 4.4 to 4.6 cm as determined by CT or MRI. Asymptomatic patients with degenerative thoracic aneurysm, chronic aortic dissection, intramural hematoma, penetrating arteriosclerotic ulcer, and mycotic or false aneurysm with an aortic diameter of 5.5 cm or greater should be considered for surgical repair. Growth of 0.5 cm · year⁻¹ in aortas of smaller diameter is also an indication for repair. Patients who have dilatation of the ascending aorta in association with a congenitally bicuspid aortic valve and who require aortic valve replacement should have concomitant replacement of the ascending aorta when it measures more than 4.5 cm. These recommendations are based on evidence that combined operative and late mortality is less than mortality observed in patients managed without operation.

Aortic Arch

Patients who are symptomatic from chronic aneurysms that involve the aortic arch should, in most instances, undergo prompt surgical treatment, because the natural history of this condition is particularly unfavorable. Because of the complexity of operations that require replacement of the aortic arch and because neurologic complications are not uncommon (see “Brain Injury”), elective operation is generally advised only for aneurysms that are 5.5 to 6.0 cm in diameter or when there is documented progressive enlargement. Aneurysms of the aortic arch are often associated with aneurysmal disease of the ascending and descending thoracic aorta, and this may be the principal indication for operation.

Arteriosclerotic disease involves the aortic arch more frequently than other parts of the thoracic aorta. Because the presence of arteriosclerotic plaques with a thickness of more than 4 mm is an important predictor of brain infarction and because such plaques are also a source of embolization to other organs, graft replacement or endarterectomy of the involved segment of the arch should be considered when severe disease is detected in patients who are undergoing operations on the heart or ascending aorta. Occasionally, presence of pedunculated mobile atheroma in patients who have had a transient ischemic attack or stroke is an indication for operation.

Descending Thoracic and Thoracoabdominal Aorta

Patients with symptoms attributable to chronic aneurysms that involve the descending thoracic and thoracoabdominal aorta should, in general, have prompt operation, because rupture before operation substantially increases risk of the procedure (see “Incremental Risk Factors for Premature Death after Repair” under Results). The appearance of even mild symptoms, particularly in patients with thoracoabdominal aneurysms, may represent progression into a subacute phase that is associated with increased risk of rupture and higher operative mortality. Advising surgical treatment for asymptomatic patients with chronic descending or thoracoabdominal aortic aneurysms is less straightforward because of risks of stroke, spinal cord ischemic injury, renal failure, and a high prevalence of pulmonary complications postoperatively (see “Complications” under Results). Careful assessment of preoperative risk factors for death and for postoperative paralysis is essential before a recommendation for surgical intervention is made. These risk factors must be weighed against the probability of rupture of the aneurysm. In good-risk patients at experienced surgical centers, elective resection is advisable when the aneurysm exceeds 5.5 cm in the descending thoracic aorta and 6.0 cm in the thoracoabdominal aorta or when there is documented progressive enlargement. All asymptomatic patients in whom surgical treatment is deferred must have periodic follow-up, with determination of the size and extent of the aneurysm or other aortic disease by CT or MRI every 6 to 12 months, depending on the size of the aorta. In general, increase in size during the period of observation is a strong indication for surgical intervention.

Other Conditions

There is evidence from natural history studies to suggest that patients with chronic aneurysms resulting from type B aortic dissections are more likely to die of rupture of the aneurysm than patients with aneurysms not associated with dissection. In the study by Griep and colleagues, patients with rupture of chronically dissected aortas had significantly smaller maximal descending thoracic aortic diameters than patients with rupture of degenerative aneurysms. These observations indicate that a more aggressive surgical approach is indicated in patients with aneurysms associated with chronic type B dissection.

Patients with penetrating arteriosclerotic ulcers or intramural hematomas in whom symptoms and signs of impending rupture are present or in whom false aneurysms develop should undergo graft replacement of the involved segment of the aorta irrespective of size. Patients with severe arteriosclerosis and repeated episodes of embolization to the abdominal viscera, kidneys, or lower extremities should be considered for excision and graft replacement of the diseased aortic segment.

SPECIAL SITUATIONS AND CONTROVERSIES

Endovascular Grafts

Techniques have been developed for placing intraluminal stent-grafts into the descending thoracic aorta and aortic arch to treat patients with aortic aneurysms, dissections, intramural hematomas, penetrating arteriosclerotic ulcers, false aneurysm, and acute traumatic aortic disruption (see Chapter 24).
Descending Thoracic Aorta

Substantial experience has been accumulated with endovascular stent-grafts for aortic disease confined to the descending thoracic aorta. Availability of several commercially manufactured devices has facilitated implementation of this technology for a wide variety of conditions (Fig. 26-31).

Major requisites for graft placement are suitable landing zones proximal and distal to the diseased segment (1.5-2.0 cm in length), and diameters of these aortic segments greater than 20 mm and less than 40 mm. Possible deployment sites of the proximal end of endovascular grafts are shown in Fig. 26-32. There is emerging consensus that if coverage of the origin of the left subclavian artery is required, a left subclavian artery-to-left carotid artery bypass graft or transposition should be performed before deployment of the graft when feasible. Absence of revascularization of the left subclavian artery in this setting has been associated with a higher prevalence of left arm ischemia, vertebrobasilar ischemia, spinal cord ischemia, and anterior circulation stroke. Drainage of cerebrospinal fluid, when extensive coverage of the descending thoracic aorta is planned or when abdominal aortic aneurysm repair has been previously performed, is also advisable to reduce prevalence of spinal cord ischemic injury.

No randomized trials have compared endovascular treatment of descending thoracic aortic disease with open operation. Meta-analysis of large numbers of patients undergoing open or endovascular repair of isolated descending thoracic aortic disease has suggested lower (with endovascular repair) or comparable early (30-day or hospital) mortality. Patients treated with endovascular stent-grafts were generally older. Prevalence of postoperative complications in the aggregate was lower among these patients as well, and length of hospital stay was shorter. In the study by Gopaldas and colleagues of patients in the United States, hospital charges were substantially higher in the endovascular cohort, and the endovascular stent-graft patients were four times more likely to have a routine discharge to home.

There is no clear evidence from these and other studies demonstrating a substantial difference between the two methods of treatment in occurrence of postoperative stroke, spinal cord ischemic injury, or renal failure among patients with degenerative aneurysms or aortic dissection. Midterm survival of patients treated with the two techniques is comparable. Survival for the subset of patients with ruptured aneurysms is also comparable.

Complications unique to endovascular stent-grafting include endoleak, retrograde type A aortic dissection, aneurysm expansion and rupture, stent-graft collapse, graft migration, aortic valve perforation by a guidewire, dilatation of proximal and distal landing zones, injury to femoral and external iliac arteries, and erosion of the aorta resulting in aorto-bronchial or aortoesophageal fistulas. Periodic surveillance imaging studies are mandatory and add to overall cost of the procedure. Durability of the currently available devices beyond 10 years is unknown.

Endovascular stent-grafting should be considered for elderly patients with important comorbidity and limited life expectancy if the risk of intervention is judged to be lower than that for nonoperative or open surgical management. The precise role of endovascular stent-grafting in younger patients at lower risk for open operation remains incompletely defined.

Hybrid Operations

Aortic Arch

Hybrid procedures combining open surgical repair with endovascular grafting to treat aneurysmal disease involving the aortic arch and descending thoracic aorta include the “stented” or “frozen” elephant trunk technique and open debranching of the brachiocephalic arteries with repair of the aortic arch and descending thoracic aorta using a stent-graft (Fig. 26-34, A and B). The stented elephant trunk procedure was developed to eliminate the second stage of the conventional elephant trunk procedure or other procedures on the remaining thoracic aorta. To date, this objective has not been realized. The debranching procedure has been applied primarily to patients deemed to be at high risk for conventional aortic arch repair. Early results do not

Native aortic branches are ligated to prevent endoleak. Stent-graft can be deployed immediately after debranching or at a second procedure. (Modified from Hughes and colleagues.)
Brain Protection during Operations on the Aortic Arch

Early attempts to use temporary shunts to the brachiocephalic arteries during repair of aneurysms of the aortic arch are described under Historical Note in this chapter. By 1957, CPB was being used in some form for operations on the aortic arch, and this practice continues to this day. A small proportion of patients experience brain damage from CPB per se (see “Neurobehavioral and Neurologic Outcomes” under Results in Chapter 7, and see “Neuropsychological Subsystem” in Section I of Chapter 5) and from profound hypothermic circulatory arrest (see “Damage of Circulatory Arrest during Hypothermia” and “Safe Duration of Circulatory Arrest” in Section I of Chapter 2). However, prevalence of brain injury is greater after operations on the aortic arch than after other types of aortic or cardiac surgery. Brain injury is a frequent cause of death and complications after these operations and likely occurs as a result of embolization of particulate matter or severe global ischemia during the interval of circulatory arrest. Several methods are currently being used for protection of the brain during operations on the aortic arch.

Antegrade Brain Perfusion

During operations on the aortic arch, more or less continuous antegrade brain perfusion is possible only when two or more of the brachiocephalic arteries are separately perfused after the aortic arch has been opened. This technique was the first to be used for operations on the aortic arch, but survival was relatively low. Frist and colleagues perfused only one brachiocephalic artery, usually the trunk, and cannulated it directly. F7 Results with normothermic or mildly hypothermic brain perfusion were disappointing.

Crittenden and colleagues documented in a sheep model the clear superiority of antegrade brain perfusion over alternative methods of brain protection. They demonstrated that hypothermic, low-flow, antegrade brain perfusion preserved intracellular pH and energy stores. Bachet and colleagues and Kazui and colleagues have accumulated large series of patients in whom this technique has been used with satisfactory outcomes. B1,K7 Its advantage is that it allows an interval of safe, total body circulatory arrest because the brain is supplied with nutrients and oxygen during this period. The technique requires manipulation and direct cannulation of these arteries, with risk of dislodging arteriosclerotic debris and the potential for embolization of this material as well as air. In a study by Hagl and colleagues, this technique, compared with other methods of brain protection, was associated with the lowest prevalence of temporary neurologic dysfunction. H1 However, it may not be fully protective in patients who require antegrade perfusion for more than 80 minutes. H1

Although direct antegrade perfusion of all three brachiocephalic arteries is considered optimal, K7 substantial experience has been accumulated with perfusion of the brain only through the brachiocephalic or right axillary artery. F7,H2,J3,K16,K19,T4,T6 This technique eliminates need for direct cannulation and perfusion of the brachiocephalic arteries. Although concern has been expressed about inadequate perfusion of the left brain, K8 particularly in the absence of a complete circle of Willis, this has not proved to be an important problem. Perfusion at low temperature (20°C-25°C) likely contributes to the safety of this technique.

Hypothermic Circulatory Arrest

The simplest and currently the most widely used technique for brain protection during operations on the aortic arch is hypothermic circulatory arrest using CPB for cooling and rewarming of the patient (see “Replacement of Aortic Arch” for a description). A major advantage of this technique is its simplicity. It provides an operative field essentially free of blood and cannulae, and permits thorough inspection of the inside of the aorta and performance of secure distal aortic and arch anastomoses.

In carefully conducted clinical studies, neurologic complications are occasionally observed following use of hypothermic circulatory arrest for operations on the aortic arch in adults. B9 In addition to strokes, which are likely embolic in origin, temporary neurologic dysfunction occurs in approximately 20% of patients. Prevalence of temporary neurologic dysfunction increases with increasing age and with duration of circulatory arrest. B3,K9 Scrupulous implementation of techniques to ensure adequate cooling and rewarming of the brain is essential to minimize occurrence of this complication. B12 Because deterioration of cognitive function postoperatively occurs more often in patients with more than 25 minutes of hypothermic circulatory arrest, its safe duration in adults may be closer to 30 minutes rather than 40 to 50 minutes, as previously reported. D18,G12,S7 Recent studies in animals and humans suggest that cerebral metabolic suppression at clinical levels of hypothermia is less complete than had been previously assumed. G12,M11 Use of adjuncts such as retrograde brain perfusion (see “Retrograde Brain Perfusion” in text that follows) may increase the safe duration of hypothermic circulatory arrest beyond this limit and may reduce the prevalence of embolic stroke. C29,J9,K14,K22,K23

If hypothermic circulatory arrest is used for procedures that require a left thoracotomy, presence of severe aortic regurgitation may be a relative contraindication to its use because distention of the left ventricle may occur when the heart fibrillates. This may result in impaired subendocardial perfusion and ischemia of the left ventricle. If substantial aortic regurgitation is known to be present preoperatively and the procedure to be performed on the aorta is elective, the aortic valve should be replaced, and the procedure on the aorta should be performed 3 to 6 weeks later. If aortic regurgitation is not detected until time of the operation, an alternative technique should be used.

Retrograde Brain Perfusion

Protection of the brain during operations on the aortic arch by perfusing cold oxygenated blood into the superior vena
cava was first reported by Ueda and colleagues. This technique offers the potential advantages of delivering nutrients to the brain during an interval of hypothermic circulatory arrest and removing embolic material from the arterial circulation of the brain. Subsequent studies in animals have demonstrated that little or no effective blood flow occurs during retrograde perfusion, even with occlusion of the superior vena cava, to confer any meaningful metabolic benefit. Retrograde perfusion is, however, an effective method for washout of particulate emboli from the brain. Thus, its principal role is as an adjunct rather than as a primary technique for brain protection during hypothermic circulatory arrest.

False Aneurysms

False aneurysms are infrequent but serious complications after operations on the thoracic aorta and following infection or trauma. Their true prevalence after thoracic aortic procedures is unknown, but systematic surveillance suggests that false aneurysms may be present in up to 13% of patients after graft replacement of the ascending aorta for aneurysm or dissection. They have been observed in up to 7% of patients following operations on the descending thoracic and thoracoabdominal aorta and occur primarily at sites of attachment of intercostal, visceral, and renal arteries to the aortic grafts. Infection of grafts, with or without associated mediastinitis, progressive degeneration of the aortic wall, aortic dissection, and use of biological glue have been implicated as etiologic factors. Aneurysms have also occurred at aortic suture lines, sites of aortic cannulation and clamping, and sites of attachment of coronary arteries with buttons of aortic tissue and coronary artery bypass grafts.

Surgical treatment includes direct repair, resection, and graft replacement of the sites of the false aneurysm with synthetic or biological grafts, patch repair, and endovascular stent-graft repair. CPB is almost always necessary, and hypothermic circulatory arrest has been required in up to 60% of patients. In several large series, operative mortality did not exceed 10%, 5-year survival ranged from 74% to 79%, and freedom from reoperation at 5 years ranged from 72% to 77%.

Infected Aneurysms

Because infected (mycotic) aneurysms may be multifocal, the entire aorta should be evaluated. Because of the high probability of rupture, surgical treatment should not be delayed in an attempt to control the infection with antibiotic therapy.

Excision of the infected aortic segment is required to control sepsis and prevent rupture. The aorta can be replaced with an aortic allograft, autologous or heterologous pericardium, or a polyester graft. Aortic root allografts may be particularly advantageous for infections that involve the aortic root. Encouraging results have been reported with these techniques, with early survival exceeding 85%. Lifetime oral antibiotic therapy is recommended to prevent recurrence of infection.

Infected Aortic Grafts

Graft infections occur in 1% to 2% of patients who have undergone replacement of the thoracic aorta. Infection may appear at any time, but peak occurrence appears to be in the first month after operation. Important risk factors for infection include inadequate sterile technique, excessive transfusion of blood products, bacteremia, and reoperation. Grafts that are placed in the ascending aorta or aortic arch are particularly vulnerable because of the absence of muscle between the graft and the sternum and subcutaneous tissues. In the experience with infected aortic grafts reported by Coselli and colleagues, 33% of patients had a wound infection or sternal dehiscence, 27% had previous cardiac procedures, 17% had a distant infection, and 10% had delayed closure of their sternal wounds. Fifty-eight percent of the infectious organisms were gram-positive (primarily staphylococcal species), 23% were gram-negative, and 2% were fungal. No organisms were isolated in some patients despite local signs of infection.

Infected prosthetic grafts is usually associated with signs and symptoms of systemic infection. CT scanning may demonstrate pockets of air or air-fluid levels adjacent to the graft. MRI with gallium- or indium-labeled leukocytes or with indium immunoglobulin scintigraphy may be helpful. TEE may demonstrate false aneurysm formation. Diagnosis of graft infection is often based on a combination of bacteriologic and radiographic findings and a high index of suspicion.

Modern surgical principles for treating infected aortic grafts were described by Hargrove and Edmunds in 1984. They include prompt reoperation and débridement of all infected tissue, removal of infected prosthetic material if suture lines are involved (this may not always be possible), local antisepctic irrigation and systemic antibiotics, and use of pedicle flaps of muscle or omentum to cover the grafts. Extraanatomic rerouting of arterial blood flow is not practical in most cases of thoracic aortic graft infection. Omentum is the pedicle graft of choice for treating an infected ascending aortic graft. It is pliable, fills dead space well, and usually provides ample coverage. In addition, it absorbs fluid, secretes angiogenic factors, and results in no loss of function compared with muscle flaps.

Several groups have reported success using these methods. In a series of 40 patients reported by Coselli and colleagues, 70% were hospital survivors and were alive 4 months to 6.5 years postoperatively. Patients received 6 to 8 weeks of intravenous antibiotics followed by lifelong oral antibiotic therapy.

Ringed Intraluminal and Patch Grafts

Ringed sutureless intraluminal prostheses that are anchored to the aorta by tapes placed around them and tied tightly over rigid spools at each end of the graft have been successfully used to replace segments of the ascending and descending thoracic aorta. Potential advantages of this technique compared with conventional suture anastomotic technique include reduced aortic clamp time and blood loss. Erosion of the aortic wall at the site of the tapes, obstruction to flow from buckling or kinking of the prosthesis or from use of a small prosthesis, and hemolysis and anemia are complications of this technique that limit its usefulness.
Patch grafts rather than tube grafts can be used to treat saccular aneurysms located on the undersurface of the aortic arch and in the descending thoracic aorta when they have a small, discrete communication with the aortic lumen. However, the adjacent aorta is often abnormal and unsuitable for safe placement of sutures. This technique should be used only when the adjacent aorta is normal in appearance and thickness.

In this chapter, five diseases involving the pulmonary arteries that are amenable to surgical treatment are discussed: acute massive pulmonary embolism, chronic pulmonary thromboembolic disease, pulmonary artery aneurysm, pulmonary artery dissection, and pulmonary artery tumors.

**Section I: Acute Massive Pulmonary Embolism**

**DEFINITION**

Acute massive pulmonary embolism is sudden entrapment in pulmonary arteries of dislodged thrombus, usually from deep veins of the legs, pelvis, or arms. It is life threatening and can result in right heart failure, low cardiac output, and sudden death.

**HISTORICAL NOTE**

The first pulmonary embolectomy was performed by Trendelenburg in 1908, but long-term survival using his technique was not achieved until 1924. It is prophetic and of great significance that Dr. John Gibbon, who in 1953 performed the first successful operation in which a patient was totally supported by cardiopulmonary bypass (CPB) using a pump-oxygenator, envisaged use of CPB to treat massive pulmonary embolism. In 1931, while working as a research fellow for Dr. Edward Churchill, he wrote the following words in a patient’s chart at Massachusetts General Hospital:
During that long night’s vigil, watching the patient struggling for life, the thought naturally occurred to me that the patient’s life might be saved if some of the blue blood in her veins could be continuously withdrawn into an extracorporeal blood circuit, exposed to an atmosphere of oxygen, and then returned to the patient by way of a systemic artery in a central direction. Thus, some of the patient’s cardiorespiratory functions might be temporarily performed by the extracorporeal blood circuit while the massive embolism was surgically removed.\textsuperscript{K3}

The first successful pulmonary embolectomies performed with use of CPB were reported by Cooley and colleagues in 1961 and by Sharp in 1962.\textsuperscript{C11,S5} This remains the preferred technique for surgical treatment of acute massive pulmonary embolism.\textsuperscript{S3}

**MORPHOLOGY**

Detached venous thrombi pass through the right heart and enter the pulmonary arteries as a single thrombus or as fragmented smaller thrombi. The majority lodge in the lower lobes, slightly more often in the right than left lung.\textsuperscript{G8} Shortly after reaching the lungs, emboli become coated with a layer of platelets and thrombin.\textsuperscript{G8} Pulmonary arterial obstruction and release by platelets of vasoactive agents such as serotonin, adenosine diphosphate, platelet-derived growth factor, and thromboxane elevate pulmonary vascular resistance (Rp).\textsuperscript{M2} Alveolar dead space increases as a result of redistribution of blood flow, and gas exchange is impaired. As right ventricular (RV) afterload increases, RV pressure rises. This may result in RV dilatation, ischemia, and dysfunction. Increased Rp results in reduced RV stroke volume and left ventricular filling (preload). Reduction in preload and coronary blood flow associated with systemic hypotension markedly reduces left ventricular stroke volume. If a patent foramen ovale or atrial septal defect is present, right-to-left shunting of blood and severe hypoxemia may occur, as may paradoxical embolization.

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

**Symptoms**

Acute massive pulmonary artery embolism can result in dyspnea, tachypnea, tachycardia, diaphoresis, cyanosis, and occasionally loss of consciousness.

**Signs**

The patient may be hypotensive, dyspneic, and cyanotic, and there may be evidence of pulsus paradoxus.\textsuperscript{H2} Evidence of low cardiac output is present, with weak peripheral pulses and oliguria. Jugular venous pressure is elevated, often with a prominent wave, and neck veins may be distended. Cardiac examination may demonstrate tachycardia, a prominent RV impulse, a loud pulmonary component of the second heart sound, and a gallop rhythm.\textsuperscript{H2} An ejection or pansystolic murmur is often present that may represent tricuspid valve regurgitation. Rarely is there evidence of airway obstruction.

**Diagnostic Studies**

In patients in cardiogenic shock, performing studies to establish the diagnosis of pulmonary embolism is often not possible, and diagnosis is made based on presenting symptoms and signs, recognizing that the diagnosis may be incorrect.\textsuperscript{G13} The electrocardiogram (ECG) may demonstrate T-wave inversion in the anterior leads, reflecting inferoposterior ischemia from pressure overload, a pseudoinfarction pattern, or an S1Q3T3 pattern.\textsuperscript{F4,K10} Transthoracic echocardiography (TTE) is particularly useful in patients suspected of having pulmonary emboli, because it can identify RV pressure overload (Fig. 27-1). Transesophageal echocardiography (TEE) can demonstrate pulmonary artery thrombi as well as RV overload.\textsuperscript{P2,W3} Computed tomography (CT) of the chest with contrast medium can also detect thromboemboli in the major pulmonary arteries (Fig. 27-2). Gadolinium-enhanced magnetic resonance imaging (MRI) can identify pulmonary thromboemboli and RV wall motion abnormalities.\textsuperscript{M7} Contrast pulmonary angiography is a definitive diagnostic study but is infrequently performed in hemodynamically unstable patients.\textsuperscript{G3,G10,R1}

**Figure 27-1** Transthoracic echocardiogram of acute massive pulmonary embolism (parasternal short axis views of right and left ventricles in diastole [A] and systole [B]). There is diastolic and systolic bowing of interventricular septum (arrows) into left ventricle (LV)—a finding compatible with presence of right ventricular volume and pressure overload, respectively. Right ventricle (RV) is appreciably dilated and hypokinetic, with little change in apparent right ventricular area from diastole to systole. There is a small pericardial effusion (PE). (From Come.\textsuperscript{K3})
NATURAL HISTORY

In the United States, approximately 100,000 patients are diagnosed with acute pulmonary embolism each year, resulting in thousands of recognized deaths. Many additional deaths occur each year as a result of undiagnosed massive pulmonary embolus that is mistaken for acute myocardial infarction or ventricular arrhythmia. In the International Cooperative Pulmonary Embolism Registry of 2454 consecutive patients with acute pulmonary embolism from 7 countries, 4.2% had massive embolization.

Untreated massive pulmonary artery embolism, when accompanied by hypoxemia and hemodynamic instability, is nearly always fatal. Most deaths occur before effective treatment can be initiated. It is estimated that mortality for an obstruction of more than 50% of the pulmonary vasculature approaches 50%, and that it increases to 70% if the patient requires vasopressor therapy. If clinical deterioration continues, mortality approaches 100%.

TECHNIQUE OF OPERATION

Preoperative Preparation

As soon as massive pulmonary embolism is suspected, high-dose unfractionated heparin should be administered. Most patients should receive a 10,000-unit bolus followed by a continuous infusion of at least 1250 units/h, with a targeted activated partial thromboplastin time (APTT) of at least 80 seconds.

Maintaining adequate oxygenation and cardiac output before establishing CPB is essential. Endotracheal intubation should be established if hypoxemia is present. If adequate cardiac output cannot be maintained with vasopressors, phosphodiesterase inhibitors, and sodium bicarbonate, or if external cardiac massage is required, CPB should be established by peripheral cannulation (see “Cardiopulmonary Bypass Established by Peripheral Cannulation” in Section III of Chapter 2). Heparin (300 units · kg⁻¹), if not already given, should be administered as soon as it is determined that operative intervention is indicated. If the patient’s condition permits, the usual preparations for establishing CPB are made (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2). If diagnosis of pulmonary embolism has not been made with certainty before the patient is transported to the operating room, TEE should be performed to establish the diagnosis before the chest is opened.

Pulmonary Embolectomy

A midline sternotomy is performed. If peripheral cannulation has not been established, cannulae are placed in the aorta and both venae cavae. If the femoral vein has been cannulated, a second venous cannula is positioned in the superior vena cava, and the femoral vein cannula is withdrawn from the right atrium into the inferior vena cava. Alternatively, a long, two-stage cannula can be used. CPB is established with mild hypothermia, and tapes are placed around the superior and inferior venae cavae and secured. The aorta is clamped and cardioplegic solution infused into the aortic root (see “Methods of Myocardial Management during Cardiac Surgery” in Chapter 3). Alternatively, the heart can be kept beating or fibrillating. The left atrium and left ventricle can be decompressed with a venting catheter inserted into the right superior pulmonary vein.

The pulmonary trunk is incised longitudinally several centimeters from the pulmonary valve. Using forceps and suction, the thrombus is removed. If necessary, the incision can be extended into the left pulmonary artery, and a separate incision can be made in the right pulmonary artery between the superior vena cava and ascending aorta. A sterile fiberoptic bronchoscope can be used to visualize and remove thrombus from secondary and tertiary branches of the pulmonary arteries. The pleural spaces can be incised, and the lungs gently massaged to dislodge smaller thrombi. Alternatively, retrograde perfusion of the pulmonary veins through the opened left atrium can remove additional thromboembolic material from smaller pulmonary arterial branches (along with entrapped air). The right atrial and RV cavities are explored through a right atriotomy to search for and remove residual thrombi.
After removing the thrombus, incisions in the pulmonary arteries and right atrium are closed with continuous 5-0 polypropylene suture. After completion of rewarming and evacuation of air from the cardiac chambers, CPB is discontinued. The procedure is completed in the standard manner (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2).

Placing an inferior vena caval clip or filter is advisable in the majority of patients. A clip can be placed after completing the embolectomy by extending the median sternotomy to the level of the umbilicus and exposing the inferior vena cava using the Kocher maneuver. Alternatively, under fluoroscopic guidance, a vena caval filter can be positioned through the femoral vein at the end of the operative procedure.

**SPECIAL FEATURES OF POSTOPERATIVE CARE**

Postoperative circulatory support with an RV assist device and intraaortic balloon counterpulsation or extracorporeal life support can be beneficial for patients with persisting severe RV failure after embolectomy.1,4,51

Anticoagulation with warfarin is recommended for a minimum of 6 months if there is no contraindication. If not already in place, an inferior vena caval filter should be inserted into patients for whom anticoagulant therapy cannot be used.

**RESULTS**

Hospital mortality is variable and depends largely on the patient’s hemodynamic state at the time of embolectomy.2,2,3,5,5,12 Among patients who require cardiopulmonary resuscitation or institution of CPB before operation, mortality has ranged from 45% to 75%.3,7,5,3,5,12 Mortality is substantially less (3% to 36%) for patients who are more hemodynamically stable.3,7,5,3,5,14 Although satisfactory results were obtained by Clarke and Abrams without CPB, review of a multicenter study by Del Campo demonstrated 40% early mortality for 651 patients operated on with CPB, and 51% for patients in whom CPB was not used.3,7,34 A more recent review by Stein and colleagues of patients operated on after 1985 reported an early mortality of 20%.5,12 Two individual series of patients operated on since 1999 have reported 30-day mortality of 6% (3 of 47 patients) and 8% (4 of 25 patients).5,1,12 Instituting CPB in patients who are in shock permits salvage of some who cannot be saved by alternative techniques. Principal modes of death following embolectomy are cardiac failure, brain injury, and sepsis.4,1,5,5

Recurrent embolism is uncommon among hospital survivors.3 The majority maintain normal exercise tolerance and pulmonary artery pressures.1,5,9

**INDICATIONS FOR OPERATION**

Surgical pulmonary embolectomy is indicated in patients who do not respond to aggressive resuscitative measures or require instituting CPB for cardiogenic shock, and in whom thrombolytic or percutaneous catheter-based interventions are contraindicated or unsuccessful. It should also be considered in selected patients who are at substantial risk for thrombolysis, or when there is insufficient time for thrombolysis to be effective.6,6

**SPECIAL SITUATIONS AND CONTROVERSIES**

**Thrombolytic Therapy**

Thrombolysis, which dissolves fibrin, can be life saving in patients with massive pulmonary embolism, overt hemodynamic instability, and cardiogenic shock.6,6,7,15 However, the potential benefit of this form of treatment must be weighed against risk of major hemorrhage, which increases with increasing age and body mass index.6,3,8 In a report by Gulba and colleagues comparing medical and surgical treatment of massive pulmonary embolism and shock, 10 of 13 patients (77%; CL 59%-90%) treated surgically survived.6,12 Twenty-four patients were given alteplase (tissue plasminogen activator [tPA]) until systemic and pulmonary artery pressures stabilized; heparin was given thereafter. Sixteen of these patients (67%; CL 54%-78%) survived (P = .5). However, major nonfatal hemorrhage occurred in 28% of the alteplase-treated patients, and 20% had recurrent embolization.

Current thrombolytic therapy most commonly involves use of recombinant human tissue plasminogen activator (tPA). One hundred milligrams is given via continuous intravenous infusion over 2 hours with or without concomitant intravenous heparin.6,6 This therapy elevates the risk of major catastrophic bleeding, and despite its use for patients with massive pulmonary embolism, no survival benefit over embolectomy has been demonstrated in large clinical trials.6,6

**Transvenous Catheter Pulmonary Embolectomy**

Several catheter-based techniques have been evaluated for treating pulmonary embolism. The objective is to reduce RP resistance and RV afterload and increase cardiac output. Techniques include (1) transvenous catheter embolectomy, which uses a steerable cup catheter to which suction is applied, (2) use of a catheter that delivers high-velocity jets of saline that draw thrombus toward the catheter and subsequently pulverize the clot, and (3) mechanical fragmentation using various devices combined with pharmacologic thrombolysis.6,12,87 The largest experience in the absence of thrombolytics is with the aspiration technique. Among 89 patients treated with this technique, 30-day mortality was 25% (n = 22; CL 20%-29%). Clinical success, defined as immediate hemodynamic improvement, occurred in 72 patients (81%; CL 77%-85%).5,12 Catheter intervention is currently indicated in patients with acute massive pulmonary embolism in whom an increased bleeding risk precludes administering systemic standard-dose fibrinolysis, and in patients not considered candidates for surgical embolectomy.6,6,88

---

**Section II Chronic Pulmonary Thromboembolic Disease**

**DEFINITION**

Chronic pulmonary thromboembolic disease is entrapment of thrombi in pulmonary arteries from a single episode or repeated embolic episodes that subsequently organize, or thrombi that develop in situ in the pulmonary arteries into firm, fibrous tissue that becomes incorporated into the vessel...
wall. These processes result in variable degrees of pulmonary artery obstruction and consequent pulmonary hypertension when obstruction becomes severe. It is estimated that chronic pulmonary thromboembolic disease develops in 1% to 5% of all cases of acute pulmonary embolism.

**HISTORICAL NOTE**

Chronic pulmonary embolism was suspected by Hart in 1916 and by Molle in 1920, but it was not until 1928 that Ljungdahl described two symptomatic patients with chronic obstruction of the pulmonary arteries who ultimately died of right heart failure. The first successful embolectomies for recurrent pulmonary embolism were reported by Allison and colleagues in 1958 and by Snyder and colleagues in 1962. The technique was refined by Cabrol and colleagues, who used a lateral thoracotomy approach to obtain access to distal branches of the pulmonary arteries. Subsequently, several small series of patients were reported by Sabiston, Daily, and Dor and their colleagues, who used the lateral thoracotomy approach or CPB with a midline sternotomy. In 1980, Daily and colleagues reported use of hypothermic circulatory arrest in combination with CPB. This technique was used to eliminate severe back-bleeding and improve visualization of the pulmonary arteries during endarterectomy. It is currently the preferred method of management.

**MORPHOLOGY**

The chronic thromboembolic process typically involves the proximal pulmonary arteries from trunk to sublobar levels. The distal arterial vasculature remains patent. This forms the basis for surgical treatment of this disorder. The disease can result from a single embolic episode with nonresolution of large thromboemboli or from repeated embolic episodes. Pulmonary arteries remaining unobstructed are chronically exposed to high flow and eventually high pressure. As a result, the proximal patent pulmonary arteries become greatly enlarged, and the distal arterial vasculature develops characteristic changes of pulmonary hypertension (i.e., intimal proliferation and medial hypertrophy as described in Chapter 35, Box 35-3). Plexiform lesions in adult lungs that are diagnostic of primary pulmonary hypertension have been observed in chronic thromboembolic pulmonary hypertension.

The occlusive process is commonly discrete and central. When the thrombi become fibrotic and endothelialized, they no longer respond to thrombolytic or anticoagulant therapy. Occasionally, fresh thrombus is attached to the organized thrombus. Microscopically, thrombotic material demonstrates well-organized fibrous tissue, penetrating blood vessels, elastic fibers, and absence of endothelial cells. There is intimal and medial hyperplasia. Infarction of lung tissue infrequently occurs.

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

**Symptoms**

In general, symptoms do not develop until months or years after the embolic event. They occur as a result of pulmonary hypertension and RV failure. Dyspnea with exertion is the most frequent presenting symptom. Other symptoms include fatigue, substernal chest pain with exercise, pleuritic pain, and hemoptysis.

**Signs**

Pertinent physical findings are related to right heart failure: jugular venous distention, hepatomegaly, ascites, and peripheral edema. The RV may be palpable near the lower left sternal border, and the pulmonic second sound accentuated and split. If right heart failure is severe, a murmur of tricuspid regurgitation is often present.

**Diagnostic Studies**

The chest radiograph may demonstrate RV enlargement and prominence of central pulmonary arteries. The ECG commonly shows RV hypertrophy with strain, right axis deviation, ST depression, T-wave inversion in the anterior precordial leads, and (less frequently) right bundle branch block. Pulmonary function studies are necessary to exclude restrictive or obstructive pulmonary parenchymal disease as the cause of the pulmonary hypertension.

A lung perfusion scan showing at least one segmental or larger defect is suggestive of chronic vascular obstruction. Often, however, the scan underestimates the severity of obstructive disease. CT scanning (Fig. 27-3) and MRI (Fig. 27-4) of the chest are important diagnostic studies and are being used with increasing frequency. Right heart catheterization is performed to measure RV and pulmonary artery pressures and document presence of shunting at the atrial or ventricular level. Pulmonary angiography is often performed as a part of right heart catheterization. It can generally be safely accomplished in patients with chronic pulmonary hypertension. A single injection of contrast material in each pulmonary artery is usually sufficient. Characteristic findings include dilated proximal pulmonary arteries, with obstruction of one or more lobar arteries and appearance of organized thrombi as filling defects, webs, or bands or completely thrombosed vessels. Angioscopy may be a useful adjunct to angiography, CT, or MRI when the diagnosis cannot be clearly established with those studies.

Coronary angiography should be performed in patients older than 40 to 45 years or in younger patients with risk factors for coronary artery disease if surgical treatment is contemplated, so that obstructive coronary lesions, if present, can be bypassed at the time of pulmonary endarterectomy.

**NATURAL HISTORY**

Patients with chronic pulmonary thromboembolic disease may remain asymptomatic for months or years. Hemodynamic progression may be the result of recurrent thromboembolism or in situ pulmonary artery thrombosis. Without intervention, survival is low and proportional to degree of pulmonary hypertension at time of diagnosis. In the study of Riedel and colleagues, survival at 5 years was 30% among patients with a mean pulmonary artery pressure exceeding 40 mmHg at time of diagnosis, and only 10% among those with a mean pressure above 50 mmHg. In the study of Lewczuk and colleagues, a mean pulmonary artery pressure of 30 mmHg was the threshold for poor prognosis. Among the 13 patients evaluated by Riedel and colleagues,
Figure 27-3  Computed tomographic image of chest in chronic pulmonary thromboembolic disease.  A, Eccentric endothelialized thrombi are present in both pulmonary arteries (arrows). B, Image at level of aortic arch shows disparity in pulmonary vasculature, with more visible branches of pulmonary artery in left lung (arrows) than in right. C, Image obtained at same level as B with lung windows demonstrates a mosaic pattern of attenuation; areas of higher attenuation (arrows) are areas of lung that are normally perfused. (From Dixon and King.\textsuperscript{66})

Figure 27-4  Pulmonary embolism demonstrated by magnetic resonance angiography.  A, Oblique sagittal maximum-intensity projection image acquired with gadolinium-enhanced sequence shows right lower lobe clot (arrow).  B, Findings on corresponding conventional pulmonary angiogram confirm right lower lobe obstruction (arrow). (From Gefter and colleagues.\textsuperscript{64})
mobilized by retracting the vena cava laterally and the aorta medially using encircling tapes (Fig. 27-6). The pericardial reflection over the pulmonary artery is incised and the more distal portion circumferentially mobilized 1 to 2 cm beyond the origin of the right upper lobe branch.

The general technique for establishing hypothermic circulatory arrest in adults is described in detail under “Aortic Arch Replacement” in Chapter 26. During cooling, methylprednisolone (7 mg · kg\(^{-1}\)) and thiopental (10-15 mg · kg\(^{-1}\)) are administered to enhance the neuroprotective effect of hypothermia. Mannitol (0.3-0.4 g · kg\(^{-1}\)) and furosemide (100 mg) are infused to preserve renal function. Hematocrit is maintained in the range of 18% to 22%. When the nasopharyngeal temperature reaches 12°C to 14°C, bladder temperature reaches 15°C to 18°C, and the electroencephalogram becomes isoelectric, circulatory arrest is established.
The patient is placed in a moderate Trendelenburg position, and the head is packed in ice. Then 20% to 25% of the patient’s calculated blood volume is withdrawn through the venous tubing into the reservoir of the oxygenator.

After circulatory arrest is established, the right pulmonary artery is incised between aorta and superior vena cava (Fig. 27-7, A), extending the incision below the orifice of the right upper lobe branch and into the anterior surface of the artery distally (Fig. 27-7, B). An endarterectomy plane is established with a sharp dissector (see Fig. 27-7, B), and the intima and a portion of media are removed. Establishing the correct plane is important; a plane that is too deep will result in perforation of the vessel, and a plane that is too superficial will result in an inadequate endarterectomy.  

The core of thrombus is isolated circumferentially (Fig. 27-7, C) and removed from the upper lobe and from the remaining portion of the pulmonary artery (Fig. 27-7, D). Applying gentle traction with forceps on the endarterectomy specimen while sweeping the wall of the pulmonary artery away will result in progressive removal of the thrombus. The thrombotic core is separated from the proximal portion of the right pulmonary artery and removed (Fig. 27-7, E). The arteriotomy is closed with a continuous 5-0 or 6-0 polypropylene suture (Fig. 27-7, F). Alternatively, a patch of autologous pericardium can be used that is sutured into place with a continuous 6-0 polypropylene suture.

Periods of circulatory arrest are limited to 20 to 25 minutes. Cold blood (18°C-20°C) is reperfused for 7 to 10 minutes between these intervals. During a reperfusion interval, the left pulmonary artery is circumferentially mobilized and the pericardium incised to permit exposure of the left upper lobe branch (Fig. 27-8). The incision begins in the pulmonary trunk and extends onto the left pulmonary artery to the level of the pericardial reflection or just beyond (see Fig. 27-8). Endarterectomy is performed as described for the right pulmonary artery. The thrombus is removed first from the upper lobe and lingular branches and then from more distal branches of the artery. The artery is closed directly or with a patch of autologous pericardium. CPB is reestablished and rewarming is begun as closure of the artery is completed.

The atrial septum is examined through a small incision in the right atrium. If a patent foramen ovale or an atrial septal defect is present, it is closed to prevent right-to-left shunting and hypoxemia in the postoperative period. If additional procedures such as valve replacement or repair or coronary artery bypass grafting are required, they are performed during rewarming. Repair or replacement of the tricuspid valve is rarely necessary.  

When rewarming is completed, air is evacuated from the cardiac chambers, CPB is discontinued, and the procedure is completed in the standard manner (see “Completing Cardio-pulmonary Bypass” in Section III of Chapter 2).

### SPECIAL FEATURES OF POSTOPERATIVE CARE

Postoperative care is conducted as described in Chapter 5. Mechanical ventilation is used with an FiO2 sufficient to maintain SaO2 greater than 95%. PaCO2 is maintained at or below 35 mmHg. Reperfusion pulmonary edema is commonly encountered postoperatively and is an important problem in approximately 10% of patients. Lung injury usually develops within the first 48 hours and is characterized by hypoxemia and radiographic infiltrates in the areas that have been endarterectomized and reperfused. Treatment is generally supportive, using the lowest FiO2 to maintain SaO2 greater than 90% and positive end-expiratory pressures of 5 to 10 cm. Infusion of prostaglandin E1 at 0.01 to 0.1 mg · min"1 and inhaled nitric oxide (20-40 parts per million) may be indicated. Aggressive diuresis is often necessary to remove fluid and reduce incidence of pulmonary edema. 

Reperfusion pulmonary edema has been demonstrated to be neutrophil mediated, and treatment with agents that block selectin-mediated adhesion of leukocytes to the endothelium has reduced the prevalence of this complication.

Heparin is administered subcutaneously (5000-7500 units every 12 hours). Permanent anticoagulation with warfarin is initiated on the second postoperative day. Aspirin (80 mg daily) may be added.

### RESULTS

In experienced centers, early mortality has ranged from 4.4% to 21%. Important risk factors for early death include reperfusion lung injury, RV failure related to residual pulmonary hypertension, and duration of CPB. Addition of other procedures to pulmonary thromboendarterectomy has not been associated with increased early mortality. In a follow-up study of 532 patients from the University of California–San Diego (UCSD), which has accumulated the largest series of patients undergoing pulmonary thromboendarterectomy, 6-year survival was 75% (Fig. 27-9). Predominant modes of late death were persistent pulmonary hypertension and recurrent pulmonary embolism.

Dramatic reduction and, at times, normalization of pulmonary artery pressure and Rp can be achieved with a mean reduction in Rp of approximately 65%. In the follow-up study from the UCSD, 56% of the 306 patients whose functional status could be assessed were in New York Heart Association functional class I, 37% class II, 6% class III, and 1% class IV. Similar findings were reported by Saoudi and colleagues. A relationship was demonstrated between Rp and cardiac output and the distance patients could walk and flights of stairs they could climb. Of 133 patients not employed before pulmonary thromboendarterectomy, 62% returned to work. Ten percent required supplemental oxygen. Disease-related hospitalizations and emergency services requirement over the duration of follow-up were minimal.

### INDICATIONS FOR OPERATION

Pulmonary thromboendarterectomy should be considered in symptomatic patients who have hemodynamic or ventilatory impairment at rest or with exercise. Potential candidates for operation who are at the lower end of the range of elevated Rp (300-2000 dyn · s · cm"−5") include those with involvement limited to one pulmonary artery, those accustomed to vigorous activity, and those who live at high altitudes. Operation should also be considered in patients who have normal or nearly normal hemodynamics at rest, but in whom marked pulmonary hypertension develops during exercise.

A critical determinant of operability is the location and extent of thromboembolic obstruction. Occlusive thrombi must involve the branch pulmonary artery, lobar, or proximal segmental arteries. More distal thrombi are not currently amenable to thromboendarterectomy.
Figure 27-7 Endarterectomy of right pulmonary artery in chronic pulmonary thromboembolic disease. A, Approach to pulmonary artery. View is from left side of operating table. Superior vena cava is fully mobilized and retracted laterally, and aorta is retracted medially; the pulmonary artery is incised between these vessels. B, Endarterectomy plane is established with sharp dissector. C-D, Core of thrombus is isolated circumferentially and removed from upper lobe and distal pulmonary artery. E, Core is separated from proximal pulmonary artery and removed. F, Arteriotomy is closed with a continuous 5-0 or 6-0 polypropylene suture.
PART V  Diseases of the Thoracic Arteries and Veins

1034

Pulmonary artery aneurysms (that are amenable to surgical treatment) are discussed.

HISTORICAL NOTE

The first description of a pulmonary artery aneurysm was by Bristowe in 1860. He reported an arteriosclerotic fusiform aneurysm of the pulmonary artery observed at autopsy. In a review of 109,571 autopsies by Deterling and Clagett in 1947, only 8 proximal pulmonary artery aneurysms were identified. The first successful repair of an aneurysm of the pulmonary trunk was reported by Williams and colleagues in 1971. It was resected and replaced with a woven polyester graft. Aneurysmorrhaphy and patch repair were subsequently used as alternative methods of treatment.

MORPHOLOGY

Structural abnormalities, pulmonary hypertension, cardiac malformations, and infection, existing alone or in combination, appear to be predisposing factors to developing pulmonary artery aneurysms. A classification of aneurysms not associated with arteriovenous communications is shown in Box 27-1. Cystic medial degeneration and arteriosclerosis may contribute to formation of pulmonary artery aneurysms. Patients with Marfan syndrome may develop them, and these are prone to dissection. Congenital cardiac abnormalities are commonly associated with aneurysms of the pulmonary arteries; these include patent ductus arteriosus (the most common), ventricular septal defect, tetralogy of Fallot, pulmonary valve stenosis, and transposition of the great arteries. Aneurysms have also been observed in association with acquired cardiac conditions such as mitral stenosis and tricuspid regurgitation. Infection can also contribute to development of pulmonary artery aneurysms. In the preantibiotic era, tuberculosis and syphilis were commonly associated with aneurysms. Bacteria, including staphylococcal, streptococcal, and gram-negative species, and fungi have

Section III  Pulmonary Artery Aneurysm

DEFINITION

Pulmonary artery aneurysm is a localized vascular dilatation with deterioration of one or more layers of the pulmonary arterial wall. In this section, only aneurysms of the pulmonary trunk and branch pulmonary arteries (proximal pulmonary artery aneurysms) that are amenable to surgical treatment are discussed.

Modified from Bartter and colleagues. F3

The only absolute contraindication to operation is presence of severe underlying obstructive or restrictive lung disease. The greatest risk factor for operation is presence of high Rp without gross abnormalities visible in the major pulmonary arteries by angiography. Advanced age, severe RV failure, and comorbid conditions are associated with increased risk and are relative contraindications to operation.
Chapter 27  Diseases of the Pulmonary Arteries

27-12), MRI, and pulmonary angiography can document the presence of proximal pulmonary artery aneurysms.\textsuperscript{[32]}

**NATURAL HISTORY**

Because pulmonary artery aneurysms are rare and coexisting conditions are common, natural history remains largely unknown. It is known, however, that rupture and dissection of such aneurysms occur.\textsuperscript{[52,6,3,9,5,11,1,3,5,4,57]} Death following rupture or dissection is common and often sudden.

**TECHNIQUE OF OPERATION**

Usual preparations for establishing CPB are made (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2). After inserting appropriate monitoring devices and placing ECG electrodes, a median sternotomy is made. Cannulae are inserted into the ascending aorta and both venae cavae, venae cavae are encircled with tapes, CPB is established, and a venting catheter is inserted into the left atrium through a purse-string suture in the right superior pulmonary vein. The procedure can be performed with the heart beating and mild (34°C) hypothermia or with cardioplegia. In the latter situation, a cannula is inserted into the ascending aorta for delivery of antegrade cardioplegia and for later aspiration of air. A cannula is inserted into the coronary sinus through a purse-string suture in the right atrial wall. Cardioplegic solution is infused every 15 minutes either through the aortic root or retrogradely through the coronary sinus (see “Methods of Myocardial Management during Cardiac Surgery” in Chapter 3).

The pulmonary artery is examined to determine the location and extent of the aneurysm (Fig. 27-13, \textit{A}). If the aneurysm is confined to the pulmonary trunk, excising a portion of the anterior wall to establish a normal diameter and closing the defect with a continuous 4-0 or 5-0 polypropylene suture can be performed.\textsuperscript{[55,52]} Alternatively, the aneurysmal segment can be excised and replaced with a woven polyester graft or pulmonary allograft.\textsuperscript{[52]} If the aneurysmal changes involve right and left pulmonary arteries as well, the aneurysmal segments are excised and pulmonary trunk, right, and left pulmonary arteries are replaced with a woven polyester bifurcation graft or pulmonary allograft (Fig. 27-13, \textit{B}).

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

Patients with proximal pulmonary artery aneurysms may present with cough, hemoptysis, chest pain, and dyspnea, although many are asymptomatic. Symptoms, if present, may be related to associated cardiac or pulmonary conditions. There can be compression of the left main coronary artery resulting in myocardial ischemia.\textsuperscript{[56]} There are no characteristic physical findings. The chest radiograph may be normal, but if the aneurysm is large, it demonstrates a prominence along the left heart border (Fig. 27-10). CT (Figs. 27-11 and

**Figure 27-10** Chest radiograph of pulmonary artery aneurysm. There is marked enlargement of pulmonary trunk.

**Figure 27-11** Computed tomographic study of chest of patient shown in Fig. 27-10, demonstrating a 6-cm aneurysm of pulmonary trunk.
If the pulmonary valve is abnormal, it can be replaced using a pulmonary valve allograft or a composite valved conduit (see Technique of Operation in Chapter 38). Other cardiac malformations, if present, are corrected.

When rewarming is completed, air is evacuated from the cardiac chambers, CPB is discontinued, and the procedure is completed in the standard manner (see Completing Cardiopulmonary Bypass in Section III of Chapter 2).

An alternative procedure, bilateral lung transplantation and reconstruction of the pulmonary arteries using the donor pulmonary artery, has been successfully accomplished by Wekerle and colleagues in an 18-year-old patient with pulmonary hypertension and massive dilatation of the proximal pulmonary arteries.\(^\text{W1}\)

**Special Features of Postoperative Care**

Postoperative care is conducted as described in Chapter 5.

**Results**

Results of operative repair are primarily contained in isolated case reports.\(^{C5,C6,C7,C8,C9,C10,C11}\) Among patients undergoing elective operation, early results have been excellent. Little information regarding long-term outcomes is available.

**Indications for Operation**

Because of the excellent results that have been achieved with elective resection of proximal pulmonary artery aneurysms, operation should be considered in patients with isolated and substantial (>5-6 cm) dilatation of the pulmonary trunk and of the right and left pulmonary arteries. Presence of pulmonary hypertension strengthens the indication for operation. Patients who have other indications for operation, such as congenital or acquired cardiac lesions, should have repair of large coexisting pulmonary artery aneurysms. Although conservative management of large aneurysms has been reported, documentation of rupture and dissection would make this strategy inadvisable for patients who would otherwise be considered suitable for operation.\(^{C4}\)

---

**Section IV  Pulmonary Artery Dissection**

**Definition**

Pulmonary artery dissection is separation of vessel layers of pulmonary arteries, most commonly of the pulmonary trunk, although it can extend into the major branches. It is a rare condition.

**Historical Note**

According to Shilkin and colleagues, the first reported case of pulmonary artery dissection was by Helmbrecht in 1842.\(^{S6}\) Fewer than 100 cases have been reported in the English literature.\(^{I1}\) Diagnosis has been established after death in the majority of cases. Few patients have been treated surgically.\(^{I1,L5,S4}\)

**Morphology**

Pulmonary artery dissection originates most commonly in the pulmonary trunk (71% of the 52 patients reviewed by Inayama et al.)\(^{I1}\) and in the major branches of the pulmonary arteries. It is frequently associated with pulmonary hypertension. Among patients who have pulmonary hypertension, only a small percentage have primary pulmonary hypertension. In the review of Inayama and colleagues, 28 patients had secondary pulmonary hypertension, and congenital cardiac malformations were present in 23; patent ductus arteriosus was the most common.\(^{I1}\) Marfan syndrome was present in only 1 of the 52 patients, although cystic medial degeneration was observed in the pulmonary arteries of 23 of 29 patients with detailed histologic studies. Pulmonary hypertension was present in 20 of these 23 patients.\(^{I1}\)

In the majority of reported cases (86%), diagnosis of pulmonary artery dissection was made at autopsy.\(^{I1}\) Rupture of
Chapter 27  Diseases of the Pulmonary Arteries

1037

valvotomy for valvar pulmonary stenosis at age 21. MRI demonstrated a 6-cm aneurysm of the pulmonary trunk. At operation, an intimal flap was noted in the left lateral wall of the pulmonary trunk. The pulmonary valve, pulmonary trunk, and proximal portions of right and left pulmonary arteries were excised and replaced with a pulmonary allograft.

A second patient, a 34-year-old woman, had primary pulmonary hypertension diagnosed 10 years previously and presented with chest pain, shortness of breath, and a large pericardial effusion. CT demonstrated an aneurysm of the pulmonary trunk and an intimal flap (see Fig. 27-15). At operation, there was evidence for rupture with a large hemothorax.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Presenting symptoms are identical to those observed with acute aortic dissection and include severe chest pain, dyspnea, central cyanosis, and shock. Several days may elapse between onset of pain and rupture. Diagnosis was established by echocardiography, pulmonary angiography, or MRI in only 6 of 52 patients reported by Inayama and colleagues (Fig. 27-14). In a subsequent report, diagnosis was established by CT (Fig. 27-15). A new left hilar mass may occasionally be seen on chest radiograph.

NATURAL HISTORY

Prognosis of untreated pulmonary artery dissection is extremely poor. Diagnosis has been infrequently made before death, and only a few patients have been successfully managed by surgical intervention.

TECHNIQUE OF OPERATION

Technique of operation is identical to that described for treatment of pulmonary artery aneurysm (see Technique of Operation in the preceding section and Fig. 27-13). Heart and lung transplantation is an alternative and has been successfully performed in several patients (see Chapter 21).

RESULTS

Few patients have been successfully treated by direct repair. One developed dissection in an aneurysmal pulmonary trunk at age 56 and presented with chest pain and shortness of breath of 2 weeks’ duration. He had undergone pulmonary

the pulmonary artery into the pericardial cavity or mediastinum or into a pleural space was a frequent finding.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Presenting symptoms are identical to those observed with acute aortic dissection and include severe chest pain, dyspnea, central cyanosis, and shock. Several days may elapse between onset of pain and rupture. Diagnosis was established by echocardiography, pulmonary angiography, or MRI in only 6 of 52 patients reported by Inayama and colleagues (Fig. 27-14). In a subsequent report, diagnosis was established by CT (Fig. 27-15). A new left hilar mass may occasionally be seen on chest radiograph.
and competent. The pulmonary trunk was replaced with a 32-mm polyester tube graft and a second 32-mm polyester graft was interposed between right and left pulmonary arteries. The two grafts were then joined in a T configuration. Several patients with severe pulmonary hypertension and extensive dissection or Eisenmenger syndrome have been successfully treated by heart and lung transplantation.\textsuperscript{2,4}

**INDICATIONS FOR OPERATION**

Because of the extremely poor prognosis associated with pulmonary artery dissection, operative treatment should be considered for any patient in whom the diagnosis is established.

---

**Section V  Pulmonary Artery Tumors**

**DEFINITION**

Primary tumors of the pulmonary artery are malignant tumors, most commonly sarcomas, usually arising in the pulmonary trunk and extending into right and left pulmonary arteries. They commonly involve the pulmonary valve and may extend into the RV.\textsuperscript{1,6} These tumors, although rare, are being reported with increasing frequency.\textsuperscript{2,4,8}

**HISTORICAL NOTE**

The first report of a sarcoma of the pulmonary trunk was by Mandelstamm in 1923.\textsuperscript{3,3} Early surgical treatment consisted of resecting the segment of pulmonary trunk containing tumor, pneumonectomy, or both.\textsuperscript{1,6} More recently, resecting and reconstructing the pulmonary arteries using CPB has been used.\textsuperscript{2,6,0}

**MORPHOLOGY**

Sarcomatous tumors arise from the intima of the pulmonary artery, most frequently from the dorsal surface of the pulmonary trunk.\textsuperscript{4,4} They rarely extend through the adventitia or invade surrounding structures. Pulmonary metastases are present in up to 60% of patients. Metastases to lymph nodes and other organs are less common.\textsuperscript{2,6} Microscopic features are highly variable. In a review of 99 pulmonary sarcomas by Lyerly and colleagues, many cell types were represented, including leiomyosarcoma, myxosarcoma, fibrosarcoma, chondrosarcoma, angiosarcoma, osteogenic sarcoma, and liposarcoma.\textsuperscript{1,6}

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

Clinical presentation resembles that of more commonly occurring conditions such as chronic pulmonary thromboembolic disease. Symptoms include dyspnea, chest pain, cough, and hemoptysis. There are no characteristic physical findings. Diagnostic studies such as ventilation/perfusion scans, CT, echocardiography, and pulmonary angiography have only infrequently established the diagnosis preoperatively.\textsuperscript{4,5,6}

(Fig. 27-16). MRI with gadolinium contrast may be a useful diagnostic tool because tumor enhances more than bland thrombus.\textsuperscript{2,8} Fluorodeoxyglucose positron emission tomography (FDG-PET) may demonstrate increased uptake within the tumor.\textsuperscript{2,8,1} In the review of Lyerly and colleagues, correct diagnosis was made at postmortem examination in 59% of cases and after surgical exploration in 31%.\textsuperscript{4,1}

**NATURAL HISTORY**

Median duration of survival from diagnosis is approximately 1.5 months without surgical resection. Survival has not been affected by addition of adjuvant therapy.\textsuperscript{2,6} In a review by Blackmon and colleagues of 66 patients reported since 1990 who received some form of therapy (chemotherapy, irradiation, or surgery), 5-year survival was 18.5%.\textsuperscript{8,5}

**TECHNIQUE OF OPERATION**

Technique of operation in most instances is identical to that described for treatment of pulmonary artery aneurysm (see **Technique of Operation** in Section III of this chapter and Fig. 27-13). All visible tumor should be removed. Pulmonary thromboendarterectomy and pneumonectomy may be added to pulmonary artery resection if indicated.\textsuperscript{2,6,0}

**RESULTS**

Among 39 patients in the report of Lyerly and colleagues in whom diagnosis of pulmonary sarcoma was made before death, only 11 survived more than 1 year after diagnosis or initiation of therapy.\textsuperscript{1,6} Isolated instances of longer survival following complete resection with reconstruction of the pulmonary valve and pulmonary arteries have been reported.\textsuperscript{2,6,0} The role of adjuvant radiotherapy and chemotherapy is inconclusive.\textsuperscript{2,8,6} Resection of pulmonary metastases in the absence of distant disease may be beneficial.\textsuperscript{2,8,5}
INDICATIONS FOR OPERATION

Because radical surgical resection likely represents the only chance for cure, operation should be considered in patients who have no comorbid conditions that would preclude the use of CPB and who have no evidence of distant metastases. Adequate pulmonary reserve should be documented for patients who may require pneumonectomy.

**DEFINITION**

Acquired disease of the systemic veins entails obstruction—partial or complete—of the major veins of the thorax. Veins of surgical importance are the superior and inferior venae cavae (SVC and IVC). Left and right brachiocephalic veins, including the jugular-subclavian vein confluence, are major tributaries of the SVC and may be considered collectively with conditions of the SVC. Congenital anomalies of the venae cavae and axillary vein conditions such as effort thrombosis are not considered in this chapter. Obstruction results from extrinsic compression, direct invasion by disease processes, or thrombosis. **SVC syndrome** is the result of venous hypertension in the head, neck, and arms caused by SVC obstruction.

**HISTORICAL NOTE**

William Hunter described the first recorded case of SVC syndrome in 1757 in a patient with syphilitic aneurysm of the aorta. SVC obstruction was due to compression by the aneurysm. William Osler described SVC compression in his classic text of 1892: “Along the convex border of the ascending part [of the aorta], aneurism frequently develops, and may grow to a large size.... In this situation the sac is liable indeed to compress the superior vena cava, causing engorge-ment of the vessels of the head and arm.” William Stokes’ text of 1853 described SVC obstruction and noted the more frequent occurrence with cancer: “As an indication of intra-thoracic tumour, an extensively varicose state of the superficial veins of the neck and thorax is probably less frequent in aneurismal than in cancerous disease.... The superior cava may be adherent to the tumour, and become narrowed, not only by pressure, but by adhesion of its internal surfaces.”

Gomes and Hufnagel reviewed cases of SVC obstruction reported before 1975. Data from more than 90 publications, including 1980 cases reported in the literature since 1934, were reviewed by Ahmann in 1984. The clinical problem was reviewed by Nieto and Doty in 1986.

The first successful bypass operations for SVC obstruction by Klassen and colleagues in 1951 and Bricker and McAfee in 1952 were performed using autologous femoral vein grafts. In 1965, Hanlon and Danis used other large veins to replace or bypass the SVC, employing variously the femoral, subclavian, and jugular veins. In 1962, Benvenuto and colleagues constructed a composite panel graft from pieces of saphenous vein for replacing the SVC. The operative approach to relieve venous obstruction up to 1970 was reviewed by Haimovici and colleagues. They concluded that autologous veins are preferable for venous replacement. All
reported experimental and clinical experiences with vena cava replacement or bypass up to 1974 were reviewed by Scherck and colleagues. A number of conduits had been tried, including autologous, homologous, and heterologous vein, aorta, and various synthetic materials. These authors concluded that autologous vein grafts of nearly the same size as the SVC were most likely to remain patent. To obtain such a large autologous vein usually requires a large vein from elsewhere in the body, with resultant venous drainage problems, or constructing a composite graft from a smaller vein.

Synthetic grafts are attractive because of their convenience and availability and because of the variety of sizes available. In 1973, Effeney and colleagues reported successful bypass of the SVC using polyester grafts. In 1977, Avasthi and Moghissi used a polyester graft interposed between the brachiocephalic vein on the left side and right atrial appendage to bypass the obstructed SVC. Thrombosis of polyester grafts limited success of the procedure. Expanded polytetrafluoroethylene (PTFE) was used successfully as a venous replacement conduit in experimental venous operations in dogs. Hiratzka and colleagues showed that PTFE and polyester were equally poor venous substitute conduits in the experimental setting, and that they did not approach the effective patency of autologous vein grafts. Reichle and colleagues suggested that this was because autologous vein grafts have a living endothelial surface even after initial endothelial desquamation, whereas prosthetic graft inner surfaces are composed of collagen matrix. Nevertheless, success using PTFE grafts has been reported. Antiplatelet-adhesive drugs may be of benefit in maintaining patency of PTFE grafts. Dartevelle and colleagues reported that 12 of 13 PTFE grafts used to replace the SVC were patent an average of 24 months after operation.

Composite vein grafts constructed from the saphenous or external jugular veins, in paneled or longitudinal fashion, have been used clinically for SVC bypass or replacement (both techniques are discussed in detail later in this chapter). In 1974, Chiu and colleagues reported constructing a composite vein graft from the external jugular vein, which was matched to the size of the SVC. The donor vein was opened longitudinally and wrapped in spiral fashion around a tubular stent of approximately the same size as the SVC. Vein edges were then sutured together to form the conduit. The graft occluded in the initial three experiments in dogs. After that, however, 10 consecutive grafts remained patent for up to 15 months. This report prompted successful application of this technique in humans by Doty and Baker in 1976. Successful percutaneous balloon dilatation of the SVC in a child was reported by Rocchini and colleagues in 1982. In 1986, Sherry and colleagues reported successful dilatation of an SVC stricture caused by pacemaker electrodes in an adult. In 1987, Rosch and colleagues used an expandable wire stent to treat SVC obstruction caused by malignant disease that recurred after extensive radiation therapy.

**MORPHOLOGY AND PATHOGENESIS**

**Morphology**

**Superior Vena Cava**
The SVC is located in the middle mediastinum and is surrounded by relatively rigid structures including the trachea, right bronchus, aorta, pulmonary trunk, and perihilar and paratracheal lymph nodes. It is thin walled, compliant, and easily compressible. Pressure within it is low. The SVC originates as the confluence of right and left brachiocephalic veins and extends for a distance of 6 to 8 cm to the right atrium. It is inside the pericardial sac for the distal several cm of its course. The azygos vein is the only major venous channel that enters the SVC; it enters posteriorly just above the pericardial reflection and is an important venous collateral pathway.

**Collateral Circulation**

SVC obstruction stimulates formation of extensive venous collateral circulation (Fig. 28-1). The azygos vein is the only major venous channel that enters the SVC and is the most important collateral pathway. When SVC obstruction is located caudad to a patent azygos vein, there is retrograde flow through the azygos and hemiazygos veins to the lumbar veins below the diaphragm and to the IVC. When obstruction is cephalad to the patent azygos vein, collateral veins in the neck allow blood flow to enter the azygos system and continue directly into the distal SVC below the obstruction. When connection of the azygos vein to the SVC is involved in the obstruction, more complex and varied pathways must develop to drain the upper body. One prominent system consists of the internal thoracic veins, which connect to superior and inferior epigastric veins and subsequently to the IVC by way of the external iliac veins. Lateral thoracic veins drain to thoracoepigastric veins; eventually, blood may enter the femoral veins. Paraspinal veins form a collateral network that connects to the IVC via lumbar veins. The esophageal venous network also can decompress the thorax via the left gastric vein to the portal system. This pathway is not very important unless esophageal varicosities develop, and only rarely are these associated with bleeding into the gastrointestinal tract. Subcutaneous veins are a particularly important means of bringing blood flow from the upper body to below the diaphragm via the IVC.

Despite extensive collateral circulation that may develop, venous pressure in the SVC as high as 200 to 500 cm of water has been recorded. Cerebral venous decompression may be provided through a single internal jugular vein, because the veins of the right and left sides of the brain are in continuity through midline venous sinuses. Superior and inferior sagittal sinuses drain the cerebral hemispheres to the confluence of sinuses that communicate through transverse and sigmoid sinuses to either internal jugular vein. The cavernous sinus also connect both sides of the brain to either internal jugular vein. Cerebral venous drainage, therefore, may remain adequate.

**Pathogenesis**

SVC obstruction may be caused by a spectrum of malignant (Table 28-1) and benign (Box 28-1) conditions. Disease in any adjacent anatomic structures may contribute to SVC syndrome. The common causes of SVC obstruction have changed over the past 50 years. In 1949, the most common were thoracic malignancy (33%), aortic aneurysm (30%), and chronic granulomatous mediastinitis (19%). Up until 1962, approximately 25% were due to benign disease; between 1969 and 1979, that proportion decreased to 3%. Currently, malignancies account for the majority of cases. Iatrogenic causes such as indwelling catheters are becoming more frequent, and an increasing number of
infectious causes are being reported in immunosuppressed patients. E3,R2

**Benign Causes**

Reviews from Mayo Clinic and Cleveland Clinic reported mediastinal granulomatous disease resulting in fibrosing mediastinitis as a prominent cause of benign SVC obstruction. M1,P1 The most common etiologic agent is histoplasmosis, which causes a caseating granulomatous process in mediastinal lymph nodes that compresses, fibroses, and contracts around the SVC and may result in secondary thrombosis. Fibrosing mediastinitis resulting from radiation therapy can be progressive and involve the SVC years after radiation treatment has been completed.

Iatrogenic causes have been increasing in importance because of increased use of invasive intravenous procedures such as cardiac pacemaker electrodes, central venous and pulmonary artery catheters, hyperalimentation and chemotherapy catheters, and extracorporeal membrane oxygenation. Mazzetti and colleagues reviewed pacemaker electrodes as a cause and found four cases of SVC obstruction among 2600 patients followed in a pacemaker clinic. M6 They also reviewed 37 cases reported in the literature and concluded that prevalence of this complication is likely lower than 1 in 1000. A more recent publication identified 104 patients from a review of 74 different publications. Williard and colleagues reported the Memorial Sloan-Kettering Cancer Center experience with thrombosis of long-term vascular access. W1 Occurrence of thrombosis of access catheters placed through the SVC was 7%, compared with 19% for catheters placed through the IVC. About half the thromboses involved just the catheter; the other half involved the blood vessel through which the catheter was introduced.

In infants, substantial morbidity is associated with chronic central venous access catheters. S16 In the series of Swaniker and Fonkalsrud, IVC occlusion occurred in 4.5% and SVC occlusion in 11% of 510 infants having 756 central venous catheters placed for parenteral nutrition. S16 Head and neck swelling developed in all with SVC occlusion, pleural effusions developed in 50%, and two infants died. Thrombosis of
the SVC around these catheters is especially troublesome when they are required for permanent life support and cannot be conveniently removed. In addition, thrombosis frequently follows the entire intravascular course of the catheter and thus is extensive, involving the major SVC venous tributaries. SVC thrombosis can be an important complication after extracorporeal membrane oxygenation. Zreik and colleagues reported 7 of 60 neonates (12%; CL 7%-18%) had either complete or partial SVC obstruction. Other benign causes include benign tumor, vascular aneurysm, a variety of cardiac and pulmonary diseases, and mediastinal hematomas.

**Malignant Causes**

Intrathoracic malignancy now accounts for more than 90% of SVC obstructions, with bronchogenic carcinoma responsible for 67% to 82%. SVC syndrome develops in 3% to 15% of patients with bronchogenic carcinoma. Bronchogenic carcinoma cell type associated with SVC obstruction appears to be somewhat variable, which may in part be related to difference in tumor classification schemes used by different investigators. Squamous (epidermoid) carcinoma accounts for 22% to 27% of cases and appears to be relatively consistent across reports. Small-cell carcinoma is the most variable (18%-46%), although its etiologic role appears to be increasing. Lymphoma is the second most frequent cause of SVC obstruction, accounting for 5% to 15% of cases. These malignancies are located in the anterior mediastinum and produce obstruction by external compression from the front. Thoracic metastasis from extrathoracic malignancies, particularly breast and testicle, accounts for a small number of SVC obstructions.

Malignancy is also the most common cause of SVC obstruction in children. In contrast to adults, however, non-Hodgkin lymphoma is the leading etiology.

### CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

#### Superior Vena Cava Syndrome

Because extrinsic compression usually produces obstruction gradually, collateral circulation develops, the obstruction is usually well tolerated, and the patient has few if any signs and symptoms. If obstruction develops rapidly, as in malignant tumor invasion and in infants and children with central venous catheters, collateral circulation may not have time to develop and adequately decompress upper body veins. The most severe syndrome develops in cases of SVC thrombosis in which obstruction is sudden and collateral venous channels have no time to develop. Thrombosis may involve major caval tributaries as well and thus eliminate major collateral pathways. Thrombosis often accompanies SVC obstruction from any cause and compounds the problem because (1) subsequent fibrotic organization of the clot results in permanent SVC stenosis or closure, and (2) thrombosis does not respond to treatment directed at the primary disease process that resulted in the SVC obstruction.

Thoracic lymphatic ducts drain into the subclavian veins and are affected by venous hypertension associated with SVC obstruction. Pulmonary lymphatics may also be secondarily affected, leading to increased lung water and dyspnea. Respiratory insufficiency is frequently associated with acute SVC obstruction and may be difficult to manage. Chyloous pleural effusion may result from thoracic lymphatic obstruction.

#### Symptoms

Patients with SVC obstruction usually present with a well-established syndrome that is easily recognized and unmistakable. Only rarely does complete SVC obstruction occur without noticeable signs or symptoms. The typical syndrome consists of swelling of face, neck, and arms; shortness of breath; orthopnea; and cough. Patients may notice tightness of a shirt collar and that their face is flushed and swollen, especially around the eyes. Other symptoms include hoarseness, stridor, tongue swelling, nasal congestion, epistaxis, dysphagia, headache, dizziness, syncope, lethargy, and

chest pain. Symptoms are aggravated by bending forward, stooping, or lying down. Many patients become dyspneic when recumbent and must sleep in a chair.

**Signs**

The most common signs are dilatation and tortuosity of upper body veins, plethora or cyanosis of the face, and swelling of face, neck, or arms. Other signs include proptosis, glossal edema, rhinorrhea, laryngeal edema, mentation changes, elevated venous and cerebrospinal fluid pressures, and chylous pleural effusion. Signs and symptoms suggesting cerebral or laryngeal edema were shown to be of prognostic importance by Lochridge and colleagues.18 Headache, vertigo, visual disturbances, decreased mentation, stupor, somnolence, and convulsions indicate cerebral edema12,14, hoarseness and stridor suggest laryngeal edema.

**Diagnosis**

Clinical diagnosis is usually obvious. Location, degree, and cause of SVC obstruction should be characterized in every case. There is some controversy about how specific this characterization should be, because more than 90% of cases are due to malignancy. Some believe that palliation of the intrathoracic malignancy should proceed without delay. Others argue that SVC syndrome is seldom a medical emergency and should be characterized as completely as possible in an orderly fashion so that treatment can be specific. Although tissue diagnosis by biopsy can usually be obtained, in some cases it may be difficult and even hazardous to do so. Patients seek relief of symptoms of SVC syndrome and seldom complain of symptoms related to the etiologic cause of the obstruction. Treatment of SVC syndrome should be accompanied by diagnostic measures and therapy directed at the causative primary disease.

**Chest Radiography**

Chest radiography is helpful but not specific in diagnosing SVC obstruction. Because bronchogenic carcinoma is the most common cause of SVC syndrome, the chest radiograph often shows a right-sided hilar mass. An anterior mediastinal mass suggests lymphoma.

**Venography**

The most useful diagnostic procedure is bilateral arm contrast venography10,13 (Fig. 28-2). It establishes:

- Location of SVC obstruction
- Degree of obstruction
- Degree of involvement of caval tributaries
- Extent of collateral venous pathways
- Extrinsic compression vs. intrinsic SVC obstruction

Identifying retrograde propagation of thrombosis that involves caval tributaries may indicate that caval obstructive symptoms are not likely to respond to nonoperative therapy.

Using venography in 36 patients, Stanford and Doty defined four patterns of venous circulation useful in planning therapy13 (Box 28-2).

**Box 28-2** Type of Superior Vena Cava Obstruction According to Venographic Pattern

| Type I | Partial obstruction (up to 90% stenosis) of the superior vena cava (SVC) with patency of the azygos–right atrial pathway |
| Type II | Near-complete to complete obstruction (90%-100%) of the SVC with patency and antegrade flow in the azygos–right atrial pathway |
| Type III | Near-complete to complete obstruction (90%-100%) of the SVC with reversal of azygos blood flow |
| Type IV | Complete obstruction of the SVC and one or more of the major caval tributaries, including the azygos systems |

**Two-Dimensional Echocardiography**

Masses in the SVC are imaged with great clarity by two-dimensional echocardiography (Fig. 28-4). The image is dynamic, so movement of obstructing lesions may be detected. It is useful in evaluating clot formation on central venous catheters and other devices.

**Computed Tomography**

Computed tomography (CT) provides an effective noninvasive means of analyzing the SVC and its tributaries. It has increasing importance in evaluating SVC syndrome and masses in the right atrium and IVC (Fig. 28-5). Its advantages are outlined by Moncada and colleagues11:

- Caval anatomy can be related to surrounding mediastinal structures.
- Mediastinal masses or lymph node pathology relative to the SVC can be located.
- Directed needle biopsy of mediastinal masses is facilitated.
- Patency of the internal jugular veins in the neck can be assessed despite extensive occlusion of tributaries of the SVC.

**Magnetic Resonance Imaging**

Magnetic resonance imaging is useful in assessing graft patency after operation for SVC syndrome15.

**Other Diagnostic Methods**

Other diagnostic methods including ultrasonography, positron emission tomography (PET), cytology, isotope venography, bronchoscopy, lymph node biopsy, mediastinal biopsy, mediastinoscopy with biopsy, and exploratory thoracotomy are indicated for individual cases. However, risks of interventional studies—patient discomfort, bleeding, and interruption of venous collaterals—should be weighed against the probability of a successful diagnosis. Invasive diagnostic tests may worsen SVC syndrome and should be avoided whenever possible.
Figure 28-2  Bilateral arm venogram showing obstruction of superior vena cava (SVC). A, Contrast injected via right basilic vein shows complete occlusion of SVC at right brachiocephalic vein junction. Collateral veins have formed in cervical region. There is reflux into right internal jugular vein, suggesting venous pressure is elevated enough to cause regurgitation of the valve at the jugular–subclavian vein confluence. B, Contrast injected via left cephalic vein shows left brachiocephalic vein occlusion back nearly to left jugular-subclavian confluence. A stump of brachiocephalic vein is accessible for attaching a bypass graft. Collateral veins formed in the cervical region communicate with paravertebral veins.

NATURAL HISTORY

The natural history of SVC obstruction and accompanying SVC syndrome is variable and depends on etiology of the obstruction, rapidity of onset, extent of the obstructive process, and extent of collateral venous circulation. Collateral venous circulation usually develops rapidly in response to SVC obstruction and is often sufficient to relieve SVC syndrome. The relationship of SVC obstruction to location and patency of the azygos vein has an important effect on natural history. When the azygos vein is closed, central thoracic collateral circulation is eliminated and SVC syndrome is worse because venous drainage from the upper body is dependent on smaller, less reliable venous channels in the chest wall and skin.

Even minimal tumor invasion of the SVC or compression by benign tumor may stimulate formation and propagation of blood clot within the vena cava. Malignant diseases resulting in acute SVC obstruction and thrombosis may not resolve with thrombolytic and radiation therapy. Acute SVC obstruction associated with signs of cerebral or laryngeal edema results in death within 6 weeks, apparently related to SVC syndrome rather than the primary etiology of the caval obstruction. The malignant process responds to therapy in
PART V Diseases of the Thoracic Arteries and Veins

Figure 28-3  Digital angiography in superior vena cava obstruction, venous phase. A, Anteroposterior projection shows extensive collateral venous network communicating with azygos system of veins in thorax and extending to a venous plexus below diaphragm. B, Oblique projection demonstrating extensive venous collateralization bringing systemic venous return from upper body to venous circulation below diaphragm.

a variable manner depending in part on cell type, ultimately determining the patient’s fate. Surgical intervention may be beneficial if the SVC syndrome is life threatening. It allows treatment of the malignancy to proceed in an orderly fashion and provides patient comfort.

Fibrosis associated with clot resolution and late clot propagation may be accompanied by worsening of symptoms and signs of SVC syndrome, despite adequate venous collateralization. Thus, SVC obstruction may persist even though there appears to be good response to treatment of the tumor. Some benign causes of SVC obstruction lead to severe and relentless inflammation and fibrosis, resulting in recurrent extending obstruction.

Clot propagation within the venous system proximal to the primary site of SVC obstruction may lead to progression of SVC syndrome in patients with benign etiology. Clot formation around indwelling catheters is especially prone to extensive thrombosis of the SVC and major thoracic and cervical venous tributaries. Some patients with SVC obstruction may never develop adequate collateral circulation even though the causative process is stabilized or eliminated.

TECHNIQUE OF OPERATION

Restoring thoracic venous drainage usually requires bypass of obstructed native venous channels using, when available, autologous tissue conduits to provide optimum long-term patency. Venous conduits include spiral saphenous vein, femoral vein, simple saphenous vein, and composite autologous vein grafts. In unusual situations, other venous conduits, such as composite azygos vein-IVC or jugular vein-femoral vein grafts, can be used. If autologous venous tissue is not available, aortic allografts, venous allografts, and autologous or homologous pericardial tubes can be used as conduit. Prosthetic grafts are generally inferior to autologous tissue grafts.

Successful bypass grafting depends on (1) adequate size of the conduit and (2) proper orientation. Graft diameter should closely match that of the native inflow vein to prevent residual obstructive flow gradients. To prevent graft kinking and obstruction, graft length should be measured so that it is not redundant. Both graft inflow and outflow sites should be free of intraluminal obstructions such as atrial trabeculations, adherent venous thrombus, or abnormal vascular intima.

Spiral Saphenous Vein Graft

The most extensive experience has been with the spiral saphenous vein graft conduit, a concept developed experimentally by Chiu and colleagues and applied clinically by Doty and Baker. Operation is performed through a median sternotomy or via a smaller incision using a partial upper half sternotomy (Fig. 28-6). A simultaneous incision is made in the thigh
over the course of the saphenous vein. The left brachioce-
phalic vein is mobilized to the left internal jugular–left sub-
clavian vein confluence. When the brachiocephalic vein and
subclavian-jugular confluence are thrombosed, it is necessary
to mobilize either the left or right internal jugular vein, which
then becomes the inflow point of the upper body venous
compartment. In this situation the midline incision may be
extended superiorly to the left or right and the strap muscles
divided to provide an unrestricted passageway for the bypass
conduit. The largest of the two jugular veins may also be
exposed and mobilized through a secondary cervical incision.
The two incisions are joined in a tunnel beneath the sterno-
cleidomastoid muscle. Biopsy samples of abnormal tissue sur-
rounding the SVC are obtained.

Diameter of the inflow vein (usually left brachiocephalic
or jugular) and distance from vein to right atrial appendage
are measured. After mobilizing the saphenous vein, its average
diameter is measured. Length of saphenous vein to be
removed is determined from (1) the ratio of the desired graft
diameter to the average diameter of the saphenous vein (SV),

Figure 28-4  Two-dimensional echocardiogram of partial obstruc-
tion of superior vena cava (SVC). Upper panel, (Before) shows image
of SVC before operation. Mass in SVC is an organized clot infected
with Candida albicans. Lower panel, (After) shows SVC cleared of
mass and patent.

organized thrombus removed at operation.

Figure 28-6  Spiral vein bypass of obstructed superior vena cava
through a ministernotomy. Midline incision about 10 cm in length
is made over upper sternum. The sternum is divided in the midline
to the third intercostal space, where it is divided transversely.
Ascending aorta and right atrial appendage are exposed. Simultane-
ous incision is made in the thigh over greater saphenous vein.
graft diameter to less than that of the inflow vein, which could produce stasis.

After administering heparin (100 units · kg$^{-1}$) intravenously, a vascular clamp is applied at the internal jugular–subclavian vein junction and the brachiocephalic vein divided, retaining as much length as possible. The distal end of the brachiocephalic vein is oversewn for secure closure (Fig. 28-8). Thrombus or any other abnormal tissue is removed from the inside of the brachiocephalic vein. The vein graft is pushed slightly off the end of the stent to allow construction of an end-to-end anastomosis to the brachiocephalic vein using continuous 7-0 polypropylene suture (Fig. 28-8, B). If the internal jugular vein is selected as the site for anastomosis, a partial occlusion clamp is applied at the intended outflow point and an end-to-side anastomosis performed. The stent is then removed from the graft.

When the graft must cross the thoracic inlet, an external stent is employed to prevent graft compression. A short segment of an externally reinforced PTFE graft somewhat larger than the spiral vein graft is placed around the vein graft as it crosses the thoracic inlet. A curved vascular clamp is placed across the right atrial appendage, and the tip is excised. The opening in the appendage is cleared of trabeculae to ensure unrestricted blood flow. The graft is anastomosed to the appendage, using continuous 5-0 polypropylene suture

and (2) distance to the right atrial (RA) appendage according to the following formula (Eq. 28-1):

\[
\text{Inflow vein to SV length} = \frac{\text{Inflow vein diameter (mm)}}{\text{SV diameter (average)}} \cdot \text{Inflow vein to RA appendage length (cm)}
\]

For example, if the brachiocephalic vein diameter is 12 mm, saphenous vein diameter is 4 mm, and distance to right atrial appendage is 10 cm, then 30 cm of saphenous vein is required ([12/4] · 10 = 30 cm).

The required length of saphenous vein is removed and its side branches ligated. The vein is incised longitudinally through its entire length (Fig. 28-7, A). A thoracostomy tube of the same diameter as the brachiocephalic or jugular vein is selected as a stent. The opened vein graft is flattened and wrapped around the stent in spiral fashion (Fig. 28-7, B), with the endothelial surface of the vein against the stent. Continuous sutures of 7-0 polypropylene are used to join the edges of the graft (Fig. 28-7, C), forming a large conduit with the same internal diameter as the stent. There is no advantage of a larger or smaller conduit. A smaller conduit could, in theory, have a hemodynamic advantage by increasing flow velocity in the graft. However, because the graft diameter is always smaller than that of the SVC, velocity of flow through the graft is substantial, obviating need to reduce...
Figure 28-8 Insertion of spiral vein graft between brachiocephalic vein and right atrium to bypass obstructed superior vena cava. A, Left brachiocephalic vein is occluded with a soft-jaw clamp. Vein is divided and distal (caval) end oversewn. B, End-to-end anastomosis of spiral vein graft to brachiocephalic vein. C, Right atrial appendage is isolated by vascular clamp. Tip of appendage is excised and all trabeculae removed, and spiral vein graft is anastomosed to it. D, Completed repair.
(Fig. 28-8, C). If the atrial appendage is not present, the graft is anastomosed to the lateral wall of the right atrium. The completed bypass graft must be oriented correctly and be the right length (Fig. 28-8, D). Extra length serves no advantage and runs a risk of kinking the graft or impeding blood flow.

Direct Operation on Superior or Inferior Vena Cava

Direct operation on the SVC or IVC is performed when there is blood clot or tumor partially obstructing the lumen. Indications include removal of thrombus surrounding intraluminal catheters used for parenteral feeding, chemotherapy, or cardiac pacing. In these cases, the thrombus may adhere to the catheter or the intima of the SVC, making nonoperative removal of the mass hazardous or impossible. There may be infection associated with the foreign body or invading the thrombus. Procedures on the IVC are usually performed for renal cell carcinoma when there is a long mobile or adherent tumor mass in the IVC or right atrium extending from the renal vein that cannot be safely removed from the right atrium.

For procedures involving the SVC, a median sternotomy is made. Strategy for inserting the venous cannulae for venous return is based on location of the mass that is to be removed (see Figs. 28-4 and 28-5). If the mass is located completely within the SVC, a two-stage venous cannula is inserted through the right atrial wall and passed into the IVC. Masses that completely fill the right atrium require peripheral cannulation (femoral vein, internal jugular vein) (see “Cardiopulmonary Bypass Established by Peripheral Cannulation” in Section III of Chapter 2).

CPB is established, and the patient’s body temperature is lowered to 16°C to 20°C (see “Aortic Arch Replacement” under Technique of Operation in Chapter 26). Cardioplegic solution can be administered to arrest the heart after placement of an aortic occlusion clamp. Alternatively, the procedure can be performed using hypothermic fibrillation. When the target temperature is reached, CPB is discontinued. Venous cannulae may be removed to enhance exposure.

The SVC is incised to expose the mass. Endarterectomy technique using a Freer septum elevator may be necessary to remove adherent thrombus (see Fig. 27-7 in Chapter 27). The mass is removed completely, even if a secondary incision is required, and the access incision closed. If a portion of the wall of the vena cava has been excised, the defect can be repaired using a patch of autologous or bovine pericardium to prevent caval stenosis. Air is evacuated from the right heart, CPB is resumed, and rewarming commenced (see “Rewarming” in Section IV of Chapter 2).

Masses in the IVC adjacent to the right atrium are exposed through incision in the right atrium after establishing hypothermic circulatory arrest. It is sometimes necessary to extend the incision into the IVC. The orifices of the hepatic veins should be thoroughly inspected to ensure that no residual tumor or thrombus remains.

Retroperitoneal tumors, especially renal cell carcinoma, have a tendency to spread into the venous system and in advanced stages can involve the suprahepatic IVC and right atrium. Hypothermic CPB with an interval of circulatory arrest permits safe removal of tumor and thrombus from the retrohepatic segment of the IVC as well as from the right atrium and pulmonary artery. Alternative strategies include beating-heart CPB and veno-venous bypass.

RESULTS

Long-term follow-up of a small number of patients receiving spiral saphenous vein grafts for SVC obstruction has demonstrated excellent results. SVC syndrome is immediately relieved. When operation is performed in patients with malignancies, natural history of the tumor determines outcome. Lochridge and colleagues reported that of six patients undergoing operation for malignant disease, all were relieved of SVC syndrome with no recurrence, although all died within 1 year from their malignancy. Smith and Brantigan also reported successful use of a spiral vein bypass graft in the setting of bronchogenic carcinoma, and Anderson and Li have used it as an interposition graft to reconstruct the SVC after resecting a leiomyosarcoma; the graft was patent on computed axial tomography 10 months postoperatively.

Long-term results are known when operation is performed for SVC obstruction from benign causes. Doty and colleagues reported on outcome of 16 such patients with mean follow-up of 10.9 years (range 1 month to 23.7 years). All patients survived the operation and were discharged from the hospital. Anticoagulation with warfarin was not used after operation in any patient, but all received aspirin. Patient outcome is summarized in Table 28-2. Grant patency was confirmed by Doppler ultrasound, which showed increased flow velocity over the jugular vein on the side of the bypass graft. In some cases, venography documented patency (Fig. 28-9). Patency was inferred in most cases by freedom from symptoms of SVC syndrome.

Data from Doty and colleagues.
Figure 28-9  Venography after bypass of superior vena cava (SVC) with composite spiral saphenous vein graft. A, Bypass graft anastomosed to left brachiocephalic vein at left jugular–subclavian vein confluence, which courses anterior to aorta to the right atrial appendage. Contrast media from bilateral arm venography opacifies right atrium and pulmonary trunk. B, Closer view shows bypass graft between left brachiocephalic vein and right atrial appendage. There is streaming of unopacified blood from left internal jugular vein flowing into bypass graft. Continued

For patients in whom graft closure was documented, SVC syndrome promptly recurred and venography showed graft closure. Three patients had graft closure within the first year after operation. One had thrombosis of the proximal brachiocephalic vein–graft anastomosis 4 days after operation, with recurrence of face and neck swelling and other signs of SVC obstruction. Graft revision was performed, and the patient remained asymptomatic nearly 13 years later. Another had recurrence of symptoms 5 months after operation for spontaneous thrombosis of the SVC; she had not been given anticoagulants and, in retrospect, probably should have been treated with warfarin after operation. Symptoms of SVC syndrome recurred, and graft closure was documented by CT scan; no further operative treatment was given. In a third patient, graft closure developed 1 year after initial operation. This patient had fibrosing mediastinitis and retroperitonitis, which subsequently obliterated both internal jugular veins, the original bypass graft, three subsequent bypass grafts, and the IVC. SVC syndrome recurred promptly each time a bypass graft occluded.

At a second operation in another institution, bilateral straight saphenous vein grafts were placed from the right and
left external jugular veins to the right atrium. These grafts provided partial symptom relief for 8 years before they also occluded. At that point a 10-mm PTFE graft was placed from the left internal jugular vein to the right atrial appendage. It occluded 3 years later, and a composite graft was constructed from common iliac vein and IVC allograft tissue. This composite graft was placed from the left internal jugular vein near the angle of the mandible and a side branch to the left external jugular vein, to the right atrium; the graft was enclosed in a 12-mm PTFE graft. Four years later, SVC syndrome recurred and the patient died shortly thereafter.

Thus, 14 of 16 patients had patent spiral saphenous vein bypass grafts for the duration of follow-up (88%; CL 73%-96%). Once established, the spiral saphenous vein graft appears to be a permanent conduit unless invaded by continuing aggressive mediastinal or intrinsic thrombotic vascular disease. Gloviczki and colleagues\(^{18}\) reported similar excellent patency of spiral grafts at 5 years for nonmalignant venous occlusive disease, noting that bifurcated conduits tended to have occlusion of one limb. In their expanded series, cumulative 4-year patency for 20 spiral grafts was 67%.\(^{18}\)

Spiral vein grafts are useful in children as well as adults, as demonstrated by successful treatment of SVC obstruction secondary to intraatrial baffle obstruction for transposition of the great arteries using a bypass graft from the brachiocephalic vein to the left atrial appendage.\(^{18}\) Results of direct operations to remove obstructing masses from the SVC or IVC are difficult to assess because of small individual institutional experiences. Results should be good in adult patients, with nearly all surviving operation and most relieved of SVC obstruction. In infants and children in whom venous channels are small, results will be less favorable. Berman and colleagues reported 37 patients aged 4 days to 17 years with thrombus in the SVC or right atrium from central venous catheters over a 6-year period.\(^{18}\) Operations to remove the clot were performed in only 4 patients, 2 of whom died (50%; CL 18%-82%).

### INDICATIONS FOR OPERATION

Current recommendations for operative intervention in SVC obstruction are as follows:

- Persistent severe SVC syndrome caused by chronic SVC obstruction from benign process
- Acute SVC obstruction caused by benign or malignant processes with signs of cerebral or laryngeal edema
- Relief of life-threatening SVC syndrome during palliation of malignant process
- Failure of nonoperative treatment to resolve SVC syndrome (see “Nonoperative Treatment” later)
- Tumor or blood clot partially obstructing the SVC or IVC that is hazardous or impossible to remove without operation

Reconstruction is contraindicated in patients with:

- Adequate collateral circulation to provide upper-body venous decompression
- Extensive thrombosis of the SVC and its tributaries such that there is no suitable vein large enough to provide outflow from the upper body sufficient to decompress venous hypertension
- Large, bulky tumors of the anterior mediastinum
- Limited life expectancy because of advanced malignancy or associated medical disorders

### SPECIAL SITUATIONS AND CONTROVERSIES

**Femoral Vein Graft**

Since the original successful bypass operations were performed in the 1950s, the femoral vein has been used as a bypass graft.\(^{18,11,14,15}\) Gladstone and colleagues revived the concept of using autologous femoral vein to construct a
bypass graft in two patients, one with mediastinal fibrosis and the other with poorly differentiated carcinoma. \(^{62}\)

After median sternotomy to confirm feasibility of the bypass operation, the femoral vein is exposed from its junction with the greater saphenous vein as far distally as the adductor hiatus if necessary. Minor branches are ligated and the appropriate length of vein removed distal to the femoral-saphenous junction. Following heparinization, the femoral vein graft is interposed between the brachiocephalic vein and right atrial appendage, as described for spiral vein graft bypass. Femoral vein grafts have remained patent up to 18 months after operation, as reported by Marshall and Kououchoukov\(^{35}\) and Kalra and colleagues.\(^{K1}\) Addition of a ringed PTFE tube around the graft provided external support to prevent recurrent fibrosis in a patient who had previously undergone spiral vein bypass.\(^{35}\) There has been some concern about leg edema after femoral vein removal, but published reports indicate that this is not a major problem. A potential problem with femoral bypass grafts is their fixed diameter, which may not match the inflow vein or may be too small to relieve obstruction.

**Autologous Paneled Saphenous Vein Graft**

Large-caliber venous bypass conduits can be constructed using saphenous vein in a composite or paneled manner as first reported by Benvenuto and colleagues in 1962.\(^{53}\) The saphenous vein is divided into several segments, each of which is incised longitudinally. The segments are flattened, placed on a stent in a paneled or tiled manner, and sewn together to create the conduit. Both the initial report and a subsequent study by Miller and Sullivan demonstrated graft patency at 1 year.\(^{53,54}\) Scherck and colleagues reviewed 11 case reports in which autologous vein grafts were used in various configurations to bypass or reconstruct the SVC.\(^{55}\) Follow-up ranged from 8 days to 5 years, and overall graft patency was 70%.

**Saphenous Vein Grafts**

Intact saphenous veins can be used as bypass conduits. Their small caliber typically dictates constructing more than one graft to provide adequate venous flow. Mitchell and colleagues described two patients with mediastinal fibrosis in whom saphenous vein was used to create a double bypass graft to the proximal SVC.\(^{56}\) One patient was asymptomatic 11 years postoperatively; both grafts thrombosed 2 weeks after operation in the other. Larsson and Lepore reported three patients with thymoma in whom saphenous vein was used for bypass grafting.\(^{1,2}\) Two had double bypass graft construction to the right atrium and the third had single bypass graft construction to the proximal SVC. All patients had patent grafts at follow-up from 8 to 10 months.

Unmodified saphenous vein grafts may be too small to relieve venous obstruction unless two or more grafts are constructed from veins above the caval obstruction to the right atrium. Although patency is good, relief of symptoms may not be as predictable as when a single large-diameter graft is used.

**Alternative Venous Anastomoses**

Occasionally, patients with SVC obstruction can be surgically treated without constructing a venous bypass graft in the thorax. Schramel and Olinde were the first to describe subcutaneous tunneling of a long saphenous vein bypass conduit to the jugular vein.\(^{54}\) Taylor and colleagues later used a similar approach.\(^{71}\) Vincze and colleagues described seven cases of patients treated with saphenous-jugular bypass for SVC obstruction caused by lung carcinoma; all were free of obstructive symptoms at the time of death, ranging from 2 to 14 months.\(^{52}\) Graham and colleagues reported a series of three patients undergoing subcutaneous jugular vein–to–femoral vein bypass;\(^{63}\) all had relief of SVC syndrome at follow-up, ranging from 6 weeks to 13 months.

Cooley and Hallman reported a case of SVC obstruction in which contrast venography demonstrated retrograde flow through theazygos system.\(^{14}\) The patient was treated with side-to-side anastomosis of the azygos vein to the IVC, which resolved the SVC obstruction. Shimokawa and colleagues\(^{410}\) described extracorporeal axillofemoral venous bypass as a useful temporizing measure to reduce venous pressure in the upper thorax.

The extensive length of bypass grafts taken from the upper-body veins to the femoral vein in the groin presents enough resistance to flow to render long-term patency of such conduits unpredictable. Simple anastomoses between veins in a high-pressure system to venous channels with normal low pressure within the thorax are unusual opportunities, but they should be sought in all cases.

**Allografts and Pericardial Conduits**

In some cases, autologous venous bypass grafting cannot be accomplished. Alternative tissue conduits in this setting include aortic, SVC, or femoral vein allografts and autologous pericardial tube grafts. Aortic allografts have excellent handling characteristics and perform well when used for arterial system replacements. Scherck and colleagues\(^{53}\) demonstrated overall graft patency of nearly 90% on review of 17 patients (CL 74%-96%) who received aortic allografts to reconstruct the SVC. In 1997, Ohri and colleagues\(^{52}\) reported a case of SVC obstruction caused by drug-resistant tuberculosis and treated with aortic allograft reconstruction; the graft was patent at 6 months. Moore and colleagues examined the potential application of SVC allografts as a possible conduit\(^{511}\); graft patency was approximately 70% in their experimental model. Clinical use of an SVC allograft has been reported only once to date; the graft was patent 1 year after operation.

Initial experience with tube grafts constructed from autologous pericardium has been disappointing in the experimental setting. Scherck and colleagues reviewed three series of experimental pericardial tube grafts; none were patent.\(^{53}\) Clinical use of autologous pericardial tubes, however, has been more encouraging. Zembala and colleagues created a pericardial tube graft between the brachiocephalic vein and right atrial appendage that remained patent for 11 months in a patient with malignant teratoma.\(^{22}\) Piccione and colleagues successfully used autologous pericardial tube grafts in six patients to reconstruct portions of the SVC after resection for carcinoma, and all were relieved of obstructive symptoms.\(^{73}\) Lemmer and colleagues created composite conduits in two pediatric patients from pedicled right atrium and pericardium to reconstruct the SVC; the conduits were patent 24 and 43 months after operation.\(^{1,5}\)

Aortic or venous allografts have high patency in many applications within the thorax. Long-term patency depends
on methods of graft preparation and complex immune factors. Allografts should be viewed as palliative, and the graft should be expected to deteriorate with time. Pericardial venous conduits are probably no better than (and perhaps not as good as) prosthetic conduits. On the other hand, composite pericardial conduits consisting of pericardium and pedicled atrium should have a high probability of remaining patent for a long time because they include normal endocardium.

Prosthetic Grafts

Prosthetic grafts, principally externally supported (ringed) polytetrafluoroethylene (ePTFE), have been used to bypass or replace the SVC for both benign and malignant disease. Kalra and colleagues used ePTFE to bypass nonmalignant obstructed SVCs in 6 patients. Cumulative patency at 1 and 4 years was 50% and 17%, respectively, and was significantly lower than for 20 patients who received spiral saphenous vein grafts (67% and 67%, respectively; \( P = .02 \)).

Dartevelle and colleagues interposed ePTFE grafts between the proximal and cardiac ends of the SVC in eight patients, and between one or both brachiocephalic veins in 14 patients with malignant lung or mediastinal tumors. One graft occluded early postoperatively and one at 14 months. Patency of all remaining grafts was demonstrated from 1 to 98 months (mean 23 months) postoperatively.

Leo and colleagues used ePTFE grafts to bypass the SVC in 28 patients with malignant lung or mediastinal tumors who had total SVC resection. Early graft occlusion was observed in one patient. At 4 months, all grafts in surviving patients were patent.

Nonoperative Treatment

Medical Therapy

Medical measures may be beneficial in temporarily relieving symptoms of SVC syndrome, especially in hospitalized patients. Bed rest with the head elevated gradually brings improvement in most cases. Diuretics and reduced sodium intake usually reduce upper-body edema. Corticosteroids may be useful in reducing cerebral edema.

Anticoagulants have been frequently employed, but effectiveness has not been demonstrated by controlled trial. They may be effective in preventing propagation of clot into caval tributaries, thereby retarding progression of the syndrome. Anticoagulants most frequently used include heparin during hospitalization and warfarin for long-term therapy. Long-acting heparin-like medications (enoxaparin) may prove beneficial for preventing clot propagation. Patients best suited for anticoagulant therapy are those with quiescent benign disease (e.g., dormant granulomatous mediastinitis) or catheter placement in the SVC.

Thrombolytic therapy may be valuable in patients with acute thrombosis of the SVC if the cause of thrombosis can be eliminated, such as by removing an indwelling catheter. Gray and colleagues reported the Cleveland Clinic experience using urokinase or streptokinase for treating SVC syndrome in 16 patients, 11 of whom had indwelling central venous catheters; 56% (CI 40%-71%) had complete clot lysis and relief of symptoms. Success was most often achieved when thrombolytic medication was infused through the central venous catheters and when thrombus had been present less than 5 days. Reports of other cases from the literature indicate greatest success of clot lysis when the thrombosis is treated within 72 hours.

Radiation Therapy

Radiation therapy is the primary treatment modality for thoracic malignancies causing SVC syndrome, and nearly all patients receive radiation at some point in their clinical course. This treatment should be administered only after establishing a tissue diagnosis of the cause of SVC obstruction, because a few patients may develop life-threatening cerebral or laryngeal edema that requires urgent intervention.

Radiation is directed to the tumor mass, to a 2-cm margin surrounding it, and to mediastinal, hilar, and supraclavicular lymph nodes. Radiation is fractionated with an initial midplane dose of 4 Gy for 3 days and then 1.5 Gy per day until an accumulated 30 to 50 Gy is achieved. Total dose depends on the patient’s condition, extent of disease, response of disease to treatment, and tumor histology.

Rodrigues and colleagues used hypofractionated radiation therapy to treat 39 patients with primary lung cancer and SVC syndrome. The most successful regimen was administration of a high dose of 8 Gy weekly for 3 weeks, for a total dose of 24 Gy. Using this protocol, 96% of patients received some relief of SVC syndrome, and 56% had complete relief. Recurrence occurred within 6 months in 20% of patients.

Most patients respond to radiation treatment. Reports from the literature suggest only 10% to 20% of patients fail to obtain relief of SVC syndrome, but up to 50% relapse. Improved survival has been reported with radiation therapy for patients with SVC syndrome resulting from malignancy. Mean survival time for untreated persons is 6 to 7 months, whereas it is at least double that with radiation therapy, and some long-term cures have been reported. Perez and colleagues found that 10% of patients with bronchogenic carcinoma as a cause of SVC syndrome were alive at 30 months, and 45% of patients with lymphoma as a cause were alive late after treatment. Emergency radiation therapy may be indicated for treating critically ill children presenting with SVC syndrome, most commonly due to non-Hodgkin lymphoma.

Chemotherapy

Cancer chemotherapy can be effective as primary therapy or as an adjunct to radiotherapy or surgery in selected cases. Random use of chemotherapy has not been shown to be effective. Combined chemotherapy and radiotherapy is beneficial for relieving SVC syndrome caused by mediastinal lymphoma. Chemotherapy alone, using a combination of agents, may be the treatment of choice for small-cell anaplastic bronchogenic carcinoma, with symptom relief within 7 days. Best results occur with incomplete SVC obstruction and with extrinsic compression from large tumors at the thoracic inlet.

Transluminal Balloon Angioplasty and Stents

Successful transluminal balloon angioplasty and stenting require that the SVC not be completely obstructed, because a vascular passageway is needed to guide the device. Endovascular therapy initially involved balloon angioplasty, which was successful for benign causes of SVC obstruction but rarely for malignant causes. However, the SVC is unable to resist external compression by tumor or inflammation. These led to the use of intravascular stents.
Gaines and colleagues used the Gianturco Z self-expanding metallic device (consisting of a stainless steel wire bent in a Z configuration) as a single or double stent in 20 patients with malignant SVC obstruction; 13 (65%; CL 51%-77%) were free of SVC obstruction until death, and 3 required a second intervention.1,6 Oudkerk and colleagues treated 22 patients with malignant obstructions with Gianturco Z stents, with 68% (CL 55%-79%) free of symptoms of SVC syndrome and without recurrence until death from tumor progression. Another 4 (18%) showed improvement, and 3 (14%) had reocclusion.8,9 Dyet and colleagues achieved similar results using the Wallstent endovascular prosthesis in 17 patients.10 This device is a tube of woven stainless steel mesh, which is more secure for short-segment stenoses.

Stents have also been successfully used to treat benign causes of SVC obstruction, including stenosis caused by pacemaker electrodes.11,12 Subsequent series have confirmed the effectiveness of endovascular stenting for both benign and malignant SVC obstruction.2,13,14 It is now considered the first line of treatment in many institutions.1,13,21

Because of clot formation in patients with SVC obstruction, concomitant thrombolytic therapy has been recommended to remove the clot and establish a channel through which the stent can be deployed.15 Anticoagulation is recommended after stent implantation to avoid thrombosis, but optimal duration and methods of anticoagulation have not been completely defined.16

In addition to early thrombosis, complications of endovascular stenting include acute pulmonary edema, hemorrhage, perforation, cardiac tamponade, stent migration, infection, cardiac dysrythmias, and pulmonary embolism.17,22

Comparison of Operation with Catheter Intervention

Wisselink and colleagues compared operative vs. percutaneous catheter intervention for treating patients with central venous obstruction.23 Their study included patients with obstruction of not only the SVC but also its major tributaries. Of 27 patients, 12 underwent operation, 14 had angioplasty, and 1 had both. Stents were used in three patients. Primary symptom relief at 1 year was achieved in 88% of the surgical group vs. 36% of the angioplasty group (P < .05). When repeat angioplasty was performed, success in that group increased to 66%. Thus, surgical success exceeded that of single catheter intervention, but repeated angioplasty achieved comparable results.

A nonrandomized trial comparing open surgical repair with endovascular stenting has demonstrated equivalent midterm effectiveness in terms of symptom relief.24 Reinterventions were required more frequently in the stented patients. Assisted primary and secondary patency was significantly higher in the stented patients (P = .02). The authors concluded that open surgical repair remains an excellent option for patients who are unsuitable for endovascular stents.

Injury to Left Brachiocephalic Vein during Sternotomy

Laceration of the left brachiocephalic vein is a hazard of sternotomy. It occurs rarely during primary sternotomy, but is a common threat during repeat sternotomy. The hazard is reduced during reentry by dividing the sternum with an oscillating saw rather than using the standard blade. Once the sternum is divided, tissues adherent to the posterior table of the sternum superiorly are separated sharply or with the electrocautery. Mobilizing the tissues surrounding the brachiocephalic vein will reduce the role of disruption. Wide separation of the sternal edges should be avoided to reduce tension on the vein.

The most common method of managing major injuries is ligation. Usually, left arm or neck swelling is not observed, although later thrombosis of the tributaries of the vein may occur. The consequences of uncontrolled hemorrhage and difficulties in repairing the vein without creating stenosis appear to outweigh the risks of ligation. Repair of the vein is feasible if the disruption is not complete, and can be accomplished using autologous or bovine pericardium. If the vein is disrupted at its junction with the SVC such that ligation will compromise flow into the SVC or cause stenosis of the right brachiocephalic vein, repair or SVC bypass should be performed to avoid SVC syndrome.

Budd-Chiari Syndrome

In 1845, Budd described three cases of hepatic vein thrombosis caused by abscess-induced phlebitis.20 In 1899, Chiari reported another three cases of obliterative phlebitis of large hepatic veins.21 Budd-Chiari syndrome was thus initially defined as symptomatic occlusion of hepatic veins, but subsequent inclusion of various obliterative changes in the hepatic portion of the IVC and hepatic vein orifices broadened the definition. Membranous obstruction of the IVC is generally regarded as a congenital vascular malformation, yet it results in impaired hepatic venous outflow blockage and hence is included with the syndrome. However, obliterative disease of this type and primary hepatic vein thrombosis (classic Budd-Chiari), are different clinical entities.30

Hepatic vein thrombosis is more common in western than eastern countries and presents as severe, sometimes acute, hepatic failure. It is associated with a hypercoagulable state, the factor V Leiden mutation.31,32,33 Mahmoud and Elias recommend screening all patients with Budd-Chiari syndrome for activated protein C resistance and factor V Leiden mutation.32 Vasculitis accompanying Behçet disease is also associated with hepatic vein thrombosis.22 When there is associated thrombosis of the portal venous system, treatment options are limited and prognosis is poor, with 70% of patients dying before any treatment can be given or after operation.34

Treatment of classic Budd-Chiari syndrome is primarily by orthotopic liver transplantation when liver failure is fulminant or chronic.35 For acute and subacute forms when hepatic injury is reversible, a surgical or percutaneous portasystemic shunt is effective.33,34,35,36 A transjugular intrahepatic portosystemic shunt (TIPS) may also be effective while awaiting liver transplantation.

Obliterative disease of the hepatic portion of the IVC is often a membranous obstruction of the vena cava or of the hepatic vein orifices. It is primarily a condition found in Nepal, South Africa, China, and India.37 It is usually idiopathic, although many consider it to be a congenital anomaly. Complex congenital venous anomalies may cause hepatic venous congestion in rare instances.38 Clinical presentation is milder than with primary hepatic vein thrombosis, and time of onset is frequently unknown. Enlarged subcutaneous veins over the body trunk are characteristic, similar to those seen in obstruction of the SVC. Hepatocellular carcinoma is a frequent complication.
Treatment is generally by transvenous balloon angioplasty or stent placement, possibly in combination with a portasystemic shunt. Despite these less invasive treatment methods, operative intervention has a role in this condition. Transtrial membranotomy, reconstruction of the IVC, and bypass from the IVC to the right atrium are alternatives when catheter interventions are not possible.

Koja and colleagues describe direct exposure of the retrohepatic IVC via thoracoabdominal incision on the right. The vena cava is occluded above and below the liver while the patient is on femorofemoral bypass with an oxygenator. Hepatoma occurred 3 to 9 years after operation in 5 patients. Survival at 1, 5, and 10 years after operation was 100%, 94%, and 67%, respectively. Esophageal varices gradually resolve, and hepatic fibrosis improves histologically after this operation. Rarely, hepatic trauma with intraparenchymal or subcapsular hematoma may cause compression of the intrahepatic IVC, resulting in Budd-Chiari syndrome. Technical problems related to closure of atrial septal defect may also cause obstruction of the IVC and hepatic veins.

The authors reported a remarkable series of 29 patients treated between 1979 and 1997. All patients survived operation and had documented IVC patency at 1 to 2 months after surgery. Restenosis of the IVC developed in 2 patients 2 and 6 years after operation; both were successfully treated by either reoperation or balloon angioplasty. Hepatoma occurred 3 to 9 years after operation in 5 patients. Survival at 1, 5, and 10 years after operation was 100%, 94%, and 67%, respectively. Esophageal varices gradually resolve, and hepatic fibrosis improves histologically after this operation.

DEFINITION

Congenital heart disease in the adult is presence of unrepaired or repaired congenital heart disease in patients aged 21 years or older. A more practical working definition is not straightforward. Because physical and emotional maturity is variable, the distinction between an adult and non-adult is unclear. The designation “adult” implies provision of specific methods of caregiving best delivered in an adult care environment. The patient age at which this approach is advisable varies, ranging from mid-teens to mid-20s, depending on the individual.

It has been recommended that the process of transitioning young patients successfully to an adult healthcare environment should begin by age 12 years. Several models of care fit the definition of “adult healthcare environment,” including adult congenital heart disease programs based in pediatric hospitals and clinics, those based in adult hospitals and clinics, and hybrid arrangements. None has proven superior.

SURVIVAL VERSUS CURE

Survival does not necessarily, and usually does not, mean cure. Cure is best defined as a state that results when survival and quality of life are indistinguishable from normal.

PREVALENCE

Survival of patients with congenital heart disease (CHD) has steadily improved over the past 4 decades since reoperative surgery has become commonplace. Since the 1970s, more than 80% of patients have survived into adult life. The 32nd Bethesda Conference report (Bethesda Report) in 2000 contains an estimate that approximately 800,000 adults in the United States have CHD. With current surgical mortality less than 10%, it is expected that in the next decade almost 1 in 150 young adults will have some form of CHD.9,12

The level of development of health care in a particular environment will strongly influence the prevalence and profile of adult congenital heart patients. In countries with underdeveloped healthcare systems, fewer congenital heart disease patients will survive to adulthood, and a preponderance of these will have unrepaired anomalies. Consequently, many of these patients will have advanced sequelae consistent with the natural history of the particular anomaly. In this chapter, we emphasize adult congenital heart disease as it presents in environments with state-of-the-art pediatric congenital heart disease management.
CATEGORIES OF ADULT CONGENITAL HEART DISEASE

Primary Congenital Heart Disease

Primary CHD in the adult refers to previously untreated anomalies. These anomalies tend to cause relatively benign pathophysiologic perturbations, allowing survival into adulthood without treatment. Primary CHD is less common than secondary CHD.

Newly Diagnosed Anomalies

Newly diagnosed anomalies fall into two categories. The first consists of patients with anomalies that not only allow survival to adulthood, but are sufficiently benign to escape detection even in environments with well-organized healthcare systems. Typical anomalies include those causing left-to-right shunt (atrial septal defect [ASD], partial atrioventricular septal defect [AVSD], restrictive ventricular septal defect [VSD], and restrictive patent ductus arteriosus [PDA]) and those causing minor valvar obstruction or regurgitation (bicuspid aortic valve). The second consists of patients with anomalies that allow survival to adulthood, but are sufficiently malignant to cause serious pathophysiologic changes; typically, these patients spend their childhood in environments without the capability of diagnosing or treating the anomaly, and only as adults enter an environment capable of detecting it. Typical anomalies include all of those listed in the first category, but they are attended by more serious pathophysiologic perturbations (larger, less restrictive VSDs), as well as selected cases of many forms of cyanotic congenital heart disease (tetralogy of Fallot, pulmonary stenosis, and even some forms of single ventricle).

Previously Diagnosed Anomalies with Benign Pathophysiology

Typical anomalies include those resulting in small or restrictive left-to-right shunts and minor valvar lesions. They are detected in infancy or childhood, but because of lack of important symptoms and pathophysiologic changes, are left untreated. These anomalies may progress in adulthood, causing symptoms (bicuspid aortic valve) or complications that result in symptoms (restrictive VSD with endocarditis).

Previously Diagnosed Anomalies Thought to Be Inoperable

Occasionally, adult patients are encountered who were diagnosed with complex congenital heart disease in infancy; however, because their pathophysiology was not life threatening and their structural heart disease was so complex as to be thought inoperable, they have been managed without surgical correction into adulthood. New surgical approaches may by then have become available. An example is the occasional patient with pulmonary atresia, VSD, or aortopulmonary collaterals, with mild cyanosis. This patient may be a candidate for unifocalization and intracardiac repair as an adult.

Secondary Congenital Heart Disease

Secondary congenital heart disease refers to patients with previously treated CHD, which is more common in the adult than primary CHD. It covers the entire spectrum of congenital anomalies. As illustrated in Fig. 29-1, some but by no means all patients who have undergone surgery for CHD as infants and children are cured and are not considered to have secondary CHD as adults.

MANAGEMENT AND ORGANIZATION OF HEALTH CARE

Currently, delivery of appropriate health care to adults with CHD is not fully met, even in the developed world. This is partly due to inadequately trained healthcare providers managing these patients after they transition from pediatric care, partly to poor organization, and partly to loss of health insurance when these patients become adults—up to 20% of adults with CHD may be uninsured. Lapse of care for adults with CHD is associated with adverse outcome. According to the Society of Thoracic Surgeons (STS) database, early mortality following cardiac surgery for CHD is higher in adults than in children, although neonates and infants have the highest mortality (Fig. 29-2). This higher mortality in adults may be caused partially by lack of healthcare organization and experience.

The Bethesda Report recommends organizing care of adults with CHD within a regionalized system of specialized adult CHD units, with each unit providing education, care, and research for its designated region. The Bethesda Report describes three levels of training for adult cardiovascular specialists managing adults with CHD. These training levels emphasize cardiology training, but do not focus on specifics of training for surgeons who care for these patients. It is recommended that cardiothoracic surgeons caring for adults with CHD have formal fellowship training in pediatric heart surgery. There is evidence obtained from an analysis of national practice patterns involving more than 40,000 patients that mortality following CHD surgery in adults is lower if the surgeon performing the operation is an experienced pediatric heart surgeon. The cardiothoracic surgeon managing adults with CHD should be fully integrated into the adult CHD unit and may take a leadership role in the functioning of the unit.

The combined American College of Cardiology (ACC)/American Heart Association (AHA) Guidelines Committee for the Management of Adults with CHD recognizes three levels of complexity of congenital heart disease in adults (Boxes 29-1 to 29-3) and makes specific recommendations for the Management of Adults with CHD.
for the management protocols based on these levels (Box 29-4).  

SPECIAL CIRCUMSTANCES

Pregnancy and Contraception

Overview

The most common cardiac cause of morbidity and mortality in pregnant women in North America is congenital malformations. Ideally, women with CHD should receive counseling by an adult CHD expert before becoming pregnant. Both fetal and maternal risks should be discussed. If pregnancy occurs, fetal echocardiography should be obtained and the consequences of pregnancy discussed.  

If functional class and systemic ventricular function are good, the outcome of pregnancy is favorable in most women with CHD. Even in women with well-compensated cardiac status, however, specific risks are present. In those with intracardiac shunts, air entry into intravenous lines may cause paradoxical embolism. Any degree of immobilization of the pregnant woman should be attended by prophylaxis for deep vein thrombosis, particularly if there is the potential for right-to-left intracardiac shunting.  

Pulmonary hypertension, especially when above 70% systemic, presents a serious risk during pregnancy. Pulmonary hypertensive events may occur after delivery. If Eisenmenger physiology is present, maternal mortality is up to 50% fetal loss at a similar level. Even after a successful pregnancy, maternal mortality may increase in the first several days after delivery. Anticoagulation during pregnancy, even to a level required for mechanical valves, is not a strict contraindication to pregnancy; however, it poses an increased risk to both mother and fetus.  

In a small group of women with complex CHD or with decompensated cardiac status, pregnancy is either dangerous or contraindicated. These women should be managed and delivered in specialized centers with expertise in adult CHD, obstetrics, anesthesiology, and neonatology. Vaginal delivery is preferable for most women with CHD; cesarean section and delivery is recommended for obstetric reasons and for women fully anticoagulated with warfarin at the time of delivery, because of the risk of fetal intracranial hemorrhage. Although pregnancy is not contraindicated in women with repaired congenital anomalies, increased complications may occur. An excess of miscarriages, preterm delivery, and maternal mortality is found after successful coarctation repair and repair of congenital aortic stenosis.  

Certain medications are contraindicated during pregnancy. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARB) cause congenital and renal disorders in the fetus. Warfarin should be used only after full discussion with the patient about its risks during pregnancy. Endocarditis is a recognized risk for maternal morbidity; however, endocarditis prophylaxis at the time of delivery is not universally recommended. Some believe that risk of bacteremia is low; others routinely

administer antibiotics. Intravenous amoxicillin and gentamicin should be considered for women with high-risk anatomy or previous history of endocarditis.

Estrogen-containing oral contraceptives are generally contraindicated in women at risk of thromboembolism. Those containing progesterone are contraindicated in women with heart failure because of their tendency to cause fluid retention. The risk of endocarditis with intrauterine devices is controversial, and recommendations should be individualized on the basis of discussions between the adult CHD specialist and gynecologist. 

Maternal Cardiac Surgery during Pregnancy
Cardiac surgery during pregnancy is rarely necessary. About 1% to 4% of pregnancies are complicated by cardiac disease. Occasionally, owing to progression of cardiac disease during pregnancy or to cardiovascular changes induced by pregnancy, cardiac surgical intervention is indicated. Although about 20% of adverse cardiac events during pregnancy will require surgery or an invasive interventional procedure, the majority of these can be managed medically. Maximal interdisciplinary efforts and proper assessment of maternal and fetal risks are mandatory in managing these patients. The maternal-fetal conflict of interest, nonelective presentation for surgery, and vulnerability during the postpartum period contribute to a higher risk of cardiovascular operations during pregnancy and postpartum than in the nonpregnant population.

Mortality risk of cardiac surgery is high, 2% to 9% for the mother and 20% to 30% for the fetus. Thus, the risk of maternal death during pregnancy increases 500- to 3000-fold if cardiac surgery is required. On the other hand, the 2% to 9% maternal mortality risk is probably onefold to twofold higher than the risk of the same cardiac operation in a nonpregnant woman of the same age. Several recent reports suggest that maternal mortality is not increased relative to the risk in nonpregnant women. Maternal risk will vary depending on the cardiac lesion. From a literature review of 161 cardiac operations during pregnancy, the greatest maternal risk was found to be associated with cardiac operations for pulmonary embolism (22%) and aortic dissection (22%), followed by operations for either native (9%) or prosthetic valve disease (9%). The underlying etiology of the embolism, dissection, and valve disease was not given; however, from the age range of the pregnant women, it is reasonable to assume, at least for the native and prosthetic valve categories, that congenital anomalies represent the underlying cause for a substantial number of the cases. In this same review, a separate category of “congenital anomalies” accounted for 11 (7%) of the 161 cases. Of these 11, 6 required cardiopulmonary bypass (CPB) to accomplish the repair. None of these 11 patients died. The other common underlying etiology of heart disease in pregnant women requiring cardiac surgery is likely rheumatic disease.

Other risk factors for death in pregnant women undergoing cardiac surgery include moderate or severe obstruction of the aortic or mitral valve, left ventricular ejection fraction below 40%, higher preoperative New York Heart Association (NYHA) functional class, and a preoperative history of stroke from arrhythmias. Risk factors for fetal death are shown in Table 29-2. To minimize risk to the fetus, if surgery is being considered during the third trimester, controlled delivery before the mother’s cardiac operation should be considered. If cardiac surgery is required at an earlier stage of gestation, alterations in managing the operation are necessary. Fetal bradycardia is a common complication; thus, fetal heart rate monitoring, and ideally fetal echocardiographic monitoring, should be performed. CPB adjustments are important to maximize uterine circulation and maintain fetal heart rate. These adjustments include increasing perfusion flow rates, maintaining high perfusion pressure (60 mmHg), avoiding hypothermia, maintaining high hematocrit, avoiding vasoconstrictive agents, and using pulsatile perfusion. The latter can be achieved using an intracoronary balloon pump during CPB, and this has been shown to improve uterine and fetal perfusion. Uterine contractions occur in response to CPB, possibly as a response to the dilution of progesterone, which stabilizes the uterus; thus, tocolytic pharmacologic therapy may be beneficial during CPB.

Pulmonary Arterial Hypertension and Eisenmenger Physiology
Irreversible pulmonary arterial hypertension (PAH) associated with CHD usually results from anomalies that allow long-standing left-to-right shunts. All such shunts cause PAH from birth onward; however, initially the PAH is flow related, meaning pulmonary blood flow (Qp) is increased and pulmonary vascular resistance (Rp) is low. Over time, PAH may evolve from flow related to resistance related, meaning that Rp becomes elevated and Qp decreases. Flow-related PAH is reversible after eliminating the shunt with surgery or other intervention. Resistance-related PAH is generally irreversible.
The shunt's type, size, and duration influence the likelihood that, and rapidity with which, irreversible PAH will develop. Thus, these factors will be important in determining the age at which patients with irreversible PAH present. Type and size of the shunt determine the magnitude of shunt flow, which in turn determines the amount of shear stress on the endothelial surface of resistance-level pulmonary arteries. Shear stress induces vasoactive changes and ultimately permanent obstructive structural changes in these arteries. Pulmonary vascular histology in shunt-induced irreversible PAH resembles that described for idiopathic PAH, with medial thickening and plexiform lesions in severe cases.\textsuperscript{24}

Individuals with atrial-level left-to-right shunts are least likely to develop irreversible PAH, those with ventricular-level shunts are more vulnerable, and those with arterial-level shunts are at greatest risk. Whether the variation in risk among these different levels is solely related to shunt flow or to an underlying genetic predisposition is unknown. A number of specific congenital heart anomalies can lead to irreversible PAH. Unrepaired large ASD, VSD, AVSD, and PDA account for most cases, simply because these defects are common.\textsuperscript{W13} However, many less common complex lesions, such as partial or total anomalous pulmonary venous return, unrepaired or palliated conoventricular defects, including truncus arteriosus or transposition of the great arteries (TGA), and single-ventricle variants, can also result in development of irreversible PAH. Other congenital causes of PAH unrelated to shunting include pulmonary vein stenosis and pulmonary veno-occlusive disease.\textsuperscript{W13}

Over time, as severe vascular obstructive changes develop, Rp approaches and exceeds systemic vascular resistance (Rs), causing a bidirectional or predominantly right-to-left shunt accompanied by oxygen-unresponsive hypoxemia, identified as Eisenmenger physiology.\textsuperscript{W27} In patients with large ventricular- and arterial-level left-to-right shunts or unrepaired complex congenital heart defects, irreversible PAH can develop as early as the first year of life and Eisenmenger physiology within the first decade of life (see “Pulmonary Vascular Disease” under Natural History in Section I of Chapter 35); however, in patients with medium or larger ASDs, Eisenmenger physiology may not appear at all, but when it does, it typically appears in the second, third, or fourth decade. Pregnancy may unmask pending Eisenmenger physiology.

PAH and Eisenmenger physiology may develop late after surgical repair of left-to-right shunts. The most common explanation is that the repair was performed too late or was incomplete. However, additional factors such as left ventricular hypertrophy and diastolic dysfunction, valve abnormalities, pulmonary venous hypertension or obstruction, restrictive or hyperventilatory lung disease, chronic liver disease, and toxin use must be considered and, if present, addressed to the degree possible.\textsuperscript{W13}

Dyspnea on exertion is the most common presenting symptom of patients with severe PAH and Eisenmenger physiology, followed by palpitations, peripheral edema, volume retention, hemoptysis, syncope, and progressive cyanosis.\textsuperscript{W27} Morbidity is progressive and becomes substantial, typically by the third decade of life. Hypoxemia-related secondary erythrocytosis leads to increased blood viscosity and intravascular sludging. Organ damage may result in the brain from cerebrovascular changes brought about by sludging, with resultant stroke, and in the kidneys, with altered renal function. Right heart pressure and volume overload cause elevated systemic venous pressure leading to hepatic dysfunction. Hyperuricemia may result in gout. Hemoptysis is potentially life threatening. Chest pain due to right ventricular ischemia, coronary artery compression by a dilated pulmonary artery, or arteriosclerosis may occur with exertion or at rest. Ultimately, right heart failure is inevitable. Poor functional status is an important predictor of mortality, as are serologic evidence of low systemic organ perfusion, worsening hypoxemia, and left ventricular systemic dysfunction.\textsuperscript{C2}

Premature death is the rule. The immediate modes of death include right ventricular failure, severe hemoptysis from bronchial artery rupture or pulmonary infarction, complications during pregnancy, and cerebral vascular events, including occlusive strokes, systemic paradoxical embolization, and brain abscesses.\textsuperscript{S2,S17} Death during noncardiac surgery also occurs.

Changes that occur with left-to-right shunt-related PAH can be reversible after eliminating the shunt, provided that the surgery is performed during the vasoactive stage of PAH development, before irreversible obstructive pulmonary vascular changes occur. Catheterization-based calculations of \( Q_p \), individualized measurements of resistance in isolated lung segments, and direct measurement of pulmonary venous pressure are typically used to assess PAH reversibility and likelihood of surgical success. One hundred percent inspired oxygen, inhaled nitric oxide, and intravenously administered prostacyclin are frequently used in such investigations to determine the degree of pulmonary vascular reactivity and the potential to subsequently lower pulmonary artery pressure with surgical correction of the shunt. Increasingly, acute and chronic pharmacologic pulmonary vasodilatory and vascular remodeling therapy accompanies surgery in these cases. Specific data are not available that firmly establish the pressures, flows, and resistances that determine if operation to remove the shunt is indicated. Typically, Rp less than 10 to 14 Wood units and a \( Q_p/Q_s \) less than or equal to 2/3 are associated with better surgical outcomes.\textsuperscript{C32,S49} Even less clear is the predictive value of degree of vasodilatation achieved in the catheterization laboratory in response to vasodilatory agents. An additional confounding factor is that calculated Rp itself can vary with \( Q_p \) based on flow; Rp calculated under shunt conditions with high \( Q_p \) may actually be lower than that calculated after the high-flow condition is eliminated by surgical repair. Pulmonary vessels that were recruited because of high \( Q_p \) may be lost after flow is reduced to normal following surgery, resulting in higher postoperative Rp and pulmonary pressure than was anticipated using the catheterization data.

If evaluation determines that surgical closure of the shunt is indicated, a multidisciplinary team approach is mandatory, including an anesthesia team and intensive care team experienced in managing both PAH and the adult with CHD. The surgical procedure itself will often be technically simple; however, pre- and postoperative management will not. The optimal type and mode of anesthetic administration should be individualized (see Chapter 4). Risk of right-to-left embolization warrants avoiding bubbles following intravenous catheter placement. Use of inhaled nitric oxide both pre- and postoperatively should be considered.

Diagnosis of Eisenmenger physiology requires a detailed history, documenting all previous cardiac surgical and interventional procedures and medical treatments. Thorough
documentation of the current cardiac morphology and cardio-pulmonary physiology is mandatory using chest radiography, electrocardiography, echocardiography, cardiac catheterization, computed tomography (CT), pulmonary function studies, and assessment of all end-organ function. Once the diagnosis is made, the option of surgical treatment by repair of the anomaly causing the shunt is no longer an option because this approach will result in physiologic decompensation from severe PAH, right heart failure, and mortality. Proven treatment options are strictly medical, with the exception of lung or heart-lung transplantation (see Chapter 21). Transplantation offers a limited survival benefit, given the unpredictability of transplant-free survival and significantly higher perioperative mortality in this cohort of patients, although individual outcomes may warrant individual considerations. Medical treatment options are complex and must be tailored to the individual patient, as discussed in detail in the ACC/AHA 2008 guidelines. The evolving concept of treat and repair, meaning initially using advanced pharmacologic regimens to treat PAH followed by surgical repair of the structural anomaly, has the potential to change some patients from “inoperable” to “operable,” although long-term benefit is currently unknown.

Heart Failure and Transplantation

Heart Failure
Myocardial dysfunction resulting in depressed cardiac function (heart failure) is present more frequently in adults being considered for surgery to correct a structural heart anomaly than in neonates, infants, and children. Distinguishing between heart failure and existing structural heart disease as the cause of cardiopulmonary decompensation is critical to successful decision making and managing of adults with CHD. Recognizing heart failure may be difficult because the associated congenital cardiacl condition may mimic symptoms of heart failure. For example, dyspnea on exertion may be due to cyanosis and not heart failure. As a result, NYHA functional status may be inadequate in this patient population.

The blurring between heart failure and structural heart disease is further complicated because the underlying disease itself may lead to heart failure in the adult, and thus both may be present in the same patient. The ACC/AHA guidelines identify the most common underlying cardiac structural substrates leading to late heart failure:

- Severe aortic stenosis or regurgitation secondary to bicuspid aortic valve and variants
- Subvalvar or supravalvar left ventricular outflow tract pathology
- Coarctation of the aorta
- Severe congenital mitral stenosis or regurgitation
- Unoperated ASD or partial AVSD
- Congenitally corrected TGA
- TGA after Mustard or Senning atrial switch procedures in which the morphologic right ventricle is the systemic ventricle
- Tetralogy of Fallot with early-era surgery, long-standing shunt, or severe pulmonary regurgitation or stenosis after repair
- Single-ventricle mixed circulation and chronic cyanosis
- Single ventricle after a Fontan procedure

Heart failure can be accelerated further in this patient population by unrelated conditions and chronic degenerative processes common in all adults:

- Acquired valvular heart disease
- Coronary artery disease
- Systemic hypertension
- Diabetes mellitus
- Pregnancy
- Endocarditis
- Chronic pulmonary disease
- Cardiotoxic chemotherapy and mediastinal irradiation
- Illicit drug use
- Acquired renal or liver disease
- Obstructive sleep apnea
- Hyperthyroidism or hypothyroidism.

Arrhythmia and heart block therapy may play a role in heart failure. Rhythm disturbances are common sequelae of cardiac surgery for CHD, and progressively deteriorating hemodynamics and rhythm disturbances often coincide without a clear etiology. Nevertheless, the functional effect of combined heart failure and rhythm disturbance in the adult with CHD is additive. A surgically placed epicardial or transvenously placed endocardial right heart sequential atrioventricular pacing system may benefit the patient with heart block or sinus node disease and related bradycardia.

Patients with heart failure induced by abnormal activation sequences from right ventricular pacing, and selected patients with structurally abnormal hearts, heart failure, and normal sinus rhythm, may benefit from resynchronization therapy.

Resynchronization therapy is not of proven benefit in single-ventricle patients with heart failure.

Pharmacologic therapy is first-line therapy for many arrhythmias; however, transvenous or surgical ablation techniques may benefit selected patients with both atrial and ventricular tachyarrhythmias. The maze procedure may have therapeutic value in patients with atrial fibrillation or flutter, particularly when combined with reconstructive surgical procedures such as Fontan revision, repair of Ebstein anomaly, and right ventricular outflow tract surgery in tetralogy of Fallot.

Other factors, such as a history of early-era surgery with poor myocardial protection or prior surgery with prolonged CPB and myocardial ischemia, inadequate surgical reconstructive techniques, or other surgical sequelae can also contribute to heart failure. When heart failure and structural heart disease coexist with these chronic pressure or volume overload and cyanotic conditions, case-by-case judgment must be made with respect to specific management. Options include surgical correction of the structural defect and simultaneous medical management of the heart failure, medical management of both the heart failure and structural disease, and heart or heart-lung transplantation.

Transplantation
When irreversible heart failure is judged to be the predominant factor limiting survival, and it is due to an uncorrected structural anomaly or residual structural heart disease after surgery, reconstructive heart surgery should be considered. Otherwise, if reconstructive surgery is not possible, heart transplantation should be considered. If pulmonary vascular obstructive disease is present and limits survival, lung or
heart-lung transplantation should be considered. The decision between lung and heart-lung transplantation is made based on the complexity of the structural heart anomaly. If a PDA, ASD, or simple VSD is present, lung transplantation along with reconstructive surgery for the heart may be possible. If the CHD is more complex, or if heart failure accompanies one of these simple defects, heart-lung transplantation is most appropriate.

Pre-transplantation evaluation is multidisciplinary, similar to that for any other heart failure patient. Rp may be elevated in any patient with heart failure; however, it is more commonly encountered when there is a history of long-standing CHD in addition to heart failure, particularly if the CHD is associated with left-to-right shunting. If there is no evidence of intracardiac or arterial-level shunting, Rp-related contraindications to heart transplantation in the adult with CHD are similar to those for any patient and include Rp greater than or equal to 6 Wood units or a transpulmonary gradient above 15 mmHg that is unresponsive to pulmonary vasodilator therapy in the catheterization laboratory. Transpulmonary gradient alone is less helpful in the presence of either increased or decreased Qp, which is commonly encountered in many forms of uncorrected CHD. In addition, magnetic resonance imaging (MRI) or CT of the chest may be helpful in defining extracardiac morphology, such as systemic venous anomalies, arch anomalies, and the relationship of the aorta, pulmonary trunk, conduit (if present), or ventricular mass to the posterior table of the sternum.

Noncardiac contraindications to transplantation in CHD are similar to those for transplantation in acquired cardiac disease:

- Uncontrolled infection
- Positive serology for human immunodeficiency virus (HIV) or hepatitis C infection
- Uncontrolled metabolic disease
- Additional severe congenital anomalies
- Multisystem organ failure
- Uncontrolled malignancy
- Psychosocial disability affecting compliance

Additionally, previous thoracotomy, especially if multiple and associated with chronic cyanosis, is a relative contraindication, particularly for lung or heart-lung transplantation, because of the likelihood of fatal bleeding from collaterals.

Mortality risk is doubled in the first year after transplantation if the indication has been adult CHD. Outcomes after lung and heart-lung transplantation for PAH in adults with CHD are comparable with those reported for children, with actuarial survival at 10 years of 20%. There is increased risk of early death compared with transplantation for obstructive pulmonary disease or cystic fibrosis because of perioperative complications related to increased complexity of the operation. Outcomes for combined lung transplantation and cardiac repair are similar to those for heart-lung transplantation.

Endocarditis

As stated earlier in this chapter, most forms of CHD are not cured by surgery or other intervention. Residual defects or surgical and interventional remnants present in most adults with CHD often predispose to infective endocarditis (see Chapter 15). More than 10% of patients with endocarditis have a history of CHD, and endocarditis is the cause for 4% of hospital admissions for adults with CHD. Some anomalies carry a higher risk of endocarditis than others, including bicuspid aortic valve, unrepaired VSD, PDA, tetralogy of Fallot, TGA, single-ventricle anomalies with systemic to pulmonary artery shunts, and those whose repair includes a conduit or prosthetic valve. Surgical closure of a VSD reduces the risk of endocarditis, and when endocarditis develops at the site of a surgically repaired defect, a residual patch leak is frequently observed. In a series of adults with CHD admitted for a diagnosis of endocarditis, certain anomalies were underrepresented, including ASD, completely closed VSD, unrepaired Ebstein anomaly, and Mustard and Senning atrial switch repairs.

Definitive diagnosis of infectious endocarditis requires positive blood cultures with appropriate organisms and physical evidence of endocardial involvement (typically identified by echocardiography). Surface echocardiography may be adequate, but transesophageal echocardiography may be particularly helpful, especially when complex structural anomalies are present. Once the diagnosis is made or suspected, further management should occur at a center with an established adult CHD program. Consultation with a cardiac surgeon who has a focus on adult CHD should be undertaken early in the patient’s course, because rapid deterioration requiring surgery is common. Relative indications for surgery are:

- Development of hemodynamic decompensation
- Evidence of embolic complications
- Intractable infection despite appropriate antibiotic therapy
- Infection of prosthetic valves, conduits, or other material
- Abscess development
- Contained rupture
- Development of heart block

The indication to operate may be clear, or it may be ambiguous. Consultation among the cardiologist, infectious disease specialist, and surgeon should take place in all cases under consideration for surgery.

Recommendations for infectious endocarditis prophylaxis have changed in recent years. The 2007 AHA guidelines recommend selective use of preventive antibiotic therapy, but also emphasize behavioral elements. The latter include maintaining daily oral hygiene and skin hygiene, particularly with respect to acne, and avoiding nail biting. Prophylactic antibiotic therapy is confined to dental procedures (no longer gastrointestinal or genitourinary procedures) in patients with prior endocarditis, prosthetic heart valves, conduits, shunts, unrepaired cyanotic CHD, CHD repaired with prosthetic patches or other material within 6 months of surgery, residual defects after reparative surgery for CHD if the residual defect is in the proximity of prosthetic material, and valve lesions in transplant patients.

Niwa and colleagues reported 69 cases of endocarditis in adults with CHD. Prior cardiac surgery and a history of cyanosis were common. Involvement of the left and right sides of the heart was equally common. Dental procedures, cardiac surgery, and pneumonia commonly preceded
endocarditis. *Streptococcus* and *Staphylococcus* accounted for 87% of cases, with *Streptococcus* the most common organism. Surgical intervention was needed in 26% of cases, and the indication for surgery was large vegetations in 45% and heart failure in 29%. Endocarditis-related mortality was 8% in patients treated medically and 11% in those treated surgically. Di Filippo and colleagues note that adults increasingly account for cases of endocarditis in patients with CHD, and that complex cyanotic heart disease is also increasingly common.\(^{316}\) *Streptococcus* and *Staphylococcus* remain the most prevalent organisms. Again, dental procedures and cardiac surgery frequently preceded endocarditis, but these authors note an increasing frequency of cutaneous infections in recent years. A precipitating cause for endocarditis, however, is often not identified. Awadallah and colleagues identified a predisposing event in 56% of cases, but Gersony and colleagues in only 32%.\(^{32,612}\)

**Arrhythmias**

Both atrial and ventricular arrhythmias are a more important source of morbidity in adults with CHD than in infants and children. *Ventricular arrhythmias* in particular, uncommon in young patients, are frequent in adults. Arrhythmias can be observed in all adult clinical groups: surgically repaired anomalies,\(^{315}\) surgically palliated and single-ventricle anomalies,\(^{312}\) and unrepaired anomalies (Table 29-3). Cause of conduction system pathophysiologic is multifactorial, including cyanosis, volume and pressure overload, surgical incisions, suture lines, and patches with subsequent scarring; ischemic insults of any etiology, including coronary embolism in patients with left-to-right shunting; and inadequate myocardial protection during previous surgery. In general, the longer the inciting cause is present, such as cyanosis or volume overload, the more likely arrhythmias will occur. It is this cumulative effect that results in the higher prevalence of arrhythmias in the adult population.

Rhythm disturbances may come to the attention of the surgeon in several ways. Most commonly, a patient being evaluated for reconstructive surgery, such as repair of a large ASD or replacement of a right ventricle to pulmonary trunk conduit, will have an associated rhythm disturbance that may influence intraoperative and postoperative care. Antiarrhythmic therapy may be required, and existence of an arrhythogenic substrate may influence the choice or concentration of inotropic support used.

The arrhythmia may require surgical therapy concomitant with the reconstructive surgical procedure, such as an atrial maze procedure or placement of ventricular cryoablation lesions (see Chapter 16). In other circumstances the sole, or primary, indication for surgery may be the rhythm disturbance. The atrial maze procedure, an epicardial pacemaker system for heart block or bradyarrhythmia, a biventricular pacemaker system for resynchronization therapy,\(^{38}\) or placement of an implantable cardioverter-defibrillator (ICD) are examples of surgery that may be needed.

*Intraatrial reentrant tachycardia* (IART), or atrial flutter, is the most common rhythm disturbance in adults with CHD. It usually develops late postoperatively, most often in patients who have had a right atrial incision or some other right atrial suture line. The amount of right atrial surgery tends to correlate with prevalence of IART, the greatest being in patients who have had Mustard atrial switch intracardiac type Fontan procedures. It can, however, occur after ASD closure. Pharmacologic therapy and catheter ablation are the first- and second-line therapeutic choices. Pacemaker placement to increase baseline heart rate may suppress fibrillation episodes if sinus bradycardia coexists. If a pacemaker is indicated, a transvenous approach is preferred; however, numerous contraindications exist, including presence of any intracardiac shunt (even if trivial, such as a small patent foramen ovale), previous bidirectional Glenn or extracardiac-type Fontan procedure, single-ventricle physiology of any kind, and upper body central venous thrombosis. In these situations, surgical pacemaker placement is indicated. Surgical therapy with a concomitant right atrial maze procedure is indicated if reconstructive intracardiac surgery is planned. Isolated right atrial maze may be considered if IART is poorly controlled by other means. The right atrial maze procedure and its modifications have been shown to be effective in eliminating IART in Fontan patients undergoing concomitant conversion of an intracardiac-type Fontan to an extracardiac type (see Chapter 41).\(^{317}\)

*Atrial fibrillation* occurs most often in adults with congenital aortic stenosis, congenital mitral valve disease, or single ventricle.\(^{315}\) Medical therapy includes anticoagulation, pharmacologic ventricular rate control, and electrical cardioversion. There is no role for catheter ablation. Indications for pacemaker therapy if sinus bradycardia coexists are similar to

Modified from Warnes and colleagues.\(^{311}\)

Key: ASD, Atrial septal defect; AV, atrioventricular; VSD, ventricular septal defect.
Ventricular arrhythmias may develop in the adult with CHD. Macroreentrant ventricular tachycardia can develop late after ventricular surgery, related to ventriculotomy or VSD patching. In repaired tetralogy of Fallot, reentry circuits typically form through narrow conduction pathways created by right ventricular outflow tract scarring. Prevalence of late ventricular tachycardia or sudden death for repaired tetralogy is 0.5% to 6.0%. Older age at repair, right ventricular dilatation, and QRS duration longer than 180 ms have been identified as risk factors for development of ventricular tachycardia and sudden death in tetralogy of Fallot patients. Palpitations, dizziness, or syncope warrant electrophysiologic testing in the adult with repaired tetralogy of Fallot. These symptoms may be elicited at the time of evaluation for surgical therapy for recurrent or residual right ventricular outflow tract disease. Electrophysiologic testing should be performed prior to surgery.

Ventricular tachycardia can develop in any form of CHD in the adult, even if there has never been a ventricular incision or suture line. The onset may coincide with deteriorating ventricular function.

Complete hemodynamic and electrophysiologic evaluation is required before therapy for ventricular tachycardia is undertaken. If sustained ventricular tachycardia is documented or the patient has a history of cardiac arrest, the next step is to determine whether there is a physiologically significant residual or recurrent structural anomaly. If there is no structural anomaly, the treatment option of choice is implanting an ICD. A surgically placed ICD is indicated for patients with single-ventricle physiology, obstructed upper body systemic veins, bidirectional cavopulmonary anastomosis, a Fontan procedure, residual intracardiac shunts, or other unusual or distorted intracardiac morphology; otherwise, transvenous systems are available. In selected cases, catheter-based ablation can also be performed to reduce the likelihood or frequency of ventricular tachycardia episodes. Catheter-based ablation is unreliable as sole therapy, with recurrence that may exceed 20%. Pharmacologic therapy alone is currently considered inadequate if sustained ventricular tachycardia or a history of cardiac arrest exists, but may be indicated if less serious ventricular arrhythmias are present.

If structural cardiac anomalies with important hemodynamic impairment are present in an adult with ventricular tachycardia, surgical repair of the anomaly combined with either concomitant surgical ablation or concomitant surgical ICD placement may be indicated. In such cases, it is necessary to map the ventricular tachycardia, either by preoperative electrophysiologic testing or intraoperative mapping. If a discrete focus of ventricular tachycardia is inducible and there is no clinical history of cardiac arrest, surgical ablation may be the best option. A typical situation appropriate for this form of therapy is the patient with tetralogy of Fallot originally repaired with a transanular patch who presents late with severe pulmonary regurgitation, a dilated right ventricle, and inducible ventricular tachycardia mapped to the right ventricular outflow tract. Surgical therapy includes placing a pulmonary valve prosthesis and creating cryoablation lesions from the outflow patch to the pulmonary trunk and from the outflow patch to the tricuspid anulus. Follow-up electrophysiologic evaluation is indicated in all such cases to determine if ventricular tachycardia is controlled. Placement of an ICD is indicated if ventricular tachycardia is inducible at follow-up. In the patient presenting with a history of cardiac arrest whose evaluation reveals structural disease as well as ventricular tachycardia, or the patient with structural disease and poorly localized ventricular tachycardia, the best choice of therapy is probably structural repair and concomitant surgical ICD placement.

Sinoatrial (SA) node dysfunction in adults with CHD typically is acquired, occurring as a result of localized trauma or ischemia following previous cardiac surgery. The most common procedures that result in SA node dysfunction are the Mustard, Senning, Glenn, and Fontan operations. Less frequently, SA node dysfunction is congenital, associated with some forms of heterotaxy syndrome. Patients with SA node dysfunction may be symptomatic as a result of chronotropic incompetence or of development of atrial fibrillation or flutter, which are more likely to occur when SA node dysfunction is present. Ventricular tachycardia can also develop as a result of prolonged sinus pauses. Placing a pacemaker system is indicated in several circumstances. Implantation of an atrial, or atrioventricular sequential, pacing system with activity responsiveness is indicated for symptoms related to chronotropic incompetence, tachy-bradycardia syndrome, recurrent atrial tachycardias, and pause-dependent ventricular tachycardia. It is also indicated for the asymptomatic adult patient with a resting heart rate of less than 40 beats per minute or atrial pauses greater than 3 seconds. Typically, atrioventricular conduction is normal when SA node dysfunction is present; therefore, atrial pacing alone is effective therapy. Nevertheless, atrioventricular sequential pacing systems are recommended in all cases, with appropriate programming of the system such that atrial pacing occurs along with natural atrioventricular conduction. Pacemaker systems can be placed transvenously or surgically. Surgical placement is indicated in the presence of single-ventricle physiology, bidirectional cavopulmonary anastomosis, Fontan surgery, distorted or thrombosed upper body central veins, and any intracardiac shunt; otherwise, transvenous placement is preferred.

Atrioventricular (AV) block in the adult with CHD may be acquired or congenital. Acquired block is more common and results from surgical trauma to the AV node or surrounding tissues during intracardiac repair. Block usually develops during surgery. Typical operations that may result in block include closure of perimembranous or inlet VSDs, resection of left ventricular outflow tract obstruction, and surgery to repair or replace the inlet valves. Transient heart block...
with full recovery of AV conduction is common after these operations, occurring in over half of all patients who suffer block at surgery. Recovery typically occurs within 10 days. Transvenous or surgical placement (see indications for each in the preceding text) of an AV sequential pacemaker system is indicated if postoperative second- or third-degree block has not recovered after 10 days of observation. A relative indication for pacemaker placement is presence of persistent bifascicular block.

The AV node and bundle of His may also be congenitally abnormal, associated with specific anomalies such as congenitally corrected TGA and AVSD. These patients are more likely to develop block with any form of intracardiac manipulation and to develop spontaneous block either before or after surgery. Spontaneous development of second- or third-degree heart block is an indication for either transvenous or surgical placement of an AV sequential pacemaker system.

Other Organ Systems

Other organ systems may be abnormal in the adult with CHD. These abnormalities may result from altered hemodynamics, chronic cyanosis, or associated syndromes (see “Syndromes Associated with Congenital Heart Disease” in text that follows), and may contribute important morbidity and mortality risks when cardiac surgery is performed in the adult with CHD.

*Altered hemodynamics* can lead to pulmonary vascular abnormalities. This subject is discussed under “Pulmonary Arterial Hypertension and Eisenmenger Physiology” earlier in this section. An altered hemodynamic state is well documented in patients with coarctation of the aorta, both repaired and un repaired. Systemic hypertension and decreased systemic vascular compliance contribute to, and may even play a causal role in, development of and morbidity related to intracranial aneurysms. All adults with a history of coarctation should undergo evaluation of the cerebral vasculature to rule out vascular aneurysms, particularly if repeat aortic surgery is being contemplated. Long-standing abnormal right-sided hemodynamics, particularly in patients with tetralogy of Fallot, single-ventricle morphology with Fontan surgery, and Ebstein anomaly, may result in chronic hepatic venous hypertension and hepatic congestion, leading to hepatic dysfunction and cirrhosis, gastroesophageal varices, and even hepatocellular carcinoma. Particularly in Fontan patients, additional problems may include protein-losing enteropathy, plastic bronchitis, and renal compromise.

*Chronic cyanosis* leads to erythrocytosis, iron deficiency, and clotting disorders. Blood viscosity is increased. Combined erythrocytosis and iron deficiency leading to microcytosis increases risk of thrombosis and stroke, which may be particularly relevant perioperatively. Additionally, cyanosis-related platelet dysfunction and deficiency of plasma and clotting factors due to erythrocytosis combine to increase the risk of hemorrhagic complications, again of particular relevance perioperatively. An additional complication of erythrocytosis is an increased rate of red cell turnover, leading to abnormal bilirubin metabolism and development of gall stones. The risk of cholecystitis and pancreatitis perioperatively is increased. Chronic cyanosis also leads to renal glomerulosclerosis. Glomerular filtration rate is decreased, resulting in creatinine elevation.

*Renal dysfunction* is found in adult patients with a wide spectrum of CHD.

*Scoliosis* is common in patients with chronic cyanosis. This may lead to deformity of the thorax, causing ventilatory compromise. Pulmonary function tests are required in all adult patients with CHD and scoliosis who are under consideration for cardiac surgery.

There is a risk of *stroke* after all cardiac procedures in patients of all ages. It was found to be 0.8% in 124 adults undergoing surgery for CHD. Interestingly, this is lower than the risk of stroke in adults undergoing different types of surgery for various acquired heart problems.

Syndromes Associated with Congenital Heart Disease

A number of syndromes are associated with CHD, many associated with neurologic, developmental, and cognitive deficits (Table 29-4). Many of these syndromes include other coexisting disease processes in other organ systems that represent specific risks during anesthesia and surgery (Table 29-5).

The deficits may be mild enough in many cases to allow these individuals to live somewhat independently. When the cardiac surgeon is asked to consult on the adult patient with CHD, he or she must keep in mind that the patient may have one of these syndromes. Additionally, many adults with CHD who do not have specific syndromes may be overprotected by caring family members and may not have the emotional or intellectual maturity expected for their age. Accordingly, these patients may have limited ability to fully appreciate the complexities, risks, complications, and alternatives to a proposed surgical procedure. Family members and primary care providers should be included in such consultations.

Repeat Sternotomy

Overview
Many adults undergoing surgery for CHD have had at least one, and often several, previous cardiac operations via median sternotomy. Risk of life-threatening hemorrhage is present with any repeat sternotomy. Other risks include entry of air into the circulation and arrhythmias. Thus, special preparation is required when repeat sternotomy is planned. First, all previous operative notes should be obtained and reviewed. Along with the details of previous cardiac procedures, they may provide important information regarding whether a prosthetic barrier was placed between the sternum and cardiac structures, whether the native pericardium was reapproximated, and whether difficulty was encountered during the previous sternotomy. Also, comments warning about such things as conduit placement in proximity to the posterior sternal border may be given. Second, CT or MRI of the chest can be helpful in defining the position of the anterior border of the heart, ascending aorta, pulmonary trunk, brachiocephalic vein, and conduits relative to the posterior sternal table (Fig. 29-3).

Technical Considerations
Several options are available for patients at high risk of injury during repeat sternotomy. An attempt to open the sternum slowly under direct vision, beginning inferiorly at the xiphoid and progressing superiority, dissecting along the posterior table of the sternum, is the best initial approach in most cases. Using this approach, a segment of posterior sternal table is dissected, and only then is the oscillating saw used to split the freed portion of the sternum. This process proceeds in steps until the sternum is completely split. If, however, at any point the posterior sternal table dissection can no longer be performed under direct vision, or if even minimal bleeding is encountered, dissection is stopped. Peripheral cannulation for CPB is then performed by several means. The femoral artery and vein may be exposed and cannulated and CPB established. If the patient has a completely separated two-ventricle circulation and risk of injury is to any right-sided structures, including right ventricle to pulmonary trunk conduits, then sternotomy can be performed as soon as CPB is established. If the patient has single-ventricle physiology, Fontan physiology, any potential for intracardiac shunting, or two-ventricle physiology but the aorta is at risk of injury, then he or she must be cooled to deep hypothermic temperatures prior to further attempts to open the sternum.

Femoral vascular abnormalities may be present secondary to previous cardiac catheterization or operative procedures. Knowledge of the status of femoral vessels is critically important in all patients undergoing repeat sternotomy. Alternative methods of cannulation for CPB exist (see Chapter 2), and these may be preferable in some patients, including those with femoral vessel abnormalities. If sternotomy cannot be performed safely, the sternal skin incision can be extended superiorly, and the brachiocephalic artery superior to the brachiocephalic vein is exposed and cannulated. The inferior vena cava is also exposed and cannulated within the pericardial space by dissecting inferior to the xiphoid along the diaphragm surface. CPB can then be initiated, and the operation proceeds as described for femoral cannulation.

Outcomes
There are no large studies examining repeat sternotomy specifically in adults with CHD. Three studies examine repeat sternotomy in patients with CHD; however, the average age was 2.1, 3.6, and 4.7 years, although all involved some adults. Overall, the risk of life-threatening hemorrhage during repeat sternotomy in these three series was low—0.3%, 0.7%, and 5.2%—with no specific analysis of adults. Risk factors included presence of right ventricular to pulmonary trunk conduits and increasing number of previous sternotomies. In another series of 2555 adult patients with acquired heart disease undergoing repeat sternotomy, 3% suffered major injury at sternal opening. Mortality, if injury occurred, was 25%.

There are specific congenital anomalies and situations for which risk may be increased. Presence of PAH (regardless of the specific cardiac morphology) may be associated with an enlarged right ventricle and right atrium, both of which have elevated pressure and may be in close proximity to the sternum. Mustard and Senning patients will have markedly hypertrophied and often dilated right ventricles positioned directly behind the sternum. Additionally, the morphologic right atrium, which serves as the physiologic left atrium, may be markedly dilated, and its free wall or appendage may be positioned anteriorly behind the sternum. Injury to this structure during sternotomy, with blood loss and hypovolemia, may result in massive air embolism to the systemic circulation as attempts to control the hemorrhage are undertaken. All conotruncal anomalies, including tetralogy of Fallot, truncus arteriosus, TGA, and double outlet right ventricle, have an

Figure 29-3 Three-dimensional computed tomography reconstruction, lateral view, of adult with L-transposition of the great arteries, double inlet single left ventricle, and previous median sternotomy. Note proximity of ventricular mass to posterior aspect of sternum. Superiorly, the transposed aorta is separated from the sternum by interposed lung tissue. Both observations are important for planning sternal reentry.
Several studies provide an overview of the practice of adult congenital cardiac surgery. Putman and colleagues report a single-institution experience with 963 adult congenital cardiac surgical procedures in 830 patients (mean age 39 years, 50% male) between 1990 and 2007. Underlying diagnoses are shown in Table 29-6; 51% were primary operations and 49% reoperations. Underlying anomalies tended to be more complex in the reoperation group and simpler in the primary operation group. The most common operations were those involving aortic valve replacement (26%); ASD closure (18%); pulmonary valve replacement (13%); mitral valve operation (7.1%); pacemaker placement (6.4%); VSD closure (5.5%); and coarctation repair (4.6%) (Table 29-7). Concomitant coronary artery bypass grafting was performed in 3.4%. CPB was used in 90%. Overall early mortality was 1.5%, and actuarial survival at 17 years was 71% (Fig. 29-4). Risk factors for mortality are shown in Table 29-8. Functional status, estimated by NYHA functional classification, was improved in most survivors.

### Specific Anomalies

Definition, surgical history, morphology, and natural history, as well as general aspects of pathophysiology, clinical presentation, diagnosis, and treatment of specific anomalies discussed in the remainder of this chapter, are described elsewhere in this book in the specific chapters named for each anomaly. The following sections focus on preoperative, operative, and postoperative care issues that are specifically related to adults with these anomalies.

Modified from Putman and colleagues.212
In a multi-institutional (37 Child Health Corporation of America [CHCA] centers) study of 719 adult congenital cardiac operations performed between 2005 and 2007, Mahle and colleagues report that the most frequent principal procedures were pacemaker placement (29%), pulmonary valve replacement (17%), aortic valve replacement (8.3%), and Fontan revision (5.2%). Early mortality was 1.9%. Among the 37 freestanding children’s hospitals that make up this consortium, 0% to 11% of all cardiac operations were performed in adults.

Data from the CONCOR (CONgenital CORvitia) Dutch national registry of adults with CHD show several notable gender-specific outcomes in 7414 patients. Women had a 33% higher risk of pulmonary hypertension, a 33% lower risk of aortic events, a 47% lower risk of endocarditis, and a 55% lower risk of arrhythmias and ICD placement. There were no gender-related mortality differences.

### Section II Atrial Septal Defect

**Definition**

Definition, morphology, and basic physiology of atrial septal defect (ASD) are described in Chapter 30. ASD is one of the most common anomalies found in adults. It typically presents as newly diagnosed primary disease, or previously diagnosed primary disease with benign physiology. It constitutes 25% to

*See reference P24 for description of EuroSCORE.

**Note:** Thirty-day and one-year mortality were analyzed using logistic regression, long-term mortality was analyzed using Cox regression.

Key: CI, confidence interval; COPD, chronic obstructive pulmonary disease; HR, hazard ratio; HT, hypertension; NS, nonsignificant; —, not tested multivariate; NYHA, New York Heart Association; OR, odds ratio; VEF, ventricular ejection fraction.
30% of newly diagnosed congenital heart disease (CHD) cases in adults.\textsuperscript{20}

**MORPHOLOGY**

Each of the four morphologic forms of ASD is found in adults, with associated cardiac defects in up to a third (see Chapter 30). Most commonly, these are classic associations found with sinus venous and ostium primum defects. Mitral valve prolapse and valvar pulmonic stenosis may be seen with ostium secundum defects.\textsuperscript{3,13,515} Patent foramen ovale (PFO) is of particular interest.

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

**Presentation**

The chronic right-sided volume and pressure overload found with large ASDs leads to reduced aerobic capacity, atrial arrhythmias, and respiratory infections. Dyspnea and palpitations are the most common presenting symptoms, typically in the third and fourth decades of life.\textsuperscript{37,22} Atrial fibrillation or flutter and paradoxical embolism may also lead to presentation. Pulmonary arterial hypertension (PAH) is usually mild and primarily flow related; however, severely elevated pulmonary vascular resistance (Rp) and obstructive pulmonary vascular disease leading to Eisenmenger physiology occur in a minority of patients.

Smaller ASDs—those less than 5 mm in diameter—and PFOs do not cause these changes, but can be the source (as can larger ASDs) of paradoxical emboli.\textsuperscript{11,29,99} Defects smaller than 1 cm may not cause symptoms for many decades, but the left-to-right atrial shunt may increase later in life as left ventricular compliance decreases because of acquired cardiac diseases such as coronary artery disease and hypertension, causing symptoms to develop late.\textsuperscript{37}

**Diagnosis**

The electrocardiographic and chest radiographic findings are the same in the adult as in the child (see Chapter 30). The mainstay of diagnosis is echocardiography. In adults, thoracic studies may produce inadequate images of the atrial septum. Transesophageal studies often produce more accurate atrial septal images and detail the dimensions and position of the defect.\textsuperscript{37,31,26,27,75} PAH is estimated by measuring velocity of tricuspid regurgitation flow, if present. Contrast echocardiography can be used to confirm atrial-level shunting if direct imaging and color Doppler evaluation are not definitive. Both magnetic resonance imaging (MRI) and computed tomography (CT) angiography may be helpful if echocardiography is not definitive, and are particularly helpful in defining the pulmonary venous anatomy in sinus venous ASD. MRI is preferred to CT, which requires substantial radiation exposure.\textsuperscript{27,31,18,32,73} Cardiac catheterization is reserved for three situations: to assess pulmonary vascular hemodynamics if PAH is suspected or confirmed; to assess presence of coronary artery disease, typically in patients over age 35 (male) and 40 (female); and as a therapeutic procedure if percutaneous device closure is planned.

**TECHNIQUE OF OPERATION**

Options for ASD closure include surgical and percutaneous device approaches. Surgical techniques used are the same as those used in children (see Chapter 30). Because most defects that come to surgery in the current era are large, patch closure should always be used in adults, even for secundum ASDs; primary closure should be avoided. Concomitant procedures such as tricuspid valve repair and the maze procedure, uncommonly used in children, may be required.

Percutaneous device closure of secundum ASDs can be performed in adults regardless of age.

**RESULTS**

Early mortality following surgery is less than 1%, and long-term survival approaches that of the general population for straightforward cases without associated anomalies or PAH. Closure effectively relieves shunt-related symptoms. New-onset late atrial arrhythmias can develop in patients after surgery. The maze procedure is effective in reducing, but not always eliminating, atrial fibrillation and flutter.

Percutaneous device closure of secundum ASDs can be performed in adults with less than 1% mortality and low morbidity, with demonstration of reduction in right ventricular size and pulmonary artery pressure in all age groups.\textsuperscript{122}

A recent study of 100 adults with secundum ASD revealed similar, but not identical, outcomes using closure by surgery or percutaneous device.\textsuperscript{53} The 52 surgical patients underwent treatment between 2001 and 2003, and the 48 device closure patients between 2003 and 2005. The procedure was successful in all surgical patients (100%; CL 96%-100%) and in 45 of the 48 (94%; CL 88%-97%) percutaneous device patients. There was no mortality in either group (CL 0%-3.6% for surgical closure and 0%-3.9% for device closure). The number of complications was similar, but the surgical group had more serious ones. Postprocedure length of stay was shorter in the percutaneous device group. At 1-year follow-up, there was no mortality and equal reduction in right ventricular size and pulmonary artery pressure.

In a series of 25 adults with surgical repair of sinus venous ASD and partial anomalous pulmonary venous return, there was no early mortality (CL 0%-7.3%) and one late death due to heart failure.\textsuperscript{15} One patient (4%; CL 0.6%-13%) had superior vena cava obstruction. In a series of 75 adult patients with either secundum or sinus venous ASD, there was one early death (1.3%; CL 0.2%-4.4%) in a patient with secundum ASD, recurrent pulmonary emboli, and severe PAH.\textsuperscript{51}

An ostium primum ASD repair was performed in 51 patients (mean age 27 years) with an early mortality of 2.0% (CL 0.3%-6.5%).\textsuperscript{34} Preoperative left atrioventricular (AV) valve regurgitation was moderate in 35% and severe in 4%. With respect to the left AV valve, cleft closure was performed in all patients, but anuloplasty in only two. At 36-month follow-up, 21% had moderate regurgitation and 8% severe regurgitation; one had mitral valve replacement. Postoperative regurgitation was progressive (Fig. 29-5). Risk factors for postoperative moderate or severe mitral regurgitation were female gender and preoperative PAH. Interestingly, moderate or severe preoperative left AV valve regurgitation was not a risk factor.

In another series, there was no early (CL 0%-12%) or late mortality in 15 patients (mean age 31 years).\textsuperscript{14} The left AV
adults with secundum ASD, 84% met criteria for device closure and 16% underwent surgical closure. Older age is generally not a contraindication to surgical ASD closure, although there is some controversy. Two older studies demonstrate symptom improvement and survival benefit in patients over age 60 undergoing surgical closure. A more recent randomized trial of surgical ASD closure in patients over age 40 showed symptom improvement but no survival benefit.

If percutaneous device closure is not contraindicated, this approach may provide a better risk/benefit ratio than surgery in older patients.

**Section III  Patent Foramen Ovale**

**DEFINITION**

Patent foramen ovale (PFO) is incomplete closure of the septum primum resulting in a valve-like flap closure. It allows intermittent interatrial shunting, which may occur in the left-to-right or right-to-left direction.

**MORPHOLOGY**

PFO appears as a small slit at the upper margin of the fossa ovale (see Chapter 1). It represents incomplete obliteration of the fetal foramen ovale.

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

**Presentation**

Of the 280,000 individuals who suffer a cryptogenic stroke in the United States every year, a PFO is found twice as often as in the normal population, suggesting an association between PFO and stroke. Nevertheless, three prospective class 1 studies addressing cryptogenic stroke all suggest that when patients who suffer an initial cryptogenic stroke are
followed, recurrent cryptogenic stroke has no relationship to the size or presence of a PFO. A number of studies examining the effectiveness of different treatment options in preventing recurrent stroke in patients with PFO have suggested that recurrent strokes occur less often when the PFO is treated with a device or surgery closure rather than with antiplatelet or anticoagulation therapy. Larger PFO size has also been associated with increased risk of recurrent cryptogenic stroke following an initial event. Thus, PFO closure is influenced by multiple factors, including the presence of a PFO and its size. When flow occurs in the right-to-left direction, the potential for paradoxical embolism exists. There is probably an association between PFO and cerebrovascular events; however, the nature of the relationship is unclear and controversial, as described in previous text.

**TECHNIQUE OF OPERATION**

Percutaneous device closure is currently favored over surgical closure; however, surgical PFO closure is an option if a patient refuses device closure, there is another reason for open heart surgery, or there is a contraindication. In patients with atrial septal aneurysm without PFO, surgical resection with reconstruction of the atrial septum can be considered when anticoagulation therapy has failed.

Unfortunately, a surgical closure arm is not included in any of the ongoing randomized trials. This oversight may be pertinent because the preliminary report of the CLOSURE 1 trial noted that in some cases thrombus has been identified on the closure device at follow-up.

**RESULTS**

Antiplatelet therapy, anticoagulation therapy, percutaneous device closure, and surgical closure are all used to prevent recurrent stroke in patients with PFO. No consensus has been reached about whether one form of therapy is better than the others. A number of studies examining the effectiveness of these different treatment options in preventing recurrent stroke point to an advantage of closure over antiplatelet or anticoagulation therapy; however, the criticism of all these studies is that none of them randomized the treatment options. A science advisory published jointly by the American Heart Association, American Stroke Association, and American College of Cardiology in 2009 notes that five different prospective randomized trials addressing this question are currently in progress, but no evidence base can determine whether PFO closure is superior to antiplatelet and anticoagulation therapy for preventing recurrent stroke. A preliminary report from one of these randomized trials, the CLOSURE 1 trial, was presented at the American Heart Association 2010 Scientific Sessions. No difference in recurrent stroke was noted between anticoagulation therapy and the STARFlex PFO closure device. Certain design flaws in this study have been noted.

The association of PFO and migraine headache is even more controversial than the association between PFO and cryptogenic stroke. It appears, based on an extensive meta-analysis, that percutaneous device closure of PFO may cure or improve migraine headache symptoms in a subset of migraine patients who have a PFO and suffer from a cryptogenic stroke. In general, the cause of migraines is multifactorial, with not all migraines due to paradoxical embolism or paradoxical streaming of causative humoral factors. This may explain the findings in the Migraine Intervention with STARFlex Technology (MIST) trial, a randomized, double-blinded, sham procedure controlled study of PFO closure in patients with PFO and migraine. In this study population, there was no other indication (i.e., no cryptogenic stroke) for PFO closure other than migraine headache. The study showed no benefit to PFO closure in this broader group of migraine patients.

**INDICATIONS FOR OPERATION**

The joint advisory recommends antiplatelet therapy as the first-line treatment for patients with PFO and cryptogenic stroke, vitamin K antagonist anticoagulation if there is an associated hypercoagulable state or atrial fibrillation, and PFO device closure if recurrent stroke occurs on anticoagulation. PFO closure is also indicated in patients exposed to alterations in atmospheric pressure, increasing the risk of paradoxical air embolism.

At the present time, PFO closure is considered standard medical practice for treating migraine headache. There is substantial evidence, however, that patients with PFO who suffer a cryptogenic stroke and also suffer from migraines will have their migraines cured or improved about 80% of the time after PFO device closure performed to prevent recurrent paradoxical embolism.

---

**Section IV Ventricular Septal Defect**

**DEFINITION**

Definition, morphology, and basic physiology of ventricular septal defect (VSD) are described in Chapter 35. In the adult, VSD presenting for surgical closure is rare. When it does occur, it is unusual for it to present as newly diagnosed primary disease. More commonly, VSD presents as previously diagnosed primary disease with benign physiology, such as a restrictive defect, with new development of a specific VSD-related complication requiring intervention. It may also present as a secondary disease, such as late after...
surgical VSD closure, in association with a new VSD-related complication.

MORPHOLOGY

Each of the morphologic forms of VSD is found in the adult (see Chapter 35).

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Presentation

Adults with a history of VSD closure as an infant or child may present with infectious endocarditis in the presence of a small residual defect; distortion of the tricuspid valve septal leaflet due to previous VSD closure, resulting in clinically important tricuspid regurgitation or progressive aortic regurgitation due to surgical injury; distortion of the valve during VSD closure; or prolapse of the valve into the VSD prior to VSD closure that progresses after closure.

Diagnosis

Transthoracic echocardiography is usually diagnostic for patients with unrepaired or previously repaired VSD unless the surface windows do not provide adequate images. In that case, transesophageal echocardiography is usually diagnostic. It is important not only to focus on size and position of the native or residual VSD, but also to rule out aortic valve prolapse and regurgitation, tricuspid regurgitation, double-chamber right ventricle, subaortic membrane, membranous septal aneurysm, primary pulmonary arterial hypertension (PAH), and ventricular dysfunction.

If PAH is suggested by echocardiography, diagnostic cardiac catheterization is indicated to assess status of the pulmonary vascular bed (see “Pulmonary Arterial Hypertension and Eisenmenger Physiology” in Section I). Cardiac catheterization may also be indicated in the patient with a small to moderate VSD, either unrepaired or repaired with a residual defect, for whom the indications for surgical closure are equivocal. Specific data obtained at catheterization may assist in the decision to close the VSD, including magnitude of the shunt, left ventricular end-diastolic pressure, pulmonary artery pressure, and pulmonary vascular resistance (Rp). Catheterization and angiography may also be indicated to assess the coronary arteries if arteriosclerotic disease is suspected, if the patient is older than age 35 (male) or 40 (female), or to further characterize unusual structural problems, such as membranous septal aneurysms (Fig. 29-7).

Magnetic resonance imaging (MRI) and computed tomography (CT) may play a role in defining anatomic details if echocardiography is not definitive. These imaging modalities may help define multiple VSDs, unusually positioned muscular VSDs, and suspected associated pulmonary artery or vein anomalies.

NATURAL HISTORY

Unrepaired large (unrestrictive, > 50% aortic diameter) VSD first presenting in the adult is rare. When it occurs, there is likely to be PAH or Eisenmenger physiology. Occasionally, evaluation reveals a reactive pulmonary vascular bed. Unrepaired moderate (restrictive, 25%-50% aortic diameter) VSD presenting in the adult is also rare. When it does, there is pulmonary overcirculation and symptoms of high-output heart failure. Unrepaired small (highly restrictive, <25% aortic diameter) VSD may be newly diagnosed or, more likely, previously diagnosed. These patients are hemodynamically asymptomatic.

Secondary complications related to a small VSD may develop in the adult. These include aortic, mitral, and tricuspid regurgitation, double-chamber right ventricle, subaortic membrane, and endocarditis. Aneurysms of the membranous septum may develop and progress in long-standing unrepaired perimembranous VSD. In one large series of 254 adults with perimembranous VSD, aneurysms developed in 51 cases (20%). When aneurysms form, flow restriction occurs through the VSD, resulting in pulmonary to systemic flow ratio (Qp/Qs) of less than 2 : 1. Aneurysms may enlarge over time, causing important secondary hemodynamic changes, including right ventricular outflow tract obstruction, tricuspid regurgitation, and rupture of the aneurysm, resulting in an acute increase in Qp/Qs (see Fig. 29-7).

Prevalence of endocarditis and aortic valve prolapse and regurgitation may increase when a membranous septal aneurysm is present.

TECHNIQUE OF OPERATION

Surgical techniques used to close VSDs in adults are the same as those used in infants and children (see Chapter 35). Percutaneous device VSD closure may be used for selected muscular VSDs remote from ventricular inlet and outlet.

If aneurysm of the membranous septum is present, it should be completely excised via exposure through the right atrium, with standard patch closure of the anatomic borders of the perimembranous VSD. Closure of the shunt by approximating aneurysmal tissue should be avoided because recurrence of the aneurysm and residual leaks have been described. Associated tricuspid regurgitation or aortic regurgitation should be addressed concomitantly.
RESULTS

Early mortality for uncomplicated VSD closure in the adult is less than 1%. If complex associated problems or pulmonary vascular disease coexist, early mortality is 5% to 10%. In a series of 51 adults (mean age 22 years, age range 15-59 years) with perimembranous VSDs complicated by aneurysm of the membranous septum, there was no early mortality (CL 0%-3.7%). In another experience, there was no early mortality (CL 0%-4.0%) in 46 adult patients (mean age 34 years) with perimembranous and subarterial VSDs.

Late mortality in patients without associated comorbidity is low: 5% at a mean follow-up of 10 years, 5% at a mean follow-up of 15 years, and 0% at a mean follow-up of 5.6 years in three separate series.

Surgical complications associated with VSD closure in adults are similar to those seen in younger patients, including residual VSD requiring reoperation, complete heart block, and injury to aortic and tricuspid valves.

In a series of 220 patients with small perimembranous VSDs followed into adulthood, 7% required surgical closure over a 6-year observation period. In the remaining 93%, 4% had spontaneous closure, 1% died of cardiac disease, and 4% developed endocarditis. Prevalence of PAH increased from 3% to 9%. In this study the average Qp/Qs was 1.2. These data emphasize that a small VSD is not always benign. In another analysis of 125 adolescent and adult patients (mean age 23 years, age range 10-51 years) with unrepaired VSD, 41 were treated surgically, 70 were considered to have no indication for surgery (small VSD and no associated problems), and 14 were inoperable due to PAH. At 15-year follow-up, even though the group with no indication for surgery had less complex defects, mortality was twice that of the operated group, and there was a higher occurrence of endocarditis and new valvar lesions. New York Heart Association (NYHA) functional class deteriorated in the unoperated group and improved in the operated group. Pulmonary artery pressure rose in the unoperated group and fell in the operated group. In the small group of 14 patients in which surgery was contraindicated because of PAH, mortality at 15 years was 71%.

INDICATIONS FOR OPERATION

Indications for operation are the same whether the VSD is un repaired or a residual defect following attempted surgical or device closure.

Large VSDs should be closed if cardiac catheterization demonstrates reversible PAH. They should not be closed if fixed-resistance severe PAH or Eisenmenger physiology is present. Levels of Rp and PAH that contraindicate surgical closure are described under “Pulmonary Arterial Hypertension and Eisenmenger Physiology” in Section I. Moderate VSDs should be closed. They almost always cause pulmonary overcirculation and Qp/Qs of 1.5 or greater. They are some what restrictive and do not cause Eisenmenger physiology. There is evidence that surgical closure provides long-term benefit for these patients. Traditionally, surgical closure has not been recommended for small VSDs. Most will have a Qp/Qs of less than 1.5. However, considering the low morbidity and mortality of surgical closure of VSD in the current era and the morbidity and mortality in adults with small unrepaired VSDs, the traditional recommendation to not close a small VSD in the adult should be questioned.

Other indications for surgical intervention include development of important associated problems, usually in the setting of a small restrictive VSD: aortic regurgitation, tricuspid regurgitation, subaortic membrane, double-chamber right ventricle, large aneurysm of the membranous septum, and infectious endocarditis. Surgery may require addressing the VSD and the associated problem concomitantly, or the associated problem alone if the VSD has been previously closed. In one series of 20 patients (mean age 43 years) an associated problem was the indication for surgery in 35%; in another series of 42 patients (mean age 27 years) an associated problem was the indication for surgery in 52%.

Section V  Atrioventricular Septal Defect

DEFINITION

The definition, morphology, and basic physiology of atrioventricular septal defect (AVSD) are described in Chapter 34. Most adults presenting with AVSD fall into the category of secondary congenital heart disease, having undergone surgical repair in infancy or childhood.

MORPHOLOGY

AVSD may be partial or complete. Adults rarely present with complete unrepaired AVSD, and when they do, it is usually inoperable because of pulmonary arterial hypertension (PAH). This is because of the combination of unrestrictive ventricular- and atrial-level shunting and the high likelihood of Down syndrome. Partial AVSD may present unrepaired in the adult and is usually operable. Down syndrome is uncommon in partial AVSD.

The most common indications for surgery in the adult with repaired AVSD are left-sided atrioventricular (AV) valve stenosis or regurgitation, followed by left ventricular outflow tract obstruction.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Presentation

The clinical presentation of repaired AVSD depends on the nature of residual or recurrent lesions after repair, and on development of new lesions. The most common residual or recurrent lesion is left-sided AV valve regurgitation, which presents with left ventricular volume overload and failure, left atrial dilatation, and atrial fibrillation. The next most common lesion is subaortic left ventricular outflow tract obstruction, which may be residual, recurrent, or new onset. Signs and symptoms are the same as for any patient with left ventricular outflow obstruction. Other presentations include signs and symptoms related to left or right AV valve stenosis, right AV valve regurgitation, residual ventricular septal defect (VSD), endocarditis related to any of these residual structural lesions, or PAH, particularly in patients with repaired complete AVSD.
Diagnosis

The electrocardiogram shows typical superior left-axis deviation, and this finding alone in a previously undiagnosed adult is highly suggestive of AVSD. In adults with residual or recurrent lesions, electrical findings of left atrial enlargement, left ventricular hypertrophy, and right ventricular hypertrophy may be present. Atrial fibrillation or flutter may also be present.

The chest radiograph will show a prominent pulmonary artery bulb and distal pulmonary artery pruning if PAH is present, cardiomegaly if valve regurgitation or left-to-right shunting exists, and pulmonary venous congestion if left-sided AV valve regurgitation is present. Echocardiography is diagnostic, just as it is in infants and children. In previously repaired patients, this study should focus on determining presence of residual atrial or ventricular shunts, right and left AV valve function, left ventricular outflow tract patency, and signs of PAH.

Cardiac catheterization is performed in all unrepaired adults under consideration for surgical repair to assess the pulmonary vasculature. Coronary angiography is indicated if the patient is over age 35 (male) or 40 (female) or if coronary insufficiency is suspected. Catheterization may also be indicated to assess PAH in repaired patients and general hemodynamics in patients with equivocal indications for surgical intervention. Magnetic resonance imaging can be helpful in assessing regurgitant fraction when AV valve regurgitation is present in patients with equivocal indications for surgical intervention.

NATURAL HISTORY

Presentation of partial AVSD in the adult has some similarities to that of a large atrial septal defect (ASD), with chronic right heart volume overload leading to right ventricular failure. Mild PAH is present, but Eisenmenger physiology is uncommon. Unlike a large ASD, however, regurgitation of the right-sided, left-sided, or both AV valves is common, causing earlier onset of ventricular failure and atrial fibrillation and flutter.

Presentation of the adult with unrepaired complete AVSD will be similar to that of a large or unrestricted VSD, with PAH and likely Eisenmenger physiology. Additionally, important AV valve regurgitation may be present, increasing the likelihood of ventricular failure and atrial fibrillation or flutter.

TECHNIQUE OF OPERATION

The surgical approach to unrepaired AVSD, whether partial or complete, is the same in the adult as in infants and children (see Chapter 34).

Postrepair residual or recurrent left AV valve regurgitation requires repeat surgery in 5% to 10% of patients. It may be due to an open cleft or breakdown of a previous cleft closure. Surgical closure of the cleft is performed. Reduction anuloplasty is almost always indicated. If the etiology of regurgitation is more complex, then standard techniques used for mitral valve repair are used (see Chapter 11). Rigid valve anuloplasty rings may be contraindicated because the shape of the anulus in repaired AVSD is different from that of the normal mitral valve. Mixed regurgitation and stenosis is particularly difficult to repair, and valve replacement may be required. The inferiorly displaced position of the AV node and bundle of His must be kept in mind to avoid causing heart block.

Left ventricular outflow tract obstruction is rarely due to a simple subaortic membrane. Typically, there is an elongated, narrow, muscular tunnel with or without the addition of AV valve chordal tissue. The chordal tissue is rarely functional. Most commonly these chords were previously normal components of the superior bridging leaflet of a Rastelli type A defect. They become nonfunctional as part of standard original AVSD repair. Surgical correction of late left ventricular outflow obstruction is best performed through the aortic valve, with extensive circumferential myectomy and resection of the obstructive AV valve and chordal tissue. Damage to the mitral valve can still occur during this procedure, as it can for any left ventricular outflow tract resection; however, injury to the conduction system is not of concern because the AV node is displaced inferiorly. Occasionally, myectomy will not be effective, and a Konno operation will be required (see Chapter 12).

RESULTS

Death

Early mortality for primary repair of partial AVSD in the adult can be less than 1%; however, some older series report early mortality as high as 6%. There was no (CL 0%-4.8%) early mortality in a series of 39 patients (mean age 36 years) in whom the indication for surgery was left-to-right shunt. One patient required concomitant left AV valve replacement and 37 underwent cleft closure, five of whom also underwent reduction anuloplasty. At a median follow-up of 7 years, there were six late deaths, five of which were cardiac in origin. In a series of 132 patients with partial AVSD, 10% of whom were older than age 20 years, early mortality was 4.5% (CL 2.7%-7.2%) and late mortality 3.2%. By univariable analysis, older age (more than 10 years at initial repair) was among the risk factors. By multivariable analysis, however, only preoperative PAH and a grossly deformed left AV valve were risk factors, suggesting that the association of death with older age is due to development of PAH and valve deformity over time. In a series of 31 patients with partial AVSD, all of whom were over age 40, early mortality was 6.4% (CL 2.2%-15%); however, some of the operations were performed as long ago as 1958, and the two deaths occurred in 1967 and 1981. There were nine additional deaths at late follow-up (Fig. 29-8). In a separate report from the same authors, an analysis of all patients with partial AVSD showed that age older than 20 years at repair was a risk factor for death. In a series of 29 adolescents and adults (mean age 28 years) undergoing repair of partial AVSD, early mortality was 3.4% (CL 0.6%-11%), and actuarial survival after 25 years was 79%. There was important left AV valve regurgitation in 68% of the long-term survivors and important arrhythmias in 20%. In a larger series of reoperations in 96 adults (median age 26 years) with prior repair of partial AVSD, early mortality was 5.2% (CL 2.9%-8.7%); however, three of the deaths occurred prior to 1983. Since 1983, 2 of 76 patients experienced early death (2.6%; CL 0.9%-6.1%) (Fig. 29-9).

Primary repair of complete AVSD in the adult is rare; however, there are isolated case reports of such repairs.
other in 6%. About half of the patients requiring reoperation for left AV valve regurgitation underwent valve repair, and the other half underwent valve replacement.

Reoperations following prior repair of complete AVSD have been reported in a series of 50 patients. As expected, the primary repair was performed early in life (median age 1 year), and the median interval between primary repair and reoperation was 15 months. Thus, most reoperations were performed in young children, although some were performed in adults as old as 38 years. Left AV valve regurgitation was the indication for reoperation in 41 patients. There were two early deaths, both in young patients; thus, there were no deaths in adults, although the specific number of adults treated is not designated. In two other series examining long-term outcomes after AVSD repair in infancy and childhood, freedom from reoperation was 80% at 25 years in one and 76% at 20 years in the other. In both studies the majority of first reoperations were for left AV valve problems, and these reoperations occurred relatively early. In one of these studies, mean age at first reoperation was 2 years. Thus, few patients present for their first left AV valve reoperation in adulthood. Second reoperations on the left AV valve are common, with freedom from reoperation after first reoperation of only 42% at 15 years.

INDICATIONS FOR OPERATION

Surgery is indicated for all unrepaired patients with partial AVSD unless important PAH is present. One analysis suggests that outcome after surgery is better than expected with medical management. Surgery is indicated only rarely for the adult with complete AVSD because of the high likelihood of advanced pulmonary vascular obstructive disease. Repaired patients with residual lesions should undergo surgery if these cause important symptoms. If residual lesions cause no or minimal symptoms, then standard physiologic criteria are used for residual shunts, AV valve regurgitation or stenosis, and left ventricular outflow tract obstruction. A maze procedure may be indicated concomitant with the structural repair if atrial fibrillation or flutter is present. Coronary artery bypass grafting is indicated as a concomitant procedure if standard criteria are met (see Chapter 7).

Left Atrioventricular Valve and Left Ventricular Outflow Tract Lesions

Early mortality after repair of residual or recurrent left AV valve lesions or left ventricular outflow tract lesions is similar to that after mitral valve or left ventricular outflow tract procedures performed in adults without AVSD. One report describes 11 patients with prior repair of partial AVSD in whom surgery as an adult was required. Indications were left AV valve regurgitation in six (two of whom required valve replacement), subaortic stenosis in three, left AV valve stenosis in one, and atrial shunt in one. There were no early deaths (CL 0%-16%), and at median follow-up of 7 years, there were two late deaths, one of which was cardiac in origin.

In a series of 96 reoperations in adults after partial AVSD repair, indications for reoperation were left AV valve regurgitation in 67%, subaortic stenosis in 25%, right AV valve regurgitation in 22%, residual atrial septal defect in 11%, and
CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Presentation

Small PDA is asymptomatic, causing clinically unimportant left-to-right shunt. A continuous murmur may or may not be detectable, depending on size of the PDA. The patient may present with endocarditis or endarteritis.

Moderate PDA results in restrictive left-to-right shunting of variable magnitude, depending on its size. The larger the PDA, the more likely it will cause shortness of breath, fatigue, a wide pulse pressure, left atrial and ventricular enlargement, and some elevation of pulmonary artery pressure. In some cases, initial presentation is an incidental finding of ductal calcification or aneurysm on chest radiography or other imaging.

Large PDA is nonrestrictive and produces a large left-to-right shunt, pulmonary arterial hypertension (PAH), and almost always Eisenmenger physiology. Lower body cyanosis develops with advanced Eisenmenger physiology. Left and right ventricular failure may be present.

Diagnosis

The electrocardiogram is abnormal with large PDA, showing left atrial enlargement and left (volume-loaded) and right (pressure-loaded) ventricular hypertrophy. Chest radiography varies from normal to abnormal depending on shunt size. With larger shunts, cardiomegaly from left atrial, left ventricular, and right ventricular enlargement is seen. The pulmonary trunk is prominent. Calcification of the ductus may be detected.

Echocardiography confirms the diagnosis by using color Doppler to identify flow across the ductus. If PAH is present, pressure gradient and flow across the ductus are small, and echocardiography may fail to identify the PDA. Cardiac catheterization is performed in most cases of adult PDA, either as a diagnostic tool to assess the state of the pulmonary vasculature in large PDAs, or as a therapeutic tool to close small and some moderate PDAs. Magnetic resonance imaging or computed tomography may be useful if the PDA is complicated by aneurysm. Using these, the specific size and position of the aneurysm and its adjacency to other structures can be determined. Most reported aneurysms are patent at only one end, either aortic or pulmonary, but cases of true patency have been reported (Fig. 29-10).

TECHNIQUE OF OPERATION

Surgical closure can be performed either via median sternotomy or left thoracotomy. This is partially surgeon preference; however, other factors may influence the choice. A prior left thoracotomy or other left pleural space problem make a thoracotomy approach less advisable. Additional cardiac disease requiring surgery, such as associated ventricular septal defect or coronary artery occlusive disease, demands a median sternotomy approach. If cardiopulmonary bypass (CPB) is required or likely to be required to close the PDA, median sternotomy is preferred.

If the PDA is not complicated by calcification, aneurysm, or very short length, closure is performed using techniques similar to those described for children. When calcification is present, these techniques are contraindicated because simple ligation and division carries substantial risk of rupture.

Figure 29-10 Aneurysm of ductus arteriosus. A, Contrast-enhanced computed tomography image showing 50-mm aneurysm (arrows) of ductus arteriosus with mural thrombus and calcification. B, Magnetic resonance image showing aneurysm (arrows) arising from distal aortic arch. C, Angiography at catheterization also showing aneurysm (arrows) and its communication with both aorta and pulmonary artery. (From Tofukuji and colleagues.)
The same approach may be used for large PDA with little or no length. Another option for this anatomy, especially if there is no calcification of the ductus or aorta, does not use CPB and can be performed by either median sternotomy or left thoracotomy. The pulmonary artery and aorta at the ductal site are clamped, the ductus is divided, and the pulmonary artery and aorta are either sutured primarily or patched.

Aneurysm resection and repair is performed using median sternotomy and CPB, and the technique is similar to that used for arch aneurysm repair (see Chapter 26). Patching the aorta or pulmonary artery may be required.

RESULTS

Early mortality for surgical PDA closure in adults is low, but probably slightly higher than that in infants and children, which approaches zero. This is due to the increased technical demands of the procedure in adults. In a series of 55 adults (mean age 24 years) reported in 1971, there was no early mortality (CL 0%-3.5%). Currently, with alternative therapeutic options, series of this size no longer exist; however, it is reasonable to assume that mortality has decreased. In a series of nine adults (mean age 55 years) reported in 2000, there were no early deaths (CL 0%-19%). CPB with temporary balloon occlusion was used in this series, along with direct suture and patch closures from within the pulmonary artery. Pulmonary artery pressure decreased from 55 mmHg systolic prior to surgery to 35 mmHg at 6-month follow-up. In a series of 25 complex patients, many of whom had heavy calcification, aneurysm, heart failure, or PAH, early mortality was 4% (CL 0.7%-13%). In a series of 29 patients age 50 or older at surgery, early mortality was 3.4% (CL 0.6%-11%). In another series of 71 adults (mean age 24 years) with relatively uncomplicated PDA, there was no early or late mortality (CL 0%-2.6%). Many of the patients in this series (35%) were asymptomatic; 91.5% were treated with simple surgical ligation and 8.5% with surgical division.

Premature late death after PDA closure in adults is related to chronic changes in left ventricular function and in the pulmonary vascular bed resulting from long-standing left-to-right shunt.

Outcomes after repair of ductal aneurysm are not well documented because the lesion is so rare. There are case reports of successful surgical management.

INDICATIONS FOR OPERATION

Surgery is rarely indicated for PDA in adults. Most small and small to moderate PDAs are closed percutaneously at cardiac catheterization with coils or other occlusive devices. Most patients with large PDAs have Eisenmenger physiology and are not candidates for closure.

An emerging technology that can be applied to selected cases of PDA is endovascular stent-grafting. Stents are placed into the aorta and deployed to occlude the aortic opening of the ductus (Fig. 29-12). Hybrid approaches, with access to the aorta via surgical incision and deployment of an endovascular device, have been described and may be useful in selected cases.

Figure 29-11 Technique of closing patent ductus arteriosus (PDA) when calcium is present. A, After cardiopulmonary bypass is initiated, pulmonary trunk is incised to the left and right pulmonary arteries. B, An 8F Foley catheter is inserted into PDA through pulmonary trunk. Inset, Two or more pledgeted 4-0 polypropylene mattress sutures are placed around pulmonary artery orifice of PDA. Catheter is removed before sutures are tied. Pulmonary arteriotomy incision is closed. (From Kataoka and colleagues and Tekin and colleagues.)

CPB via median sternotomy, with internal patch or primary closure of the ductal orifice through the pulmonary trunk, is the preferred approach (see Chapter 37). It may be helpful to use a catheter device with a balloon, such as a Foley catheter, to temporarily occlude the ductus after it is exposed via the pulmonary arteriotomy and prior to definitive surgical closure. Cardioplegic arrest is not necessary (Fig. 29-11).
Surgery is indicated for any PDA that causes shunt-related symptoms, shunt-related cardiac enlargement, or PAH, or for a PDA that cannot be closed percutaneously because of endarteritis. Typical cases include those with a large lumen and short length, those complicated by aneurysm, and those with other unusual anatomic features.

In contrast to infants and children, adults requiring surgery for intracardiac problems who have a coexisting PDA should have the PDA closed percutaneously prior to the cardiac operation.

**DEFINITION**

The definition, morphology, and basic physiology of bicuspid aortic valve (BAV) are described in Chapter 12 and Chapter 47. Most commonly, BAV presents in the adult as primary congenital heart disease, either newly diagnosed or previously diagnosed with benign physiology. It may present as secondary congenital heart disease, because some patients may have undergone previous surgical or interventional procedures on the aortic valve.

**MORPHOLOGY**

Primary disease presenting in the adult is usually an isolated lesion, with the exception of associated aortic disease. Frequency of ascending aortic dilatation varies widely. It has been reported to be as low as 10% to 12% and as high as 83%. These variations are largely due to differences in patient population, length of follow-up, and definition of dilatation. Dilated aortas are at increased risk of developing complications (Fig. 29-13). BAV presenting in infants and children may be associated with other left-sided obstructive lesions, including coarctation (which is particularly common), subvalvar aortic stenosis, parachute mitral valve, and supramitral ring. When multiple lesions occur together, the term **Shone complex** is applied. Rarely, adults present with newly diagnosed Shone complex; however, secondary presentation occurs in adulthood essentially all survivors, because most of the cardiac lesions are palliated and not cured during childhood intervention. BAV may be a component of William and Turner syndromes.

Bicuspid aortic valve is a gross morphologic oversimplification. Two large and equally sized cusps are unusual, in

**Figure 29-12** Endovascular stent-grafting for selected cases of patent ductus arteriosus (PDA). **A**, Arteriography of thoracic aorta via left brachial artery showing large PDA with aneurysmal pulmonary artery. Placing an occlusion device via this access was considered contraindicated. **B**, Access to thoracic aorta via right femoral artery was obtained and a stent-graft placed distal to left subclavian artery with PDA closure. (From Munoz and colleagues.)

**Figure 29-13** Risk of aortic complications based on diameter of ascending aorta. Graph shows that all patients with abnormally increased diameters have increased risk of an aortic complication. For a given diameter, risk is higher for patients with either Marfan syndrome or bicuspid aortic valve relative to patients who do not manifest either of these. Blue dotted line represents patients without bicuspid aortic valve or Marfan syndrome; red line, patients with bicuspid aortic valve; and green line, patients with Marfan syndrome. Key: **MD**, Measured diameter of ascending aorta; **PD**, predicted normal diameter of ascending aorta; **R**, relative risk of aortic complication. (From Codecasa and colleagues.)
contrast to the bicuspid pulmonary valve seen in tetralogy of Fallot. Typically, BAV morphology has one large well-formed cusp, usually making up 40% to 50% of the anular circumference, and a second cusp consisting of a fusion of two cusps with a thick raphe representing the point of fusion. This abnormal cusp may prolapse, causing regurgitation, or it may calcify, particularly at the immobile raphe, leading to late stenosis. In cases of early stenosis, there is usually associated anular hypoplasia or variable degrees of fusion of the two other relatively normally formed commissures.

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

**Presentation**

Patients with primary or secondary disease often present with gradual stenosis and/or regurgitation that eventually leads to symptoms or physiologic criteria for surgical intervention. Less often, the primary presentation is ascending aorta dilatation and, rarely, aortic dissection, aneurysm, or rupture. Occurrence of dissection may be tenfold higher than in the normal population. Associated coarctation appears to increase risk of dissection. Occasionally, BAV presents with signs and symptoms of infective endocarditis.

Adults with secondary disease may present with a failed aortic valve repair, failed bioprosthetic aortic valve, failed or outgrown mechanical aortic valve, or failed pulmonary autograft (Ross procedure) in the aortic position. Bioprosthetic valves tend to require earlier replacement in young adults compared with older adults. This is likely due to a combination of patient growth after original placement and more rapid calcific degeneration. Need for replacement of mechanical valves is mostly related to patient growth, but gradual encroachment of pannus may also play a role. After the Ross procedure, neoaortic regurgitation necessitates reoperation in up to 10% of patients within a decade. Neoaortic root dilatation occurs in about half of cases by 7 years and may or may not be associated with neoaortic regurgitation. Risk of dissection or aneurysm formation in the dilated neoaortic root is not clear. Coronary obstruction may also present late after the Ross procedure because of scarring and kinking of the translocated coronary arteries and from compression by the calcified right ventricle to pulmonary trunk conduit. One of the most common late developments after the Ross operation is right ventricular outflow tract conduit failure. Freedom from conduit reoperation is better following the Ross operation than for conduits placed for other congenital heart diseases, such as tetralogy of Fallot. Brown and colleagues demonstrated freedom from conduit reoperation of 96% at 10 years. Raanani and colleagues report one reoperation for conduit failure in 109 patients at a mean follow-up of 39 months, although moderate to severe stenosis was noted in 3.8% and moderate to severe regurgitation in 9.5%. 

**Diagnosis**

Electrocardiography and chest radiography show typical findings associated with aortic valve disease. Echocardiography is the mainstay of diagnosis. It is able to assess the degree of stenosis or regurgitation once the diagnosis is made and can identify when physiologic criteria are met for intervention.

Cardiac catheterization is performed when coronary assessment is indicated, primarily in patients over age 40, or if there is concern that primary coronary insufficiency is present or that coronary scarring or compression has developed following a Ross procedure or other aortic root replacement procedure. Magnetic resonance imaging (MRI) and computed tomography are indicated to assess ascending aorta size and to rule out dissection and aneurysm. Additionally, MRI can be used to quantify aortic regurgitation if symptoms and echocardiographic findings disagree.

**NATURAL HISTORY**

BAV is the most common congenital heart defect, occurring in up to 2% of the population. In many cases it is associated with normal physiology for years or even decades. Aortic stenosis or regurgitation may develop at any time. Dilatation of the ascending aorta occurs, caused by connective tissue aortopathy with a genetic basis. Many cases of neonatal and infant aortic stenosis requiring intervention have underlying BAV. If aortic valve physiology is normal in infancy and childhood, the typical age for surgical intervention is 60 years. Among adults requiring surgery for aortic stenosis, a congenital abnormality of the valve is considered the cause in 54%.

In a natural history study of 642 adults with BAV (mean age 35 years at baseline) followed for 9 years (mean), one or more primary cardiac events, including death, surgical intervention, aortic dissection, and heart failure, occurred in 25% of patients at a mean age of 44 years. Nevertheless, fatal events were rare, with actuarial survival comparable with that of the general population. In another large series of adults (mean age 32 years at baseline) with mean follow-up of 15 years, cardiac events occurred in 40% at a mean age of 52 years. Again, however, actuarial survival was indistinguishable from that of the general population. The frequency of adverse cardiovascular events in adults with BAV is stratified based on risk profile, with risk factors including older age, moderate or severe aortic stenosis, and moderate or severe aortic regurgitation (Fig. 29-14).

**TECHNIQUE OF OPERATION**

Many surgical techniques used for adults with BAV and its associated lesions are the same as those used in children with...
require either primary or repeat surgery for aortic arch obstruction and mitral valve disease in addition to left ventricular outflow tract surgery.

Reduction aortoplasty, with or without external aortic support, for ascending aorta dilatation is described and depicted in Figs. 29-15 and 29-16, respectively. Other variations on external aortic support are described by Robicsek and colleagues and by Cohen and colleagues. Some controversy remains about whether a supportive wrap is a beneficial accompaniment to reduction aortoplasty in patients with BAV. Some even question the utility of reduction aortoplasty.

RESULTS

Outcomes for adults undergoing aortic valve replacement for congenital aortic valve disease are similar to those for adults with acquired aortic valve disease (see Chapter 12). Early and midterm outcomes after reduction aortoplasty for dilated ascending aorta associated with BAV, either alone or in...
association with aortic valve repair or replacement, are excellent. In a series reported by Bauer and colleagues, 115 patients (mean age 56 years) underwent reduction aortoplasty. There were no early deaths (CL 0%-1.6%). At a mean follow-up of 40 months, there was no postoperative dilatation and no complications in the nine patients who underwent reduction aortoplasty. There were no reoperations in the entire series.

Others have raised concerns about outcomes when reduction aortoplasty is performed without external support, arguing that the results reported by Bauer and colleagues are unreliable because follow-up was not long enough and citing the two causes of aortic dilatation: the hemodynamic principles of the Law of Laplace and the intrinsic aortopathy found in these patients. These authors recommend external support for all cases of reduction aortoplasty. Cohen and colleagues report 102 adult patients (mean age 54 years) with ascending aorta dilatation, 80% of whom also had aortic valve disease. All underwent a procedure involving external polyester mesh support of the ascending aorta, with or without concomitant reduction aortoplasty, aortic valve surgery, or coronary artery surgery. There was no early mortality (CL 0%-1.8%) and no late mortality related to aortic disease. At a mean follow-up of 5.7 years, mean increase in aortic diameter was 2.6 mm.

Aortic root replacement with concomitant aortic valve replacement can be performed with low early mortality. Nazer and colleagues report early mortality of 2.1% (CL 0.9%-4.2%). Diminished late survival was related to older age at operation. Valve-sparing aortic root replacement has been reported. In one series of 190 patients, 60 (mean age 53 years) had BAV. There was no early mortality (CL 0%-3.1%) and no late mortality at 5-year follow-up. Function of the spared BAVs was similar to a comparison group of 130 patients undergoing valve-sparing root replacement with tricuspid aortic valves. In another series of 153 patients (mean age 51 years) with BAV, early mortality was 0.6% (CL 0.1%-2.2%). Survival was 99% at 5 years and 91% at 10 years. At 10 years, freedom from valve replacement was excellent (Fig. 29-17).

The Ross procedure, with concomitant ascending aorta reduction or polyester graft replacement, was reported by Conaglen and colleagues in 154 patients (mean age 32 years). There was no early (CL 0%-1.2%) or late mortality and no cardiac reoperations at a mean follow-up of 9 years.

**INDICATIONS FOR OPERATION**

Indications for intervention in adult patients with BAV include the standard symptoms and hemodynamic and physiologic thresholds associated with any form of aortic stenosis.

![Figure 29-16](image.png)
or regurgitation (see Chapter 12). If aortic stenosis exists without regurgitation and without a dilated ascending aorta, percutaneous balloon valvotomy is indicated. If isolated aortic regurgitation, combined aortic stenosis and regurgitation, or associated dilatation of the ascending aorta exists, then surgical intervention is indicated. If balloon valvotomy fails to relieve the gradient or causes important regurgitation, surgical intervention is indicated.

An ascending aorta diameter of 5 cm or more or a change in aortic diameter of 0.5 cm · y⁻¹ are absolute indications for intervention. Indications for surgery on ascending aortas with lesser degrees of aortic dilatation are not as clear. Most agree that an ascending aorta diameter of 3.5 to 4.9 cm should be surgically addressed if surgery is otherwise indicated to treat aortic valve disease. Many, but not all, recommend surgery for an ascending aortic diameter of 3.5 to 4.9 cm even if there is no indication for aortic valve disease; some recommend observation in this situation. Valve-sparing prosthetic aortic root replacement, composite prosthetic valve and root replacement, Ross procedure, reduction aortoplasty with or without external aortic support, and isolated external support of the ascending aorta have been recommended for surgical management of a dilated ascending aorta.

Clinical judgment comes into play when strict criteria for intervention are not met. For example, in the young adult, new-onset mild or moderate regurgitation and an enlarging ascending aorta that has not yet reached 5 cm in diameter may be considered for surgical intervention. Aortic root replacement at this point in the disease process may allow a valve-sparing procedure. Another example is the patient with severe aortic stenosis and an ascending aorta that is dilated, but does not meet criteria for replacement. The best advice is to surgically address the aorta and replace the valve.

In women of childbearing age, especially those planning pregnancy or likely to become pregnant, timing of intervention may be altered. Intervention may be considered when milder physiologic alterations are present, anticipating the cardiovascular demands during the third trimester of pregnancy. Additionally, choice of intervention may be altered. Mechanical valves, with the attendant requirement for anticoagulation therapy, are poor choices for the pregnant woman (see “Pregnancy and Contraception” under Special Circumstances in Section I).

### Section VIII Subaortic Stenosis

#### Definition

The definition, morphology, and basic physiology of subaortic stenosis are described in Chapter 47. In the adult it may present as a primary disease, either newly diagnosed or previously diagnosed with benign physiology, or as a secondary disease. In a report from 1978, 36 of 138 patients (26%) undergoing surgery for primary subaortic obstruction presented in adulthood. It is likely that in the current era, improved diagnostic imaging has resulted in a smaller percentage of patients presenting for surgery in adulthood.

#### Morphology

As with subaortic stenosis in infants and children, morphology may range from a discrete fibrous membrane, to mixed fibromuscular obstruction, to tunnel-like muscular obstruction. Accessory atrioventricular (AV) valve tissue may play a role in the obstruction. As in children, the angle formed by the ventricular septum and aorta (aortoseptal angle) is more acute in adults with isolated discrete subaortic obstruction. In contrast to the case in children, there is evidence that this angle, as well as other left ventricular outflow tract geometric abnormalities found in patients with isolated subaortic stenosis, does not remodel postoperatively in adults.

#### Clinical Features and Diagnostic Criteria

**Presentation**

Subaortic stenosis presents in a variety of ways in adults. It may be a primary and isolated lesion with the typical signs and symptoms of aortic stenosis, sometimes with associated aortic valve regurgitation. In one study, aortic regurgitation was present in 80% of patients, but was hemodynamically important in only 20%. Subaortic stenosis may also be a primary lesion associated with ventricular septal defect (VSD), atrioventricular septal defect (AVSD), or a conotruncal anomaly with subaortic conus. About half of all primary cases are isolated, and half are associated with other cardiac anomalies.

Subaortic stenosis may also be a secondary lesion that develops after surgical repair of a spectrum of anomalies, including left ventricular outflow tract obstruction, perimembranous VSD, posterior malalignment VSD with arch obstruction, AVSD, and conotruncal anomalies such as double outlet right ventricle or certain types of transposition of the great arteries. Signs and symptoms at presentation are similar to those of valvar aortic stenosis.

**Diagnosis**

Electrocardiography and chest radiography show typical findings associated with aortic stenosis (and aortic regurgitation if present). Echocardiography will demonstrate the morphologic characteristics of the subaortic region and proximity of the subaortic lesion to the aortic valve, assess aortic regurgitation, estimate the pressure gradient, and demonstrate...
left ventricular function. As with most complex intracardiac lesions in adults, transesophageal echocardiography may add important details to the surface echocardiogram. Cardiac catheterization plays a limited role in subaortic stenosis, primarily to assess the coronary arteries if necessary. There is no role for therapeutic catheterization. In complex cases, magnetic resonance imaging may provide a more detailed estimation of the left ventricular outflow tract.

NATURAL HISTORY

Subaortic stenosis is relatively uncommon among adults with congenital heart disease, accounting for 6.5% (134 of 2057 patients) of presenting cases in one series. In this series, 22% (29/134) presented with severe obstruction and no prior surgical history, 48% (64/134) had no indication for surgery and no prior surgical history, and 30% (41/134) had surgery for subaortic obstruction during childhood.

Subaortic stenosis is a progressive lesion that creates greater degrees of obstruction over time and causes progressive aortic valve damage, which leads to aortic regurgitation. In adults, progression of obstruction and aortic regurgitation is slower than in children. It is not unusual for an adult to be followed with known uncomplicated mild subaortic stenosis for a period of time, only to develop more progressive stenosis, aortic regurgitation, or infective endocarditis. Aortic regurgitation is more likely the higher the pressure gradient in the subaortic region. Severe obstruction carries the same risks as severe valvar aortic stenosis.

TECHNIQUE OF OPERATION

The appropriate operation for subaortic obstruction depends on the morphology of the obstruction—membranous, fibromuscular, or tunnel-like—and presence and severity of aortic regurgitation. Procedures include membrane resection, myectomy, aortic valve repair, aortic valve replacement, and Konno or modified Konno procedures. Operations and principles determining their application are described in Chapter 47, those for aortic valve replacement in Chapter 12, and those for aortic valve regurgitation in Chapter 35 (see Section II, Ventricular Septal Defect and Aortic Regurgitation).

RESULTS

Early mortality in the current era is 3% to 4%, with late survival substantially lower than that of the general population and a relatively high rate of reoperation. In a 1976 report of 36 adults undergoing surgery for subaortic stenosis, only 53% had an isolated anomaly and 25% presented with infectious endocarditis, reflecting the complex nature of the patients in this study. Early mortality was 8.3% (CL 3.7%-16%).

In a more contemporary series of 52 patients (mean age 25 years) reported in 2005, early mortality was 3.8% (CL 1.3%-8.8%). Concomitant aortic valve replacement was required in 29% because of chronic aortic regurgitation graded as 3+ or 4+. The mean age of patients requiring valve replacement was older than those not requiring replacement (37 vs. 21 years). Late mortality was 16% (Fig. 29-18). Recurrent obstruction requiring another operation occurred in five patients over a mean follow-up period of 17 years.

From Erentug and colleagues. AS, Aortic stenosis; ASD, atrial septal defect; AVR, aortic valve replacement; PDA, patent ductus arteriosus; PS, pulmonary stenosis; RVOT, right ventricular outflow tract; VSD, ventricular septal defect.

In another series of 88 patients (mean age 20 years) reported in 2005, 66% (58/88) had discrete obstruction and 34% (30/88) had diffuse tunnel-like obstruction. Moderate or worse aortic regurgitation requiring a concomitant aortic valve procedure was present in 15%. Aortic valve hypoplasia requiring a Konno procedure was present in 17%. Associated cardiac anomalies requiring concomitant surgery were present in 45% (Table 29-9). Early mortality was 3.4% (CL 1.5%-6.7%) and late mortality 1.1% at a mean follow-up of 6.1 years. Diffuse tunnel-like obstruction was a risk factor for early mortality by multivariable analysis. Reoperation for progressive aortic regurgitation or recurrent left ventricular outflow tract obstruction was required in 16.5% of patients over the follow-up period (Fig. 29-19).

INDICATIONS FOR OPERATION

Surgical resection of subaortic stenosis is indicated in several circumstances. The first relates to classic obstructive physiology: peak echocardiographic gradient of 50 mmHg or greater or a lesser gradient associated with left ventricular hypertrophy and strain or documented symptoms. The
aorta and even descending aorta, renal artery hypoplasia, coronary artery obstruction and dysplasia, and branch pulmonary artery hypoplasia with multiple peripheral stenoses. The intima, media, and adventitia of the coronary arteries may all be involved with fibrotic and dysplastic changes.

### CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

#### Presentation

Because the pathologic processes in the arterial wall are diffuse and progressive, disease that was asymptomatic in childhood may lead to systemic hypertension (renal arteries and diffuse aortic hypoplasia), late-onset discrete systemic outflow obstruction (progression of supravalvar aortic stenosis), pulmonary hypertension (peripheral branch pulmonary artery stenosis and hypoplasia), or cardiac ischemia (coronary artery ostial obstruction, sinus of Valsalva inflow obstruction from progression of the supravalvar obstructive process, or coronary artery aneurysm or dissection). These modes of presentation can occur in the adult whether or not the patient underwent surgery in childhood to address supravalvar aortic stenosis.

#### Diagnosis

The electrocardiogram will show varying degrees of left ventricular hypertrophy, reflecting the degree of left-sided outflow obstruction. If there is coronary artery involvement, there may be signs of ischemia. The chest radiograph may also show signs of left ventricular hypertrophy. Surface echocardiography reliably demonstrates the abnormal supravalvar aortic morphology, but cannot completely define the coronary artery, pulmonary artery, or diffuse changes in the remainder of the aorta and its branches. Transesophageal echocardiography may further define the intracardiac and proximal aortic morphology, but has the same limitations as surface echocardiography with respect to more peripheral artery and coronary artery problems. Both magnetic resonance imaging and computed tomography (CT) are useful in defining the ascending and descending aorta and its major branches and the peripheral branch pulmonary arteries. Although CT can define some coronary artery abnormalities, cardiac catheterization and angiography are indicated for precise definition. Obstruction to coronary arterial flow may be caused by progression of the supravalvar stenosis leading to inhibition of blood entering the sinus of Valsalva, or from intrinsic coronary artery ostial obstruction from intimal thickening. In the most severe cases the sinus of Valsalva can be totally occluded as the free edge of the valve cusp fuses to the overhanging fibrous ridge of the discrete supravalvar ring.

#### NATURAL HISTORY

Supravalvar aortic stenosis is typically diagnosed and treated in childhood. In the William syndrome form, it is rare for the individual to reach adulthood undiagnosed, even if the cardiovascular manifestations are mild, because the distinctive associated facial and neurodevelopmental abnormalities make the diagnosis obvious.

#### TECHNIQUE OF OPERATION

Second relates to status of the aortic valve: presence of subaortic stenosis, regardless of gradient, is an indication for surgery if new-onset aortic regurgitation develops or more than mild regurgitation is present. Mild subaortic stenosis in the absence of aortic regurgitation, particularly if the membrane is in contact with or in close proximity to the aortic valve, is considered an indication for resection by some. Aortic valve repair is indicated at the time of resection if aortic regurgitation is more than mild. Aortic valve replacement is indicated for moderate or severe regurgitation if repair is not possible.
Other vascular procedures may be indicated, including reconstruction of stenotic or hypoplastic ascending aorta, arch, head and neck arteries, and branch pulmonary arteries.

**RESULTS**

Evidence-based outcome estimates for outcomes of supravalvar aortic stenosis repair in adults are based on case reports and the few adult patients included in larger pediatric series. Early mortality after repair of supravalvar aortic stenosis in adults is probably in the range of 2% to 5%. Mortality should be no higher than for similar operations in children unless important complicating factors are present. At least one large series, mostly involving children (median age 7 years), reports an early mortality of 9%; however, most of the deaths occurred in the 1950s and
1960s or involved patients brought to the operating room in extremis.145

It is probably true that adult patients with supravalvar aortic stenosis will demonstrate sequelae not usually seen in children, primarily related to the coronary arteries. Inan and colleagues report a case of a 21-year-old man with associated left main coronary artery stenosis caused by cusp fusion and thickening and intimal thickening of the coronary ostium.11 Surgical repair was uncomplicated. Yilmaz and colleagues report two cases, age 20 and 21 years, of associated coronary artery aneurysm. Both patients underwent repair of the supravalvar aortic stenosis without surgically addressing the aneurysms. Postoperatively, anticoagulation therapy was instituted. Both patients were doing well at midterm follow-up.17 Thistlethwaite and colleagues report on a 32-year-old patient with long-segment left main coronary artery narrowing successfully managed with supravalvar aortic repair and concomitant saphenous vein coronary artery bypass grafting.17

As in children, risk factors for late survival and reoperation are likely to be diffuse supravalvar aortic hypoplasia and concomitant aortic valve disease.145

INDICATIONS FOR OPERATION
Surgery is the only therapeutic option for supravalvar aortic stenosis; there are no percutaneous techniques applicable to this lesion. The hemodynamic indication for surgery is a 50-mmHg mean echocardiographic gradient. If symptoms are present, there is left ventricular hypertrophy or failure, or increased cardiac demand is expected (e.g., an active lifestyle, anticipation of pregnancy), surgery is indicated for less severe resting obstruction. Evidence of myocardial ischemia with obstruction to coronary flow is an indication for surgery regardless of aortic gradient.

Section X  Aortic Arch Obstructive Problems

DEFINITION
The definitions, morphology, and basic physiology of coarctation of the aorta and interrupted aortic arch are described in Chapter 48. Problems related to aortic coarctation are relatively common among adults with congenital heart disease. Often these problems relate to secondary disease, with the patient having undergone a surgical or interventional procedure as an infant or child. Patients can, however, present with native disease in adulthood.147,220,226,13,14,220

MORPHOLOGY
Many patients with a history of previous coarctation repair have some form of residual disease as adults, and lifelong follow-up is required after repair at any age. Residual disease may take many forms. There may be obstruction at the coarctation repair site or, particularly if the repair technique involves a prosthetic patch, aneurysm at the repair site. Diffuse aortopathy is recognized as part of the coarctation disease process, and this can contribute to chronic hypertension, dissection, aneurysm, and rupture. Intracranial aneurysm may be present in patients with coarctation, leading to intracranial bleeding and stroke.

A spectrum of associated left-sided cardiac structural anomalies can occur with coarctation, most commonly bicuspid aortic valve, but also other anomalies that, with coarctation, make up Shone complex. These are supramitral ring, parachute mitral valve, and subaortic membrane. All may be part of the presentation of either recurrent or residual coarctation, or well-repaired coarctation in the adult. With the exception of bicuspid aortic valve, these associated anomalies are much less likely to be part of the presentation of newly diagnosed coarctation in the adult, because most patients with multiple associated anomalies will present much earlier. These associated left-sided obstructive problems are not discussed further in this section. Aortic valve and subvalvar aortic obstruction are discussed in Sections VII and VIII of this chapter.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA
Presentation
The adult with unrepaired coarctation typically presents with systemic hypertension. This may be accompanied by symptoms such as headache and lower extremity weakness, especially with exercise. On further evaluation a differential between upper body and lower body blood pressure is commonly noted; however, long-standing obstruction leads to collateral development, which can blunt or even eliminate the pressure differential. A lower body pulse delay remains in all cases.

Interrupted aortic arch rarely presents in adulthood as primary disease; rather, the majority of patients present critically ill as neonates and either undergo surgical repair or die. Adults with secondary disease following prior repair of interrupted aortic arch will present with signs and symptoms similar to those of patients with prior coarctation repair. There will be, however, a higher prevalence of late aortic valve and subaortic problems.

Patients with previously repaired coarctation or interrupted aortic arch most commonly present with residual or recurrent coarctation or hypertension, but may present with any of the signs and symptoms related to aortic, coronary, or cerebral vascular disease, or associated cardiac structural anomalies. Aortic aneurysm at the repair site is particularly likely in patients with prior patch aortoplasty repair (Fig. 29-22).149 Even if there is no recurrent obstruction, adults with a history of coarctation repair in childhood have reduced exercise capacity compared with normal individuals, particularly if systemic hypertension is present or repair was performed at an older age.120

Diagnosis
In unrepaired coarctation, the electrocardiogram will show left ventricular hypertrophy. Chest radiography may show cardiomegaly from left ventricular hypertrophy, aortic silhouette irregularities such as the reverse-3 sign of unrepaired coarctation or dilatation and ectasia associated with prior repair, and rib notching from intercostal arterial collaterals. Echocardiographic imaging of the thoracic aorta is difficult in the adult,
although color Doppler may show an obstructive pattern at the coarctation site, flow in intercostal collaterals, and blunted pulsation distal to the coarctation. Echocardiography is essential for documenting associated intracardiac structural anomalies and myocardial function. Magnetic resonance imaging (MRI) and computed tomography (CT) are the preferred methods for precisely defining the morphologic details of both primary coarctation and previously repaired coarctation or interrupted aortic arch in the adult, particularly when three-dimensional reconstruction is obtained (Figs. 29-23 and 29-24). Accurate measurement of reduction in luminal diameter at the primary coarctation or repair site is an important factor used in management decisions. MRI can be used to calculate the amount of collateral flow present by subtracting flow in the aorta just distal to the primary coarctation or repair site from flow in the aorta at the diaphragm. It can also assess

**Figure 29-22** Cumulative incidence of descending thoracic aortic aneurysms after native coarctation repair by (A) patch aortoplasty (n = 494) or (B) other methods (n = 397). (From Knyshov and colleagues.19)

**Figure 29-23** Computed tomography images of a 36-year-old woman with severe native coarctation of the aorta. Sagittal multiplanar reformatted (A) and left lateral volume-rendered (B) images show severe aortic narrowing (white arrows) below left subclavian artery. Enlarged internal thoracic arteries and dilated posterior collateral intercostal arteries connecting to the postcoarctation descending thoracic aorta are seen. C, Anterior volume-rendered image shows enlarged internal thoracic arteries (black arrows) and dilated superior thoracic and thoracoacromial arteries (white arrows). D, Coronal maximum-intensity projection image shows dilated posterior collateral intercostal arteries causing rib notching. (From Turkvatan and colleagues.25)
functional elastic properties of the aortic wall.\textsuperscript{H1} These data may be particularly helpful in cases of both primary and recurrent coarctation when there is a smaller gradient than expected across the coarctation site and reduction in luminal diameter is equivocal.

MRA of the head is indicated in all adults to rule out intracranial aneurysm. Diagnostic cardiac catheterization is indicated primarily to assess the coronary arteries; however, in cases with questionable criteria for intervention, a catheter pullback peak-to-peak gradient across the coarctation may provide definitive information. Therapeutic catheterization may be indicated.

**NATURAL HISTORY**

If coarctation is unrecognized for many years, premature coronary artery obstructive disease, cerebrovascular disease, and aortic disease may lead to myocardial infarction, heart failure, stroke, intracranial hemorrhage, infective endarteritis, or aortic dissection or rupture. Aortic complications are more likely with advanced age and with presence of a bicuspid aortic valve.\textsuperscript{e97} Life expectancy is approximately half of normal in patients with unrepaired coarctation. Survival at 30-year follow-up after surgical repair ranges from 72% to 82%.\textsuperscript{W18}

**TECHNIQUE OF OPERATION**

There are many surgical options for addressing both native and recurrent coarctation in the adult. The actual techniques are no different from those used for coarctation in infants and children, which are described in detail in Chapter 48. Decision making used in choosing among these, however, is very different from that used in infants and children. The difference is based on several factors:

- Somatic growth does not have to be considered in the adult.
- Adults have much less elasticity in their aortic tissue than children.
- Adults are much more likely to have had one or more prior operations for coarctation.
- Adults are much less likely to have intracardiac anomalies requiring surgery concomitant with coarctation repair.

Thus, for native coarctation in the adult, it is more likely that an interposition graft will be required rather than resection and primary anastomosis, especially if there is any length to the coarctation or if proximal arch hypoplasia is present. For native coarctation, the surgical approach will usually be by left thoracotomy in adults, because intracardiac anomalies are relatively uncommon. Use of various forms of extended resection and primary anastomosis are essentially never an option in the adult because lack of elasticity in the adult aorta precludes the degree of mobilization required. Resection and primary anastomosis is reserved for discrete coarctation with no proximal arch hypoplasia. If coronary artery or aortic valve disease is present and requires surgical treatment, median sternotomy is used.\textsuperscript{J14, T15}

For recurrent coarctation, the surgeon must consider whether previous repairs were performed by sternotomy or left thoracotomy. If by sternotomy, and the recurrent obstruction is in the distal arch, then left thoracotomy may be the best approach. Resection and primary anastomosis is rarely possible in this setting or in any recurrent setting in the adult; most often, either patch repair or interposition grafting will be performed. If the previous operation was by left thoracotomy, a median sternotomy with cardiopulmonary bypass (CPB) may be the best approach, especially if the recurrent obstruction is in the proximal arch. If the obstruction is distal in the arch and relatively simple anatomic, and there has been only one previous thoracotomy, a repeat thoracotomy may be considered. CPB can also be considered when a thoracotomy is chosen, either for native or recurrent coarctation, if the repair appears to be complex (anticipated long aortic clamp time) and there are few or no collaterals (Fig. 29-25).\textsuperscript{B1} Deep hypothermic circulatory arrest has been described for complex coarctation repair via thoracotomy.\textsuperscript{G22} As the number of previous thoracotomies and anatomic complexity of the recurrent obstruction increase, the more attractive becomes the option of performing the repair using one of the many extracardiac graft reconstruction techniques.\textsuperscript{A18, A16, C3, D3, M13, S14, W7} Two of these techniques, one using median sternotomy and one left thoracotomy, are shown in Figs. 29-26 and 29-27. Right thoracotomy can also be used.

Therapeutic catheter-based intervention for recurrent obstruction is preferred in many institutions. Endovascular approaches, including balloon aortoplasty and covered stenting, may be used.\textsuperscript{G19, W3} In selected complex patients with previous surgery or with important comorbidities, hybrid approaches may be applicable (Fig. 29-28).\textsuperscript{C5, C6}

**RESULTS**

Early mortality after surgical repair of native coarctation in the adult is less than 1%, and hypertension is reliably improved and even normalized in many cases, with reduced requirement for antihypertensive medication.\textsuperscript{V16} Jatene and
Figure 29-25 Repair of coarctation of the aorta in adults. 

A, Through a posterolateral thoracotomy, lung has been retracted anteriorly with a “Kirklin fence.” Aortic cannula is shown in position in the descending thoracic aorta distal to site for distal aortic vascular clamp. Coarctation site and aortic arch have been dissected. “Patent ductus arteriosus” (PDA) represents either ductus or ligamentum arteriosum, which may or may not be present.

B, Lung has now been retracted posteriorly (temporarily) and pericardium opened posterior to phrenic nerve. Venous cannula has been inserted into left atrial (LA) appendage. C, Patient is placed on partial cardiopulmonary bypass. Venous drainage must be carefully controlled by perfusionist such that left atrium is not drained completely, allowing enough left ventricular filling so that upper body perfusion is maintained by left ventricular ejection. Proximal and distal vascular clamps have been applied. Ligamentum, if present, is ligated and divided. Dotted lines indicate extent of coarctation resection. In this case, two intercostal collateral vessels have been ligated and divided.
colleagues report on 50 adults (mean age 25 years) who underwent surgical repair of native coarctation via left thoracotomy. Procedures used included resection with anastomosis in 40%, patch augmentation in 44%, and interposition graft in 16%. There was no early mortality (CL 0%-3.7%). At a mean follow-up of 46 months, there was one late death due to endocarditis. Blood pressure was normal in more than 90%, with 75% free of antihypertensive medication (Fig. 29-29). The gradient was reduced from a mean of 61 mmHg preoperatively to a mean of 19 mmHg and was independent of the surgical technique used. Similarly, Bouchart and colleagues report on 35 adults (mean age 28 years) with native coarctation. Resection with anastomosis and interposition graft were the dominant techniques used. Mean follow-up was 165 months. There was no mortality (CL 0%-5.3%) and no reoperation for recoarctation over the course of follow-up. At follow-up, 66% (23/35) were normotensive without medication; however, 35% (8/23) had a hypertensive response to exercise testing at 6-month follow-up. Six patients underwent subsequent surgery for aortic valve disease. Wells and colleagues report on 26 adults (mean age 32 years) undergoing surgical repair of native coarctation, with a mean follow-up of 2.3 years. There was no mortality (CL 0%-7.0%). At rest, 88% were normotensive, but most remained on medication. Hashemzadeh and colleagues report on 38 adults (mean age 26 years) undergoing surgical repair using the techniques of resection with anastomosis, patch repair, and graft interposition, with a mean follow-up of 37 months. Results were similar to the previously cited studies, with no mortality (CL 0%-4.9%) and relief of resting hypertension in the majority of patients. Bhat and colleagues report on 84 adults (mean age 29 years) undergoing surgical repair of native coarctation, with a mean follow-up of 5.2 years. There was 1 early death (1.2%; CL 0.2%-4.0%) and no deaths at follow-up. All survivors experienced significant regression of hypertension, with 42% off medication, and persistent hypertension was observed in 31%. Bauer and colleagues report 15 patients over the age of 50 years undergoing surgical repair of native aortic coarctation, with a mean follow-up of 4 years. There was no mortality (CL 0%-21%). Two minor strokes occurred perioperatively with full resolution, and there was one case of endocarditis. Hypertension was relieved in 80% (12/15), but 73% (8/11) of evaluated patients who were normotensive at rest had a hypertensive response to exercise.

Complications after repair of native coarctation in adults are similar to coarctation repair in children, including blood loss, phrenic nerve injury, recurrent nerve injury, hypertension, residual coarctation, pseudoaneurysm, and paraplegia. Interventional procedures for native coarctation in the adult, either balloon angioplasty or stenting, provide similar gradient relief and hypertension control as surgery. Earlier reports of aneurysm formation and intimal tears following balloon angioplasty in up to 13% of patients may be reduced as experience increases and technology advances to include stents and covered stents. Reports as recent as 2008, however, show aneurysm formation in 7.5%. Several deaths have also occurred using interventional techniques. Long-term sequelae of endoluminal prostheses remain an important unanswered question, and this concern is the major objection to their use in native coarctation. It is also the major argument for surgical management of native coarctation, especially when end-to-end anastomosis can be achieved, thereby avoiding prosthetic material.

Early mortality for surgical repair of recurrent coarctation varies from 1% to 14%, depending on complexity of the surgery and presence of comorbidities. There are reports of no surgical mortality. Early mortality
of recurrent coarctation treated by stents and endografts, there was no early mortality and no paraplegia (CL 0%-16%). Surgical reconstruction of the left subclavian artery was necessary in two patients because of coverage of the origin of the artery and arm ischemia. At a mean follow-up of 12 months, three cases of leaks around the endograft were documented, one as late as 2 years after implantation. Long-term clinical effectiveness has not been demonstrated.

**INDICATIONS FOR OPERATION**

Intervention may be surgery or percutaneous catheter-based therapy. Indications for intervention include a gradient of 20 mmHg or more (documented by catheterization using extra-anatomic bypass techniques varies from 0% to 4.6%. Late outcome, ranging up to 22 years in these studies, is excellent, with no reported graft-related complications or reoperations.

Endovascular approaches, including balloon aortoplasty, stenting, and covered stenting, are as effective as surgery in relieving the gradient in adults with recurrent coarctation. These approaches avoid much of the morbidity associated with reoperative surgery and complex reconstruction; however, they are themselves complex procedures. Morbidity includes vascular injury at the site of percutaneous puncture, residual and recurrent coarctation, hypertension, aneurysm formation at the coarctation site, aortic leaks, and vascular compromise. In a series of 11 cases (mean age 47 years) of recurrent coarctation treated by stents and endografts, there was no early mortality and no paraplegia (CL 0%-16%). Surgical reconstruction of the left subclavian artery was necessary in two patients because of coverage of the origin of the artery and arm ischemia. At a mean follow-up of 12 months, three cases of leaks around the endograft were documented, one as late as 2 years after implantation. Long-term clinical effectiveness has not been demonstrated.

**INDICATIONS FOR OPERATION**

Intervention may be surgery or percutaneous catheter-based therapy. Indications for intervention include a gradient of 20 mmHg or more (documented by catheterization using extra-anatomic bypass techniques varies from 0% to 4.6%. Late outcome, ranging up to 22 years in these studies, is excellent, with no reported graft-related complications or reoperations.

Endovascular approaches, including balloon aortoplasty, stenting, and covered stenting, are as effective as surgery in relieving the gradient in adults with recurrent coarctation. These approaches avoid much of the morbidity associated with reoperative surgery and complex reconstruction; however, they are themselves complex procedures. In a series of 11 cases (mean age 47 years) of recurrent coarctation treated by stents and endografts, there was no early mortality and no paraplegia (CL 0%-16%). Surgical reconstruction of the left subclavian artery was necessary in two patients because of coverage of the origin of the artery and arm ischemia. At a mean follow-up of 12 months, three cases of leaks around the endograft were documented, one as late as 2 years after implantation. Long-term clinical effectiveness has not been demonstrated.
in equivocal cases) across the coarctation and a luminal narrowing of 50% or more (by MRI, CT, or catheter-based aortography) at the coarctation site. If the gradient is less than 20 mmHg and luminal narrowing is less than 50%, MRI documentation of important collateral flow is an indication for intervention.

Some institutions consider percutaneous catheter-based balloon dilatation and stenting as an option for adult native coarctations that meet specific morphologic criteria, but others consider surgery to be the procedure of choice for all native coarctations, reserving percutaneous therapy for recurrent coarctation. Most institutions with experienced interventional cardiology teams consider percutaneous catheter-based therapy as the procedure of choice for recurrent coarctations that meet these specific morphologic criteria:

- Coarctation must be discrete.
- There must be no associated proximal arch hypoplasia.
- Coarctation must be remote from the origin of head and neck arteries.
- There must be no aneurysm, dissection, or important ectasia associated with the coarctation.
- No intracardiac anomalies requiring surgical repair are present.

Surgery is indicated for recurrent coarctation if any one of these criteria is not met or if percutaneous therapy is not successful. For those institutions that prefer percutaneous techniques for selected native coarctation, the criteria that must be met are the same as for recurrent coarctation.

### Section XI  Tetralogy of Fallot

#### DEFINITION

Definition, morphology, and basic physiology of tetralogy of Fallot are described in Chapter 38. Tetralogy of Fallot is common in adults presenting with congenital heart disease. Almost exclusively, adult patients have secondary disease, having undergone repair in infancy or childhood. Rarely, the adult with tetralogy will present with primary disease.

#### MORPHOLOGY

Most often, previously repaired patients present as adults with residual right ventricular (RV) outflow tract (RVOT) disease, either pulmonary stenosis, regurgitation, or both. This may develop in the native RVOT, in a prosthetic valve placed in the native RVOT, or in a RV-to-pulmonary trunk conduit. When stenosis is present, it may be subvalvar, valvar, or supravalvar. Residual RVOT disease is common because this problem is built into the standard initial repair. Pulmonary valve anular hypoplasia and abnormal cusp development occur in the majority of tetralogy patients. Initial repair involves a transanular patch in more than 50% of patients, causing obligatory important pulmonary regurgitation. Surgical pulmonary valvotomy is performed in many of the remaining patients, leaving them vulnerable to both regurgitation and stenosis.
Other less common reasons for adult presentation include residual ventricular septal defect (VSD), residual atrial septal defect, tricuspid regurgitation, aortic regurgitation, dilated aortic root, branch or peripheral pulmonary artery stenosis, stroke, and various arrhythmias.

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

**Presentation**

The typical adult with previously repaired tetralogy of Fallot presents with signs and symptoms related to pulmonary regurgitation, including exercise intolerance and palpitations. If intervention is not undertaken at that time, RV dilatation progresses and right heart failure or atrial or ventricular tachycardia may be the mode of presentation. The effect of RVOT dilatation, “aneurysm,” and akinesis, independent of the pulmonary regurgitation itself, on the RV is currently the focus of attention. The role of these factors is not clear at this time. One study shows that the best predictors of reduced quality of life are reduced RV ejection fraction and later age at repair.

Many patients in developed countries are followed carefully into adulthood after infant or childhood tetralogy repair, and the presentation may be of an asymptomatic patient who at follow-up evaluation eventually meets a number of imaging, hemodynamic, and electrophysiologic criteria for intervention. These criteria continue to evolve and are designed to trigger intervention before irreversible myocardial or electrical damage occurs in the right atrium and ventricle.

The arrhythmia burden is substantial in repaired tetralogy patients, and it increases dramatically with age (Figs. 29-30 to 29-32 and Table 29-10).

Presentation in the adult may be altered by any of the residual or secondary lesions mentioned in Section I of this chapter.

Although about 15% of adult tetralogy patients have a dilated ascending aorta (associated with a history of long shunt-to-repair interval and with pulmonary atresia), it rarely leads to presentation. Of 671 acute aortic dissections reported in one large series, only one was in a patient with tetralogy of Fallot. A few additional isolated single case reports of aortic dissection and aneurysm in tetralogy patients

also exist; however, given the number of adults with tetralogy, these events are rare.813,817,821 Dilated ascending aorta, however, is associated with important aortic regurgitation.829

Diagnosis

The diagnosis is already known in the great majority of adults with tetralogy of Fallot. Further diagnostic workup is aimed at identifying residual defects (primarily pulmonary regurgitation) and determining when intervention is indicated. The electrocardiogram (ECG) is critical to evaluation, identifying the predominant rhythm (sinus, junctional, or atrial fibrillation or flutter), presence of ventricular ectopy, and QRS complex duration. Holter monitoring and formal electrophysiologic evaluation should be undertaken to fully characterize any rhythm disturbance (see “Arrhythmias” in Section I of this chapter).

Electrocardiography estimates severity of pulmonary regurgitation, RVOT obstruction, RV function and size, tricuspid regurgitation, residual ventricular and atrial septal defects, as well as left-sided valvar and ventricular function.

Magnetic resonance imaging (MRI) is particularly helpful in quantifying pulmonary regurgitant fraction, tricuspid regurgitant fraction, and RV end-diastolic volume.596,597 It may also provide important information about the peripheral branch pulmonary arteries. If MRI is contraindicated, computed tomography (CT) can be used to determine RV volume and to image the branch pulmonary arteries.828,829,830

Cardiac catheterization is indicated to assess the coronary arteries and to determine pulmonary vascular resistance, which may be abnormal, particularly in patients formerly palliated with shunts. Coronary arteries are imaged to rule out arteriosclerosis and to characterize the coronary artery anatomy if it is not already known. Specifically, the left anterior descending coronary artery arises from the right sinus of Valsalva and crosses the RVOT in about 10% of tetralogy patients and thus is vulnerable to injury during RVOT intervention. Catheterization may also be indicated to obtain complete hemodynamic evaluation if alterations in right or left ventricular function require further clarification.

NATURAL HISTORY

Tetralogy is a common form of congenital heart disease (5%-7% of all congenital defects), and most patients survive to adulthood after repair. Thirty-year survival after repair is 80% to 85%. Surgical cure is rare, however.814

When an adult presents with unrepaired tetralogy, the physiology is usually that of mild or mild to moderate RVOT obstruction.

TECHNIQUE OF OPERATION

The surgical procedures used in adults with tetralogy of Fallot will be for residual or recurrent disease in most cases. Rarely, the adult will present with unrepaired tetralogy, either with a history of previous palliative shunt or with no previous surgery. The procedures used in these patients are the same as in children and are detailed in Chapter 38. In adults with previously repaired tetralogy who have pulmonary regurgitation, porcine, xenograft, bovine pericardial, and allograft valved conduits may be placed into the RVOT. The technique of operation is described in Chapter 38, as is surgical reconstruction of the RVOT.

Catheter-based placement of a pulmonary valve is possible as a “valve-in-valve” procedure requiring a previously placed bioprosthetic conduit 18 to 20 mm in diameter. Peripheral or segmental pulmonary artery stenoses may be addressed by balloon dilatation, either proceeding the procedure or as a hybrid procedure. Catheter-based methods may be applicable for residual atrial or ventricular septal defects, branch pulmonary artery stenoses, aortopulmonary collateral arteries, and closure of previously placed surgical shunts.

RESULTS

Surgical outcomes after operations on the RVOT in adults with previously repaired tetralogy are excellent, with early mortality of 0% to 2%.520,521,711 Lesser performed operations, such as closure of residual atrial or ventricular septal defect or repair of branch pulmonary artery stenosis, probably have similar mortality. Late survival is also excellent, with mortality of 0.5% per patient-year.520 Sudden death from arrhythmias is the main mode of premature death. Ventricular tachycardia is the most common cause of this; however, acute atrial tachycardia and heart block may also contribute. Its risk factors include a long interval before repair (this risk is present whether the patient has received no operation or a palliative shunt); residual RVOT disease (regurgitation or stenosis); known ventricular ectopy; poor left ventricular function; and prolonged QRS duration. Prolonged QRS duration and ventricular ectopy both correlate with poorly functioning and dilated RVs and with cardiac events. Prolonged QRS also correlates with left ventricular dysfunction, and left ventricular dysfunction is a risk factor for sudden death.514,728

Normalization of RV hemodynamics (placing a competent pulmonary valve and relieving RVOT obstruction) can reduce ventricular arrhythmias.52,B15,D12,E39,F2,D5,D7,G14,H15,H17,T11,W5 The operation can also reduce QRS duration in some cases, but not in others.16,M18 The study by Scherptong and colleagues showed that QRS duration improved in about two thirds of patients after operation, and this occurred whether the preoperative QRS was below or above 180 ms.511 Postoperative cardiac events were most likely to occur in the subset of patients with preoperative QRS of greater than 180 ms and no postoperative reduction in duration (Table 29-11). In another study, placing a competent pulmonary valve did not reduce QRS duration in any patient, and late follow-up showed no reduction in cardiac events.16 Why some patients show reduction in QRS duration after placement of a competent valve and others do not is unclear. Nevertheless, these studies imply that preserving RV function is probably the best way to minimize late fatal arrhythmias. This is best achieved by early primary repair with attention to myocardial preservation, and aggressive intervention in adults with residual or recurrent hemodynamic abnormalities that threaten to compromise RV function.

Improvement in both systolic and diastolic function and in RV dimensions has also been documented after placement of a competent pulmonary valve. Some studies, however, show continued RV dilatation and reduced function despite improvement in functional health status of the patient. These discrepancies may be due largely to timing of intervention, again underscoring the benefit of early intervention.52,A19,E6,F9,H12,T11,V10,V15

Performance of prosthetic pulmonary valves placed into the RVOT in adults with previously repaired tetralogy and pulmonary regurgitation has been studied by Fiore and colleagues.16 In comparing porcine (Medtronic Mosaic valve), bovine pericardial (Carpentier-Edwards), and pulmonary allograft vaulted conduit (Cryolife) prostheses, they found that allograft vaulted conduits initially had the lowest gradients; however, they also developed regurgitation and required reintervention sooner (Fig. 29-33). Outcomes for adult tetralogy patients undergoing right heart procedures and concomitant aortic valve or ascending aortic surgery have been reported by Stulak and colleagues.552 In their study of 81 patients, early mortality was 7.4% (CL 4.4%-12%); however, there was no mortality after 1991 in the last 56 patients (CL 0%-6.4%).

Adults presenting with unrepaired tetralogy of Fallot are becoming a vanishing subset. Most reports of large series are either from the 1960s and 1970s or, if more recent, are from countries with emerging healthcare technology.515 Attenhofer and colleagues recently reported on 52 patients (mean age 50 years) operated on between 1970 and 2007, half of whom had no previous palliation and half of whom did.521 Early mortality was 5.8% (CL 2.6%-11%). At 15-year follow-up, 29 of 48 early survivors had died at a mean age of 65 years. Previously palliated patients who died did so at a mean age of 59 years, and patients with no previous palliation...
who died did so at a mean age of 70 years. Survival in the entire group was lower than in the general population 10 years after repair, consistent with other evidence that earlier repair provides the most benefit. Surviving patients were functionally improved. Alizadeh and colleagues reported on 51 patients (mean age 22 years) operated on between 1995 and 2005. A previous systemic-to-pulmonary artery shunt had been performed in 16%. Early mortality was 2.0% (CL 0.05%-10%). During a mean follow-up of 42 months, one additional death occurred. Functional improvement was documented in survivors. Atik and colleagues reported on 39 patients (mean age 27 years) operated on between 1982 and 2001. A previous shunt had been performed in 10%. Early mortality was 5.1% (CL 0.6%-17%), and actuarial survival at 15 years was 68%. Again, functional improvement was seen in survivors. Lu and colleagues report on 57 patients (mean age 25 years) operated on between 1990 and 2004. Early mortality was 7.0% (CL 1.9%-17%), and survival was 73% at 14 years. Functional improvement was documented, with 76% of patients in New York Heart Association (NYHA) functional class I. Rammohan and colleagues report on 100 patients (mean age 20 years) operated on between 1991 and 1996. A previous shunt was present in 22%. Early mortality was 4% (CL 1.1%-9.9%), and there was one late death at a mean follow-up of 3.4 years. Of survivors, 94% were in NYHA functional class I.

These studies indicate that primary repair can be performed in the adult with varying, but generally low, early mortality risk, and with substantial improvement in functional status and quality of life. Late survival, however, is substantially lower than in the general population, and lower than for tetralogy patients who undergo operation earlier in life.

INDICATIONS FOR OPERATION

Decisions relating to intervention in the adult with previously repaired tetralogy of Fallot occur commonly and are complex. There are multiple potential defects, many of which may occur simultaneously and with varying degrees of severity. Appropriate intervention may be by surgery, percutaneous catheter-based intervention, or both. The adult congenital cardiologist, pediatric cardiologist, adult congenital cardiothoracic surgeon, and electrophysiologist should all be involved in formulating the individualized management plan for each patient. In patients with equivocal indications for intervention, cardiopulmonary exercise testing may be helpful.

Careful judgment should be used for the adult who presents with long-standing profound cyanosis and no previous surgery. This patient may struggle with severe right or even biventricular failure following primary repair even if no residual lesions are present and excellent myocardial protection is used. There are many reasons for this, including chronic cyanosis and long-standing RV hypertension.

There is another important variable: It must be appreciated that with markedly reduced pulmonary blood flow, this patient will have a combined ventricular output far less than normal, in the range of 1.3 to 1.5 times normal systemic output, rather than the normal combined ventricular output of 2 times normal systemic output. Primary repair of tetralogy, even when there are no residual defects, represents an acute volume load as biventricular output is obligatorily increased to 2 times normal systemic output. In the setting of a very noncompliant, small hypertrophied RV, the circulation may be unsustainable after repair. In such cases a preliminary systemic-to-pulmonary artery shunt procedure, followed by shunt takedown and repair after 3 to 6 months, should be considered. This approach will increase volume load during the shunt phase, effectively training the two ventricles to work at normal volumes prior to repair.

Catheter-Based Interventions

Catheter-based intervention may be applicable in selected cases of RVOT obstruction or regurgitation, residual atrial and ventricular septal defect, and branch and peripheral pulmonary artery stenosis that meet the same indications as for surgical intervention. Catheter-based intervention is preferred for closing acquired aortopulmonary collaterals and often for closing previously placed surgical shunts.

Catheter-based therapy may be considered for RVOT obstruction if the obstruction is at the valve level or beyond, but not if it is in the infundibulum. Balloon dilatation of valvar obstruction (either native valve or conduit), with or without stenting, is commonly performed; however, it is difficult to demonstrate objectively the efficacy of this procedure. Gradients can diminish but are not eliminated; however, regurgitation is made worse. The tradeoff in this physiologic change is of questionable benefit.

Catheter-based placement of a pulmonary valve in combination with balloon dilatation and stenting of obstruction is a more rational approach that has gained favor in recent years. This approach can also be used in selected cases of isolated regurgitation after repair. Catheter-based placement of a pulmonary valve, however, is only applicable in about 10% of repaired tetralogy patients with RVOT problems. Criteria for this procedure include requirement of a previously placed RV-to–pulmonary trunk conduit with a diameter of at least 16 mm, or previously placed bioprosthetic valve with a diameter of 18 to 20 mm. Thus, the great majority of repaired tetralogy patients—those with native RVOTs or transanular patches—are not candidates.

Most atrial septal defects are candidates for percutaneous device closure, with the criteria the same as for closure of isolated atrial septal defect. Selected muscular and patch-related VSDs are candidates for percutaneous device closure. Size and position of the defect must be such that impingement of the device on the tricuspid, mitral, or aortic valve is not of concern. Most acquired collaterals can be occluded with percutaneously placed coils or other occlusive devices.

Open surgical shunts are exceedingly rare in adult tetralogy patients in the current era; however, the occasional patient who reaches adulthood with palliated tetralogy may be a candidate for device closure. Branch and peripheral pulmonary artery stenosis can be considered for percutaneous balloon dilatation, particularly if surgical intervention is not in the immediate future of the patient. Stenting of branch pulmonary arteries should be avoided in most cases, even though it is fully acknowledged that some institutions recommend them. The central branch pulmonary
arteries are easily accessible surgically, even when the surgeon does not have particular expertise in pulmonary artery reconstruction. When placed in central pulmonary artery branches, stents do not relieve obstruction with the same efficacy as surgical reconstruction, and furthermore, stents can erode into the tracheobronchial tree and aorta.

Surgical Interventions

If surgical reconstruction of the RVOT is indicated, then balloon dilatation or stenting of central branch pulmonary artery stenosis should not be performed. Rather, the branch pulmonary artery obstruction should be repaired surgically as part of the RVOT procedure. If no immediate surgical procedure is anticipated for a patient, balloon dilatation of isolated central branch pulmonary artery stenosis is a reasonable approach, but stenting should be avoided.

If surgery is planned for RVOT disease, concomitant more peripheral stenoses in lobar or segmental pulmonary arteries may be addressed by balloon dilatation prior to surgery or at surgery. This decision should be made on an individual institutional basis depending on available surgical and interventional expertise. Stenting of peripheral lobar and segmental pulmonary arteries that do not respond to balloon dilatation should not be performed if surgical expertise is available for direct repair.

SPECIAL SITUATIONS AND CONTROVERSIES

A number of cardiac anomalies have morphologic characteristics similar to those of tetralogy of Fallot. These are all conotruncal anomalies. They include all types of pulmonary atresia with VSD, all types of truncus arteriosus, and some types of double outlet right ventricle, transposition of the great arteries (TGA), congenitally corrected transposition of the great arteries, and double outlet left ventricle. The similar characteristics include normally developed atria, atroventricular (AV) valves, and ventricles, with large conoventricular type VSD, overriding or transposed aorta, and pulmonary stenosis or atresia. It follows that surgical repair of these anomalies will be similar to that of tetralogy of Fallot. It also follows that many of the late complications and management issues seen in adults with these anomalies will be similar to those seen with tetralogy.

The majority of these anomalies will be repaired in infancy, and repair requires two main components: VSD closure such that the left ventricle aligns with the aorta, and RV-to-pulmonary trunk reconstruction, often involving a valved conduit. Thus, adults with these anomalies almost always present with secondary disease, having been repaired in infancy or childhood. Issues related to the late follow-up status of the RV and RVOT in all these anomalies are similar to those seen in tetralogy; each, however, has unique additional morphologic characteristics that can lead to other late management problems not typically seen in tetralogy. These are discussed in the following text.

Pulmonary Atresia with Ventricular Septal Defect

Definition

See Chapter 38.

Morphology

There are two forms of this anomaly. The duct-dependent form is similar to classic tetralogy of Fallot. Because of the atretic pulmonary valve, initial reconstruction in infancy typically involves a valved conduit. By the time these patients reach adulthood, essentially all will have a RV-to-pulmonary trunk conduit. Late problems in adults are similar to those in tetralogy patients who have received a conduit. Dilatation of the ascending aorta, and associated aortic regurgitation, is more common in tetralogy with pulmonary atresia than in classic tetralogy.

The other form of pulmonary atresia with ventricular septal defect does not have a ductus arteriosus, but instead has large aortopulmonary collateral arteries. Branch and peripheral pulmonary artery abnormalities, such as deficient arborization, hypoplasia, or complete absence, are the hallmark of this anomaly.

Clinical Features and Diagnostic Criteria

Because of the complex and variable pulmonary artery morphology of this anomaly, individual patients will be managed differently during childhood and will therefore present differently in adulthood. The spectrum of presentation includes primary disease that is newly diagnosed (rarely), primary disease that was previously diagnosed but with benign physiology (rarely), primary disease that was previously diagnosed but deemed inoperable, and secondary disease after previous repair or palliation.

In adults with newly diagnosed primary disease, mode of presentation will likely be with signs and symptoms of cyanosis, but also may be with complications related to longstanding mixed circulation, such as paradoxical embolus, endocarditis, arrhythmias, or heart failure. Formal evaluation with echocardiography to assess ventricular function and valve function, and cardiac catherization to assess the pulmonary artery and collateral morphology and physiology, are required.

Technique of Operation

Surgical management decisions are the same as for children diagnosed with this disease (see Chapter 38), although adults have a greater degree of pulmonary vascular obstructive disease and collateral loss as well as cardiac dysfunction. Unoperated adults with preserved cardiac function and a full complement of patent but partially stenotic collaterals may be operable and fully correctable. In the large series by Malhotra and Hanley, unifocalization and intracardiac repair was possible in selected patients as old as 45 years. If evaluation reveals that intracardiac repair is contraindicated, palliative shunt or conduit operations to improve oxygenation may be warranted if the dominant symptoms are from cyanosis. Heart-lung transplantation may be considered in patients with decompensated cardiac function (see Chapter 21).

In adults with previously diagnosed primary disease with benign physiology, careful evaluation is similarly warranted. The original assessment that the patient had benign physiology is likely to have been incorrect if that designation was based only on adequate systemic oxygen saturation and not on detailed morphologic and physiologic assessment of the individual collaterals. Appropriate evaluation of each patient in this category, as in the former category, will determine whether repair, palliation, or transplantation is indicated.
Chapter 29 Congenital Heart Disease in the Adult

Natural History

Unrepaired truncus arteriosus is rare in the adult, and when it is encountered it is almost always unreparable because of Eisenmenger physiology. There are no reported series or case reports of primary surgical repair of truncus in the adult. There are several case reports of unrepaired truncus presenting in adulthood with complications such as pulmonary hypertension with Eisenmenger physiology, endocarditis, and fatal truncal root dissection.

Technique of Operation

Because the truncal valve commonly has more than three cusps and the anulus is large, the regurgitant valve can often be repaired using techniques that are not usually applicable in true aortic valves (Figs. 29-34 to 29-36).

Results

Outcomes and techniques for truncal valve repair are reported, but mostly for younger patients. In the series of 17 repairs by Kaza and colleagues, there was a single older patient (age 42 years).

Indications for Operation

Patients with truncal regurgitation usually present for repair at the time of neonatal correction, or within the first 10 to 15 years after repair \[11,19,115\]; therefore, presentation in the adult is unusual. Indications for repair or replacement are standard.

Double Outlet Right Ventricle

Definition

The type of double outlet right ventricle (DORV) with subaortic VSD and pulmonary stenosis is discussed in this section (see Chapter 53). It is the most common form of DORV.

Morphology

DORV with subaortic VSD and pulmonary stenosis or atresia is managed surgically like tetralogy of Fallot. Late problems occur primarily in the reconstructed RVOT, as in tetralogy. Additionally, there are concerns about the left ventricular outflow tract (LVOT) because of the subaortic conus and the more complex patch (or baffle) that is required to close the VSD and align the left ventricle with the aorta. The result is a complex tunnel-like LVOT. A combination of hypertrophy of the conus muscle and patch distortion lead to a greater chance of late subaortic stenosis than in tetralogy of Fallot.
survive to adulthood have Eisenmenger physiology and are inoperable. Those with pulmonary stenosis who survive and are cyanotic from low pulmonary blood flow may be candidates for surgical repair, similar to individuals with unrepaired tetralogy of Fallot.

### Natural History

Individuals with DORV rarely survive to adulthood without surgical repair. Those without pulmonary stenosis who do survive to adulthood have Eisenmenger physiology and are inoperable. Those with pulmonary stenosis who survive and are cyanotic from low pulmonary blood flow may be candidates for surgical repair, similar to individuals with unrepaired tetralogy of Fallot.
CTGA with VSD and pulmonary stenosis or atresia shares certain features with tetralogy of Fallot: surgical repair requires VSD closure and placement of a conduit from the heart to the pulmonary trunk. The definitive repair in infancy or childhood is either the “classic” repair or the “double switch” repair. There are important sequelae in the adult after both operations. In the classic repair, VSD closure is straightforward, and the conduit is placed from the morphologic left ventricle to the pulmonary trunk. The expected late conduit problems are a concern with this anomaly, just as with the other anomalies under discussion in this section. However, obstruction in the conduit may be better tolerated because the morphologic left ventricle and mitral valve are part of the pulmonary circulation.

An additional important late problem following “classic” repair is function of the tricuspid valve and morphologic RV that are positioned in the systemic circulation. Premature failure of these structures is common at late follow-up after “classic” repair, as it is under any other circumstance when the RV is left in the systemic circulation. (This subject is covered in more detail in Sections XII and XIII of this chapter.) When this circumstance is encountered after “classic” repair, the option of training the left ventricle and subsequent reoperation to place the left ventricle in the systemic circulation, under any circumstance a controversial choice, is almost always inadvisable, because the left ventricle already has a large ventriculotomy in it (raising concerns about its long-term function in the systemic circulation), and the operation would require placing a prosthetic valved conduit from the left ventricle to the aorta. The alternative of cardiac transplantation is the better option.

In the other type of repair in infancy or childhood, the “double switch” repair, the left ventricle is aligned with the aorta via the VSD using a patch or baffle, a conduit is placed from the morphologic RV to the pulmonary trunk, and an atrial switch is performed. Because of the position of the heart and aorta in CTGA, the conduit must often be positioned in the midline in this operation. The late concerns of conduit compression from the sternum are similar to those previously discussed for TGA. Additionally, in the double switch repair, atrial baffle complications, including intra-atrial shunting, systemic or pulmonary venous obstruction, and sick sinus syndrome or junctional rhythm, can occur, similar to complications found after the Mustard or Senning operation for simple TGA.

Natural History
CTGA with VSD and pulmonary stenosis or atresia may present as primary disease in adulthood, but in the current era, most patients with this form of CTGA undergo surgery in infancy or childhood. This may involve initial palliation with a systemic-to-pulmonary artery shunt followed by later definitive repair, or initial definitive repair. After any kind of repair of CTGA, complete heart block is frequent, occurring either at the time of initial repair or spontaneously at any time.

Technique of Operation
In Connelly and colleagues’ series of 52 patients with all forms of corrected transposition presenting in adulthood, 64% underwent definitive surgical repair. The most common procedure was the “classic” repair for patients with associated VSD and pulmonary stenosis, performed in 80% (20/25) of the definitive repairs. In six of these patients, the
systemic tricuspid valve was replaced. Early mortality was 5%.
Two patients who had no systemic tricuspid valve regurgita-
tion preoperatively developed severe regurgitation after repair, probably related to shift of the ventricular septum after left ventricular pressure was reduced. Exercise testing in sur-
vivors was subnormal. There was no increase in systemic ventricular ejection fraction with exercise.

Results
In a series of 189 patients of all ages with all forms of corrected transposition, 152 had associated VSD and either pulmonary stenosis or atresia. Although mean age at surgery was 8 years, the upper end of the age range was 47 years, implying that at least some patients with VSD and pulmonary stenosis presented for initial repair in adulthood.

Double Outlet Left Ventricle
There are several forms of this extremely rare anomaly (see Chapter 54). In the repaired adult, in addition to the typical right-sided conduit problems, the LVOT must be monitored for late obstruction, just as in the other anomalies with left ventricular–to-aortic intracardiac patch or baffles. Commonly, repair involves complex closure of a VSD (with varying degrees of baffling required) and placement of a RV-to–pulmonary trunk conduit.

Section XII Transposition of the Great Arteries

DEFINITION
The morphology, physiology, and natural history of transposition of the great arteries (TGA) are described in Chapter 52.

MORPHOLOGY
There are several common morphologic variants of TGA: with intact ventricular septum (simple TGA); with ventricular septal defect (VSD); with arch obstruction; and with VSD and pulmonary stenosis or atresia. TGA with VSD and pulmonary stenosis or atresia is discussed in Section XI. The other variants require neonatal or infant surgical correction for the patient to survive.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Presentation
The adult presentation of these variants of TGA will almost exclusively be that of secondary congenital heart disease follow-
