Isolated coarctation is slightly more than twice as common in males as in females, but there is no gender difference in those with important coexisting cardiac anomalies.\textsuperscript{522}

**Isolated Coarctation**

This category includes patients with or without associated patent ductus arteriosus.

**Survival**

Coarctation has been surgically correctable since 1944. As a result, information on natural history is difficult to find. Postmortem data from series and case reports published before the era of surgical correction indicate that the median age of death is 31 years, with 76% of deaths attributable to complications of the coarctation.\textsuperscript{A1,B,1,R14} These reports did not include patients under age 2 years, and therefore neonatal and infant mortality are not accounted for. Among babies born with isolated coarctation, about 10% may be expected to die of acute cardiac failure during the first month of life if untreated. Another 20% may be expected to die later during the first year of life of heart failure or its sequelae. Thus, the true median age of death may be closer to 10 years.

Antemortem series prior to the era of surgical correction indicate that mortality after infancy is about 1.6% per year during the first 2 decades, and then gradually rises to 6.7% per year by the sixth decade.\textsuperscript{15} The most common causes of death, in decreasing order, are heart failure, aortic rupture, infective endocarditis, and intracranial hemorrhage.\textsuperscript{15} The few individuals who survive to age 60 years are usually women, because of their lesser tendency to develop hypertension and arteriosclerosis.\textsuperscript{14}

**Heart Failure in Infancy**

A number of factors act singly or in combination to produce heart failure in infants with isolated coarctation. *First*, ductal closure, as it progresses from pulmonary to aortic end during the first 7 to 10 days of life, increases the degree of aortic narrowing,\textsuperscript{R26,T2} which prior to this event may have been mild and of little functional importance. Consequent development of severe coarctation precipitates left ventricular failure at age 1 to 2 weeks. If the coarctation does not become severe, heart failure does not occur. *Second*, the degree to which collateral circulation is present at birth may also be important. Mathew and colleagues found that all infants with isolated coarctation had collaterals on angiography performed at age 8 days to 15 months, indicating that collaterals developed either during fetal life or, more likely, soon after.\textsuperscript{M14} Presumably, collateral development is absent or inadequate as long as the ductus is widely patent and there is pulmonary hypertension.\textsuperscript{R6} *Third*, presence of major noncardiac anomalies contributes. Thus, of 46 autopsied infants reported by Malm and colleagues in 1963,\textsuperscript{R6} 12 died in the first week of life from major noncardiac anomalies (prematurity, tracheoesophageal fistula), and in the New England Regional Study,\textsuperscript{R15} 26% of the infants had extracardiac anomalies that, when severe, contributed to mortality.

Sequence of pathophysiologic events leading to severe heart failure that develops in the first few weeks of life has been further elucidated by Graham and colleagues.\textsuperscript{G8} They found that left ventricular wall mass was normal and left ventricular stroke volume and ejection fraction severely
depressed. Because left ventricular systolic function as reflected in stroke volume and ejection fraction returned to normal after coarctation repair, the mechanism of its preoperative reduction is clearly afterload mismatch (see “Increased Ventricular Afterload” in Section I of Chapter 5 and Natural History in Chapter 12) brought about by sudden increase in left ventricular afterload from the rapidly developing coarctation as the ductus closes in the presence of a nonhypertrophied left ventricle. Severe cardiomegaly is present, but it is the result of markedly increased right ventricular end-diastolic volume; left ventricular end-diastolic volume is normal. Right ventricular enlargement usually is associated with left-to-right shunting through the stretched foramen ovale.

Graham and colleagues reported somewhat different findings in the 10% of patients with isolated coarctation presenting with mild or moderate heart failure at 1 to 6 months of age. Left ventricular wall mass was increased in this group (as it is in older children with coarctation), and left ventricular ejection fraction and stroke volume were only mildly decreased. Increased left ventricular thickness had reduced left ventricular afterload (see “Ventricular Afterload” in Section I of Chapter 5); that is, “afterload mismatch” had largely been overcome.

Apart from incidental causes, death after infancy in patients with isolated coarctation is generally due to heart failure, infective endocarditis, aortic rupture or dissection (each in

Figure 48-11 Magnetic resonance (MRA) and computed tomographic (CTA) angiograms of previously repaired coarctation. A, Maximal-intensity projection image from contrast-enhanced MRA of a 25-year-old man who had a remote childhood repair of coarctation. Image demonstrates an eccentric filling defect (arrow) that nearly occludes repaired segment of the aorta. It may represent thrombus and fibrous scar. B, Maximal-intensity projection image from cardiac gated CTA of an 18-year-old man who had a focal periductal coarctation distended by a stent. C, Maximal-intensity projection image from contrast-enhanced MRA of a 27-year-old woman who developed an aneurysm at site of repaired coarctation.
Heart Failure in Childhood and Adult Life

In Reifenstein’s series of adolescents and adults, there was only one death from heart failure in a patient younger than 20 years of age; most such deaths occurred in the fourth and fifth decades. In most instances, there was associated valvar heart disease, usually aortic but occasionally mitral, that combined with hypertension to produce heart failure. Congenitally abnormal aortic valve (bicuspid valves were present in 42% of the hearts) was the usual cause of stenosis or regurgitation. Heart failure occurs at the extremes of age; about two thirds occurs in infancy. It is uncommon between age 1 and about age 30 and reappears in about two thirds of patients who survive beyond 40 years.

Infected Endocarditis or Endarteritis

Infected endocarditis or endarteritis causes death at an average age of 29 years and is equally common in the first 5 decades of life. Infection usually occurs on a bicuspid aortic valve and rarely on a mitral valve or in relationship to a VSD. Endarteritis is less common and usually occurs in the poststenotic segment in relationship to the jet lesion on the aortic wall. Mycotic aneurysms can result.

Aortic Rupture

Rupture occurs at an average age of 27 years and is most common in the second and third decades. It usually involves the ascending aorta and often occurs into the pericardium with tamponade; less often, the aorta immediately beyond the coarctation ruptures at the site of poststenotic dilatation where the wall is dilated and thin. Many of these ruptures are probably true dissecting aneurysms, but pathologic details of the aortic wall are scarce.

Intracranial Lesions

Intracranial lesions caused death at an average age of 28 years in Reifenstein’s series and at 30 years in Abbott’s series. Among the 35 patients younger than age 21 years with coarctation and cerebrovascular disease reported in the literature and reviewed by Shearer and colleagues, only three were younger than age 7 years at the time, and in most the incident was fatal. In the majority of cases, there is a subarachnoid hemorrhage from rupture of a congenital berry aneurysm on the circle of Willis arteries. These lesions are considerably more common in patients with coarctation than in the general population and are more likely to rupture because of associated hypertension. Other causes of cerebrovascular accidents are arteriosclerosis, particularly in older patients, and emboli, particularly in the presence of infective endocarditis. In the treated series reported by Liberthson and colleagues, a cerebrovascular accident had occurred in only 1 of 91 patients (1.1%; CL 0.1%-3.7%) younger than age 11 years at the time of diagnosis and in 12 of 143 (8%; CL 6%-12%) age 11 to 39 years. However, in those older than 40 years, 21% (5 of 24; CL 12%-33%) had had a cerebrovascular accident.

Coarctation Associated with Ventricular Septal Defect

Most infants born with a large VSD and coarctation develop severe heart failure in the first month. By contrast, presentation so early is uncommon in patients with isolated large VSD (see under Natural History in Section I of Chapter 35). Unless the VSD rapidly diminishes in size, most of these babies die within a few months without surgical treatment. However, in many the VSD rapidly becomes small (see Fig. 35-21 in Chapter 35), and the natural history then becomes essentially that of isolated coarctation.

Coarctation Associated with Other Major Cardiac Anomalies

The combination of coarctation with other major cardiac anomalies nearly always produces severe heart failure during the early weeks of life. Without surgical treatment, from 80% to 100% of such babies die in their first year of life.

All reported series show a high proportion of associated cardiovascular anomalies in patients with coarctation presenting in infancy (see Table 48-2). In such infants, isthmus and arch hypoplasia is almost constant as a consequence of disturbed fetal blood flow patterns (see Morphology earlier in this section). In many of these infants, particularly those with complex and severe intracardiac anomalies, the natural history is primarily that of the associated anomaly. However, associated severe coarctation undoubtedly precipitates early heart failure.

TECHNIQUE OF OPERATION

In general, resection of the coarctation and reconstruction of the aorta should be considered the ideal method of repairing coarctation. For a number of reasons, however, this cannot always be achieved, and alternative methods must be used. The technique of each operation is described in this section.

Preparation, Incision, and Dissection

Neonates and Infants

After anesthetic induction, body temperature is allowed to drift down to a nasopharyngeal temperature of about 35°C. This downward drift is helped by reducing the operating room temperature to about 18°C (65°F) and by using the cooling mode in the heating-cooling pad under the child. Blood pressure in the right arm is monitored by an indwelling radial or brachial artery catheter. Near-infrared spectroscopy can be used to monitor tissue oxygenation both proximal and distal to the coarctation. Substantial changes in tissue oxygen values both above and below the coarctation have been documented with varying technical maneuvers; however, these changes have not yet been correlated with clinical adverse events.

The patient is positioned in full lateral position, secured with strapping across the hip and onto the operating table, with a sandbag tucked against the front of the chest. Approach is made through a left posterolateral thoracotomy, with the entry through the fourth intercostal space. For this, the intercostal muscles may be incised in the center of the interspace or entry made via the fifth rib bed, elevating the periosteum from the superior half of this rib and incising the rib bed rather than the intercostal muscles. Care is required posteriorly because careless elevation of the periosteum too far in this direction or attempts to dislocate the costotransverse joint will result in excessive bleeding from
collaterals. In most cases, the trapezius muscle need not be incised. Scoliosis is well documented following left thoracotomy in infants and children\(^4\); however, it is not known whether minimizing trauma to chest wall muscles and ribs will reduce this late development.

The rib spreader is inserted and opened in stages to avoid rib fractures (Fig. 48-12, B). The lung is retracted anteriorly, and the mediastinal pleura is opened over the aorta downward for several centimeters below the coarctation site and upward to include the distal arch and subclavian artery and, if necessary for arch hypoplasia, all the brachiocephalic arteries. Numerous closely placed stay sutures are placed along each side of the pleural incision, and the ends are gathered into clamps for exposure (Fig. 48-12, C). No other retractors are then required. The left superior intercostal vein is ligated and divided.

Keeping dissection in the areolar tissue just superficial to the adventitial aortic coat, the proximal left subclavian artery, the distal transverse arch, and the aortic isthmus are dissected. All dissection is kept close to the aorta, in part because this is the best plane of dissection and in part to minimize the possibility of damage to the thoracic duct. “The Abbott
artery occasionally arises from the medial aspect of the isthmus and, when present, should be ligated and divided. Next, with great care to avoid damaging the intercostals and bronchial arteries, the aorta beyond the coarctation is dissected. It is occasionally necessary to divide one or more bronchial arteries medially. Finally, the ductus arteriosus or ligamentum arteriosum is dissected. If the nasopharyngeal temperature has not decreased to about 35°C, and especially if the patient is hyperthermic, the left pleural space is lavaged with ice-cold saline for the few minutes required to accomplish the repair (see “Paraplegia after Aortic Clamping” under Special Situations and Controversies in Chapter 24).

Children
The operation is technically more demanding in children than in neonates and infants because collateral circulation is much larger. A long posterolateral thoracotomy incision is made, cutting 1 to 4 cm of the trapezius muscle posteriorly and carrying the incision to the nipple line anteriorly. The pleural space is entered through the top of the bed of the nonresected fifth rib and the rib spreader is opened gradually until a wide exposure is obtained. The mediastinal pleura is opened widely over the upper half of the descending thoracic aorta and subclavian artery. Numerous stay sutures are applied as described for infants (see previous text).

The aortic dissection then proceeds as described for infants; however, it must be done with particular accuracy and precision because of the large intercostal arteries. Even the smallest subadventitial dissection must be scrupulously avoided by keeping dissection in the areolar tissue just superficial to the adventitia. In most cases, after incising the pleura over the aorta and brachiocephalic arteries and dividing the superior intercostal vein, dissection is carried around the aorta just proximal to the coarctation and a tape placed around it. A similarly sharp dissection is made just distal to the coarctation, taking care to avoid damage to a hidden Abbott artery above or an enlarged intercostal artery below. Further dissection is facilitated by gentle traction on the tapes.

The ligamentum arteriosum, the third and sometimes fourth pair of intercostal arteries, Abbott artery if present, and left subclavian and carotid arteries are now completely dissected. The Abbott artery requires ligation and division, as may a bronchial (or esophageal) artery beyond the stricture. All dissection details described for infants are important here as well.

Immediate Post-Repair Management
Following repair by any technique, the distal clamp is removed first. After the proximal clamp has been slowly opened, great care is taken to maintain proper ventilation and baseline systemic blood pressure for at least the next 5 minutes as a precaution against sudden development of intractable ventricular fibrillation 3 to 4 minutes after release of the clamp (de-clamping syndrome). It may be necessary for the anesthesiologist to give sodium bicarbonate or an infusion of a pure peripheral vasoconstrictor (or both) just before clamp removal in particularly unstable infants or in those with prolonged clamp times.

After repair, pressures are measured proximal and distal to the repair with fine needles. If there is a systolic gradient of greater than 10 mmHg, clamps are reapplied, sutures removed, and the repair refashioned. In neonates, the residual gradient may reside in the hypoplastic distal aortic arch between left carotid and subclavian arteries. Other causes may be inadequate excision of the intimal flap combined with failure to carry the incision in the aorta far enough distally if the subclavian flap technique is used (see following text), or a poorly formed anastomosis using resection and end-to-end anastomosis.

After the clamps are removed, the heating blanket, warming lamps, a warmed operating room, and warmed and humidified inspired gases are used to warm the infant. Usually the suture line is hemostatic, and the mediastinal pleura can soon be closed over it. A small chest tube is placed through a lateral and inferior stab wound. Incision through the interspace is closed with a few interrupted sutures. Muscles and subcuticular layers are closed with a continuous suture. The chest tube may be removed in the operating room in neonates and infants after closing the incision. The baby is usually returned to the intensive care unit still intubated.
Resection and Primary Anastomosis

**Neonates and Infants**

Some form of this operation is currently the preferred technique for young patients. Preparations for operation, incision, and dissection are described previously under “Preparation, Incision, and Dissection.” Once the coarctation is resected, there are various options for reconstruction, each of which is described in this section.

When the coarctation is well beyond the origin of the left subclavian artery, the proximal clamp is usually placed across the aorta to include the origin of the left subclavian artery. The distal clamp is placed on the aorta below the third and fourth set of intercostal arteries. The ligamentum arteriosum or ductus arteriosus, which has been tied at its pulmonary end, is transected at its aortic insertion. The aorta is transected proximal to the coarctation at a level that ensures removal of any narrowed portion of the isthmus as well as the coarctation (Fig. 48-13, A). Similar transection of the aorta is made beyond the coarctation, where the aortic diameter is usually ample.

The suture line is made with a continuous simple suture of 6-0 or 7-0 absorbable monofilament suture, sewing “from within” for the posterior wall (Fig. 48-13, B). After the posterior row of sutures has been placed, the ends of the aorta are approximated by the assistant and the sutures are pulled up snugly. The remainder of the anastomosis is completed by sutureing the anterior wall using the other end (Fig. 48-13, B).

---

**Figure 48-13**  Resection and end-to-end anastomosis for repair of coarctation. **A,** With patient in right lateral decubitus position, a curving incision is made around the angle of the scapula, the chest opened, and stay sutures placed on the edges of the mediastinal pleura and held under tension to aid exposure (as shown in Fig. 48-12, but eliminated here for simplicity). After sharply dissecting out the coarctation and contiguous structures, tapes are placed around aorta just above and below coarctation site. Traction on tapes elevates aorta anteriorly or posteriorly to provide exposure that facilitates dissection. Dashed lines show levels of aortic transection above and below coarctation site. **B,** Ductus arteriosus (or ligamentum arteriosum) has been ligated and divided, and small bulldog clamps (clips) have been placed on third and fourth pairs of intercostal arteries. Proximal clamp is positioned across aorta and base of subclavian artery to leave ample length for the proximal cuff. Coarctation is excised, getting back to a wide orifice proximally and distally. Running monofilament absorbable suture line is begun at far end of the circumference and progresses along posterior aspect of anastomosis.

*Continued*
Finally, the clamps are removed as described under “Immediate Post-Repair Management” and the operation completed similarly (Fig. 48-13, D).

When the coarctation is near the takeoff of the left subclavian artery, or when the segment between it and the subclavian artery is importantly hypoplastic, proximal transection is begun just beyond the origin of the left subclavian artery.

When the distal portion of the aortic arch between the left common carotid and subclavian arteries is hypoplastic, as it often is in neonates and young infants, the operation may be modified so as to enlarge this area. In young patients, end-to-end anastomosis is easily accomplished after extended resection, and the distal transverse arch and aorta proximal to the coarctation are widened by the procedure. Alternatively, hypoplasia in the distal arch and even the proximal arch can be managed by placing the curved proximal side-biting clamp to occlude the proximal arch just distal to the brachiocephalic artery origin, occluding both the left carotid and left subclavian arteries, in preparation for performing an end-to-side distal aorta to arch reconstruction (see Fig. 48-14, A). After resecting the discrete coarctation, the isthmus is ligated with a 5-0 polypropylene ligature, and the undersurface of the proximal arch is incised opposite the left carotid artery origin and extended to the point opposite the left subclavian artery origin. The cut end of the descending aorta, trimmed of all ductal tissue, is connected to the incision in the undersurface of the arch with an end-to-side anastomosis using a running suture technique with 6-0 or 7-0 absorbable monofilament suture (Fig. 48-14, B and C).

Resection with end-to-end anastomosis can be combined with subclavian flap aortoplasty (see “Subclavian Flap Aortoplasty” in text that follows) if there is concern about the size of the aorta just beyond the subclavian artery. This problem is better managed by resection with extended end-to-end anastomosis or resection with end-to-side anastomosis, as described earlier; however, the combined operation will be briefly described for completeness. After preparing the subclavian artery and placing clamps as for the standard subclavian flap repair, the coarctation area is excised as described for standard end-to-end anastomosis. The proximal and distal aortic segments are reconstructed with an end-to-end anastomosis, with the exception that the posterior wall and anterior wall continuous suture lines are not tied to each other posterolaterally after their completion. Rather, each suture line is tied to itself posterolaterally, leaving a small posterolateral gap. The subclavian artery is split open longitudinally, and incision is extended into the proximal aortic segment, then carried through the small suture line gap onto the distal aortic segment. The subclavian flap is sewn into position as described previously in the standard subclavian flap method, straddling across the end-to-end anastomosis.

Children and Adults
Operation is carried out in the same steps as in very young patients. However, the vessels are much more friable, intercostal arteries larger and more easily damaged, and the dissection potentially more hazardous. Use of controlled hypotension by the anesthesiologist (see “Coarctation of the Aorta” in Section II of Chapter 4) during dissection is important because it allows dissection to be done more safely and expeditiously. Once the aortic clamps are in place, upper body blood pressure is allowed to increase to moderately hypertensive levels (to promote collateral blood flow, see “Paraplegia after Aortic Clamping” under Special Situations and Controversies in Chapter 24). It is helpful to monitor left ventricular function by transesophageal echocardiography during the aortic clamping. Vasodilatory agents must be withdrawn before the clamps are removed.

Hemorrhage from intercostal arteries or from the Abbott artery can be massive and difficult to control, especially if one of these vessels is damaged early in the dissection before adequate exposure is obtained. Therefore, no effort is made...
tucked against the aorta, the tapes swung to the other side, and dissection continued.

It is safer to control the intercostals temporarily with small metal bulldog clamps during resection and anastomosis than it is to ligate and divide them, because delayed hemorrhage can occur from slippage of such a ligature.

Occasionally, because of immobility of the aortic structures in an older patient or because of a long-segment coarctation, end-to-end anastomosis is not possible, and either an interposed polyester tube graft or an augmentation patch is necessary.

Figure 48-14  Resection and end-to-side aortic anastomosis for aortic coarctation with hypoplasia of isthmus and aortic arch. A, Incision and dissection are similar to that described in Fig. 48-12. Dashed lines show transection sites on distal aspect of isthmus, ductus arteriosus, and descending aorta, and incision site on undersurface of proximal aortic arch. B, Proximal aortic clamp is placed on aortic arch to include bases of left subclavian and left carotid arteries, with tip of the clamp angled precisely to extend as far proximally as possible without causing obstruction of flow to brachiocephalic artery. Distal aortic clamp is placed between third and fourth sets of intercostal vessels, and the third set of intercostal vessels is controlled with clips. Aortic isthmus is ligated. Ductus arteriosus is ligated at its pulmonary artery end, and coarctation site, including aortic end of ductus, distal aspect of aortic isthmus, and first portion of descending aorta beyond coarctation site, is completely resected along the lines shown in A. Incision in undersurface of aortic arch is made such that the length of the incision accommodates entire circumference of the normal aspect of descending aorta. Suture line is begun at far end of the circumference with a running monofilament absorbable suture. C, Anastomosis is performed essentially identically as described in the end-to-end anastomosis (see Fig. 48-13), proceeding along the posterior aspect of the circumference and then the anterior aspect. Completed end-to-side distal aorta to arch anastomosis is shown. Key: BA, Brachiocephalic artery; LCA, left common carotid artery; LSCA, left subclavian artery; PDA, patent ductus arteriosus.
Subclavian Flap Aortoplasty

Currently this technique is most frequently used selectively in neonates, when circumstances make resection and reconstruction inappropriate—for example, when it is advantageous to preserve the ductus in the setting of a borderline left ventricle (see Indications for Operation later in this section). PGE1 infusion is maintained throughout the procedure (see Fig. 48-12, A and B, which illustrate the exposure). To begin the subclavian flap aortoplasty, dissection of the subclavian artery is carried distally to expose the branches. It is ligated and divided proximal to all branches, none of which are ligated (Fig. 48-15, A). The ductus arteriosus is dissected, and a delicate vascular clamp, such as a temporary neurovascular clip, is placed across the ductus. A delicate vascular clamp is placed across the aortic arch between the left common carotid and left subclavian arteries, and a second clamp is placed well distal to the coarctation but proximal to the intercostal arteries, allowing space above and below the coarctation for the incision, as shown by the dotted line in Fig. 48-15, A. Uncommonly, it must be placed beyond the third pair of intercostal arteries (the first set beyond the coarctation), which are then controlled with removable metal clips or vessel loops made from heavy suture material.

The subclavian artery, before its transection, is split open longitudinally along its posterior margin, carrying this incision across the coarctation into the dilated distal aorta for at least 1 cm. Stay sutures are placed on either side at the level of the coarctation. The subclavian artery is transected just proximal to the ligature. Sharp corners at the end of the opened subclavian artery are trimmed; if the subclavian flap is unusually wide, the lateral edge is trimmed so that its width is about 1.5 times the diameter of the aorta. The turned-down subclavian flap may be tacked to the distal opened aorta using a double-ended 6-0 or 7-0 absorbable monofilament suture, which is then carried proximally as a continuous stitch (Fig. 48-15, B). Alternatively, the suture line may be started proximally on the medial side and carried just beyond the inferior angle of the aortic incision; another suture line is then started proximally on the lateral side and carried down to the previous one. Absorbable monofilament suture material 6-0 or 7-0 is used. Angles at either end of the turned-down subclavian flap must lie beyond the level of the coarctation, achieving this when necessary by sliding the flap distally in the process of suturing. In this manner, a proper “cobra head” is achieved. Following completion, the aortic clamps and the neurovascular clamp on the ductus are removed (Fig. 48-15, C).

Modifications of the subclavian flap repair have been used successfully.

Repair of Coarctation Proximal to Left Subclavian Artery

When hypoplasia occurs proximal to the left subclavian artery, the usual methods of repair can be unsatisfactory. When the situation is encountered in infants, a reversed subclavian flap aortoplasty may be used, or resection with end-to-side anastomosis as described earlier in this section and shown in Fig. 48-14 can be performed. The reverse subclavian flap combined with end-to-end anastomosis is illustrated in Fig. 48-16. After usual exposure and dissection, the left common carotid artery and aortic arch between this and the subclavian artery are completely dissected. Clamps are placed on the left common carotid artery and on the aorta just distal to this vessel and on the aorta distal to the left subclavian artery. The subclavian artery is ligated and divided distally. The subclavian artery is split down its medial side and the incision extended proximally onto the arch and the origin of the left common carotid artery (Fig. 48-16, A). The subclavian artery is turned down, in reverse to the classic subclavian flap operation, and sewn into place (Fig. 48-16, B and C). Alternatively, the end-to-side anastomosis of the descending aorta to the arch, as described earlier in this section under “Resection and Primary Anastomosis,” can be used. In addition, when an anomalous right subclavian artery is present, it can be used in the reconstruction to address arch hypoplasia.

In older patients, replacement of the coarcted area with an interposed tube graft may be done when the coarctation is severe, but techniques for aneurysms of the distal portion of the transverse aortic arch are necessary (see “Replacement of Aortic Arch” under Technique of Operation in Chapter 26). The simpler palliative placement of a bypassing polyester tube graft between the ascending aorta and lower descending thoracic aorta via a right thoracotomy may be used, but is less satisfactory and should be reserved for particularly complex recurrent arch obstructive problems (see Special Situations and Controversies later in this section for further discussion).

Repair When Aneurysm Is Present

When an aneurysm is present, either in the intercostal arteries (single or multiple) or aorta (see Morphology earlier in this section), resecting the segment of aorta involved along with the coarctation is required, and continuity is reestablished with an interposed tubular polyester graft. This procedure can be hazardous, particularly in regard to hemostatic control of the large intercostal artery feeding into the aneurysm. Pharmacologically induced hypotension is helpful to dissection. Early placement of the proximal aortic clamp and then ligation and division of the ligamentum arteriosum and placement of a clamp across the coarctation itself allows transection of the aorta proximal to the coarctation. Then gentle forward traction on the clamp across the coarctation allows the distal aorta and posteriorly placed intercostal artery aneurysm to be brought into better view for dissection and management.

Postrepair paraplegia is a greater hazard than usual because of the need to sacrifice intercostal arteries (see “Paraplegia after Aortic Clamping” under Special Situations and Controversies in Chapter 24). Special precautions required for all aneurysm surgery in this area are used (see “Replacement of Descending Thoracic Aorta” under Technique of Operation in Chapter 26).

Repair of Persistent or Recurrent Coarctation

Several options are open to the surgeon. The choice is partly determined by morphologic details of the obstruction and partly by surgeon preference. Resection and primary anastomosis, subclavian flap repair with or without resection, patch aortoplasty, and placing an interposition graft can all be considered. Repeat left thoracotomy is feasible in selected cases with discrete obstruction that does not involve the arch;
Figure 48-15  Subclavian flap repair for coarctation with preservation of patent ductus arteriosus. Exposure is shown in Fig. 48-12, A and B. A, Mediastinal pleura has been opened and stay sutures placed on the edges for exposure. After dissection is completed (see text) and after left subclavian artery has been ligated just proximal to vertebral artery, a vascular clamp is placed across aortic arch between left common carotid and left subclavian arteries. Distal aortic clamp is placed on descending aorta and may be positioned proximal to the third set of intercostal arteries, or as far distally as just distal to the fourth set of intercostal arteries (see text). A delicate temporary neurovascular clip is placed across the ductus arteriosus. Dashed line indicates proposed aortic incision. B, Subclavian artery has been divided distally and turned down for the flap. C, Flap sewn into place and aortic clamps and ductal clip removed (see text). Key: ICA, Intercostal artery; LCA, left common carotid artery; LPA, left pulmonary artery; LSCA, left subclavian artery; PDA, ductus arteriosus; RLN, recurrent laryngeal nerve.
bypass graft, is contraindicated because of the rupture risk. Standardized management techniques have not been established, but they include surgical, interventional, and hybrid techniques. Optimal outcomes will be achieved with a multidisciplinary team including a cardiac surgeon, interventional cardiologist, and radiologist. The variables that influence treatment strategy include the severity of residual stenosis or hypoplasia, location of the aneurysm relative to the obstruction, suitability of "landing zones" for transcatheter devices, patient age and comorbidity, and likelihood of exclusion of the left subclavian artery or other brachiocephalic artery. Surgical management can vary but typically requires CPB, either via median sternotomy or left thoracotomy. Results are excellent. In particularly difficult technical situations in older patients, a bypassing polyester tube graft on the left or right side may be all that is possible. This is most conveniently performed through a right thoracotomy. The end of a properly prepared polyester tube is anastomosed to the side of the intrapericardial portion of the ascending aorta using a side-biting clamp on the aorta. A side-biting clamp is placed on the descending aorta, just above the diaphragm, the tube graft is routed posterior to the right pulmonary hilum, and end-to-side anastomosis is performed. Intermediate-term results are generally good. Alternative extra-anatomical approaches have been described.

**Repair of Persistent or Recurrent Coarctation with Aneurysm**

Aneurysm following coarctation repair is more likely when transverse arch hypoplasia is present. The aneurysm may be very large and thin walled, with rupture almost a certainty over a 15-year period. These cases represent a major challenge and must be addressed directly. The option of "indirect management," such as by an extra-anatomical bypass graft, is contraindicated because of the rupture risk. Standardized management techniques have not been established, but they include surgical, interventional, and hybrid techniques. Optimal outcomes will be achieved with a multidisciplinary team including a cardiac surgeon, interventional cardiologist, and radiologist. The variables that influence treatment strategy include the severity of residual stenosis or hypoplasia, location of the aneurysm relative to the obstruction, suitability of "landing zones" for transcatheter devices, patient age and comorbidity, and likelihood of exclusion of the left subclavian artery or other brachiocephalic artery. Surgical management can vary but typically requires CPB, either via median sternotomy or left thoracotomy, with resection of the aneurysm and obstructive segment and interposition graft insertion. These procedures carry a mortality risk of 14% to 23%, and therefore endovascular management should be considered when anatomic details are favorable.

**Repair from an Anterior Midline Approach**

Particularly in neonates and young infants, coarctation of the aorta can be well repaired from an anterior midline approach using CPB. Although use of hypothermic circulatory arrest is
advocated by some, \textsuperscript{95,91,719,171,275} continuous CPB with antegrade cerebral perfusion can be used routinely for this repair.\textsuperscript{13,24,11,12,21} (Fig. 48-17). The midline approach is particularly useful when concomitant repair of intracardiac defects is contemplated, but it can also be used to advantage when coarctation is accompanied by severe hypoplasia of the proximal transverse arch, or when there is no proximal arch segment because the left carotid and brachiocephalic arteries share a common origin (“bovine” trunk) in association with hypoplasia of the segment between this common brachiocephalic trunk and the left subclavian artery.

Technical and CPB considerations are similar to those involved with repair of interrupted aortic arch (see Section II). The anterior midline approach has also been described for both children and adults with coarctation and other complex arch problems using interposition conduits.\textsuperscript{99,14}

**SPECIAL FEATURES OF POSTOPERATIVE CARE**

**General**

Generally, care of patients after coarctation repair is simple and similar to that accorded any patient after thoracotomy. In neonates and young infants, usual care accorded to small babies who have been critically ill preoperatively is used (see Section IV of Chapter 5).

**Managing Systemic Arterial Hypertension**

Systemic arterial hypertension is usually present after operation, and its management is controversial. In older patients, mean arterial blood pressure is lowered to about 110 mmHg with nitroprusside for the first 24 hours, and the drug is then rapidly tapered and discontinued (see Appendix 5A in Chapter 5). Thereafter, if systolic blood pressure is greater than 150 mmHg, a \( \beta \)-adrenergic receptor blocking agent or captopril is administered for a few weeks. Care must be taken to avoid a dose that leads to hypotension.

In infants and young children, treatment is given less routinely for postoperative hypertension. Intravenous nitroprusside is the treatment of choice; however, esmolol is also effective.\textsuperscript{99}

**Abdominal Pain**

Careful interrogation and observation of older patients postoperatively indicate that most have mild abdominal discomfort for a few postoperative days. In 5% to 10% of cases, this is prominent, and abdominal distention with hypoactive bowel sounds may develop.

Treatment consists of bowel decompression via a nasogastric tube and antihypertensive drugs. Antihypertensive therapy is begun and continued until symptoms subside. Intravenous fluids may be required for a day or two. In a study from 1972, Ho and Moss\textsuperscript{122} reported that routine treatment with antihypertensive drugs resulted in fewer (no) instances of laparotomy for abdominal pain than did nontreatment. In current practice, the need for laparotomy for abdominal crisis is rare.

**Chylothorax**

The nature of chest tube drainage should be observed. Copious serous or milky drainage is probably chyle, a finding in about 5% of patients. The chest tube should be left in place until this stops. If it continues profusely until the sixth or seventh postoperative day, reoperation is indicated.

A chest radiograph is obtained about 7 days after coarctation repair, because chylothorax may develop late and be initially manifested as an unexpected pleural effusion. If present, it should be aspirated. Occasionally, repeated aspirations are required; if the chyle reaccumulates after the third aspiration, reoperation is indicated (see “Chylothorax” under Special Considerations after Cardiac Surgery in Section II of Chapter 5).

**RESULTS**

**Repair of Isolated Coarctation**

**Survival**

**Early (Hospital) Death** Hospital mortality over the last 20 years has been low (2%-10%) in neonates undergoing operation with or without persisting patency of the ductus arteriosus\textsuperscript{718,82} (Table 48-3). In recent years it is not unusual for reports to show early mortality of 0% to 2%.\textsuperscript{80,81,12,83,84,25,29,124,125,23,713,718,913} When repair of coarctation is performed in older infants, children, adolescents, and young adults, early mortality is about 1%.

**Time-Related Survival** In a heterogeneous group of neonates reported by the Congenital Heart Surgeons Society (CHSS), 12- and 24-month survivals were both 95%.\textsuperscript{91} In a single-institution study of 191 heterogeneous patients, survival at 2, 5, and 10 years was 92%, 88%, and 88%, respectively. Survival was better at all time points for patients with isolated coarctation\textsuperscript{28} (Fig. 48-18).

**Modes of Death** When repair is performed in the first few months of life, the few deaths that occur result from continuing heart failure, management errors, or poor preoperative status. Persisting or recurrent hypertension, rupture of intracranial or other aneurysms, acute aortic dissection, acute myocardial infarction, and complications of late-appearing aortic valve disease (related to congenitally bicuspid aortic valve) account for most of these.\textsuperscript{82,83,84}

**Incremental Risk Factors for Death after Repair** There are few well-established risk factors for death except older age at operation. Although low birth weight is likely to increase morbidity when repair is performed in the neonatal period,\textsuperscript{82} this has not been extensively evaluated. Coarctation repair has been successfully performed in neonates weighing less than 1 kg.\textsuperscript{81,82} In one single-institution study, presence of transverse arch hypoplasia was a risk factor for death.\textsuperscript{92}

**Hypoplastic left heart class** (see Table 48-1) also seems to be related to survival, although most patients with isolated coarctation are in hypoplastic left heart class I (Fig. 48-19; see also Table 48-3). A single-institution study of 55 isolated coarctation repairs with at least one hypoplastic intracardiac left heart structure indicates that outcomes, both early and midterm, are equal to outcomes of patients without associated left heart hypoplasia, and that the hypoplastic intracardiac structures demonstrate somatic growth over time.\textsuperscript{91,111}

Whether technique of repair is a risk factor for death is arguable.\textsuperscript{92,711,914,915}

**Late Postoperative Exercise Capacity**

Exercise capacity is lower than normal (80% of predicted) at late follow-up in patients who have had coarctation repair.
Figure 48-17  Coarctation repair through median sternotomy using cardiopulmonary bypass (CPB). This approach is used when proximal aortic arch obstruction is severe or when an intracardiac procedure (usually a ventricular septal defect) is also repaired. A, A standard median sternotomy incision is shown, and great vessels are dissected extensively, similar to that required for neonatal repair of hypoplastic left heart (see Technique of Operation in Chapter 49). After standard preparation for CPB, cannulation is performed with the arterial cannula placed into brachiocephalic artery through a standard purse string, and superior and inferior venae cavae cannulated individually. At institution of CPB, left and right branch pulmonary arteries are temporarily ligated. (See text for details of CPB management.) Dashed lines show incision in proximal aortic arch and transection sites at the distal aspect of hypoplastic aortic isthmus, at the descending aorta, and at the ductus arteriosus. B, Cardioplegia needle is placed into mid-ascending aorta, and after clamping the ascending aorta cephalad to the needle, cardioplegic solution is administered (see text for details). After achieving adequate cardiac arrest, the original aortic clamp is moved to base of brachiocephalic and left carotid arteries as shown, allowing continued perfusion into these arteries. The distal aorta is clamped and coarctation site resected along the dashed lines shown in A. Aortic isthmus and ductus arteriosus are both ligated, and temporary branch pulmonary artery ligatures are removed. An incision is made in undersurface of proximal aortic arch, and anastomosis is begun at midpoint of posterior aspect of the circumference of descending aorta as shown. A running monofilament absorbable suture is used. C, Anastomosis is shown in its completed form, aortic clamps have been removed, and patient is separated from CPB (see Technique of Operation in Section 1 of Chapter 35, and details in text of this chapter for approaches to closure of the ventricular septal defect). Data from multiinstitutional study of the Congenital Heart Surgeons Society, 1990 to 1991.

Figure 48-18  Survival of 191 patients undergoing coarctation repair. Group 1 = isolated coarctation. Group 2 = coarctation with ventricular septal defect. Group 3 = coarctation with complex intracardiac anatomy. (From Kaushal and colleagues.

This is independent of type or success of repair, age at repair, and presence or absence of upper-lower body blood pressure gradient.

Late Postoperative Upper Body Hypertension at Rest and during Exercise

Resting Values  About 50% of patients who have undergone coarctation repair have an upper body resting systolic blood pressure higher than the mean value for normal individuals. The two groups behave differently with exercise as well, with the coarctation group demonstrating exercise-induced hypertension, even in some patients whose blood pressure is normal at rest (Fig. 48-20). It is important to recall that systolic hypertension portends the same prevalence of unfavorable outcome events as diastolic or mean blood pressure hypertension.

Time course of upper body blood pressure may be generalized as follows. It is often considerably elevated early postoperatively. Thereafter it tends progressively to normalize in most patients such that by 5 years after repair, 80% to 90% of patients have normal upper body systolic and diastolic blood pressures at rest (Fig. 48-21). After 5 years, prevalence of patients with normal blood pressure begins to decline, and by 20 years after operation, only 40% to 50% have normal blood pressure (Fig. 48-22). Prevalence declines still further after that.

The younger the patient is at operation, the longer the period of normotension, or the greater the prevalence of normotension at any given interval after operation (see Figs. 48-21 and 48-22). However, the differences appear
Evidence is beginning to emerge that late hypertension is less prevalent in patients who undergo coarctation repair preoperatively. In patients undergoing coarctation repair as adults to be small so long as repair is done before about age 10 years. In patients undergoing coarctation repair as adults (age ≥ 16 years), generally more than half are normotensive; the remainder are on antihypertensive medication, but blood pressure is improved and medication reduced compared with preoperatively.

Values with Exercise Patients who have undergone coarctation repair experience a considerable increase in upper body blood pressure during exercise, although variability in response is even greater than that at rest (Fig. 48-23; also see Fig. 48-20) and is more variable than that of normal persons, who also experience some increase during exercise (Fig. 48-24; see also Fig. 48-23). The increase with exercise in postcoarctectomy patients with upper body hypertension is similar to that of hypertensive patients without coarctation (see Fig. 48-20). There appears to be an age-related association, with patients operated on after age 1 year having a greater chance of developing exercise-induced hypertension.

Correlates (Risk Factors) of Upper Body Hypertension Possible basic correlates of an excessive upper body tension and compliance of the systemic arterial system a decade or more after coarctation repair, patients undergoing primary resection and end-to-end anastomosis had less hypertension and better vascular compliance than those undergoing subclavian flap aortoplasty. Additionally, method of repair may influence the likelihood of developing hypertension. In two studies evaluating hypertension and compliance of the systemic arterial system a decade or more after coarctation repair, patients undergoing primary resection and end-to-end anastomosis had less hypertension and better vascular compliance than those undergoing subclavian flap aortoplasty.

within the first year of life rather than at an older age. Additionally, method of repair may influence the likelihood of developing hypertension. In two studies evaluating hypertension and compliance of the systemic arterial system a decade or more after coarctation repair, patients undergoing primary resection and end-to-end anastomosis had less hypertension and better vascular compliance than those undergoing subclavian flap aortoplasty.
Older age at operation (i.e., >20 years or so) increases prevalence of upper body hypertension after repair of coarctation (described in preceding text), but its effect is probably mediated by one or more basic factors. It is not known whether this prevalence is decreased by operation in very early life.

After repair of coarctation, a positive correlation exists between resting upper body systolic blood pressure (and magnitude of increase with exercise) and the systolic blood pressure gradient between the upper and lower body \( M33,Z2 \) (Fig. 48-25). A positive correlation also exists between resting pulse pressure and development of an upper body–lower body gradient with exercise in repaired coarctation patients who have no resting gradient \( M10 \). There is no such correlation in controls. This does not identify the cause of the gradient—that is, whether it is true morphologic residual or recurrent coarctation, or whether it is stiffness in the upper body blood vessels. In general, no correlation has been found between width of the anastomosis as determined by aortography and excessive hypertensive tendency. Thus, it is problematic as to whether a true morphologic narrowing at the surgical site (persistent or recurrent coarctation) can be diagnosed without imaging the operative area to identify or exclude an anatomic narrowing. This is because non-compliance in large-diameter portions of the upper body arterial tree can result not only in hypertension but also in gradients between upper and lower body blood pressure.

Urschel and colleagues showed long ago that diversion of

---

blood pressure response to rest or exercise in persons who have undergone coarctation repair include:

- Endocrine factors
- Abnormal compliance or reactivity of upper body small blood vessels
- Poorly compliant aorta proximal to coarctation repair
- Morphologically persistent or recurrent coarctation
- Presence of an angulated or “gothic-shaped” arch \( ^{13} \)
left ventricular output into a rigid tube resulted in increased systolic pressure.\textsuperscript{25,26}

Poorly compliant upper body aorta and large and small arteries, as discussed earlier in this chapter under Morphology, probably explain these tendencies to hypertension and to developing upper body–lower body systolic pressure gradients during exercise and hypertension of a greater magnitude than in normal individuals.\textsuperscript{35} However, any explanation must account for the fact that upper body hypertension and an exaggerated response to exercise are usually less after coarctation repair. The persisting hypertensive tendency probably explains the persistence of left ventricular hypertrophy in some patients.\textsuperscript{78}

Upper body systolic hypertension appears to be more marked and its exacerbation by exercise greater when a long bypassing tube graft is used for the repair than when end-to-end anastomosis is accomplished.\textsuperscript{52} This may, again, be the effect of a poorly compliant “aortic” segment between the upper and lower body arterial trees.

Studies by Peleck and colleagues, as well as by others, indicate that differences in elaboration of hormones with vasomotor activity or in sensitivity to them do not explain differences in resting and exercise blood pressure in postcoarctectomy patients or between them and normal persons.\textsuperscript{78}

Persisting Upper Body Vascular Abnormalities
Numerous studies in patients many years after coarctation repair have provided convincing evidence for persisting upper body arterial and arteriolar wall abnormalities that produce increased stiffness unrelieved by vasodilating agents.\textsuperscript{54} Whether performing repair in neonates or infants will change this situation is not known. One study suggests that vascular abnormalities are reduced in the postcoarctation arteries, but not in the precoarctation arteries, when repair is performed in infancy, supporting the concept that there is a diffuse developmental defect in the proximal arterial tree.\textsuperscript{82,19}

Other studies have shown increased reactivity to norepinephrine compared with normal in the blood vessels of the upper body of patients who had received adequate repairs of their coarctation, at least among those with persisting hypertension.\textsuperscript{52}

Persistent or Recurrent Coarctation
Arm/leg gradients commonly develop with exercise in postcoarctation repair patients who have no resting gradient (see Fig. 48-26), but it is uncertain whether this represents a persistent or recurrent coarctation.\textsuperscript{516} The previous discussions make it clear that persistent or recurrent coarctation can be identified with any degree of certainty only by imaging or by examining the repair itself. Reliable information of this type is not widely available.

Many have defined persistent or recurrent coarctation as a postoperative condition characterized by a resting peak pressure gradient exceeding 20 mmHg across the repair area.\textsuperscript{537} Usefulness of this criterion is limited. Freedom from recoarctation is not a satisfactory surrogate for known absence of a resting gradient or imaging of the area of repair. It may overestimate or underestimate prevalence of persistent or recurrent coarctation. A ratio of the aortic diameter at the repair site to the aortic diameter at the diaphragm of less than 0.7 has been suggested as a criterion for more than mild aortic narrowing; however, even patients with a higher ratio may exhibit elevated blood pressure and vascular abnormalities.\textsuperscript{523}

It is probable that many early “recoarctations” with luminal narrowings are in fact persistent coarctations.\textsuperscript{514,51,18} True recurrent recoarctation probably occurs, although its demonstration by serial aortography has been infrequent. True recoarctation after end-to-end anastomosis has been attributed to lack of growth of the suture line and presence of abnormal mesodermal tissue that proliferates and produces marked intimal and medial hypertrophy.\textsuperscript{511,11,51,13,84,54,55,101,20}

Remnants of ductal tissue behave in this same way.\textsuperscript{82} Damage to the aorta from the vascular clamps used at repair has also been implicated.\textsuperscript{34} Also, aortic wall mucopolysaccharides in coarctation have an increased chondroitin sulfate fraction, more marked in recoarctation specimens,\textsuperscript{82} a difference that leads to increased wall rigidity (decreased distensibility) that predisposes to or mimics restenosis.\textsuperscript{523}

Technical factors are no doubt responsible for persistent coarctation—for example, insufficient resection of a long, narrow segment followed by end-to-end anastomosis, or excessive tension on the suture line due to inadequate mobilization of the aorta above and below the coarctation. Other technical causes include incorrect fashioning of a subclavian flap or polyester onlay patch, failure to resect an obstructing intimal ridge, use of a too-small tube graft in a child, or kinking of such a graft particularly when used as a bypass.

A residual hypoplastic segment of aortic arch, usually between the left subclavian and common carotid arteries (tubular hypoplasia), can possibly contribute to a residual gradient. However, serial aortograms have shown progressive growth of this segment in many cases after coarctectomy, no doubt secondary to restoring normal arch blood flow.\textsuperscript{533,515} This has been corroborated by Brouwer and colleagues in a well-controlled study; they found that even severely hypoplastic arch segments between the left common carotid and left subclavian arteries substantially increased in size within 6 months of simple repair of coarctation in young infants. Despite the increase, however, $z$ values sometimes remain as low as −3, and one early recoarctation has been documented\textsuperscript{536} (Fig. 48-27). To further cloud the picture, in an MRI follow-up evaluation of 65 coarctation repairs, 47% of patients had hypoplasia of the isthmus and arch, and clinical evidence of recoarctation was related to this finding.\textsuperscript{12} Finally, in follow-up of 191 isolated coarctation patients extending to 30 years, recurrent coarctation was noted to

![Figure 48-26 Relation between pulse pressure at rest and exercise arm/leg gradient. Coarctation group is represented by triangles, and normal group by circles. (From Markham and colleagues.\textsuperscript{516})](image-url)
Develop even as late as several decades after repair and was correlated with arch hypoplasia.531

Experimental animal data showing that normal growth of an artery can occur after end-to-end anastomosis843,524 are not necessarily relevant to the situation after coarctectomy if indeed the tissue left behind is abnormal and tends to proliferate and produces excessive scar tissue. Experimental data do not conclusively demonstrate superiority of one suture technique over another for end-to-end anastomosis.

Recoarctation in children and adults is considerably more common when anatomy of the coarctation is unsuitable for direct end-to-end anastomosis because of a long narrowing or aneurysm formation, necessitating some other type of repair.

Prevalence after End-To-End Anastomosis Prevalence of persisting coarctation or recoarctation after the end-to-end anastomosis technique has been reported as high as about 20% in patients operated on before age 2 years and appears to be related smaller size (weight) at time of repair.2,37,126 One study indicates that presence of anomalous right subclavian artery is a risk factor for recurrence.312 Other studies suggest that prevalence of persistent or recurrent coarctation is much lower, about 2% to 6%, but they have used reoperation-free data as evidence.16,126,37,128,113 Harlan and colleagues interpret their data to indicate a lower prevalence when 7-0 polypropylene rather than silk sutures are used, but they also used reoperation-free data rather than measurement of gradient as their criterion.512 Lack of imaging information handicaps drawing appropriate inferences.

More recent studies of infants and neonates in whom more aggressive resection and primary anastomosis techniques were used54,55 indicate a reduction in recurrence, suggesting that eliminating abnormal tissue, rather than suture technique or some other factor, may be the predominant reason for achieving a sustainable unobstructed anastomosis. Prevalence of persistent or recurrent coarctation (a resting postoperative gradient <20 mmHg) of less than 5% has been demonstrated in neonates and infants younger than age 3 months using the technique described by Hanley and colleagues of resection with end-to-side primary anastomosis of the descending aorta to the aortic arch.54 Midterm follow-up of 88 patients from this series revealed that at 2 years after operation, 2 of 54 neonatal repairs required reintervention, and none of the non-neonatal repairs did.511 End-to-side repair using median sternotomy has also been reported, and outcomes compare favorably with the extended end-to-end technique.576

Prevalence after Subclavian Flap Aortoplasty The subclavian flap operation may have low prevalence of persistent coarctation in infants.151,13,111 Hamilton and colleagues reported that of 34 infants younger than age 6 months, none (0%; CL 0%-6%) had residual or recurrent coarctation when followed up to 6 years postoperatively118,119. The report of Waldhausen and colleagues also indicates zero occurrence (0%; CL 0%-8%) within 6 or more months of operation in 23 infants younger than age 14 months.911 Campbell and colleagues reported small gradients (15 and 20 mmHg) in two of four patients studied an average of 42 months after repair in infancy using continuous nonabsorbable suture, and no gradients in seven patients in whom a subclavian flap aortoplasty was made using interrupted or absorbable sutures (P = .1).49,58 Penkoske and colleagues at the Toronto Hospital for Sick Children found persisting or recoarctation in 6% (CL 3%-10%) of 81 infants repaired by the subclavian flap, in contrast to 27% using end-to-end anastomosis.711 In eight patients studied 4 years after subclavian flap aortoplasty, Fripp and colleagues found a normal arm/leg blood pressure response to exercise.516 Growth of the subclavian flap has been demonstrated by Moulton and colleagues.434

The favorable experience reported by Campbell and colleagues included 45 neonates and infants younger than age 8 weeks, as did that of Hamilton and colleagues.2,148 In contrast, Metzdorff and colleagues inferred from their experience that occurrence of persistent or recurrent coarctation is excessive when subclavian flap angioplasty is performed in patients younger than age 8 weeks.525 They reported only 75% 2-year freedom from reoperation after subclavian flap aortoplasty in infants younger than age 8 weeks, compared with 100% in older patients.

Finally, Cobanoglu and colleagues reported equally low prevalence of recurrence at 5- and 10-year follow-up using either subclavian flap aortoplasty or resection.337 Differences in results in the various series cannot be reconciled, but lack of imaging information probably explains most of them.

Prevalence after End-To-End Anastomosis with Subclavian Flap Aortoplasty Dietl and colleagues reported a lower prevalence of recoarctation in neonates and infants repaired by the combined resection-flap procedure than in those repaired with a subclavian flap or a patchgraft aortoplasty.477 This has been confirmed by others using this combined technique.426

Prevalence after Patch Aortoplasty Late results of poly-}

ester or polytetrafluoroethylene (PTFE) patch aortoplasty have been variable. Sade and colleagues reported persisting coarctation (mean arm/leg systolic blood pressure difference 33 ± 7.5 mmHg) after end-to-end anastomosis in infants but not after PTFE patch aortoplasty (difference was 5.1 ± 2.3 mmHg).52 They also reported growth of both the preoperatively hypoplastic isthmus and the intact posterior aortic wall at the site of repair.511 Similar findings were reported by Connor and Baker.521 Smith and colleagues found arm/leg pressure gradient during exercise to be only mildly increased over the minimal resting gradient when patch aortoplasty had
been used, but it was importantly increased when end-to-end anastomosis was used.\(^{52}\) However, Hesslein and colleagues from Houston reported a prevalence of persistent or recoarctation (by the criteria used in this chapter) of 18% with no difference for end-to-end anastomosis vs. patch aortoplasty.\(^{117}\) Younger patients had a higher prevalence with either operation. Again, the lack of imaging information makes interpretation difficult.

**Paraplegia after Repair**

A collective review by Brewer and colleagues\(^{834}\) identified 51 instances of paraplegia (0.41%; CL 0.35%-0.48%) among 12,532 coarctectomies.

Enough knowledge of the incremental risk factors for paraplegia and their neutralization (see “Paraplegia after Aortic Clamping” under Special Situations and Controversies in Chapter 24) is currently available to make it possible for occurrence of paraplegia after coarctectomy to approach zero. Wherever the collateral circulation typical of coarctation has not developed, risk of paraplegia is increased. This is probably because blood pressure in the distal aorta is lower during aortic clamping when collaterals are poorly developed.\(^{521}\)

Situations that may fail to stimulate development of the usual amount of collateral circulation include:

- Coarctation in infants
- Coarctation proximal to the left subclavian artery
- Coarctation with patent ductus arteriosus supplying the descending thoracic aorta
- Coarctation associated with stenosis at the origin of the left subclavian artery
- Coarctation with the right subclavian artery arising as the fourth branch distal to the coarctation
- Something less than severe narrowing at the coarcted area
- Re-repair\(^{834}\)

**Early Postoperative Hypertension and Abdominal Pain**

Nearly all patients, including infants, have some systolic and diastolic hypertension for a variable period after coarctation repair. Many patients, if observed carefully, have mild abdominal discomfort and distention during the first 5 or 6 postoperative days.\(^{122,87}\) In 10% to 20% of cases, this becomes sufficient to produce important discomfort and distention. Then there may be abdominal tenderness, fever, ileus, and leukocytosis. Management should be nonsurgical in virtually all cases (see “Abdominal Pain” under Special Features of Postoperative Care earlier in this section for treatment).

Further discussion of this syndrome is difficult because in the early years of coarctation surgery, many complications that are currently rare were reported as examples of the syndrome. Also, “paradoxic” hypertension is the rule after coarctation repair rather than the hallmark of a special syndrome. However, the syndrome was first described in a single case report by Sealy in 1953.\(^{51}\) At laparotomy on the tenth postoperative day, the jejunum and proximal ileum were “edematous and cyanotic but the superior mesenteric arteries and veins were patent.” At autopsy, “inflammation of the small arteries and arterioles was confined to the body area below the coarctation,” and there were infarcts in liver, spleen, kidney, and intestines. Lober and Lillehei added two cases in 1954,\(^{114}\) and Perez-Alvarez and Oudkerk another in 1956.\(^{817}\) Ring and Lewis in 1956\(^{817}\) considered that the lesion justified the term syndrome and that it was due to sudden increase in pulsatile pressures in vessels distal to the coarctation, with acute overdistention of these vessels. In 1957, Sealy and colleagues\(^{112}\) linked onset of abdominal pain with presence of paradoxical hypertension, which they described in detail. They noted that following successful coarctectomy, an early systolic hypertension could develop within the first 36 postoperative hours or a more delayed mainly diastolic hypertension could develop after 48 hours that lasted 7 to 14 days. This delayed phase was associated with abdominal pain in 6 of 14 of his patients. This observation was confirmed by many others.\(^{122,111}\) Sealy suggested that the hypertension might be due to an altered baroreceptor response plus an increased excretion of epinephrine or norepinephrine.\(^{67,312}\) Rocchi and colleagues\(^{8,20}\) suggest that the sympathetic nervous system is responsible for the early phase and that the renin-angiotensin system plays a major role in the later phase, although more recent information would indicate that the renin-angiotensin system also plays a role in the early phase.\(^{73}\)

Pathologic findings have been described in small arteries and arterioles in vessels below the repaired coarctation\(^{111}\) in these patients, and they probably are present to some degree routinely after coarctation repair. They include thrombosis, inflammatory cell infiltration of the entire wall, fragmentation of the internal elastic lamina, and fibroelastic proliferation, as well as marked mesenteric lymphadenitis in the jejunum and proximal ileum.\(^{910}\) Rarely there may be infarcts in liver, spleen, and kidneys, and rupture of aneurysms that may have formed on large intraabdominal arteries.\(^{114}\)

In a review of the literature up to 1970, Ho and Moss\(^{122}\) found the syndrome was reported in 9% (107 of 1193) of patients surviving coarctectomy. It is said to be rare in children younger than age 2 years,\(^{114,17,117,111}\) but this is questionable because it is difficult to be sure of its presence or absence in young infants.

**Left Arm Function after Subclavian Flap Aortoplasty**

Long experience with the Blalock-Taussig shunt showed considerable variability in arm function late after coarctation repair. They include thrombosis, inflammatory cell infiltration of the entire wall, fragmentation of the internal elastic lamina, and fibroelastic proliferation, as well as marked mesenteric lymphadenitis in the jejunum and proximal ileum.\(^{910}\) Rarely there may be infarcts in liver, spleen, and kidneys, and rupture of aneurysms that may have formed on large intraabdominal arteries.\(^{114}\)

In a review of the literature up to 1970, Ho and Moss\(^{122}\) found the syndrome was reported in 9% (107 of 1193) of patients surviving coarctectomy. It is said to be rare in children younger than age 2 years,\(^{114,17,117,111}\) but this is questionable because it is difficult to be sure of its presence or absence in young infants.

**Late Aneurysm Formation**

A true or false aneurysm may occur late postoperatively. A true aneurysm from progressive deterioration of the aortic wall opposite a prosthetic onlay patch has been reported on long follow-up by Knyshtov and colleagues,\(^{114}\) Vosschulte,\(^{117}\) Bergdahl and colleagues,\(^{819}\) Olsson and colleagues,\(^{83}\) and Rheuban and colleagues.\(^{816}\) Ala-Kulju and colleagues found this to develop in 27% (CL 21%-34%) of 62 patients followed up 2 to 14 years.\(^{84}\) Others report a much lower occurrence, 1% to 3% with up to 30 years of follow-up.\(^{819}\) One study identifies arch hypoplasia as a risk factor for late aneurysm formation after patch aortoplasty for coarctation.\(^{85}\) Another
identifies concomitant ridge resection at the time of patch placement. Presumably, the stiff patch transmits additional tension to the adjacent elastic aortic wall, which thus bears the total burden of the pulse wave and dilates. This makes the polyester onlay patch technique undesirable in most circumstances. An interposed aortic allograft tube may become aneurysmal, but this is not common on long follow-up.

A dissection may occur occasionally, either in the ascending or descending aorta, proximal or distal to the coarctation repair site. This may lead to late aneurysm formation.

False (suture line) aneurysms can be mycotic when they occur early postoperatively, but they are usually uninfected and have an etiology similar to the false femoral aneurysm that occurs at the distal anastomosis of an aortofemoral prosthetic graft. They may complicate prosthetic tubular grafts as well as prosthetic onlay patches. In the former instance, they are said to be more common at the proximal anastomosis of a bypass tube graft, where the suture line is more oblique in relationship to the transverse forces in the aortic lumen. They are rare with end-to-end tubular grafts, unless mycotic.

Aneurysms of uncertain type but in the region of the repair have been reported after the subclavian flap repair. Prevalence of this problem is uncertain.

Valvar Heart Disease
Valvar heart disease may complicate long-term management of patients who have undergone coarctation repair and occasionally prevents a good result. No doubt a larger number with bicuspid valves will require surgery for calcific aortic stenosis when they reach their fifth and sixth decades of life. Thus, among the 23 patients in Crafoord’s original series followed by Bjork and colleagues for more than 26 years, definite aortic valve disease developed in 11 (48%), although operation had not yet been required in four.

Congenital mitral valve disease has been thought to be infrequent in this setting. Celano and colleagues found coexisting mitral valve anomalies in 12 of 56 (21%) patients with coarctation studied by two-dimensional echocardiography.

Other Events
Heart failure may occasionally persist postoperatively in older patients who have had bicuspid valves requiring surgery for calcific aortic stenosis when they reach age 50. Maron and colleagues noted a high prevalence of conduction defects in ECGs of their patients. Bjork and colleagues found degenerative disease of the hip joints present in 20% of their 25 patients who had been followed up for 27 to 32 years and who were age 7 to 31 years at coarctectomy. Pregnancy is reasonably well tolerated after coarctation repair, and is even well tolerated in women with unrepaired coarctation. Hypertension, cardiovascular complications, miscarriage, and premature delivery rates are elevated, however. Late aortic root and ascending aortic complications including rupture, dissection, aneurysm, and perforation occur more frequently in patients with repaired coarctation and bicuspid aortic valve than in patients with isolated bicuspid aortic valve or isolated coarctation (Fig. 48-28).

Repair of Coarctation and Coexisting Ventricular Septal Defect
Little specific information other than survival is available in this group of patients. The information suggests that similar VSDs have the same tendency to close as when coarctation is not present (see “Spontaneous Closure” under Natural History in Section I of Chapter 35). VSD in patients with coarctation, however, is more likely to be malaligned posteriorly, and malalignment VSDs are less likely to close than those without malalignment. In one study following 23 infants with coarctation and VSDs of various sizes in whom coarctation repair alone was initially performed before 3 months of age, 14 of 23 required subsequent VSD closure, and importantly, size of VSD was not correlated with need for closure. Other studies indicate that VSD size, as well as other characteristics of the VSD, are important predictors that surgical closure will be required (see Indications for Surgery for an in-depth discussion of surgical decision making for coarctation with VSD). Among neonates with large VSD undergoing only coarctation repair, by age 12 months 12% of VSDs had become small, and by 24 months 19% had done so in the multi-institutional study of the CHSS. Results of repair of coarctation when VSD coexists, with regard to early, intermediate-term, and late upper body blood pressure, are presumably the same as when the coarctation is isolated, but this has not been confirmed by specific study.

Figure 48-28 Freedom from aortic root or ascending aorta complications for patients with isolated bicuspid aortic valve (244 patients) and patients with associated bicuspid aortic valve and coarctation (97 patients). Numbers in brackets indicate numbers of patients remaining in each period. Key: BAV, Bicuspid aortic valve; COA, coarctation. (From Ciotti and colleagues.)
Figure 48-29 Early survival after repair of coarctation of aorta in neonates (n = 127) with no other hypoplastic left heart components (hypoplastic left heart class I), according to whether the coarctation is isolated, or with coexisting ventricular septal defect (VSD), or with other important coexisting cardiac anomalies. A, Survival. B, Hazard function. (From multinstitutional study of the Congenital Heart Surgeons Society, 1990 to 1991.)

*Data from multiinstitutional study of the Congenital Heart Surgeons Society, 1990 to 1991.

Again, some single-institution studies indicate that presence of a VSD has no effect on either early or late risk, with excellent early and midterm outcomes reported.\textsuperscript{1,13,15,22}

A higher proportion of patients with coarctation and VSD may be in hypoplastic left heart class II than is the case in those with isolated coarctation, and survival may be less in those in class II than in class I (Table 48-4).

Current information does not permit comparison of outcomes with different management protocols in a risk-adjusted fashion, although in contrast with interrupted aortic arch and VSD,\textsuperscript{10} the multienstitutional study of the CHSS found staged repair gave a survival advantage.\textsuperscript{21} Options include repair of coarctation via thoracotomy with medical management of the VSD, repair of coarctation via thoracotomy with pulmonary trunk banding, and coarctation repair via median sternotomy with VSD closure, using either hypothermic circulatory arrest or continuous perfusion. Excellent results using the midline approach have been reported, employing either continuous perfusion\textsuperscript{15} or hypothermic circulatory arrest.\textsuperscript{21} Although natural history of VSD associated with coarctation is not established, attempts have been made to predict in early infancy the likelihood a VSD associated with coarctation will require surgical closure.\textsuperscript{538} Another approach involves coarctation repair with pulmonary trunk banding using absorbable material (polydioxanone).\textsuperscript{827} Band reabsorption occurred over approximately 6 months in an experience with
11 selected patients. VSD closure was necessary in only one patient following band reabsorption.

Repair of Coarctation and Other Major Coexisting Intracardiac Anomalies

Early and intermediate-term survival is less good in this group than in others (see Fig. 48-29), particularly when patients are in hypoplastic left heart classes II and III. This was a highly heterogeneous group of patients (see Table 48-2), and experience with any one group is small. Individual institutions have recently demonstrated substantially better outcomes in these patient groups, with 5-year survival of more than 70% for the milder hypoplastic left heart classes and even better outcome for other complex lesions such as transposition, truncus, and other conotruncal lesions (87% hospital survival and 83% survival at 7 years).

Difficulties in prospectively (preoperatively) defining a left heart as hypoplastic is discussed in detail in the introductory remarks to Chapter 49 and the footnote to Table 48-1. These difficulties are underscored by the experience of Tani and colleagues, who performed coarctation repair only in 20 neonates, without mortality, who were designated preoperatively as having a degree of left heart hypoplasia too severe to survive with two-ventricle physiology as judged by a widely used grading system. One confounding factor was that immediate changes in left ventricular cavity size can occur with change in loading conditions after coarctation repair.

INDICATIONS FOR OPERATION

Isolated Coarctation

Diagnosis of isolated coarctation is an indication for operation, because the probability of survival and a resting upper body normotensive state is greater after repair than in the natural history of the condition.

In the first few months of life, resection with reanastomosis is indicated. Need for enlarging or bypassing a hypoplastic segment of arch between the left common carotid and left subclavian arteries (distal arch) remains arguable, although good results have been reported. If no arch hypoplasia is present, end-to-end anastomosis is the choice for aortic reconstruction. If distal aortic arch hypoplasia is present, this may be addressed using either a reverse subclavian flap, an extended end-to-end anastomosis, or an end-to-side anastomosis of the descending aorta to the segment of arch between the brachiocephalic and left carotid arteries (proximal arch).

In critically ill neonates with coarctation, intravenous PGE$_1$ (0.1 mg · kg$^{-1}$ · min$^{-1}$) is begun immediately and continued until the situation is remedied at operation. (For more details about use of PGE$_1$, see Indications for Operation in Chapter 41.) Response is dramatic in about 80% of infants, with reappearance of femoral pulses and disappearance of metabolic acidosis from hypoperfusion of the lower body. Operation is then delayed 6 to 12 hours or more until the baby’s condition has stabilized in this improved state (for more details, see Indications for Operation in Section II).

Operation (after proper preparation) is indicated when diagnosis is made in neonates and young infants who present in important cardiac failure. If cardiac failure or failure to thrive is not present, urgency of the operation is less; however, surgery should still be considered at the time of presentation, although some prefer to delay it for 3 to 6 months. Argument to proceed at diagnosis is based on recent studies showing a prevalence of persistent or recurrent coarctation that is no different between neonates and older infants. Argument to delay is based on older information showing an apparently higher prevalence of persistent or recurrent coarctation when repair is performed in the first few months of life, and on the absence of any demonstrated lesser probability of long-term survival and a resting upper body normotensive state after repair in neonates than after repair in infants.

In occasional patients with a mild to moderate degree of left heart hypoplasia in whom it may not be clear that the left heart is adequate to sustain the systemic circulation, the subclavian flap operation can be particularly useful. With this operation, the ductus arteriosus can be preserved, and the PGE$_1$ can then be weaned slowly to test the adequacy of the left heart once the coarctation is repaired.

In patients presenting beyond early infancy, coarctation resection and aortic reconstruction is also the procedure of
choice if there is no proximal hypoplasia. If important proximal hypoplasia is present, the options available for neonates and young infants are generally not applicable for older patients. The older the patient, the less mobile the aortic tissue becomes, making extensive mobilization of the aorta impossible. If proximal hypoplasia is moderate in severity, patch augmentation of the arch and coarctation site, or graft interposition, are the options of choice. If proximal hypoplasia is severe, graft interposition in indicated.

Coarctation and Coexisting Ventricular Septal Defect

When coarctation coexists with a VSD in a neonate or infant with heart failure, the probability of the VSD closing spontaneously is the major determinant of the treatment protocol. Some have found that if the VSD is larger than small, VSD size is not particularly predictive of spontaneous closure. Others have found that the likelihood of spontaneous VSD closure is correlated inversely with VSD size. This same study also suggests that only muscular-type VSDs are likely to close, not perimembranous, outlet, or malalignment types. Thus, it is reasonable to assume that if the VSD is a large conoventricular one, is large in the outlet portion of the right ventricle, or is posteriorly malaligned, the probability that it will spontaneously narrow appreciably or close is very small. One-stage repair of the coarctation (by end-to-end anastomosis) and the VSD through a median sternotomy is the procedure of choice for such situations. There are, however, alternative practices. Coarctation repair alone may be performed, with later VSD closure if it remains large or the infant has failure to thrive. Also, coarctation repair with concomitant banding of the pulmonary trunk can be performed, with later removal of the band and VSD closure. Finally, a single-stage repair with two incisions has been described. The arch is repaired using a thoracotomy; the patient is then repositioned, and a median sternotomy is performed for VSD closure using standard CPB techniques. When the VSD is small or moderate in size, and particularly if it is muscular and occasionally perimembranous, spontaneous reduction in size, and closure, are real possibilities. In this situation the option of coarctation repair alone, with subsequent observation of the VSD and patient, is the preferred treatment protocol.

Whatever the initial procedure, if heart failure persists and the VSD remains large, it is repaired before hospital discharge (see Indications for Operation in Section I of Chapter 35).

Coarctation and Other Major Coexisting Intracardiac Anomalies

When coarctation coexists with other major intracardiac anomalies, the decision to proceed with one-stage repair of both, or to address the coarctation only, is a complex one. This is especially true in cases of single-ventricle physiology in which either a complex cardiac repair or a pulmonary trunk band must accompany coarctation repair. (See Chapter 41 for a more complete discussion of this issue.) With coarctation and truncus arteriosus, both are repaired. With coarctation and transposition, the preferred approach is to repair both, although a staged coarctation repair with subsequent arterial switch can be performed. With coarctation and atrioventricular septal defect, the preferred approach in most cases is to repair the coarctation and defer intracardiac repair for several months.

SPECIAL SITUATIONS AND CONTROVERSIES

Coarctation Proximal to Left Subclavian Artery

Coarctation proximal to the left subclavian artery is rare (=1% of all cases). Stenosis is localized, and femoral pulses are usually only slightly decreased and systolic pressure gradient across the coarctation mild (<20 mmHg) or moderate. Coarctation is often not detected until young adult life, at which time upper body hypertension is often present. A collateral circulation is generally not well developed.

The natural history of this lesion and its prognosis with antihypertensive medication is not clear, so neither are indications for operation. However, when upper body systolic and diastolic hypertension are severe during moderate exercise, operation is advisable.

A reverse subclavian flap or resection with end-to-side anastomosis is optimal treatment in infants and young children (see Technique of Operation earlier in this section). When a resection and anastomosis is used in older children and adults, either directly or with interposition of a tubular polyester graft, risk of hospital death or a major complication is probably less than 5%.

When an operation is performed in this subset of patients, particular attention must be paid to preventing paraplegia (see “Repair of Coarctation Proximal to Left Subclavian Artery” under Technique of Operation earlier in this section).

Some controversy remains regarding the importance of proximal hypoplasia in the aortic arch in association with coarctation (see Morphology earlier in this section). When it is considered important in association with coarctation, end-to-side reconstruction or reverse subclavian flap plus coarctation resection and anastomosis are effective solutions.

Mild and Moderate Coarctation in Classic Position

Uncommonly in infants and older patients, moderate coarctation is present in the classic position. Collateral vessels are absent. The natural history of this entity is not clear and thus neither are indications for operation. Degenerative changes are, however, prone to occur in the region of the coarctation, and when calcification is apparent, resection and replacement of this area with a tube graft may be recommended. Surgical techniques are the same as for thoracic aneurysms in this area (see “Replacement of Descending Thoracic Aorta” in Chapter 26).

When coarctation is so mild that there is no gradient across the area, in which case the lesion is usually found because of the buckled appearance of the aorta on chest radiography (pseudocoarctation), operation is advised only when degenerative changes have developed and thus an increased risk of aneurysm formation.

Preventing Paraplegia as a Complication of Repair

Paraplegia does not occur as an operative complication in classic coarctation of the aorta with well-developed collateral circulation. Thus, in preventing paraplegia, great importance attaches to preoperative identification of patients with potentially inadequate collateral circulation. In children and adults
with periductal coarctation, absence of rib notching on the chest radiograph or of palpable parascapular pulsations suggests that collateral circulation is not well developed. Only mildly diminished femoral pulsations in such patients are often associated with a poorly developed collateral circulation, as are a diminished left radial pulse (usually caused by involvement of the origin of the left subclavian artery in the coarctation) or a diminished right radial pulse (present when the right subclavian artery arises distal to the coarctation). Aortography or CT angiography is indicated under these circumstances, and when adequate collateral arteries are not present, special measures are taken at operation (see “Paraplegia after Aortic Clamping” under Special Situations and Controversies in Chapter 24). If uncertainty remains, pressure can be measured at thoracotomy in the descending aorta with the proximal aortic clamp temporarily in place; if this pressure is less than 50 mmHg, special measures are needed.

Likelihood of paraplegia in very young patients is uncertain, because some collateral circulation is present at birth. However, use of mild hypothermia (35°C nasopharyngeal or tympanic membrane temperature) is a good precaution. This probably allows 30 minutes of safe aortic clamping (see “Subclavian Flap Aortoplasty in Infants” under Technique of Operation earlier in this section). This degree of hypothermia is as protective in older patients as in infants, and a similar technique may be used when the collateral circulation is not well developed. Ice-cold saline lavage may need to be prolonged to about 10 minutes. Instead, a temporary bypass shunt, usually from left subclavian to descending thoracic aorta, or femorofemoral CPB (see “Cardiopulmonary Bypass Established by Peripheral Cannulation” in Section III of Chapter 2) may be used during the period of aortic clamping (see “Paraplegia after Aortic Clamping” under Special Situations and Controversies in Chapter 24). Another alternative is placing a large bypass graft as a permanent method of repair.

Reintervention for Persistent or Recurrent Coarctation

Current indication for reintervention is demonstrating a reduced luminal diameter of greater than 50% at the anastomosis. Under this circumstance, heart failure or upper body hypertension (systolic pressure greater than 140 mmHg in infants and children) is an indication for reintervention. Currently, percutaneous balloon aortoplasty is generally the treatment of choice (see text that follows), but surgical measures also provide good results.

Balloon Aortoplasty and Stenting for Coarctation

Percutaneous balloon aortoplasty is controversial as a method of primary treatment for aortic coarctation, particularly in small patients. For neonates and young infants, balloon aortoplasty appears to have the same disadvantages as subclavian flap aortoplasty, in that the sling of ducral tissue at the coarctated site is not removed.

Aneurysmal dilatation has developed in some patients treated by balloon angioplasty. This is not surprising, because the mechanism of gradient relief appears to be tearing of the intima and media. This process is confirmed in clinical studies by contrast extravasation in 25% of patients at the time of balloon dilatation. However, some interventional cardiologists have observed no aneurysms, even when an intimal tear is noted acutely, whereas others have observed aneurysms in 10% to 20% of patients. An immediate reduction in gradient across the coarctation is usually observed (a decrease from 48 ± 21 to 10 ± 7.3 mmHg was obtained by Rao and colleagues and usually persists during the intermediate term).

The question remains as to whether this result is similar to that obtained by optimal surgical techniques. Several studies directly address this question, although it is acknowledged that there are important difficulties in properly comparing surgical and catheter-based outcomes. In a recent multicenter study that retrospectively evaluated 80 patients older than age 1 year who were treated either by surgery or transcatheter intervention (balloon angioplasty or stenting), initial relief of the obstruction was similar in the two groups; however, reintervention (32% vs. 0%, P < .001) and aneurysm formation (24% vs. 0%, P < .01) were both higher after transcatheter therapy. In a comparison of 57 neonates, retrospective analysis showed that surgery resulted in fewer recurrences and aneurysms, better arch growth, and less need for antihypertensive therapy than did balloon angioplasty. In a randomized clinical trial of 36 patients between age 3 and 10 years, Shaddy and colleagues showed equal initial outcomes in the surgical and balloon groups, but a significantly greater rate of recurrence and aneurysm formation in the balloon group.

Arterial occlusion at the site of catheter insertion occurs in some small patients. This is not a trivial complication and can lead to underdevelopment of the ipsilateral leg and claudication, despite good collateral flow.

A detailed multivariable study of risk factors for a poor result from primary balloon dilatation emphasized that age younger than 1 year was particularly associated with a poor result; recoarctation developed in 71% (CL 45%-90%) of infants. Highest prevalence of recurrence (83%) is found in neonates. Small size of the aorta between the left subclavian artery and coarctation also was found to predispose patients to a poor result.

Recurrent aortic obstruction after surgical treatment is a more favorable situation than primary coarctation for percutaneous balloon angioplasty. Angioplasty may be most effective for recurrent postsurgical coarctation when it is performed in infancy. Both surgery-free survival and reintervention-free survival after angioplasty for recurrence are higher if the angioplasty occurs beyond infancy (Fig. 48-31). Excellent initial and intermediate-term results, without aneurysm formation in most patients, appear to be the rule after percutaneous balloon aortoplasty in this setting, as well as in the setting of recurrent aortic obstruction after repair of interrupted arch and hypoplastic left heart (see “Persistent or Recurrent Aortic Arch Obstruction” under Results in Section II). Newer data from the Valvuloplasty and Angioplasty of Congenital Anomalies (VACA) Registry, however, indicate that acute suboptimal outcome was present in 25% of recurrent obstruction but only 19% of primary lesions. On the other hand, arguments have been made that surgical reintervention is preferable to balloon angioplasty for recurrent coarctation, particularly in patients beyond the infancy period and in those with arch hypoplasia.

Percutaneous stenting of both native and recurrent coarctation is currently well established, particularly in older
Figure 48-31 Survival and event-free survival in 99 consecutive patients undergoing balloon angioplasty for recurrent coarctation following initial surgical coarctation repair. Outcomes are shown for (A) all patients undergoing angioplasty, (B) those younger than age 1 year, and (C) those older than age 1 year. (From Shaddy and colleagues.)

Short-term evaluation shows effective relief of obstruction and favorable effects on the myocardium and peripheral vasculature, but longer-term outcome is lacking. Intimal thickening and luminal reduction were observed in young patients at follow-up, and aneurysm formation was identified in 7%. In selected adults, complications have generally been lower, and follow-up at 5 years revealed no recurrent obstruction in 46 native and recurrent coarctation patients in one series. In the 17-institution study of 565 patients (mean age 15 years, all over age 4 years) reported by Forbes and colleagues, 98% had effective relief of obstruction. Acute complications including dissection, intimal tears, aneurysms, cerebrovascular events, and peripheral vascular problems at the insertion site occurred in 14%, and there were two deaths. A subsequent intermediate-term outcome report on this same multistitutional cohort showed that 25% of patients undergoing aortic imaging at a mean follow-up of 19 months had abnormal studies, consisting of dissection, reobstruction, stent fracture, or aneurysm. Dissection risk may be higher in elderly patients. Studies examining post-stent hypertension and peripheral vascular abnormalities indicate that similar persistence of these problems occurs as in patients treated surgically.

Some have taken the position that interventional management is the treatment of choice for native coarctation in older children and adults. The acute and very early midterm complications noted in the previous paragraph bring into question the validity of this position, because they do not compare favorably with current-era surgical outcomes in similar populations. Furthermore, the truly long-term fate of the aorta after ballooning and stenting is unknown. Interventional management is not considered the procedure of choice in neonates and infants because of the well-documented extremely high recurrence rate; however, it may be of benefit as a temporizing maneuver in selected circumstances, such as the presence of profoundly depressed left ventricular function. Some have recommended temporary stenting in premature infants, but this is not recommended. Several studies demonstrate that low birth weight is not a risk factor for death or recurrence following surgical repair and that catch-up growth of the arch occurs.

Finally, the engineering of stents continues to evolve. Covered stents, growth stents, and self-expanding nitinol stents have recently been introduced into clinical practice for coarctation management.

Coarctation in Adults

Native coarctation diagnosed in adulthood should be treated regardless of age (see Section X in Chapter 29). Excellent results have been achieved with operation in patients older
Section II  Interrupted Aortic Arch

DEFINITION

Interrupted aortic arch is complete luminal and anatomic discontinuity between two segments of the aortic arch. Those rare specimens that exhibit a fibrous strand connecting two widely separated ends are also included under aortic arch interruption rather than coarctation.

HISTORICAL NOTE

The first description of interrupted aortic arch is attributed to Steidele in 1778. In this case, the aortic isthmus was absent, so morphology was similar to preductal coarctation. Description of the absence of more proximal portions of the arch occurred later, for the segment between the left subclavian and left common carotid arteries in 1818 by Siedel and for that between the left common carotid and brachiocephalic arteries by Weisman and Kesten in 1948. By 1959, Celoria and Patton were able to collect 28 cases that they classified according to the site of obstruction into types A, B, and C (see Morphology and Morphogenesis later in this section).

The first patient to have successful surgical treatment was a 3-year-old girl operated on by Samson in 1955. The aortic isthmus was absent between the left subclavian artery and a widely patent ductus arteriosus, but both structures were adjacent, and it was possible to join the divided ductus to the undersurface of the proximal left subclavian artery; the two VSDs were closed 4 years later. Mustard apparently performed a similar successful procedure in a similar patient age 7 months in 1957. Villalobos and colleagues and Blake and colleagues each reported a successful case during the early 1960s, using a prosthetic graft to bridge the gap. Sirak and colleagues were the first to use the turned-down arch branches successfully (left subclavian or left common carotid artery, or both) for end-to-end anastomosis to the descending aorta (combined with pulmonary trunk banding for the VSD), although this type of operation was attempted as early as 1959. Sirak’s patient was also the first neonate to survive operation, followed by an 18-hour-old boy reported by Norton and colleagues and an 11-day-old infant operated on in Houston in 1970. In 1970, a palliative operation consisting of a polyester graft between the pulmonary trunk and descending aorta, combined with pulmonary trunk banding, was used successfully by Litwin and colleagues in an 11-day-old infant, but this procedure is no longer advocated.

The first simultaneous repair of both interrupted arch and all intracardiac lesions was performed successfully in 1970 in an 8-day-old infant with an interruption distal to the left subclavian artery, a VSD, and total anomalous pulmonary venous connection through a left thoracotomy. The distal end of a 12-mm polyester conduit was anastomosed to the descending aorta; then, through a median sternotomy, the proximal end was anastomosed to the ascending aorta and both intracardiac lesions repaired. The procedure demonstrated that circulatory arrest techniques made an anastomosis to the ascending aorta feasible. In 1973, Murphy and colleagues reported a successful complete repair in a 3-day-old infant of an aortic interruption proximal to the left subclavian artery and a VSD, using circulatory arrest. They used a segment of the father’s basilic vein as the graft between descending and ascending aorta and approached the heart and descending aorta through a median sternotomy with an extension into the third left intercostal space. In 1975, Trusler and Izuwaka demonstrated that a median sternotomy alone provided adequate exposure for this procedure in small infants; using circulatory arrest techniques, after excising ductus tissue, they were able to anastomose successfully the descending aorta end to side to the ascending and transverse arch without interposing a graft. The VSD was also closed. Finally, primary repair via median sternotomy using continuous perfusion cardiopulmonary bypass (CPB) techniques was reported by Asou and colleagues in 1996 and by McElhinney and colleagues in 1997.

In 1976, the remarkable immediate preoperative improvement produced by the ductus-opening effect of PGE was reported as part of the treatment plan for interrupted aortic arch.

MORPHOLOGY AND MORPHOGENESIS

Types

The aortic arch may be interrupted at one of three sites (Table 48-5). It may be interrupted just distal to the left subclavian artery (type A of Celoria and Patton), with blood flowing into the descending aorta from the ductus arteriosus. All forms of interrupted aortic arch display this latter feature, except in rare cases in which the ductus is absent or closes during fetal life. About 40% of cases are type A. The most common site of interruption (55% of cases) is between the left subclavian and left common carotid arteries (type B). In

only about 5% of cases is the interruption between the left common carotid and brachiocephalic arteries (type C).\textsuperscript{11}

**Aortic Arch**

Anomalies of the origins of brachiocephalic vessels are frequent in interrupted aortic arch.\textsuperscript{19} Thus, an aberrant right subclavian artery, usually originating as a fourth brachiocephalic branch from the upper descending thoracic aorta, is common in type B but can also occur in type A.\textsuperscript{8} The right subclavian artery may arise high in the neck from the right common carotid artery (cervical origin of right subclavian artery).\textsuperscript{24} A right-sided ductus may persist from the right pulmonary artery and give origin to the right subclavian artery, and the right pulmonary artery may arise from the ascending aorta (see “Anomalous Origin of Right Pulmonary Artery” in Chapter 48). Rarely, interrupted arch occurs with a right aortic arch, and in this instance both the left and right ducts may remain patent and give origin to the subclavian arteries.\textsuperscript{25}

Characteristically, the ascending aorta is about half normal diameter and is straight, dividing into two branches of about equal size (the V sign), and the pulmonary trunk is huge. The descending aorta is a direct continuation of the ductus arteriosus, as in the fetus, and is usually a little larger than the ascending aorta.

In the newborn, there is usually a gap of variable width between the aortic ends, although when the interruption is beyond the left subclavian artery (type A), the gap tends to be wider. Rarely, a fibrous strand connects the two ends. In this situation, the “interruption” should be viewed as a case of severe coarctation and may be distinctly different embryologically. “Interrupted” aortic arch diagnosed beyond infancy as an isolated lesion almost certainly represents coarctation that has progressed to luminal closure.\textsuperscript{22,21}

**Left Ventricular Outflow Anomalies**

The aortic valve is bicuspid in 30% to 50% of patients, analogous to coarctation (see Morphology in Section I). Congenital valvar aortic stenosis may be present occasionally, and subaortic stenosis may be present or develop.\textsuperscript{11,13,22,23} Generalized narrowing of the left ventricular outflow tract, conal septal posterior malalignment, the muscle of Moulaert, small aortic anulus, and aortic hypoplasia occur to some degree in most patients with interrupted arch.\textsuperscript{24,27,28,29,30}

As discussed in Section I for coarctation, interrupted aortic arch may be part of the complex of lesions that constitute hypoplastic left heart physiology.

**Coexisting Cardiac Anomalies**

A large VSD is present in over 95% of patients, and frequently the infundibular (conal) septum is malaligned and displaced posteriorly and leftward (Figs. 48-32 and 48-33). Most of the VSDs are conoventricular in type, although virtually all types may occur. Some conoventricular defects are also perimembranous, although some may be only juxtratricuspid in position. The malaligned and displaced infundibular septum usually produces subaortic obstruction of variable severity.\textsuperscript{13,14,24,31} This is an important complicating feature. When there are two structurally normal ventricles and inlet valves but no VSD, an aortopulmonary window is typically present. In a multicenter retrospective study of 472 patients with interrupted aortic arch, 4.2% had aortopulmonary window.\textsuperscript{22} Aortopulmonary window may occur with either type A or type B interruption (Fig. 48-34).

Other coexisting lesions are shown in Table 48-6. Pulmonary stenosis rarely if ever occurs as a coexisting lesion. Coexisting lesions occur with equal frequency and with a similar spectrum for interrupted arch types A and B.\textsuperscript{14} Coexisting lesions have been documented with type C as well.\textsuperscript{17}

**Morphogenesis and Associated Syndromes**

Microdeletion of the q11 segment of chromosome 22 and variable manifestations of velocardiofacial syndrome are common.\textsuperscript{1,2,3,19,11,20,27,28} Absence of thymic tissue (DiGeorge syndrome) is frequent\textsuperscript{24,27,28} and should be sought routinely. Van Mierop and Kutsche found this association only in type B interrupted arch, and they believe this finding has pathogenetic significance.\textsuperscript{27} Up to half of type B cases have DiGeorge syndrome.\textsuperscript{12,19} However, a population-based regional study indicates that although DiGeorge syndrome is more common in type B interruption, it occurs in type A as
Figure 48-33 Intracardiac image of neonate with interrupted aortic arch and posteriorly malaligned ventricular septal defect. Aortic anulus is mildly hypoplastic, and aortic valve is bicuspid. Infundibular (conal) septum protrudes into left ventricular outflow tract just below aortic valve, narrowing outflow tract substantially.

well\textsuperscript{G6} and has also been reported with type C interruption.\textsuperscript{V14} When DiGeorge syndrome is present, hypocalcemia requires treatment,\textsuperscript{N5} as do immunologic problems.

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

Almost all patients with aortic interruption present as critically ill neonates in severe heart failure as a result of the combined effects of volume overload from left-to-right intracardiac shunting and the high afterload imposed by the closing ductus. Metabolic acidosis and anuria develop rapidly.\textsuperscript{S15} Femoral pulses become diminished and then impalpable as the ductus closes, and may vary in volume from hour to hour.\textsuperscript{H19} When the ductus closes, flow reverses in the vessels distal to the interruption (left subclavian and left common carotid) without recognizable neurologic symptoms developing.\textsuperscript{H19} With the ductus still shunting, the expected differential cyanosis between arms and legs is usually not visible, in part because the intracardiac bidirectional shunt minimizes oxygen saturation differences between ascending and descending aorta. Reversed differential cyanosis (blue arms and pink legs) can be obvious, however, when there is associated transposition of the great arteries (see Clinical Features and Diagnostic Criteria in Chapter 52).

Cardiac murmurs are not specific, nor is ECG. The chest radiograph shows gross cardiomegaly and pulmonary plethora. Cardiac catheterization with cineangiography were required for diagnosis in the past.\textsuperscript{B8} Currently, enhanced echocardiography usually provides all the necessary diagnostic information relating to both the aortic arch and intracardiac structures.\textsuperscript{G3,T21} (Fig. 48-35; see also Fig. 48-33). Increasingly, interrupted arch is being diagnosed by fetal echocardiography.\textsuperscript{G3} In the unusual case that echocardiography does not provide all the pertinent information, CT angiography provides excellent spatial resolution (Fig. 48-36); thus, cardiac catheterization and contrast studies are unnecessary and disadvantageous.

**NATURAL HISTORY**

Interrupted aortic arch accounts for 1% to 4% of autopsy cases of congenital heart disease and 1.3% of infants presenting with critical congenital heart disease.\textsuperscript{C18,V2} Estimated prevalence is 0.06 per 1000 births.\textsuperscript{G3} There is male predominance, and the ratio of type B to type A is 11:4.\textsuperscript{G3}
This uncommon anomaly is highly lethal, with median age of death 4 to 10 days; 75% of such babies die within 1 month of birth.\textsuperscript{19,20} Because the ductus arteriosus is almost always widely patent at birth, collateral circulation does not develop, and death occurs when the ductus closes soon after birth. When the ductus is obliterated in fetal life, collateral circulation is already present at birth\textsuperscript{199} and survival is usual. If the ductus arteriosus stays open, longer survival is possible, but even then, 90% of babies die by age 1 year. In those unusual circumstances in which major associated cardiac anomalies are absent, natural history is similar to that of coarctation without major associated cardiac anomalies.\textsuperscript{199,200}

**TECHNIQUE OF OPERATION**

**Repair of Interrupted Arch and Ventricular Septal Defect**

One-stage repair is considered optimal by some\textsuperscript{19,20,23,25,71} and in the multinstitutional study of the CHSS, one-stage repair gave the best 5-year survival.\textsuperscript{198} Others indicate that little advantage is gained using this technique when compared with staged repair in which the arch is repaired via left thoracotomy, and the VSD is managed by either a concomitant pulmonary trunk band or by subsequent intracardiac closure at a separate operation.\textsuperscript{195} Nevertheless, in institutions experienced with complex neonatal surgery, one-stage repair provides the benefits of immediate normalization of physiology, a single operation, and avoidance of involving the right side of the heart with iatrogenic problems (pulmonary artery stenosis) while achieving good outcomes.

Traditionally, interrupted aortic arch has been repaired using hypothermic circulatory arrest. Recently, CPB techniques have been developed that allow repair to proceed using moderate hypothermia and continuous perfusion.\textsuperscript{201,202} In a single-institution analysis of 50 patients, mortality using continuous perfusion in 25 patients was 8% (CL 2.8%-18%), and using deep hypothermic circulatory arrest in 25 patients, 32% (CL 21%-44%). By multivariable analysis, however, the difference did not achieve significance.\textsuperscript{185} Another analysis showed that continuous perfusion, when compared with hypothermic circulatory arrest, was an independent factor protecting against death.\textsuperscript{187} In a study of 26 cases focusing on neurodevelopmental outcome at 18 to 24 months following repair, longer hypothermic circulatory arrest time was associated with worse neurodevelopmental outcome.\textsuperscript{189} Both techniques are described in the text that follows.

**Repair Using Continuous Perfusion**

Operation for a patient with type B interruption and VSD with posteriorly displaced and deficient infundibular septum is described (Fig. 48-37, A). Following standard preoperative stabilization and preparation in the operating room, a median sternotomy with slight superior extension is made. The thymus gland is removed except for a small remnant in the neck, and the pericardium is widely opened. The anterior pericardium is removed and fixed in glutaraldehyde. The ascending aorta, pulmonary trunk, ductus arteriosus, all arch vessels, and both venae cavae are dissected. The arch vessels are dissected and mobilized superior to the brachiocephalic vein. A purse-string suture is placed on the brachiocephalic artery midway between its origin and bifurcation; another is placed on the pulmonary trunk. Venous purse strings are placed on the superior and inferior venae cavae. A purse string is placed on the right superior pulmonary vein as it merges with the left atrium. After heparin is given, a side-biting clamp is placed on the brachiocephalic artery and a careful arteriotomy is made inside the purse-string suture. A 6F or 8F cannula is then inserted, as allowed by the vessel size, taking care to position the tip of the cannula well within the vessel lumen but not against the back wall of the artery (Fig. 48-37, B). A second 8F cannula is then placed into the pulmonary trunk. These cannulae are then connected to the bifurcated arterial end of the CPB circuit. Superior and inferior venae cavae are each cannulated with angled metal-tipped 12F venous cannulae connected to the bifurcated venous end of the CPB circuit. CPB is then begun. The branch pulmonary arteries are individually snared. A 10F vent is placed through the right upper pulmonary vein purse string and guided across the mitral valve to decompress the left ventricle. The patient’s core temperature is lowered to 25°C over a 15-minute period.

During this time, the distal part of the ductus and the upper descending aorta are dissected. After the target core temperature is reached, perfusion flow rate is reduced to 40 to 50 mL · kg\textsuperscript{-1} · min\textsuperscript{-1}, and the arterial cannula in the pulmonary trunk is clamped and removed. A 5-0 polypropylene suture on the ductus arteriosus is tied to occlude the pulmonary artery end of the ductus. A small C clamp is placed on the descending aorta at approximately the second pair of intercostal vessels below the ductus insertion. The left subclavian artery is occluded temporarily with a removable neurovascular clip. The ductus arteriosus is transected near the ligature, and the remaining ductal tissue is removed from the descending aorta, using origins of the intercostal arteries as a landmark indicating normal aortic tissue. The C clamp on the descending aorta prevents backbleeding through the aorta and is also used to manipulate the descending aorta to facilitate its approximation to the ascending aorta at the time of anastomosis.

A small angled clamp is placed obliquely across the arch of the aorta at the base of the brachiocephalic and left carotid arteries, allowing continuous perfusion through the brachiocephalic artery cannula to both of these vessels (Fig. 48-37, C). Cardioplegia is introduced in standard fashion through a cannula placed into the midportion of the ascending aorta. Incision is made on the left posterolateral aspect of the distal ascending aorta onto the base of the left carotid artery over a sufficient length to match the circumference of the orifice of the descending aorta. End-to-side anastomosis between the descending and ascending aorta is performed using a running suture technique with 7-0 absorbable monofilament suture. Upon completion of the anastomosis, the obliquely placed clamp on the aortic arch and the descending aortic clamp are removed. The ascending aorta is then clamped in standard fashion, allowing perfusion to the entire systemic circulation except the coronary arteries. The perfusion flow rate is increased to 100 mL · kg\textsuperscript{-1} · min\textsuperscript{-1}. A repeat dose of cardioplegia is given about this time, and the operation proceeds with VSD closure (see Chapter 35) and, if needed, atrial septal defect (ASD) closure. In the typical case, the VSD is closed via an incision in the pulmonary trunk, and the ASD via right atriotomy. After these defects, the pulmonary trunk incision and atrial incision are closed, and standard maneuvers...
Primary repair of interrupted aortic arch using continuous cardiopulmonary bypass (CPB). **A**, Cardiac exposure is through a standard median sternotomy, and preparation and dissection are similar to that used for repair of hypoplastic left heart (see Chapter 49). This figure shows type B aortic arch interruption, with patent ductus arteriosus (PDA) and ventricular septal defect (VSD). **B**, Two separate arterial cannulae are used, one introduced into the brachiocephalic artery and the other into the pulmonary trunk. Venous cannulation is performed into superior and inferior venae cavae through standard purse strings. After beginning CPB, branch pulmonary arteries are temporarily occluded (see text for details). Moderate hypothermia and standard cardioplegic myocardial protection are used (see text for details). Dashed lines show points of transection of distal ductus arteriosus and incision in posterolateral aspect of ascending aorta.

**Repair Using Circulatory Arrest**

After proper stabilization as described under Indications for Operation later in this section, the baby is brought to the operating room, usually with an umbilical artery catheter in place. After usual preliminary steps, primary median sternotomy is made (see Preparation for Cardiopulmonary Bypass in Section III of Chapter 2). Most of the thymus gland, if present, is removed to adequately mobilize branches of the aortic arch. The pericardium is opened widely and stay sutures applied. A portion of the pericardium is prepared in case it is necessary to use it in repairing the ASD. The
Cardioplegia has been introduced through a catheter in mid-ascending aorta. Proximal aortic clamp is positioned to allow continued flow through brachiocephalic and left carotid arteries. Arterial cannula in pulmonary trunk has been removed and ductus arteriosus ligated and divided. All ductus tissue has been removed from distal aorta. Incision in posterolateral aspect of ascending aorta has been made. Running suture anastomosis is begun at posterior aspect of circumference of descending aorta. Completed arch repair. Aortic clamps have been removed and patient separated from CPB (see text for details of methodology for ventricular septal defect closure). Key: IVC, inferior vena cava; LPA, left pulmonary artery; RPA, right pulmonary artery; SVC, superior vena cava.

Figure 48-37, cont’d  C, Cardioplegia has been introduced through a catheter in mid-ascending aorta. Proximal aortic clamp is positioned to allow continued flow through brachiocephalic and left carotid arteries. Arterial cannula in pulmonary trunk has been removed and ductus arteriosus ligated and divided. All ductus tissue has been removed from distal aorta. Incision in posterolateral aspect of ascending aorta has been made. Running suture anastomosis is begun at posterior aspect of circumference of descending aorta. D, Completed arch repair. Aortic clamps have been removed and patient separated from CPB (see text for details of methodology for ventricular septal defect closure). Key: IVC, inferior vena cava; LPA, left pulmonary artery; RPA, right pulmonary artery; SVC, superior vena cava.
the aortic cannula and one arm of the arterial tubing, and the arterial tubing is carefully arranged to lie smoothly and as much as possible outside the surgical field. After inserting the aortic cannula, a round-nosed right atrial catheter of appropriate size is introduced through the right atrial appendage and positioned in the orifice of the superior vena cava. This allows the cannula and the venous tubing to sweep inferiorly and lie outside the surgical field. CPB is established with the perfusate about 34°C; a second arterial cannula is inserted into the pulmonary trunk through a purse string and is connected to the other arm of the arterial Y; the tip of the cannula remains within the pulmonary trunk. The left pulmonary artery is dissected out promptly and a snare placed and tightened around it, and the snare on the right pulmonary artery is tightened. Cooling of the patient with the perfusate then proceeds. Infusion of PGE₁ is continued during the cooling phase of CPB.

During cooling, the brachiocephalic, right subclavian, right common carotid, left common carotid, and left subclavian arteries are fully mobilized. This step is extremely important to preclude tension on the aortic suture line once it is made. The ductus arteriosus is dissected, and a tie is placed loosely around it. Elastic snare is placed around the right and left common carotid arteries, but not around the subclavian arteries. When the patient’s nasopharyngeal (or tympanic membrane) temperature reaches 16°C to 18°C, circulatory arrest is established, leaving the venous tubing open until the patient’s blood volume has been transferred to the pump-oxygenator. The aorta is clamped just distal to the aortic cannula, and cold cardioplegic solution is infused through the stopcock on the aortic cannula (see Section IV of Chapter 2). All cannulae are then removed from the surgical field, the carotid artery tourniquets tightened, and the aortic clamp removed.

The ductus arteriosus is ligated, taking care to avoid distorting the bifurcation of the pulmonary trunk, and it is transected at its junction with the aorta. As much ductal tissue as possible is removed from the opened aorta, but this cannot be performed in as satisfactory a manner as in discrete coarctation. Particularly in type B interruption, the distal aortic segment is thoroughly mobilized. If the right subclavian artery arises anomalously from the upper descending aorta, it is dissected and divided between ligatures. If the anastomosis cannot be made tension-free in any other manner, the left subclavian artery is also ligated and divided. A small delicate C clamp is placed on the descending aorta so that an assistant can bring it into apposition with the proximal aortic segment without tension. An opening for the anastomosis is made in the left posterolateral aspect of the ascending aorta, as much as possible in its midportion and approximately opposite the arterial cannulation site. An end-to-side anastomosis is made with continuous 7-0 absorbable monofilament suture, beginning along the far side of the inferior angle and sewing so that the stitching in the proximal aorta is from the inside out, because this is the most delicate structure. Five or six of the stitches should be placed before they are carefully pulled up as the aortic segments are brought together; the remainder of the suture line is then completed.

The VSD is repaired. If there is considerable infundibular (conal) septal tissue separating the superior margin of the VSD from the pulmonary valve, the VSD is repaired through the right atrium (see Technique of Operation in Chapter 35). If preliminary echocardiographic studies have shown that the infundibular septum beneath the pulmonary valve is deficient, as is often the case, the VSD is repaired through the pulmonary trunk, which is usually very large in this condition. The foramen ovale, which may have been considerably stretched by a preexisting left-to-right shunt, must be closed. This can be accomplished either primarily or by suturing into place a piece of pericardium using continuous sutures.

Saline is flushed into the left side of the heart before completing closure of the foramen ovale, to emerge through the aortic cannulation site to de-air the left heart. The right atrium is closed. Only the ascending aortic cannula is reinserted, and it is important to have blood gently coming out the cannula as it is inserted into the ascending aorta to prevent air entrapment. After reinserting the right atrial cannula, CPB is begun, the carotid artery tourniquets are released, and rewarming is accomplished. Before removing the aortic cannula, pressure in the ascending aorta can be measured by connecting to a pressure transducer to the stopcock that has previously been placed. It is compared with that recorded from the umbilical artery catheter to assess the status of the aortic anastomosis. The remainder of the procedure is completed in the usual manner (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2).

Alternative Methods of Arch Repair

Occasionally, other methods of arch repair are indicated when a primary ascending-to-descending aortic anastomosis is not advisable. Methods that preserve growth potential, such as using the left carotid or subclavian artery, are preferred to interposition grafts. When an anomalous right subclavian artery is present, it can be used for the arch reconstruction.[21]

Repair of Interrupted Arch and Ventricular Septal Defect and Left Ventricular Outflow Obstruction

Left ventricular outflow tract (LVOT) obstruction occurs to varying degrees with interrupted aortic arch and VSD. The decision to perform a specific procedure to address the LVOT at the initial neonatal operation is a difficult one (see Special Situations and Controversies later in this section). When the LVOT is deemed inadequate, various techniques have been used to address this problem:

- Pulmonary trunk–to-aortic anastomosis (Damus-Kaye-Stansel [DKS] procedure) with arch repair and Rastelli septation (VSD closure and right ventricle–pulmonary trunk conduit)[71,71]
- DKS procedure with arch repair and systemic–pulmonary artery shunt, followed by staged Rastelli septation
- Direct muscular or fibromuscular LVOT resection along with arch and VSD repair[40]
- Norwood operation with Rastelli septation[15,15]
- Norwood operation, followed by staged Rastelli septation[8]
- Ross-Konno operation[12,55]

Repair of Interrupted Arch and Other Coexisting Cardiac Anomalies

In general, coexisting cardiac anomalies such as transposition of the great arteries or truncus arteriosus are repaired
concomitantly with repair of the interrupted arch, except for those in which a Fontan operation is required. For these exceptions, the procedures described under Indications for Operation in Chapters 41 and 56 are applicable. Several techniques have been described for one-stage repair of interrupted arch with aortopulmonary window.

**SPECIAL FEATURES OF POSTOPERATIVE CARE**

Care is as usual (see Chapter 5). Special attention is paid to the possible occurrence of hypocalcemia if DiGeorge syndrome is present.

Because in this setting appreciable left-to-right shunting is apt to occur through a small residual VSD or ASD (presumably because of some degree of hypoplasia of the left ventricular cavity or outflow obstruction), left-to-right shunting must be carefully sought (see “Risk Factors for Low Cardiac Output” in Section I of Chapter 5). If found in patients whose hemodynamic state is not good, reoperation is indicated.

If extensive atelectasis of the left lung develops, its cause may be left bronchial compression by a directly reconstructed aortic arch. Prevalence of this complication is low when the operation has included wide mobilization as described. However, if this complication occurs, reoperation may be considered if it is believed that the vessels can be further mobilized.

Because the aortic valve is commonly small or bicuspid, and the subvalvar LVOT is small as a result of the posteriorly malaligned infundibular septum, it is common for some degree of LVOT obstruction to be present after repair once the left ventricle ejects a full cardiac output. The degree of obstruction should be assessed immediately after separation from CPB using transesophageal echocardiography. If preoperative assessment and surgical judgment are appropriate, the gradient should be less than 30 mmHg systolic. If the gradient is higher, particularly if there is left ventricular dysfunc-

**RESULTS**

**Survival**

**Early (Hospital) Death**

Most early reports were based on a small number of patients, and in these mortality ranged from 20% to 80%. However, in patients with interrupted arch and VSD, early mortality in the current era can be 10%. In the multinstitutional study of the CHSS, mortality after optimum repair for type A interruption with or without concomitant VSD was 4% at 30 days; for type B, 11%.

**Time-Related Survival**

Realizing that many patients are seriously ill, survival from time of diagnosis (birth), including deaths before operation, is the most realistic evidence of the impact of treatment on the natural history. Overall, 5-year survival after birth can be predicted to be about 45%; rate of dying (hazard function) is rather high immediately after birth but declines rapidly thereafter, reaching a low level by 12 months (Fig. 48-39).

Survival after repair of interrupted aortic arch and VSD in the CHSS multinstitutional study of a heterogeneous population was 63% at 4 years (Fig. 48-40), and optimal repair in type A interruption with or without coexisting obstructive lesions elsewhere in the left heart was associated with 5-year survival of 93%, and for type B, 83% (Fig. 48-41). Recent follow-up of this patient cohort indicates that non–risk-adjusted 16-year survival is 59%, and not unexpectedly, it improved the later the date of birth (Fig. 48-42). Single-institution studies from approximately the same era suggest similar 5-year survival of greater than 70%, Unadjusted survival for interrupted arch with aortopulmonary window (Fig. 48-43) is better than unadjusted survival for interrupted arch with VSD (see Fig. 48-40), and is similar to “optimal repair” survival for interrupted arch with VSD (see Fig. 48-41).

**Modes of Death**

Most deaths are with acute or subacute heart failure without or with multiple subsystem failure, although some are related to late reoperations for LVOT obstruction or aortic arch obstruction.
Incremental Risk Factors for Premature Death

The 2005 report on the CHSS multiinstitutional study of 472 cases of interrupted aortic arch focuses on risk factors for mortality and reintervention. A relatively cohesive picture of the risk factors for mortality can be constructed based on this study and a number of other individual institutional studies.

Nature of the coexisting cardiac anomaly has been identified as an important risk factor for death, with VSD the most favorable (see Fig. 48-41). The CHSS study confirms the presence of truncus arteriosus as a risk. Additionally, the CHSS study identifies certain VSD characteristics as risks. Small and moderate VSD and VSDs that are not malaligned are noted to be risks. Several relatively small series showed no association with survival of complexity of coexisting cardiac anomalies. Location of the interruption has its most important effect when it has been between the brachiocephalic and left common carotid artery (type C); this has been a highly lethal but rare lesion. A smaller difference in survival has been observed between interruptions distal to the left subclavian artery (type A) and those between the left

subclavian and left common carotid artery (type B) (see Fig. 48-41). The CHSS study confirms higher risk for types C and B; thus, type A carries the lowest risk.

Type of initial surgical procedure used to address interrupted aortic arch with VSD does not appear to importantly influence outcome, whether the approach is arch repair with VSD closure, arch repair with pulmonary trunk banding, or arch repair alone\(^{38}\) (Table 48-7). The CHSS study confirms this as well. As intimated under Technique of Operation earlier in this section, condition of the patient on entry into the operating room is important, and a low arterial pH at that time has been a strong risk factor for death (Tables 48-8 and 48-9; Fig. 48-44).

Other levels of LVOT obstruction is a risk factor, and is depicted as decreasing survival as left ventricular aortic junction diameter decreases (see Table 48-8). More complex procedures designed to address this obstruction are identified as carrying greater risk, as is ignoring the obstruction and performing a simple repair of the interruption and VSD closure (see Table 48-9). The CHSS study suggests that a pulmonary trunk to aortic anastomosis (DKS anastomosis) increases risk.

Date of operation has been a powerful risk factor because of great improvements achieved over time (see Fig. 48-38). The CHSS study confirms this. Thus, data from earlier eras have little applicability in the current era in institutions prepared for neonatal cardiac surgery.

Low weight at operation is identified as a risk in the CHSS study, as is lack of augmentation of the arch at the time of initial arch repair; however, other studies seem to contradict the latter.\(^{129}\)

Left Ventricular Outflow Obstruction

Patients with interrupted aortic arch often have at least some degree of hypoplastic left heart physiology as well (see

Key: Asc Ao, Ascending aorta; DKS, Damus-Kay-Stansel; IAA, interrupted aortic arch; LHA, left heart–aorta; PT, pulmonary trunk.

“Coarctation as Part of Hypoplastic Left Heart Physiology” under Morphology in Section 1. The specific features all relate to the LVOT, as pointed out several times elsewhere in this section, including:

- Posterior malalignment of infundibular septum
- Hypertrophy of anterolateral muscle bundle of the left ventricle (muscle of Moulaert)
- Bicuspid dysplastic aortic valve
- Narrowness of aortic anulus
- Hypoplasia of ascending aorta and aortic arch; occasionally this is apparent before operation, but more often it becomes evident after repair.

LVOT obstruction has important implications for both short- and long-term prognosis, and for decision making and surgical technique (see Results in following text and Special Situations and Controversies later in this section). In a minority of neonates with interrupted aortic arch and VSD, the LVOT is inadequate, and repair of the arch and VSD alone results in unacceptable obstruction. Although difficult to accomplish, it is best to identify such patients before the initial operation (see Special Situations and Controversies later in this section). In about 40% of patients with a conoventricular VSD, or with a VSD in the outlet portion of the right ventricle, evidence of LVOT obstruction develops at midterm or late follow-up, even when the LVOT was adequate after initial operation.¹⁴,¹⁵ (Fig. 48-45).

Whether the LVOT obstruction develops during or sometime after the initial operation, or whether it was present at birth and only becomes evident later is uncertain, but both probably occur. Probability that at least the anatomic basis for the obstruction was present at birth is heightened by the shape of the hazard function, which indicates that the rate of recognizing (or developing) LVOT obstruction declines to a constant hazard after about 2 years following initial repair (see Fig. 48-45).
Late Reoperation from All Causes

Late reoperation is frequent after neonatal repair of interrupted aortic arch, reflecting the complexity of the underlying lesion. There are multiple reasons for reoperation, including:

- Recurrent arch obstruction
- LVOT obstruction
- Residual VSD
- Bronchial compression
- Diaphragm palsy
- Complete heart block

In a single-institution analysis of 94 patients undergoing initial operation between 1975 and 1999, with follow-up of up to 21 years (mean 6.7 years), reoperation from all causes was 40% at 15 years. Similar prevalence of
reintervention was noted in other series from the same period.\textsuperscript{34} Reflecting the general trend that outcomes improve over time, another single-institution analysis of 65 patients undergoing initial operation between 1982 and 2005 showed that reoperation from all causes was 60\% at 15 years\textsuperscript{M5} (Fig. 48-48).

The cumulative incidence of all types (surgical or catheter-based) reinterventions after repair of interrupted aortic arch exceeds one per patient within about 3 years and approached two per patient by about 25 years (Fig. 48-49). The most common are catheter-based arch procedures (Fig. 48-50).

**INDICATIONS FOR OPERATION**

Diagnosis of interrupted aortic arch is an indication for operation, no matter what the coexisting cardiac anomaly. Severe chromosomal abnormalities may contraindicate surgical intervention.

Intensive treatment is an essential part of the therapeutic program and begins the moment the diagnosis is suspected, which should be shortly after birth. An infusion of PGE\textsubscript{1} is begun, usually in a dose of 0.05 to 0.1 µg · kg\textsuperscript{-1} · min\textsuperscript{-1}, and the infant is intubated and appropriately ventilated; high FIO\textsubscript{2} is avoided. If the infant’s condition is good in all ways, operation is undertaken at the first convenient time, but not as an emergency. If the infant’s condition is not good, then:

- Right-to-left shunting into the descending aorta for augmenting systemic blood flow is encouraged by increasing

CO\textsubscript{2} in the inspired gas mixture or mildly hypoventilating the patient so that PaO\textsubscript{2} is about 40 mmHg (to increase pulmonary vascular resistance).

- Cardiac output and renal blood flow are increased by infusing dopamine at 2.5 to 5 µg · kg\textsuperscript{-1} · min\textsuperscript{-1}.

- Acidosis is corrected by intravenous sodium bicarbonate (see Appendix 5N in Chapter 5).

Nearly always, the baby can be brought into a good clinical condition by these measures. At that point, operation is performed.

One-stage repair of the interrupted arch and the coexisting anomaly, or repair of the interruption with staged repair of the coexisting anomaly, is carried out, except when some form of single ventricle is the coexisting anomaly. An alternative plan is then necessary (see Section I of Chapter 41).

**SPECIAL SITUATIONS AND CONTROVERSIES**

Preoperative assessment of adequacy of the LVOT, including the aortic valve and subaortic region, can be challenging in patients with interrupted aortic arch. The aortic valve is frequently bicuspid with some degree of hypoplasia. The subaortic region is often narrowed by a posteriorly malaligned infundibular septum. Preoperative assessment of the LVOT is difficult because preoperative physiologic measurements are unreliable predictors of postoperative physiology. Because flow across the LVOT is typically low preoperatively from the patent ductus with right-to-left shunting, preoperative obstruction is almost never detected, even when the LVOT proves to be inadequate after repair. Therefore, other preoperative measures must be relied on to predict LVOT adequacy after repair. The most difficult assessment is of the subaortic region. Specific criteria for identifying the patient with inadequate LVOT preoperatively have not been widely accepted; currently, individual institutions use various measures to identify these patients. In many cases a subjective intraoperative decision is made by the operating surgeon regarding whether to perform a procedure that addresses the LVOT.\textsuperscript{436} Hanley and colleagues at Stanford (personal communication) have used a simple formula that permits an objectively based

\end{figure}
decision preoperatively. Using echocardiography, if the smallest diameter of the subaortic region (measured in millimeters) is equal to or greater than body weight (measured in kilograms), the LVOT will be adequate, as defined by a postrepair LVOT gradient of less than 20 mmHg. (Others have described different anatomic dimensions used to predict subsequent obstruction.117,153) Thus, a 4-kg neonate must have a minimum subaortic dimension of at least 4 mm. If this criterion is met, a standard repair involving direct arch reconstruction and VSD closure is performed. If this criterion is not met, an alternative one-stage repair is performed. This involves direct arch reconstruction, DKS procedure, VSD closure allowing the LV to eject to both the aortic and pulmonary valves, and placement of a right ventricle–to–pulmonary trunk valved conduit. Although the 1994 CHSS data indicate that the DKS procedure carries elevated risk,18 several single-institution studies suggest that the DKS procedure or similar variants can be performed with low mortality.18,61,153 Others advocate directly resecting the obstruction in the LVOT at the time of the arch repair and VSD closure52,546; however, the 1994 CHSS data suggest that attempting to do this is a risk factor for death.18

Finally, the Ross-Konno operation (see Technique of Operation in Section II of Chapter 47) has been applied to this problem.112,153

Hypoplastic left heart syndrome is defined as inability of the left heart to sustain adequate cardiac output following birth because of underdevelopment of one or more left heart structures despite surgical or medical intervention. Box 49-1 emphasizes four important implications of this definition.

We have chosen to use the term hypoplastic left heart physiology rather than the more common and entrenched term hypoplastic left heart syndrome, because it more accurately describes the entity. In fact, both terms have important limitations when applied in the clinical setting. In practice, the exact point along the aforementioned continuum where an inadequate left heart is encountered cannot be defined with certainty. This limitation is not intrinsic to the definition of hypoplastic left heart physiology itself, but rather is due to two important factors: (1) tests designed to define morphologic and physiologic characteristics are limited in their ability to accurately predict overall left heart function, and (2) new
Box 49-1 Hypoplastic Left Heart Physiology

1. The term left heart refers to the morphologic composite or unit that includes left atrium, mitral valve, left ventricle, aortic valve, and aorta. Each of these plays an important role in determining left heart function.  

2. Definition of hypoplastic left heart is physiologic, not morphologic, despite morphologic abnormalities being the underlying cause of left heart inadequacy. A morphologic definition of the hypoplastic left heart is not possible because underdevelopment of a variable number of specific left heart structures, either alone or in various combinations, may be responsible for physiologic inadequacy of the left heart. Some morphologic constellations (e.g., aortic and mitral atresia in combination) essentially always result in hypoplastic left heart physiology, whereas others (e.g., aortic or mitral stenosis) may or may not. Nevertheless, typical morphologic abnormalities that result in hypoplastic left heart physiology can be identified. These include a constellation of atresia or marked hypoplasia of the mitral valve, left ventricle, and aortic valve, in association with hypoplasia of the ascending aorta and aortic arch, aortic coarctation, patent ductus arteriosus, and atrial septal defect. It is important, however, to reemphasize that this constellation does not define hypoplastic left heart physiology; hypoplastic left heart physiology can be present without including all morphologic abnormalities mentioned in this typical example.  

3. Hypoplastic left heart physiology is present within a relatively narrow band of the broad continuum of hypoplastic lesions of the left heart. This continuum ranges from isolated simple lesions (e.g., discrete coarctation) at one end of the spectrum to complex multilevel lesions (e.g., combination of aortic atresia, mitral atresia, and absent left ventricle) at the other end. The point along this gradually increasing continuum of left heart abnormalities where hypoplastic left heart physiology is encountered is impossible to pinpoint morphologically. Hypoplastic left heart physiology may be the result of a severe abnormality of a single left heart structure (e.g., mitral atresia) or a combination of several milder abnormalities (e.g., mitral stenosis, left ventricular hypoplasia, and aortic stenosis).  

4. Inclusion of the phrase despite surgical or medical intervention in its definition is critical to the concept of hypoplastic left heart physiology, because abnormalities such as isolated critical aortic stenosis or isolated severe aortic coarctation may meet the criteria of this physiologic definition before but not after intervention to correct the abnormality. As a result, the lesions cited in the previous sentence are not considered examples of hypoplastic left heart physiology. An important implication of the term hypoplastic left heart physiology is that the left heart is incapable of sustaining systemic cardiac output, thereby limiting therapeutic options to (1) reconstructions that use a single (right) ventricular pumping chamber (Norwood procedure, superior cavopulmonary connection, Fontan procedure) or (2) heart transplantation.

The concept of borderline hypoplastic left heart physiology, therefore, refers to a zone along this continuum in which it is currently not possible to predict with certainty whether the left heart can be salvaged with surgical reconstructive methods. This concept is of practical importance because it helps characterize the clinical dilemma faced by surgeons who must make a dichotomous decision (reconstructive surgery to salvage the left heart vs. the Norwood procedure or transplantation) in the context of a continuum of morphologic and physiologic left heart compromise. At either pole of this continuum, decision making is straightforward. However, within the zone of borderline hypoplastic left heart physiology, the appropriate management decision requires exquisite attention to many subtle details.

The various malformations that result in hypoplastic left heart physiology together represent a special example of univentricular atrioventricular connection (see Chapters 41 and 56). Because of the special clinical and surgical importance of this group of malformations, this subject is discussed separately from other forms of univentricular heart.

### HISTORICAL NOTE

The first description of aortic atresia was apparently by Canton in 1850. Although Abbott had recognized aortic and mitral atresia, Brockman in 1950 emphasized that in about 50% of cases of mitral atresia, there was coexisting aortic atresia and severe underdevelopment of the left side of the heart. In 1952, Lev further emphasized the group of congenital heart malformations associated with underdevelopment of the left-sided cardiac chambers and a small ascending aortic arch, articulating for the first time the concept that multiple left-sided structures tended to occur together. In 1958, Noonan and Nadas brought together the morphologic features of combined aortic and mitral atresia and introduced the phrase “hypoplastic left heart syndrome.” In 1976, Roberts and colleagues further organized the knowledge about this subject by emphasizing that in the presence of a large ventricular septal defect (VSD), aortic atresia can coexist with normal development of the left ventricle and mitral valve.

The history of attempted reconstructive procedures for hypoplastic left heart physiology dates back to 1970 when Cayler and colleagues described an anastomosis between right pulmonary artery and ascending aorta with placement of bilateral pulmonary artery bands. Other variations in neonatal reconstructive procedures designed to allow survival without the use of prostaglandins to maintain ductal patency were described by Doty and colleagues in 1977, Norwood and colleagues in 1980, Levitsky and colleagues in 1980, Behrendt and colleagues in 1981, and others. 

Even though some of these reports noted short-term successes, there is no documentation of long-term survival. In 1983, Norwood and colleagues described for the first time neonatal palliative surgery leading to a subsequent successful Fontan procedure. Following this report and subsequent reports that systematically documented long-term survival of patients with hypoplastic left heart physiology, it has become widely accepted that many of the technical details of the procedure as described by Norwood are critical to achieving long-term survival. These technical details ensure long-term aortic growth potential, minimize pulmonary valve distortion, address distal arch obstruction, preserve pulmonary developments and reconstructive techniques may allow previously unsalvageable left hearts to function adequately.
artery patency, balance pulmonary and systemic blood flows, and ensure adequate atrial-level mixing. Many of the procedures described before implementation of the Norwood procedure failed to address one or more of these issues critical for long-term survival.

Allograft heart transplantation for hypoplastic left heart physiology dates back to 1985, when Bailey performed the first successful cases as primary therapy in neonates. Since then, Bailey and colleagues and a limited number of other groups have considered transplantation as one option for treatment, along with reconstructive surgery.

The hybrid procedure for hypoplastic left heart physiology was first developed in 1993 in response to poor outcomes following the Norwood procedure. The hybrid procedure combines surgical placement of bilateral branch pulmonary artery bands, placement of a stent in the ductus arteriosus, and catheter-based atrial septostomy, avoiding cardiopulmonary bypass (CPB). Initially, it was not widely embraced because of poor interim outcomes; however, more recently it has been used by some programs as an alternative to the Norwood procedure in high-risk patients, and variations of the hybrid procedure have been used as a bridge to transplantation.

MORPHOGENESIS AND MORPHOLOGY

Morphogenesis

Currently, it is unclear whether the etiology of hypoplastic left heart physiology is similar in all cases. There are genetic factors involved, although these are multiple, complex, and poorly understood at the present time. Available evidence suggests that a number of primary morphologic etiologies may lead to the end result of hypoplastic left heart physiology. Primary morphologic abnormalities at the aortic valve level, mitral valve level, left ventricular myocardial level, or atrial septal level (intact atrial septum) could all in theory lead ultimately to hypoplasia of the entire left side of the heart as gestation progresses.

Fetal echocardiography has yielded much information regarding progression of hypoplastic left heart physiology. In some cases, critical aortic stenosis with documented forward flow on early fetal echocardiograms progresses to aortic atresia before birth. In such cases, the left ventricle shows evidence of progressive dysfunction and hypoplasia as stenosis proceeds to atresia. Echocardiographic evidence of fetal left ventricular dilated cardiomyopathy progressing to hypoplastic left heart physiology has been reported. Controversy remains as to whether a closed foramen ovale in utero is a cause or a result of hypoplastic left heart physiology.

Morphology

In hypoplastic left heart physiology, the heart is enlarged to about twice normal weight for age. Its shape is determined by the large right and small left heart chambers (Fig. 49-1, A). Beyond this, morphologic details vary widely. Four morphologic subtypes of hypoplastic left heart physiology can be defined based on status of the left heart valves:

- Aortic and mitral atresia
- Aortic atresia with mitral stenosis

Of these, aortic stenosis with mitral atresia is the least common subtype, representing approximately 5% of cases; aortic and mitral atresia is the most common, representing approximately two thirds of cases. Within these subtypes, the status of the atrial septum, size of the left ventricular cavity and muscle mass, ascending aorta and aortic arch, and ductus arteriosus are also important.

Aortic Valve and Ascending Aorta

In aortic atresia, the aortic valve is totally absent. Diminutive aortic sinuses of Valsalva are frequently present, giving origin to relatively normally positioned right and left coronary arteries that have a normal distribution pattern. The ascending aorta is narrow, sometimes as small as 1.5 mm in diameter. The portion of the aorta between the atretic valve and brachiocephalic artery serves only as a conduit for coronary blood flow (Fig. 49-2).

At and beyond the brachiocephalic artery, the aortic arch gradually widens and is joined beyond the origin of the left subclavian artery by a large patent ductus arteriosus. The ductus carries blood from the right ventricle into the descending aorta and retrograde to the brachiocephalic and coronary arteries. A localized aortic coarctation exists in approximately 80% of cases and is usually juxtaaortic in location (see Chapter 48). Prevalence of coarctation is highest in patients with the most severe hypoplasia of the ascending aorta. In some cases, there may be only mild infolding of the aortic media on the wall opposite the ductal insertion site, or there may be no aortic coarctation whatsoever.

When a patent but hypoplastic aortic valve is present, there may be a variable but still reduced amount of forward flow across the aortic valve (see Chapter 47). The ascending aorta and arch tend to be larger than in aortic atresia, with the diameter of the ascending aorta ranging from 2 to 6 mm. Aortic coarctation is common.

Left Ventricle and Mitral Valve

The left ventricle is severely hypoplastic in 95% of cases of aortic atresia. In this setting, the ventricular septum is intact. The mitral valve is either atretic (about one third of patients) or patent but severely hypoplastic (about two thirds of patients) (see Fig. 49-1, B and C). When the mitral valve is patent in association with aortic atresia, there may be left ventricular–coronary connections (Fig. 49-3) similar to those present in the right ventricle in cases of pulmonary atresia with intact ventricular septum (see “Right Ventricle” under Morphology in Chapter 40). It is postulated that these connections serve to decompress the left ventricular chamber. Localized thickening of coronary arteries occurs adjacent to these connections, and there is also a variable degree of endocardial thickening (endocardial fibroelastosis).

Rarely, there is focal calcification and scarring limited to the ventricular subendocardium. The hypoplastic left ventricle shows myocardial fiber disarray qualitatively similar to that present in hypertrophic obstructive cardiomyopathy (see “Left Ventricle” under Morphology in Section II of Chapter 47), and in the right ventricle in pulmonary atresia with intact ventricular septum (see “Right Ventricle” under Morphology in Chapter 40).
extremely hypoplastic with hypertrophic muscle and severe endocardial fibroelastosis to a dilated, thin-walled, poorly functioning chamber. The mitral valve is almost always hypoplastic and may be atretic when severe aortic stenosis is present.

Right Ventricle

In approximately 5% of cases of aortic atresia, the left ventricular cavity is near normal size in association with a large VSD. In such cases, there may be mitral valve atresia or a normal mitral valve. In cases of a normal mitral valve, the malformation does not represent hypoplastic left heart physiology, because such patients can undergo two-ventricle repair (see Special Situations and Controversies).

When aortic stenosis rather than atresia is present, the left ventricle tends to be larger than the typically minute, slitlike left ventricle of aortic atresia. Its size may vary widely from

Figure 49-1 Autopsy specimen of aortic atresia and hypoplastic left heart physiology from a 4-day-old neonate. A, Globular external shape of heart results from massive right ventricular (RV) hypertrophy and enlargement. Pulmonary trunk (PT) is large and ascending aorta (AscAo) small. Left ventricle (LV) is small and displaced posteriorly and does not reach cardiac apex. Arrow points to left anterior descending coronary artery. B, Interior of left atrium (LA) and partly opened LV. Septum primum (SP; fossa ovalis) is thickened and protrudes into right atrium (RA). Mitral valve (MV) is hypoplastic and stenotic, and LV wall is grossly thickened. C, Interior of fully opened LV. Its cavity is small, and there is marked endocardial fibroelastosis (EFE), which also involves rudimentary papillary muscles (PM) of small MV. Key: LAA, Left atrial appendage; PVs, pulmonary veins.

Right Ventricle

The right ventricle is enlarged, with uniform hypertrophy and a marked increase in cavity size (to approximately three times normal). Both tricuspid and pulmonary valves are larger
PART VII Congenital Heart Disease

than normal, and tricuspid regurgitation of variable degree is common.

Pulmonary Arteries
The pulmonary trunk is large and continues directly into the large patent ductus arteriosus. The right and left branches arise relatively posteriorly and at right angles from the short pulmonary trunk.

Atria and Atrial Septum
The left atrium is relatively small and thick walled, with its long axis directed transversely toward the right atrium. The atrial septum is also thick, making balloon atrial septostomy generally unsatisfactory. An atrial communication is usually present; in the great majority of cases, this communication is a stretched patent foramen ovale. The septum primum is thickened and stretched so that it herniates into the right atrium and allows left-to-right shunting (see Fig. 49-1, B). There may be an aneurysm of the septum primum projecting to the right. The right atrium is larger than normal, with uniform hypertrophy of its walls. When the atrial septum is intact or severely restrictive in association with mitral or aortic atresia or both, there is pulmonary venous hypertension and a variable degree of decompression of pulmonary venous return through connections to the systemic venous system. Pulmonary venous hypertension usually begins in fetal life. This may have important implications for fetal lung development. Dilated pulmonary lymphatic channels form, and these can have an important effect on postnatal lung physiology and surgical outcome.

Other Associated Cardiac Anomalies
Associated anomalies are uncommon. Structural abnormalities of the tricuspid and pulmonary valves are rare. Bicuspid pulmonary valve has been described in 4% of specimens; cleft tricuspid valve, tricuspid valve dysplasia, and double orifice tricuspid valve have also been reported. Other unusual cardiac anomalies include intact atrial septum, total anomalous pulmonary venous connection, levoatrial cardinal vein, coronary sinus atresia, atretic pulmonary veins, complete atrioventricular septal defect, transposition of the great arteries, and interrupted aortic arch. Coronary artery abnormalities are rare except in patients with aortic atresia and mitral stenosis, in which they occur in approximately 50% of cases.

Associated Noncardiac Anomalies
Other abnormalities unrelated to the cardiovascular system are found frequently with hypoplastic left heart physiology. Chromosomal abnormalities, genetic defects, and major extracardiac structural malformations, including central nervous system abnormalities, occur in 28% to 40% of patients.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA
Presentation is in the newborn period, with mild cyanosis, respiratory distress, and tachycardia. If supportive measures are not undertaken, there can be rapid deterioration, heart failure, and death due to a combination of pulmonary overcirculation and systemic obstruction from ductal closure. Ductal closure is almost inevitable, but its timing varies from

Figure 49-2 Lateral cineangiogram obtained after pressure injection of contrast medium into a brachial artery cannula in a neonate with hypoplastic left heart physiology. (This resulted in marked bradycardia and hypotension and is not a recommended technique.) Size of blind ascending aorta, which supplies large coronary arteries, and larger aortic arch and its branches are displayed. Pulmonary trunk (PT) is faintly outlined by contrast medium reaching it through the ductus arteriosus.

Figure 49-3 Postmortem coronary angiogram obtained by cannulating and injecting contrast medium into a coronary artery ostium in a heart with aortic atresia and hypoplastic left heart physiology. Small left ventricular (LV) cavity filled rapidly as contrast medium reached it through numerous coronary-LV connections. These form a prominent network within the thickened LV myocardium (arrows).
 Chapter 49  Aortic Atresia and Other Forms of Hypoplastic Left Heart Physiology

hours to weeks. This event is followed by rapid circulatory collapse.

On examination, there is a hyperactive right ventricular precordial impulse and a moderate-intensity mid-systolic murmur along the left sternal border. The second heart sound is accentuated and single. Heart failure is associated with rales and liver enlargement. In many instances, peripheral pulses and perfusion are poor and blood pressure is low.

The chest radiograph shows moderate cardiomegaly and pulmonary plethora secondary to increased pulmonary blood flow. The electrocardiogram demonstrates right axis deviation and right ventricular hypertrophy and usually no left ventricular forces. However, left ventricular voltages can be present but do not necessarily signify an adequate left ventricular cavity. Two-dimensional echocardiography is diagnostic and usually definitive. It demonstrates the large right ventricle, tricuspid valve, and ductus arteriosus and the small or absent left ventricle, aortic and mitral valves, and ascending aorta (Fig. 49-4). Status of the atrial septum is also easily determined. Doppler color flow signals indicate retrograde flow in the aortic arch and ascending aorta in cases of aortic atresia. Antegrade flow in the ascending aorta in the setting of aortic atresia strongly suggests that left ventricle-to-coronary artery fistulae are present, with left ventricular blood flowing retrograde in the coronary arteries and into the ascending aorta. When the aortic valve is not atretic, forward flow from the left ventricle across the aortic valve is normal. The amount of flow varies widely and may reach as far as the aortic arch. If Doppler color flow indicates substantial forward flow to the level of the arch or bidirectional flow in the patent ductus arteriosus, the patient should be considered to have borderline hypoplastic left heart physiology (see Special Situations and Controversies).

Cardiac catheterization is rarely indicated if it is clear by echocardiographic evaluation that the patient has unequivocal hypoplastic left heart physiology. However, in borderline hypoplastic left heart physiology, cardiac catheterization is often indicated to further characterize the physiology, especially mitral valve gradient and left ventricular end-diastolic pressure. The physiologic information obtained may help determine whether two-ventricle reconstruction is advisable. Catheterization is also indicated when a severely restrictive or intact atrial septum is present, resulting in pulmonary venous hypertension.

Rather than urgently bringing an hours-old infant to surgery under unstable conditions, the atrial septum can be opened by various interventional techniques (e.g., balloon dilatation, blade septostomy, atrial septal puncture with dilatation).

At this writing, computed tomography (CT) and magnetic resonance imaging (MRI) have a limited role in neonates with hypoplastic left heart physiology. CT angiography, however, may play an important role in follow-up, providing precise anatomic detail of aortic arch and pulmonary artery growth and development (Fig. 49-5). MRI can provide quantitative analysis of neoaortic and tricuspid valve regurgitation, and may be helpful in assessing left ventricular size in neonates with borderline left heart physiology in whom two-ventricle reconstruction is being contemplated.

NATURAL HISTORY

Various morphologic forms of hypoplastic left heart physiology constitute the fourth most common congenital cardiac defect. About 70% of cases are boys. Severe heart failure usually develops in the first week of life. Many neonates die within 1 to 2 weeks of birth; only 40% survive the neonatal period, and survival beyond 6 weeks of age is uncommon (Fig. 49-6). Hypoplastic left heart physiology accounts for 25% of cardiac deaths during the first week of life and 15% of those in the first month of life.

The ductus arteriosus typically begins to close shortly after birth. In some infants, ductal closure leads to restriction of systemic perfusion, metabolic acidosis, and circulatory collapse.

Figure 49-4  Echocardiographic findings in hypoplastic left heart physiology. A, Parasternal long-axis view of neonate with aortic atresia, severely hypoplastic ascending aorta (AAO), severely hypoplastic left ventricle, and mitral atresia. In this image, the 1.5-mm-diameter ascending aorta is shown longitudinally. The large pulmonary trunk (PT) is also shown. Right pulmonary artery (RPA) is visible in cross-section posterior to small ascending aorta. Left atrium (LA) is present in this image, but ventricular mass is not shown. B, Subcostal image showing four-chamber view of neonate with aortic atresia and mitral atresia, with severely hypoplastic left ventricle (LV). Right atrium (RA) and right ventricle (RV) are visualized and are markedly enlarged. LA is small, and LV cavity is miniscule. There is no direct communication between LA and hypoplastic LV. Ascending aorta and pulmonary trunk are not visualized in this image.
collapse; and death. If the ductus continues to remain patent, a progressive increase in pulmonary circulation and a subsequent decrease in systemic circulation lead to pulmonary edema, coronary hypoperfusion, generalized systemic hypoperfusion, and ultimately death. Rarely, long-term survival will occur if the ductus remains patent and pulmonary vascular resistance (Rp) fails to fall in the perinatal and neonatal period.

**TECHNIQUE OF OPERATION**

There are two basic surgical options—reconstruction and cardiac transplantation—for treating hypoplastic left heart physiology. Reconstructive surgery includes the Norwood procedure and its variants, and the hybrid procedure. In a recent survey of practices related to this condition, 86% of 52 institutions recommend as primary treatment the Norwood procedure or one of its variants, and 14% did not make a recommendation, but left the decision solely up to the parents. No institution recommended primary transplantation, the hybrid procedure, or comfort care.\(^2\)

**Reconstructive Surgery**

The overall goal of reconstructive surgery is similar to that for any patient with single-ventricle physiology (see Chapter 41)—that is, establishing in the neonatal period an effective mixed circulation in which pulmonary (Qp) and systemic (Qs) blood flow are well balanced, followed by one or more operations performed later in infancy or early childhood after Rp has dropped to normal postnatal levels. The purpose of subsequent operations performed outside the neonatal period is to move away from the inefficiency of the completely mixed circulatory state. It should be emphasized that all definitive repairs in hypoplastic left heart physiology are palliative.

The exact form of definitive repair may vary from patient to patient based on the individual’s physiologic status. Given the inherently limited reserve of the single right ventricle, it is generally agreed that a completely mixed circulatory state, even one that provides ideal balance between Qp and Qs, is not an acceptable definitive state for hypoplastic left heart physiology. Acceptable definitive repairs include the completed Fontan procedure, the Fontan procedure with fenestration, superior cavopulmonary anastomosis, and superior cavopulmonary anastomosis with additional limited systemic to pulmonary blood flow.

Regardless of the definitive repair, principles of initial surgical management are generally agreed upon. Some variation of the Norwood procedure is considered optimal initial therapy. Its purpose is to provide (1) a completely unobstructed systemic arterial pathway from the right ventricle to all organs, (2) a restrictive connection between the systemic and pulmonary circulations such that Qp and Qs are adequately balanced, and (3) unobstructed flow of pulmonary venous return across the atrial septum to the right atrium.

**Preoperative Management**

Perinatal preoperative management is critical to successful outcome. This may include prenatal transport of the mother and fetus to a cardiac center following fetal diagnosis.\(^25,33\) Circulatory collapse is usually the result of closure of the ductus arteriosus in the setting of undiagnosed hypoplastic left heart physiology. This may occur when the infant is still in hospital following birth, or after discharge home. If prenatal diagnosis is made and mother and fetus are transferred to an appropriate facility where the infant will undergo surgery, circulatory collapse is all but eliminated.
Low- to moderate-dose dopamine and dobutamine should increase systemic vascular resistance, which profoundly increase systemic vascular resistance and may unpredictably alter systemic circulation. PGE\(_1\) achieves moderate elevation of Pa\(_o\_2\) and Qp/Qs includes a Pa\(_o\_2\) of about 40 mmHg (Torr) and a systemic diastolic blood pressure greater than 30 mmHg. Even these ideal values do not guarantee that the expected blood flow values in fact do exist. For example, Pa\(_o\_2\) can be influenced by other factors: hemoglobin level, metabolic state, temperature, and presence of sepsis to name a few. Furthermore, the inevitable reduction in Rp that occurs over time commonly thwarts all efforts to maintain systemic output and balanced Qp and Qs. If this occurs, operation should be scheduled immediately.

For the typical neonate diagnosed early after birth and in whom circulatory collapse has not occurred, the ideal time for surgical intervention is about 2 to 5 days. In this window of time, the infant completes the profound physiologic changes from fetal life to independent life, yet consequences of a continuously increasing Qp have not yet taken their toll. If circulatory collapse does occur and end-organ damage results, a longer time before operation is often necessary to allow end-organ recovery. Although not always advisable, ideally, normal function of renal, hepatic, neurologic, gastrointestinal, and cardiopulmonary systems should be documented following resuscitation prior to proceeding with operation. It is not uncommon for organ systems to recover fairly rapidly but then plateau short of complete recovery. Further delay of operation at that point is usually detrimental.

Although mild obstruction of flow across the atrial septum is typical at the time of Doppler color flow interroga- tion during diagnostic echocardiography, severe obstruction at the atrial septum may occur, resulting in a clinical presentation similar to that found with obstructive total anomalous pulmonary venous connection (see Chapter 31), with deep cyanosis, pulmonary edema, and eventual hemodynamic instability. This presentation evolves rapidly immediately after birth and must be addressed within hours. Such patients are best managed with percutaneous interventional techniques to create an adequate atrial septal opening, followed by several days of stabilization before proceeding with operation. Management as described earlier continues during transport to the operating room and during surgery until CPB is instituted. The operation can be performed using continuous CPB by way of antegrade cerebral perfusion or using hypothermic circulatory arrest, according to choice of the operating surgeon. Both techniques are described in text that follows.

Neurologic development following operations for hypoplastic left heart physiology is below normal. Although impaired neurologic development is multifactorial, there is little question that circulatory arrest is contributory. Antegrade cerebral perfusion provides the advantage of continuous blood flow and oxygenation to the brain; however, it is possible that this technique also introduces new risks. It is unlikely that techniques of reconstruction that avoid circulatory arrest will result in dramatic changes in short-term

---

**Figure 49-7** Survival of neonates with optimal medical treatment. Format of figure is as in Fig. 49-6. Although estimates represent survival before transplantation, similar survival is achieved with optimal medical treatment prior to reconstruction. (Modified from Jacobs and colleagues.)

After diagnosis, the infant is resuscitated, and prostaglandin E\(_1\) (PGE\(_1\)) therapy is initiated. Depending on details of the physiologic status of the infant and stability of the infant at initial diagnosis, subsequent preoperative management may vary from essentially no further intervention on the one hand, to maximal intervention on the other. The typical patient, however, shows signs of pulmonary overcirculation, and preoperative management is aimed at reversing or at least controlling this to preserve end-organ and myocardial function.

Supportive therapy in the perinatal and neonatal periods can substantially alter natural history. Judicious use of inotropic support, PGE\(_1\) therapy, nutritional supplementation, and ventilation with 17% or 19% oxygen along with supplemental CO\(_2\) administration may delay the typical physiologic decompensation for a number of weeks (Fig. 49-7). When indicated, mechanical ventilation can add an extra measure of support. In many cases, the respiratory depression side effect of PGE\(_1\) therapy may warrant mechanical ventilation.

These maneuvers are aimed at achieving a balance of Qp and Qs and maintaining unobstructed and adequate systemic perfusion. Because flow into the pulmonary circuit is unobstructed, Rp at the microvascular level will determine Qp. Any maneuver that causes dilatation of the pulmonary microvasculature will result in excessive Qp. Specifically, avoiding supplemental inspired oxygen is critical to the overall strategy; 21% oxygen or even lower Fi\(_o\_2\) helps maintain tone in the pulmonary microvasculature. If this maneuver is not adequate, controlled ventilation through an endotracheal tube achieves moderate elevation of PaCO\(_2\), causing acidosis, which further constricts pulmonary microvasculature. PGE\(_1\) maintains ductal patency, ensuring unobstructed blood flow to the systemic circulation.

Inotropic agents can be used to enhance cardiac output in the setting of moderate pulmonary overcirculation, but this strategy must be undertaken cautiously because these agents also affect systemic and pulmonary vascular resistances and may unpredictably alter Qp/Qs. Epinephrine and high-dose dopamine, which profoundly increase systemic vascular resistance, should be avoided (see Section IV of Chapter 4). Low- to moderate-dose dopamine and dobutamine should be considered the first-line inotropic agents when supplemen- tal cardiac output is considered necessary.

All these maneuvers are used to create optimal preoperative cardiopulmonary status. Assessing cardiopulmonary status is somewhat indirect. Currently, Qp and Qs cannot be easily directly measured in the cardiac intensive care unit (ICU). Indirect measures of adequate systemic output include normal peripheral perfusion, adequate urine output, and absence of metabolic acidosis. Evidence of a reasonable balance of Qp and Qs includes a Pa\(_o\_2\) of about 40 mmHg (Torr) and a systemic diastolic blood pressure greater than 30 mmHg. Even these ideal values do not guarantee that the expected blood flow values in fact do exist. For example, Pa\(_o\_2\) can be influenced by other factors: hemoglobin level, metabolic state, temperature, and presence of sepsis to name a few. Furthermore, the inevitable reduction in Rp that occurs over time commonly thwarts all efforts to maintain systemic output and balanced Qp and Qs. If this occurs, operation should be scheduled immediately.

For the typical neonate diagnosed early after birth and in whom circulatory collapse has not occurred, the ideal time for surgical intervention is about 2 to 5 days. In this window of time, the infant completes the profound physiologic changes from fetal life to independent life, yet consequences of a continuously increasing Qp have not yet taken their toll. If circulatory collapse does occur and end-organ damage results, a longer time before operation is often necessary to allow end-organ recovery. Although not always advisable, ideally, normal function of renal, hepatic, neurologic, gastrointestinal, and cardiopulmonary systems should be documented following resuscitation prior to proceeding with operation. It is not uncommon for organ systems to recover fairly rapidly but then plateau short of complete recovery. Further delay of operation at that point is usually detrimental.

Although mild obstruction of flow across the atrial septum is typical at the time of Doppler color flow interroga- tion during diagnostic echocardiography, severe obstruction at the atrial septum may occur, resulting in a clinical presentation similar to that found with obstructive total anomalous pulmonary venous connection (see Chapter 31), with deep cyanosis, pulmonary edema, and eventual hemodynamic instability. This presentation evolves rapidly immediately after birth and must be addressed within hours. Such patients are best managed with percutaneous interventional techniques to create an adequate atrial septal opening, followed by several days of stabilization before proceeding with operation. Management as described earlier continues during transport to the operating room and during surgery until CPB is instituted. The operation can be performed using continuous CPB by way of antegrade cerebral perfusion or using hypothermic circulatory arrest, according to choice of the operating surgeon. Both techniques are described in text that follows.

Neurologic development following operations for hypoplastic left heart physiology is below normal. Although impaired neurologic development is multifactorial, there is little question that circulatory arrest is contributory. Antegrade cerebral perfusion provides the advantage of continuous blood flow and oxygenation to the brain; however, it is possible that this technique also introduces new risks. It is unlikely that techniques of reconstruction that avoid circulatory arrest will result in dramatic changes in short-term
survival, because factors related to hypothermia, CPB itself, and myocardial ischemia are not avoided. Long-term benefits related to neurologic development may exist but are yet to be proven.

Norwood Procedure Using Continuous Perfusion
Although several techniques for accomplishing the Norwood procedure using continuous perfusion have been described, the one presented has been used routinely since 1997 by one of the authors (FLH), with some modifications.

After median sternotomy, the thymus is subtotaly removed and the anterior pericardium opened widely. Aortic arch vessels are dissected well above the brachiocephalic vein. The small aorta is separated from the pulmonary trunk and right pulmonary artery, and the ductus arteriosus, aortic arch, and proximal descending thoracic aorta are dissected.

Marking 7-0 monofilament sutures are placed on adjacent portions of the pulmonary trunk and ascending aorta to indicate the point of eventual pulmonary trunk–to-aorta anastomosis. Positions of these marking sutures are chosen with great care because they will determine the correct orientation of, and incisions in, the aorta and pulmonary trunk necessary to create a functional anastomosis; alignment of this anastomosis is critical for unobstructed coronary blood flow in aortic atresia. The first marking suture is placed in the adventitia of the pulmonary trunk 1 to 2 mm above the sinotubular junction and circumferentially exactly where the small ascending aorta lies against it. The second suture on the aortic adventitia is placed so that its position coincides exactly with the pulmonary trunk suture.

A purse-string suture is placed on the brachiocephalic artery about 5 mm distal to the takeoff of the artery from the arch. It is often necessary to place it above the brachiocephalic vein. Purse-string sutures are placed on the superior and inferior venae cavae. A 5-0 monofilament suture is placed around the pulmonary artery end of the ductus arteriosus.

An 8F (or in patients weighing <3 kg, 6F) arterial cannula is inserted into the brachiocephalic artery, and angled 12F venous cannulae are placed into the venae cavae. Alternatively, a single venous cannula can be used, placed in the right atrial appendage (Fig. 49-8, A). Brachiocephalic artery cannulation must be performed accurately; however, experience shows that it can be routinely performed successfully even in patients weighing 3.0 kg or less. Cannulation is best performed by puncturing the artery without using a clamp, and inserting the tip of the cannula to a depth less than the width of the artery, typically 2 to 3 mm.

After venous cannulation and institution of CPB, the ductus arteriosus is immediately ligated (see Fig. 49-8, A). Core temperature is reduced to 20°C. During cooling, the pulmonary trunk is transected just above the pulmonary valve in standard fashion (Fig. 49-8, B). The distal opening in the pulmonary trunk is then closed directly or patched with an oval piece of pulmonary allograft or other material (see Fig. 49-8, B). A clamp is placed across the ascending aorta just proximal to the brachiocephalic artery once the target core temperature has been achieved. Cardioplegia is introduced into the ascending aorta. The ascending aorta is then opened to the level of the transected pulmonary trunk, and the side-to-side anastomosis between proximal pulmonary trunk and ascending aorta is accomplished with interrupted 6-0 or 7-0 monofilament sutures (Fig. 49-8, C).

In preparation for arch reconstruction, direct CPB flow is isolated to the brachiocephalic artery only. This is accomplished by clamping the base of the brachiocephalic, left carotid, and left subclavian arteries individually with delicate neurovascular clips, and placing a C-shaped clamp across the descending thoracic aorta approximately 1.5 to 2 cm below the ductal insertion (Fig. 49-8, D). Perfusion, now through the distal brachiocephalic artery only, is reduced to 30 to 40 mL · kg⁻¹ · min⁻¹, allowing normal brain perfusion.

The original clamp placed across the ascending aorta is removed. The ductus is divided distal to the previously placed suture. The previous incision in the ascending aorta is then continued around the arch, then beyond the ductus, approximately 1.5 cm onto the descending aorta. Ductal tissue is trimmed, and allograft patch reconstruction of the aortic arch, ascending aorta, and pulmonary trunk is performed. The caval cannulae are snared. A right atriotomy is made, and the septum primum is completely removed to create a nonrestrictive interatrial communication. The right atriotomy is closed, and the neurovascular clips on the base of the brachiocephalic artery and the C-clamp on the descending aorta are removed. Total body perfusion is reestablished and increased to normal levels; rewarming is begun.

The last step in the operation is creating a source of pulmonary blood flow. At the choice of the operating surgeon, this can be achieved using either a restrictive systemic arterial–to-pulmonary arterial shunt or a restrictive right ventricular–to-pulmonary arterial conduit. If a shunt is chosen, typically a polytetrafluoroethylene (PTFE) interposition graft is sewn into place from the junction of the brachiocephalic and right subclavian arteries to the proximal portion of the right pulmonary artery (Fig. 49-8, E). Both anastomoses are performed using end graft–to-side artery connections with running 7-0 monofilament or PTFE suture. Variation in positioning the PTFE shunt must be considered based on individual patient characteristics to achieve an appropriate balance of Qp and Qs.

In patients weighing less than 3 kg and in those demonstrating very low Rp preoperatively, it may be necessary to perform the systemic connection of the shunt anastomosis at a more distal site on the right subclavian artery. In most cases, a 3.5-mm-diameter PTFE tube graft is used for the shunt procedure; rarely is a larger diameter necessary. Often in patients weighing less than 3 kg, and most frequently in patients weighing less than 2.5 kg, a 3.0-mm-diameter graft should be considered, although risk of shunt thrombosis may increase with a small-diameter shunt. If the right ventricular–to-pulmonary arterial conduit is performed, a PTFE graft of appropriate diameter is chosen. Alternatively, a composite graft consisting of a proximally positioned PTFE tube and a distally positioned small (6- to 7-mm-diameter) allograft pulmonary or aortic valve can be used (Fig. 49-8, F and G). Regardless of whether a simple conduit or composite conduit is chosen, the diameter of the PTFE tube determines the resistance to flow into the pulmonary arteries. Typically, a 4-mm-diameter graft is used for patients weighing less than 3 kg, a 5-mm-diameter graft for those between 3 and 4 kg, and a 6-mm-diameter graft for those greater than 4 kg.

An incision is made in the infundibular portion of the right ventricle, just below the pulmonary valve. A 5- to 6-mm-diameter circular full-thickness resection of infundibular muscle is then made. It is extremely important that...
the caliber of the resulting hole in the infundibulum is maintained transmurally to prevent premature stenosis at this level postoperatively. Using a running 7-0 monofilament suture, the graft is first sewn end to side to the pulmonary trunk, either to the pulmonary artery directly adjacent to the suture line that previously closed the distal pulmonary trunk, or to the center of the patch that was used to close the distal pulmonary trunk. The graft is then positioned to the left of the reconstructed aorta and tailored in length to reach the infundibulotomy. The proximal end of the graft is carefully beveled to the appropriate angle to ensure a smooth course around the large reconstructed aorta. The anastomosis is performed using a running 6-0 monofilament suture.

Once normothermia is achieved, the patient is separated from CPB and decannulated. Management following separation from CPB is described under “Post–Cardiopulmonary Bypass Management” later in this chapter.

**Norwood Procedure Using Hypothermic Circulatory Arrest**

The heart is exposed by median sternotomy, removal of most of the thymus gland, and opening of the pericardium. If the patient is unstable at this point because of increased $Q_p$, the right pulmonary artery can be exposed immediately and clamped to reduce overall $Q_p$ and maintain systemic circulation until CPB is established.
The patient is prepared for CPB by placing a purse-string suture on the pulmonary trunk just distal to the pulmonary valve. A second purse-string suture is placed around the tip of the right atrial appendage. At that point, if the patient is physiologically stable, the pulmonary trunk is separated from the ascending aorta using either scissors or electrocautery. The ductus arteriosus, aortic arch, and arch vessels are then mobilized using scissors or electrocautery all the way to the first set of intercostal vessels on the descending aorta. Temporary snares are placed around all brachiocephalic arteries.

If the patient becomes physiologically unstable, CPB can be initiated at any time and the great vessel dissection performed with its support. CPB is established using an arterial cannula in the pulmonary trunk and a single venous cannula in the right atrial appendage (Fig. 49-9, A). At initiation of CPB, the branch pulmonary arteries are temporarily occluded with clamps or snares to eliminate pulmonary blood flow.

After initiating CPB, while the pulmonary trunk and aorta are still distended with blood, 7-0 monofilament sutures are placed on adjacent portions of the pulmonary trunk and ascending aorta to mark the point of eventual pulmonary trunk-to-aorta anastomosis. Positions of these marking sutures are chosen with great care because they will determine
completed aortic arch reconstruction. To complete the procedure using a right ventricle to pulmonary artery conduit, an appropriately sized tube of PTFE, or, as shown, composite of PTFE and valved allograft, is used. Prior to placing the conduit, the composite graft is constructed during the initial cooling phase of cardiopulmonary bypass. An aortic or pulmonary allograft valved conduit, either 6- or 7-mm diameter (or a 9- or 10-mm diameter allograft reduced to a bicuspid conduit) is connected end to end to a 3-cm length of PTFE graft. Valved conduit is placed distally within the composite, as shown. A 5- to 6-mm diameter core of infundibular free-wall myocardium is removed from right ventricle just below pulmonary valve. It is critical to remove a uniform full-thickness core of tissue rather than just incise the hypertrophied right ventricle; this prevents stenosis at the inlet to the conduit. Great care should be taken not to injure pulmonary valve or chordae of tricuspid valve (infundibular incision and tissue core removal can, if preferred, be performed before reperfusion of myocardium is initiated; this may provide more controlled conditions). Distal aspect of allograft conduit is connected end to side into transverse pulmonary artery centrally, either near the suture line that closed the distal pulmonary artery stoma created by previous pulmonary trunk transection, or into the patch used to close distal pulmonary artery stoma. This is accomplished with a running suture technique using 7-0 nonabsorbable monofilament suture. Pulmonary arteries are allowed to assume their natural position, and the PTFE proximal portion of the composite is tailored to appropriate length and beveled in preparation for proximal anastomosis of PTFE component to infundibulotomy site. 

**Figure 49-8, cont’d**  
**F.** Completed aortic arch reconstruction. To complete the procedure using a right ventricle to pulmonary artery conduit, an appropriately sized tube of PTFE, or, as shown, composite of PTFE and valved allograft, is used. Prior to placing the conduit, the composite graft is constructed during the initial cooling phase of cardiopulmonary bypass. An aortic or pulmonary allograft valved conduit, either 6- or 7-mm diameter (or a 9- or 10-mm diameter allograft reduced to a bicuspid conduit) is connected end to end to a 3-cm length of PTFE graft. Valved conduit is placed distally within the composite, as shown. A 5- to 6-mm diameter core of infundibular free-wall myocardium is removed from right ventricle just below pulmonary valve. It is critical to remove a uniform full-thickness core of tissue rather than just incise the hypertrophied right ventricle; this prevents stenosis at the inlet to the conduit. Great care should be taken not to injure pulmonary valve or chordae of tricuspid valve (infundibular incision and tissue core removal can, if preferred, be performed before reperfusion of myocardium is initiated; this may provide more controlled conditions). Distal aspect of allograft conduit is connected end to side into transverse pulmonary artery centrally, either near the suture line that closed the distal pulmonary artery stoma created by previous pulmonary trunk transection, or into the patch used to close distal pulmonary artery stoma. This is accomplished with a running suture technique using 7-0 nonabsorbable monofilament suture. Pulmonary arteries are allowed to assume their natural position, and the PTFE proximal portion of the composite is tailored to appropriate length and beveled in preparation for proximal anastomosis of PTFE component to infundibulotomy site. 

**G.** Proximal anastomosis of conduit to infundibulotomy is performed with a running stitch using 6-0 nonabsorbable monofilament suture.

the correct orientation of, and incisions in, the aorta and pulmonary trunk necessary for creating a functional anastomosis; alignment of this anastomosis is critical for unobstructed coronary blood flow in aortic atresia. The first marking suture is placed in the adventitia of the pulmonary trunk 1 to 2 mm above the sinutubular junction and circumferentially exactly where the small ascending aorta lies against it. The second suture on the aortic adventitia is placed so that its position coincides exactly with the pulmonary trunk suture (see Fig. 49-9, A).

When the nasopharyngeal or tympanic membrane temperature reaches 16°C to 18°C after cooling with CPB for an appropriate period (see Section IV of Chapter 2), the snares around the brachiocephalic vessels are tightened and circulatory arrest established. Snares around the left and right pulmonary arteries are removed, and cannulae are removed from the pulmonary trunk and right atrial appendage after draining as much blood volume from the patient into the pump-oxygenator as possible.

Management of myocardial protection is variable. Some experienced centers use no specific cardioplegia and rely on profound hypothermia as the only form of myocardial management. Other experienced institutions use cardioplegia, which can be supplied in several ways. Cannulation of the ascending aorta can be achieved with an appropriately small needle and cardioplegia delivered directly into the aortic
Figure 49-9  Norwood procedure using hypothermic circulatory arrest. **A,** Arterial cannula is placed into pulmonary trunk through a purse-string suture, and the single venous cannula is placed into right atrial appendage. Dashed line on proximal pulmonary trunk shows intended transection site, and dashed line on ascending aorta and aortic arch shows site and extent of intended aortic incision. Marking sutures are placed on pulmonary trunk and ascending aorta precisely where the two dashed lines in this figure converge. After these two marking sutures are placed, aorta and pulmonary trunk should be allowed to assume their natural positions. Under these conditions, examining the two marking sutures with the vessels in their distended state should reveal that these two sutures are touching each other, without even the slightest amount of circumferential or longitudinal offset. As soon as cardiopulmonary bypass (CPB) is instituted, left and right pulmonary arteries must be controlled with either snares or small vascular clamps (not shown in this figure). **B,** After target core temperature is reached, circulatory arrest is instituted and myocardial protection addressed; ductus arteriosus is ligated and transected as shown. It is common practice to temporarily occlude brachiocephalic, left carotid, and left subclavian arteries with snares or small vascular clamps before opening the aorta. Either at this point or following arch reconstruction, atrial septum must be resected. A limited right atriotomy is made and the septum primum identified and resected with scissors. Septum primum should be resected completely, but care taken not to overextend the resection into thickened portion of limbus or conduction area. Right atriotomy is then closed with a running monofilament suture. Dashed lines signify point of pulmonary trunk transection and extent of ascending arch and descending aortic incision. Note that the descending aortic incision extends approximately 5 to 10 mm beyond the ductal insertion site. **C,** Pulmonary trunk has been transected. There is often very little distance between top of pulmonary valve commissures and origin of right pulmonary artery. During pulmonary trunk transection, care should be taken not to injure the commissure of the pulmonary valve or extend incision into orifice of right pulmonary artery. Once transection is completed, the stoma in the distal pulmonary trunk is closed transversely as shown with a running 7-0 absorbable monofilament suture. Incision in aorta is also shown. Proximal extent of this incision is terminated precisely at previously placed marking suture. **D,** Before beginning arch augmentation, allograft patch is tailored to the size of the infant. Patch is roughly triangular in shape; base of triangle will ultimately be sutured to circumference of proximal pulmonary trunk, so width of base should roughly equal circumference of pulmonary trunk. Other two free edges of patch will be anastomosed to posterior and anterior free edges of incised aorta. The edge of the patch that will be sutured to posterior aspect of incised aorta should be shorter than edge that will be sutured to anterior free edge of aorta. If this is not the case, or if entire patch is too long, kinking of reconstruction can result. Also, apical half of the triangularly shaped patch should not be too broad. Patch is sewn into place beginning at most distal aspect of aortic incision, well beyond ductal insertion site. A running 7-0 monofilament nonabsorbable suture is used and posterior suture line is developed first, extending roughly to area opposite brachiocephalic artery origin. Following this, anterior suture line is developed in like fashion.
Continued

Figure 49-9, cont’d  E, Distal aspect of patch suture line is completed. Attention is then turned to proximal aspect of aortic incision and to proximal pulmonary trunk. Interrupted 7-0 monofilament nonabsorbable sutures are placed to connect proximal ascending aorta to proximal pulmonary trunk. First suture in this series of five to seven interrupted sutures should be placed precisely at the points of the two previously placed marking sutures. Once this is completed, proximal end of patch is connected to circumference of proximal pulmonary trunk. Prior to final sutures being placed, a probe that can comfortably pass into proximal aorta to the level of coronary arteries is used to confirm patency and appropriate alignment of proximal aorta. F, Completed aortic arch reconstruction. To complete procedure using a systemic-to-pulmonary shunt, an appropriately sized tube of expanded polytetrafluoroethylene (PTFE) is chosen and connected from systemic circulation into pulmonary circulation. If shunt is placed during circulatory arrest, vascular clamps generally are not necessary. However, if shunt is placed after reestablishing CPB, brachiocephalic artery and its branches and right pulmonary artery must be controlled with side-biting vascular clamps.

The ductus is transected just beyond the previously placed ligature. Redundant ductal tissue is cut away from the distal aorta, leaving a small cuff of ductal tissue at the level of the aortic isthmus. A 5- to 10-mm incision is made from the ductal orifice into the descending aorta to the level of the first set of intercostal vessels (see Fig. 49-9, C). A proximal incision is made beginning at the ductal orifice and moving retrograde toward the aortic valve. This incision proceeds along the undersurface of the aortic arch and extends down the hypoplastic ascending aorta to within several millimeters of the atretic or hypoplastic aortic valve, terminating at the same level as the transected pulmonary trunk at the point of the previously placed marking suture (see Fig. 49-9, C).

The aorta is then augmented throughout its length from the level of the aortic valve around the arch, to the first set of intercostal vessels, using a patch of pulmonary or aortic allograft tissue (Fig. 49-9, D). The patch is tailored to provide adequate but not excessive widening of the aorta. Suturing is begun at the distal end of the incision beyond the isthmus on the upper descending aorta and progresses retrograde until the proximity of the brachiocephalic artery is reached.

root. Alternatively, the cardioplegia system can be connected to the arterial cannula in the pulmonary trunk, and cardioplegia delivered into this cannula after circulatory arrest has been established while the brachiocephalic vessel snare is still in place. The only additional maneuver before proceeding with cardioplegia delivery using this method is to clamp the descending aorta distal to the ductal insertion site. The cardioplegic solution is delivered through the arterial cannula into the pulmonary trunk through the ductus and retrograde around the arch to the coronary arteries. All other peripheral runoff through this circuit must be reliably eliminated (see “Methods of Myocardial Management during Cardiac Surgery” in Chapter 3).

After myocardial protection has been addressed and circulatory arrest established, the ductus arteriosus is ligated distal to the origin of the left pulmonary artery. A small atriotomy is made, and through it the entire septum primum is removed to create an unrestrictive intraatrial communication. To avoid conduction problems, care is taken not to extend the resection beyond the septum primum. The atriotomy is closed (Fig. 49-9, B).

The pulmonary trunk is divided transversely as proximal as possible without risking damage to the pulmonary valve, leaving the previously placed marking suture proximal to the transection. As the transection is made, particular care is taken to avoid the orifice of the right pulmonary artery. The distal end of the divided pulmonary trunk is then closed with a patch (typically autologous pericardium or pulmonary artery allograft) using continuous 7-0 polypropylene. Alternatively, the distal pulmonary trunk may be closed primarily in transverse fashion (Fig. 49-9, C). Direct closure has the advantages of time efficiency and less bulk, and in experienced hands has shown no greater tendency to result in pulmonary trunk stenosis than the patch technique.
Figure 49-9, cont’d  

G, Completed aortic arch reconstruction. To complete procedure using a right ventricular–to–pulmonary artery conduit, an appropriately sized PTFE tube or, as shown, composite of PTFE and valved allograft is used. Before placing conduit, composite graft is constructed during initial cooling phase of CPB. An aortic or pulmonary allograft valved conduit, either 6- or 7-mm diameter (or a 9- or 10-mm-diameter allograft reduced to a bicuspid conduit) is connected end to end to a 3-cm length of PTFE graft. Valved conduit is placed distally within the composite, as shown. Next part of procedure can be performed either under circulatory arrest or after perfusion has been reestablished. A 5- to 6-mm-diameter core of infundibular free-wall myocardium is removed from right ventricle just below pulmonary valve. To prevent stenosis at the inlet to the conduit, it is critical to actually remove a uniform full-thickness core of tissue rather than just incise the hypertrophied right ventricle. Great care should be taken not to injure pulmonary valve or tricuspid valve chordae. Distal aspect of allograft conduit is connected end to side into transverse pulmonary artery centrally, either near suture line that closed the distal pulmonary artery stoma created by previous pulmonary trunk transaction, or into the patch used to close distal pulmonary artery stoma. This is accomplished with a running suture technique using 7-0 nonabsorbable monofilament suture. Pulmonary arteries are allowed to assume their natural position, and PTFE proximal portion of composite is tailored to appropriate length and beveled in preparation for proximal anastomosis of PTFE component to right ventriculotomy site. 

H, Proximal anastomosis of conduit to infundibulotomy is performed with a running stitch using 6-0 nonabsorbable monofilament suture.

The posterior suture line is developed first, using a running technique and 6-0 or 7-0 nonabsorbable monofilament suture, followed by the anterior suture line.

At this point, the allograft augmentation of the arch is temporarily set aside, and the proximal end of the divided pulmonary trunk is anastomosed side to side to the incised hypoplastic aorta (Fig. 49-9, E). This portion of the anastomosis is typically performed with five to seven interrupted 6-0 or 7-0 monofilament nonabsorbable sutures. The first of these connects the end of the aortic incision to the cut edge of the pulmonary trunk exactly where the previously placed marking suture was positioned. On each side of this interrupted suture, two to three other interrupted sutures are placed, attaching first the posterior and then the anterior edge of the longitudinally incised aorta to the circumference of the proximal pulmonary trunk. Care should be taken with small aortas (<3 mm diameter) not to connect them to too broad a segment of pulmonary trunk circumference, because this can stretch the aortic tissue and flatten and obstruct the orifice leading to the coronaries.
Finally, the allograft patch suture line progresses from the level of the brachiocephalic artery down to the aortic-to-pulmonary anastomosis and around the remaining free edge of the proximal portion of the right pulmonary artery (see Fig. 49-9, F). This completes the right ventricular-to-systemic arterial outflow reconstruction.

The last step in the operation is creating a source of pulmonary blood flow. At the choice of the operating surgeon, this can be achieved using either a restrictive systemic arterial–to–pulmonary arterial shunt or a restrictive right ventricle–to–pulmonary arterial conduit. If a shunt is chosen, typically a PTFE interposition graft is sewn into place from the junction of the brachiocephalic and right subclavian arteries on the systemic side to the proximal portion of the right pulmonary artery (see Fig. 49-9, F). Both anastomoses are performed using end graft–to–side artery connections with running 7-0 monofilament or PTFE suture. Variation in positioning of the PTFE shunt must be considered, based on individual patient characteristics, to achieve an appropriate balance of $Q_p$ and $Q_s$.

In patients weighing less than 3 kg and in those demonstrating very low Rp preoperatively, it may be necessary to perform the systemic pulmonary arterial shunt anastomosis at a more distal site on the right subclavian artery. In most cases, a 3.5-mm-diameter PTFE tube graft is used for the shunt procedure; a larger diameter is rarely necessary. Often in patients weighing less than 2.5 kg, a 3.0-mm-diameter graft should be considered, although risk of shunt thrombosis may increase with a smaller-diameter shunt. If circulatory arrest is prolonged, or by surgeon preference, the shunt may be placed after reestablishing flow on CPB.

If a right ventricular–to–pulmonary arterial conduit is chosen, a PTFE graft of appropriate diameter is selected. Alternatively, a composite graft consisting of a proximally positioned PTFE tube and a distally positioned small (6- to 7-mm diameter) allograft pulmonary or aortic valve can be used (Fig. 49-9, G and H). Regardless of whether a simple conduit or composite conduit is chosen, the diameter of the PTFE tube determines the resistance to flow into the pulmonary arteries. Typically, a 4-mm-diameter graft is used for patients weighing less than 3 kg, a 5-mm-diameter graft for those between 3 and 4 kg, and a 6-mm-diameter graft for those greater than 4 kg.

An incision is made in the infundibular portion of the right ventricle, just below the pulmonary valve. A 5- to 6-mm-diameter circular full-thickness resection of infundibular muscle is then made. It is extremely important that the caliber of the resulting hole in the infundibulum is maintained transmurally to prevent premature stenosis at this level postoperatively. Using a running 7-0 monofilament suture, the graft is first sewn end to side to the pulmonary trunk, either to the pulmonary artery directly, adjacent to the suture line that previously closed the distal pulmonary trunk, or to the center of the patch that was used to close the distal pulmonary trunk. The graft is then positioned to the left of the reconstructed aorta and tailored in length to reach the infundibulotomy. The proximal end of the graft is carefully beveled to the appropriate angle to ensure a smooth course around the large reconstructed aorta.

The anastomosis is performed using a running 6-0 monofilament suture. The right atrial and systemic arterial cannulae are reinserted, CPB is reestablished, and rewarming begun. If a systemic-to-pulmonary shunt has been placed, it is occluded with a vascular clamp during the rewarming phase of CPB. When the patient’s tympanic membrane or nasopharyngeal temperature reaches 25°C to 30°C, perfusate ionized calcium concentration is measured and calcium chloride added to bring the ionized calcium concentration to a normal level (see Section III of Chapter 2). Separation from CPB is accomplished and decannulation achieved. Details of post-CPB management follow.

**Post–Cardiopulmonary Bypass Management**

Whether the operation is performed using continuous perfusion or circulatory arrest, post-CPB management is generally the same. Before the patient is separated from CPB, inotropic support is initiated, and particular attention is given to complete reexpansion of both lungs. Endotracheal suctioning by the anesthesiologist is routine. If a systemic-to-pulmonary shunt was used, after complete rewarming has been achieved, approximately 5 minutes before discontinuing CPB, the clamp on the shunt is removed.

Careful attention is given to the mean arterial pressure on CPB at this point; typically a decrease of 10 to 15 mmHg should be expected, indicating adequate runoff into the pulmonary vascular bed. If this decrease is not observed, the cause must be identified. The systemic-to–pulmonary trunk shunt should be immediately assessed for obstruction due to a technical problem. If a right ventricle–to–pulmonary arterial conduit was used, diastolic blood pressure is not affected.

After rewarming has been completed, CPB is discontinued and the aortic and venous cannulae removed. Postoperative care begins immediately (see Special Features of Postoperative Care later in this chapter). Two separate polyvinyl catheters (or a single double-lumen catheter) are placed directly into the right atrial appendage and brought out through the chest wall to continuously monitor atrial pressure and provide reliable access for delivering blood products and pharmacologic support. Arrial and ventricular temporary epicardial pacing wires are placed. Chest drainage tubes are placed appropriately for neonates undergoing CPB (see “Completing Operation” in Section III of Chapter 2).

It may be beneficial to leave the sternum and soft tissue temporarily unapproximated during the early recovery period. This allows for maximal cardiopulmonary function during the first 24 to 48 hours postoperatively and easy accessibility to the mediastinum if aggressive resuscitative measures are necessary. When this “open chest” option is exercised, the skin is sealed with an oval silicone rubber sheet or some other appropriate material. After the patient’s cardiopulmonary status has stabilized (48 to 96 hours postoperatively), the sheet is removed under sterile conditions, and the sternum and soft tissues closed in standard fashion. This can be accomplished routinely and effectively in the ICU without returning the patient to the operating room. At some institutions, the “open sternum” option is standard following first-stage reconstruction for hypoplastic left heart physiology.

**Technical Modifications of the Norwood Procedure**

A number of modifications of the standard ascending aorta and arch reconstruction described in the preceding text have been developed. However, the physiologic principles of providing unobstructed ventricular-to-systemic arterial output and appropriately balanced $Q_p$ and $Q_s$ remain the same. Several groups have introduced techniques of reconstructing
the ventricular-to-systemic arterial outflow without use of patch material.\textsuperscript{10,12} Much experience has been obtained, and perioperative outcome and some midterm outcome data are available using these alternative techniques. Theoretical advantages include avoiding foreign patch material and the possibility of a modest reduction in circulatory arrest time. Disadvantages include potential problems with suture line tension, left pulmonary artery and left bronchus compression, and increased resistance to flow to the coronary system.

Currently, there is no clear evidence that these alternative techniques are better or worse than the more standard arch reconstruction technique. Other modifications in the surgical treatment of neonates with hypoplastic left heart physiology have been reported.\textsuperscript{58,74} The right ventricle-to-pulmonary artery conduit, if used, can be placed to the right side of the reconstructed ascending aorta rather than to the left side as described. This is believed by some to have advantages.\textsuperscript{89}

Hybrid Procedure

Some surgeons prefer the hybrid procedure to the Norwood procedure or one of its variants as a primary procedure in high-risk patients (i.e., those with prematurity, low birth weight, associated genetic or other noncardiac comorbid conditions, extreme shock, or various real or perceived cardiac risk factors, such as severe tricuspid regurgitation, depressed right ventricular function, intact or highly restrictive atrial septum, aortic atresia with mitral stenosis, and very small-diameter ascending aorta). The procedure is ideally performed in a hybrid operating suite, essentially a cardiac catheterization laboratory that also has the dimensions and capability to support major surgery and use of CPB.

Preoperative management is the same as for a patient undergoing a Norwood procedure. The patient is anesthetized, prepped, and draped in the supine position, just as in a formal operating room. CPB support is available. Pulmonary artery branch bands are prepared from segments of PTFE tube grafts. For patients weighing 3 kg or more, 3-mm-diameter grafts are selected. For patients weighing less than 3 kg, 2.5-mm grafts are chosen. The bands are cut to a width of approximately 2 mm.

A median sternotomy incision is made, the pericardium opened, and the branch pulmonary arteries exposed. If the patient is unstable because of pulmonary overcirculation, the right branch pulmonary artery can be temporarily occluded with a delicate neurovascular clip. Care must be taken not to distort the small ascending aorta, particularly if aortic atresia is present. The right and left branch pulmonary arteries are sequentially exposed and banded (Fig. 49-10, A). The bands are performed before the ducal stent is placed to prevent migration of the stent during manipulation of the pulmonary artery branches. Position of the bands is confirmed by angiography (Fig. 49-10, B). A purse-string suture is placed on the pulmonary trunk immediately proximal to the take-off of the right pulmonary artery, and a 5F or 6F sheath system is inserted through the purse string and advanced over a guidewire through the ductus and into the descending aorta.\textsuperscript{33}

Accurate delineation of the ductal anatomy by angiography is important before deploying the ductal stent. After determining ductal dimensions with angiography, the stent is inserted and deployed (Fig. 49-10, C). Another angiogram is performed to assess stent position. If the stent does not cover the entire length of the ductus, ductal narrowing and systemic outflow obstruction may result. If the stent is too long, it could obstruct the origin of the pulmonary arteries or retrograde flow into the proximal arch and ascending aorta, which could be catastrophic in patients with aortic atresia (Fig. 49-10, D).

Once position of the stent is confirmed, PGE\textsubscript{1} infusion is discontinued. Based on hemodynamic and echocardiographic data, adequacy of the atrial septal communication is assessed. If deemed restrictive, and depending on the nature of the restriction, a balloon atrial septotomy or deployment of an atrial septal stent is performed. The completed procedure is shown in Fig. 49-10, E. Routine echocardiographic assessment is performed on arrival in the ICU and weekly until the patient is discharged. The chest is closed over a single drainage tube. Postoperative care is similar to that after the Norwood procedure.

Alternative techniques have been described for the hybrid procedure. These include a left thoracotomy approach,\textsuperscript{91} different methodology and materials for the pulmonary artery bands,\textsuperscript{94} and use of long-term PGE\textsubscript{1} (avoiding stents) to maintain ductal patency.\textsuperscript{57}

Bidirectional Superior Cavopulmonary Anastomosis (Hemi-Fontan Procedure)

These procedures are performed as a second stage following the Norwood procedure. Bidirectional superior cavopulmonary anastomosis and the hemi-Fontan procedure are described under Technique of Operation in Chapter 41. Because it is generally accepted that there remains substantial risk of mortality in the period between hospital discharge following a successful first-stage reconstruction for hypoplastic left heart physiology and creation of the bidirectional superior cavopulmonary anastomosis,\textsuperscript{1,8} the second-stage procedure should be performed relatively soon, typically between age 3 and 6 months. Following creation of the bidirectional superior cavopulmonary anastomosis, hemodynamic efficiency is markedly improved and mortality risk substantially reduced.\textsuperscript{1,8} Data suggest that somatic growth does not occur in patients with first-stage palliation after age 4 months.\textsuperscript{45}

Early construction of the bidirectional superior cavopulmonary shunt has two other advantages:

1. It allows use of a relatively small-diameter systemic-to-pulmonary shunt or right ventricular-to-pulmonary conduit at the time of first-stage reconstruction. This creates an ideal Qp/Qs ratio during the first months following birth and does not require the initial shunt or conduit to have a life expectancy of more than 6 months. As a result, the initial shunt or conduit does not have to be “oversized” in anticipation of the growing infant requiring increased Qp in later infancy. This promotes early hemodynamic stability.

2. It reduces duration of inefficient mixed circulation that is present with a shunt or conduit. This allows maximal preservation of right ventricular function by reducing right ventricular volume work, mortality risk, and chance of distortion of the pulmonary arteries caused by tethering from the PTFE graft.

Comprehensive Second-Stage Procedure Following Hybrid Procedure

This is a complex operation requiring CPB, aortic clamping, and (by preference) either antegrade cerebral perfusion or hypothermic circulatory arrest. Exposure is by median
A, Inset shows preparation of bands from appropriately sized polytetrafluoroethylene (PTFE) tube grafts. (See text for criteria used to choose correct tube graft diameter). Main figure shows the PTFE band placed on right pulmonary artery. Care must be taken not to place the band too proximal, thereby potentially obstructing the small ascending aorta, and not too distal, thereby potentially distorting upper-lobe branch of right pulmonary artery. Left pulmonary artery band is being positioned, preferably midway between the origin and the lobar arterial branching point. Bands are secured to adventitia of branch pulmonary arteries to avoid migration. B, Angiogram confirming positioning of right pulmonary artery band. C, Pulmonary artery bands are in place. Purse-string suture of 5-0 polypropylene is placed anteriorly in pulmonary trunk. Using the Seldinger technique, a 5F or 6F sheath system is inserted through purse string and advanced over a guidewire into descending aorta. A hand injection of contrast using a lateral projection is used to demonstrate ductal anatomy. After determining ductal dimensions, a (premounted) Palmaz Genesis stent (Cordis Co., Miami, Fla.) is advanced through the sheath system into position and expanded with the balloon angioplasty catheter.

Reconstruction involves removing the ductus arteriosus and stent, Norwood neoaorta and arch reconstruction, removing the pulmonary artery bands with possible branch pulmonary artery reconstruction, atrial septectomy or removal of atrial septal stent, and creating a bidirectional superior cavopulmonary anastomosis. In essence, it embodies most of
the technical components of the Norwood operation, with
the addition of a reoperative setting. Technical details of
the procedure are shown in Fig. 49-11.

Fontan Operation
The Fontan operation is described under Technique of
Operation in Chapter 41. Once the bidirectional superior
cavopulmonary shunt has been constructed, considera-
tions for completing the Fontan procedure, although somewhat
complex, remain no different from those for any other
single-ventricle anomaly.

Cardiac Transplantation
Principles of preoperative management are generally similar
to those described for reconstructive surgery, but donor
hearts are not usually available within the 3- to 5-day period
thought to be ideal for performing the Norwood procedure.
The waiting period for a donor heart may extend to several
weeks or longer. Infants who maintain relatively high Rp can
be discharged from the acute care facility, but they must be
maintained on a constant infusion of PGE₁ by a portable
intravenous pump (see Fig. 49-7). Infants in whom pulmo-
nary overcirculation with systemic undercirculation develops
require constant intensive care with varying degrees of
support to maintain cardiopulmonary stability.

General techniques of cardiac transplantation are described
under Technique of Operation in Chapter 21. The special
methods necessary for patients with forms of hypoplastic left
heart physiology have been described as well. Donor
hearts are harvested with the ascending, transverse arch, and
upper descending thoracic aorta intact.

After recipients are placed on CPB as described for
the Norwood procedure, cooling to 16°C to 18°C is begun.

The ductus arteriosus is excised from the aorta as in the
Norwood procedure. An aortic incision is made into the
descending aorta approximately 1 cm beyond the ductal
insertion site and retrograde around the aortic arch to the
base of the brachiocephalic artery. Native cardiectomy is per-
formed by transecting the ascending aorta proximal to the
brachiocephalic artery and the pulmonary trunk near its bifur-
cation. The atrial-level incisions are performed in standard
fashion.

The donor heart is then implanted. The broadly beveled
aorta is anastomosed to the recipient aortic arch beginning
at a level opposite the origin of the brachiocephalic artery
and extending to the proximal descending aorta beyond
the ductal insertion. Donor pulmonary trunk is anastomosed
to recipient distal pulmonary trunk. Atrial anastomoses
are performed in standard fashion. The transplantation
procedure is modified appropriately when the patient has
already undergone first-stage reconstruction (Norwood
procedure).

SPECIAL FEATURES OF POSTOPERATIVE CARE
Care after first-stage reconstruction is particularly complex
and important (see “Management of Hypoplastic Left Heart
Physiology” in Section I of Chapter 4 and Section IV of
Chapter 5). Many of the same physiologic issues present
preoperatively remain. Qp/Qs must still be balanced; however,
an appropriately sized shunt or conduit makes this
more manageable postoperatively. Maintaining adequate sys-
temic cardiac output despite well-balanced systemic and
pulmonary blood flow distribution is more of a challenge
postoperatively because of depressed cardiac function result-
ning from operation. Aggressive use of inotropic support is
usually more warranted postoperatively than preoperatively.
Chapter 49  Aortic Atresia and Other Forms of Hypoplastic Left Heart Physiology

Figure 49-11  Comprehensive second-stage procedure following hybrid reconstruction. A, Pre–second-stage illustration showing bilateral pulmonary artery banding and ductal stenting in place. B, Excision of ductus and ductal stent en bloc in preparation for aortic arch and neoaortic reconstruction, performed as a standard Norwood arch reconstruction using pulmonary artery allograft patch. Patch closure of distal pulmonary trunk as well as proximal end of ductus is performed using pulmonary artery allograft patch. Pulmonary artery bands have been removed. Note mild distortion at band sites. If stenosis is present at band sites, patch augmentation using pulmonary artery allograft patch is performed (not shown). C, Endarterectomy-like removal of ductal stent through transected distal pulmonary trunk. As shown, depending on the time elapsed since initial palliation, partial removal of intima and part of the media is common, without complete disruption of vascular wall, therefore reducing magnitude of reconstruction. D, Completed second-stage reconstruction with superior bidirectional cavopulmonary anastomosis. (From Pizarro and colleagues.6)

Following transport from the operating room to the cardiac ICU, these infants are managed with aggressive sedation and pharmacologic paralysis for at least 24 hours. Sedation is typically administered using intravenous fentanyl and midazolam, and paralysis is achieved with a continuous infusion of pancuronium. Thus, the infant’s metabolic demands are minimized, and complete ventilatory control is possible. Depending on status of $Q_p/Q_s$—assessed by clinical evaluation and arterial blood gases—rate of ventilation, tidal volume, and $F_{O_2}$ can all be manipulated to maximize $Q_p/Q_s$ balance. An appropriate combination of tidal volume and ventilatory rate is used to achieve optimal $PaCO_2$. If assessment of the infant is that $Q_p$ is inadequate, either due to a restrictive shunt or conduit or pulmonary hypertension, ventilation is increased to reduce $PaCO_2$ to approximately 30 to 35 mmHg (Torr). If the assessment is that $Q_p$ is excessive, ventilation is adjusted to allow $PaCO_2$ to increase to approximately 45 to 50 mmHg. If $Q_p$ is assessed to be adequate, $PaCO_2$ is adjusted to 40 mmHg. Similarly, $F_{O_2}$ can be adjusted over a range from 17% to 100%, depending on $Q_p$ and $R_p$. Higher levels of $F_{O_2}$ are used when $Q_p$ is judged to be inadequate, and lower levels if it is judged to be excessive. In a patient whose
Qp is considered adequate, FiO₂ is usually reduced to approximately 25% to 30% within several hours after operation.

Some institutions suggest using additional inspired CO₂ both to limit excessive Qp and independently improve Qs. This practice is somewhat controversial.

Use of nitric oxide in the setting of reduced Qp should be limited to patients in whom there is clear evidence of an adequately sized shunt or conduit and elevated pulmonary Rp. Use of nitric oxide for a patient with inadequate Qp caused by an excessively restrictive shunt or conduit is ineffective and inappropriate. Such a patient should immediately be returned to the operating room for shunt or conduit revision.

A typical level of inotropic support in the early postoperative period includes moderate dopamine (3 to 10 mg · kg⁻¹ · min⁻¹, continuous infusion) and milrinone (0.5 mg · kg⁻¹ · min⁻¹), with or without addition of low-dose epinephrine (0.03 to 0.05 mg · kg⁻¹ · min⁻¹) (see Section IV of Chapter 5). Substantially larger doses of inotropic drugs are as likely to harm as help. Specifically, for the patient who shows evidence of excessive Qp and reduced systemic perfusion, increasing inotropic support is likely to exacerbate the physiologic imbalance.

Other maneuvers that maximize oxygen delivery to the systemic tissues include optimizing cardiac output by taking advantage of the Frank-Starling curve (see “Cardiovascular Subsystem” in Section I of Chapter 5). Typically, adjusting atrial filling pressures with volume supplementation to achieve pressures between 6 and 12 mmHg addresses this point. Optimizing oxygen-carrying capacity by adjusting the hematocrit to a minimum of 45% is advised. Despite maximizing cardiac output and balancing Qp and Qs, it is not uncommon for patients to show evidence of marginally inadequate systemic perfusion during the first 24 hours after operation.

Metabolic acidosis with base deficits ranging from 0 to −5 are not uncommon and should be treated aggressively with either intermittent bicarbonate or continuous bicarbonate infusion.

Urine output is also commonly reduced during the first 24 hours (<1 mL · kg⁻¹ · h⁻¹), and periods of anuria may occur. If anuria or oliguria persists beyond the first 6 hours postoperatively, serious consideration should be given to placing a peritoneal dialysis catheter (see “Renal Subsystem” in Section I of Chapter 5).

If the infant is returned to the ICU from the operating room with the sternum left open, it should not be closed until hemodynamic status is stabilized. This typically takes 36 to 48 hours. If instability persists, sternal closure can be delayed for as long as 4 to 5 days. If the infant arrives in the ICU from the operating room with the sternal wound completely closed, consideration should be given to opening it in the ICU if hemodynamics are inadequate during the first 24 hours. Substantial cardiac and pulmonary stability can be achieved with this simple maneuver.

After approximately 36 to 48 hours, or after sternal closure, sedation and paralysis can be gradually removed, allowing the patient to take over respiratory function. The weaning process from the ventilator follows the standard principles that apply to all infants following cardiac surgery (see “Pulmonary Subsystem” in Section I of Chapter 5). Prolonged ventilatory support is not unusual following the Norwood procedure and may extend to 5 to 10 days, even in patients who have no definable cardiovascular or pulmonary problem. Under these circumstances, nutrition becomes critical.

Typically, total parenteral nutrition is begun within 48 hours of operation and may be continued or converted to direct enteral feeding using a nasogastric tube. Enteral feeding should be used as soon as cardiovascular stability has been achieved and return of intestinal function is documented.

Some form of antiplatelet therapy is generally recommended to inhibit thrombosis of the shunt or conduit. A typical regimen is to institute aspirin therapy (1 mg · kg⁻¹ · d⁻¹) as soon as perioperative hemorrhage is controlled. Care after the bidirectional superior cavopulmonary shunt and Fontan operation is described under Special Features of Postoperative Care in Chapter 41. Postoperative care following transplantation is similar to that for other cardiac transplant patients (see Features of Postoperative Care in Chapter 21).

RESULTS
First-Stage Reconstruction (Norwood Procedure)

Early (Hospital) Death
Early mortality remains variable among institutions. At institutions with a large experience in neonatal cardiac surgery, mortality following first-stage reconstruction steadily improved in the decades between 1985 and 2005, and then subsequently plateaued, with current hospital mortality of approximately 20%, 41,3,13,3,5,5,6,8,7,1,7,1 In a report from a single institution with a large experience (Mott Children’s Hospital, Ann Arbor, Mich.), hospital mortality after first-stage reconstruction was 58% (CL 51%-65%) between 1986 and 1989, and 15% (CL 11%-20%) between 1990 and 1993, reflecting the trend in improved results experienced at most institutions committed to neonatal cardiac surgery. 41

Other single-institution studies reporting cases from 2002 to 2005 indicated hospital mortality of 6.2% (2/32; CL 2.2%-14%), 44 9.1% (6/66; CL 5.4%-14%), 41 and 11% (10/88; CL 7.8%-16%). 45 The Congenital Heart Surgeons Society (CHSS) report of 622 cases performed between 2001 and 2004 indicated early mortality of 17% (CL 16%-19%). 51 In contrast, at less experienced institutions, hospital mortality still approached 50%. The University Hospital Consortium reported 53% mortality (118/222) among 40 institutions, each performing an average of 7.2 procedures during the 5-year period of the study; however, all cases were performed before 1995. 41,16

Survival following first-stage reconstruction performed in multiple institutions between 1994 and 1997 for patients specifically with aortic atresia is shown in Fig. 49-12. Survival was about 10% higher at all intervals at the two institutions with the best outcomes in this multicenter study.

Time-Related Survival
Overall, 12-month survival after first-stage reconstruction has been approximately 60%, with nearly all deaths occurring before the second-stage procedure (bidirectional superior cavopulmonary shunt). In one large series, survival was 66% at 1 month, 48% at 12 months, and 44% at 18 months, emphasizing ongoing risk of death even after successful first-stage reconstruction. 41,14 In another series, 6 of 41 early survivors (15%) died within 3 to 5 months after operation. 43 In the recently completed 15-center study conducted by the
**Figure 49-12** Non-risk-adjusted survival and hazard function for 253 patients with hypoplastic left heart physiology initially entered into a protocol of staged reconstructive surgery (Norwood procedure) at multiple institutions. **A,** Survival after entry. **B,** Hazard function for death. Lines, bars, and numbers have representation similar to Fig. 49-6. (From Jacobs and colleagues.\(^2\))

**Figure 49-13** Death or transplantation among infants undergoing Norwood procedure, randomized to either modified Blalock-Taussig shunt (MBT shunt) or right ventricle–to–pulmonary artery conduit (RVPA shunt). \(P = .02\) for difference in treatment effect for period before and period after 12 months. **A,** Transplantation-free survival. **B,** Hazard function. (From Ohye and colleagues.\(^5\))

Pediatric Heart Network, 1-year survival was 74% for patients with a right ventricle–to–pulmonary trunk conduit procedure, and 64% for those with a systemic artery–to–pulmonary artery shunt procedure\(^6\) (Fig. 49-13). Recognition of this pattern of ongoing mortality after hospital discharge has spawned the term *interstage death.* Interstage death of 10%\(^4\) and 16%\(^8\) are typical.\(^4\)

Establishment of home monitoring programs, designed to engage parents and primary cardiologists in recognizing early signs and symptoms of patient destabilization, has substantially decreased mortality between a successful first operation and the anticipated second-stage operation, with some reports showing no interstage deaths.\(^4,11\)

**Incremental Risk Factors for Death after Operation** Morphologic factors have been associated with risk of death in some series but not in others. In an early study from 1986 by Norwood’s group, atrial septal anatomy, preoperative right ventricular hypertrophy, ascending aorta diameter, and coarctation were not correlated with early survival.\(^5\) Although not supported by the two largest institutional experiences, some institutions suggest that aortic atresia and very small size of the ascending aorta (diameter < 2 mm) may be associated with increased risk for death, both early\(^7\) and late\(^3\) after first-stage reconstruction. Intact or highly restrictive atrial septum has been widely associated with increased risk of both early and interstage death.\(^9,14,15\)
The combination of mitral stenosis and aortic atresia has recently been identified as a risk, particularly when left ventricular-to-coronary artery fistulae are present. In one study, fetal diagnosis has been shown to decrease the risk of death following first-stage reconstruction, suggesting that factors such as prenatal transport and early postnatal stabilization may improve survival. In another, however, prenatal diagnosis was strongly correlated with superior preoperative clinical status but did not influence surgical outcome. Moderate or severe tricuspid valve regurgitation preoperatively and depressed right ventricular function preoperatively have correlated with increased risk of death after first-stage reconstruction.

An initially low arterial pH has not correlated with increased risk of deaths in some studies; whereas in others it has. Small size at operation has been identified as a risk. Associated noncardiac anomalies (e.g., tracheoesophageal fistula, renal dysplasia, biliary atresia, intracranial abnormalities, pulmonary dysplasia) have been shown to increase risk. In one large single-institution study, age older than 7 days at time of first-stage reconstruction was a risk factor for interstage death. In another study, postoperative bradycardia and reduced ventricular function were noted to be risks. A less-than-optimal technical operation has also been identified as a risk factor for death.

These various studies that identify different risk factors underscore the wide variability among institutions.

**Hemodynamic and Morphologic Results**

Atrial septectomy performed at first-stage reconstruction usually results in a nonrestrictive opening between the two atria. A gradient in excess of 4 mmHg across the atrial septum develops in about 4% of patients. About 10% of patients have significant (grade 3 or 4) tricuspid valve regurgitation late after first-stage reconstruction. In interpreting this, the fact that this physiologic variable is a risk factor for death after first-stage operation must be considered.

Systolic pressure gradients are rarely present between right ventricle and reconstructed ascending aorta, indicating that the native pulmonary valve functions well in the setting of systemic outflow. In approximately 10% to 15% of patients, the distal portion of the aortic arch is narrowed such that a systolic pressure gradient greater than 25 mmHg is present. This gradient typically occurs at the distal limit of the allograft patch. It is most likely due to lack of growth potential at this site resulting from a combination of patch material and circumferential ductal tissue in the native aorta. All patients who have undergone reconstruction for hypoplastic left heart physiology should be evaluated for potential gradients at this site. Aggressive treatment is necessary; often this can be accomplished effectively with percutaneous balloon dilatation.

Most patients have a $Q_p/Q_s$ of 0.8 to 2.0 at the time of cardiac catheterization performed in preparation for the second-stage superior cavopulmonary shunt. Approximately 15% to 20% of patients have elevated Rp greater than 4 Wood units. Pulmonary artery distortion is present in a minority of patients, typically at the central pulmonary trunk site under the aortic arch, or at the shunt or conduit insertion site. Right ventricular end-diastolic pressure is typically somewhat elevated but is greater than 12 mmHg in approximately 10% of patients. A hypoplastic left pulmonary artery has been associated with larger diameter of the reconstructed aorta.

**First-Stage Reconstruction (Hybrid Procedure)**

**Early (Hospital) Death**

Early mortality has been as low as 2.5% (1/40; CL 0.41-8.2%) and as high as 29% (6/21; CL 18%-42%), with other series reporting 5.6% (1/18; CL 0.90%-18%), 12% (4/33; CL 6.3%-21%), 18% (2/11; CL 6.8%-38%), and 20% (2/10; CL 7.0%-41%).

**Time-Related Survival**

Time-related survival after the hybrid procedure, which includes interstage survival and survival following comprehensive second-stage surgery, is about 60%. It is influenced by development of obstruction to retrograde flow in the aortic arch caused by the ductal stent in patients with aortic atresia.

Fig. 49-16 shows time-related survival following the hybrid procedure. Other reports confirm a relatively high interstage mortality (21%) and comprehensive second-stage mortality (14%).

---

**Figure 49-14** Survival after first-stage reconstruction for hypoplastic left heart physiology in anatomic subtype aortic atresia with mitral stenosis. Survival is stratified by presence or absence of echocardiographic or angiographic presence of left ventricle (LV)-to-coronary artery fistulae. Risk appears to reside in this subgroup having fistulae because mortality for aortic atresia with mitral stenosis without fistulae is more favorable, similar to other anatomic subtypes. (From Pigula and colleagues.)

**Figure 49-15** Early survival after the first-stage Norwood operation (October 1984–March 1987), according to degree of preoperative tricuspid regurgitation. (From Barber and colleagues.)
Based on results from several institutions with a large experience managing hypoplastic left heart physiology, early mortality following bidirectional superior cavopulmonary anastomosis currently is about 5\%^{12,25} (Fig. 49-17).

**Time-Related Survival**
Because of the marked improvement in physiologic status following bidirectional superior cavopulmonary anastomosis, mortality following the perioperative period and before the Fontan procedure is generally extremely low\(^{12}\) (see Fig. 49-17).

**Third-Stage Reconstruction (Fontan Operation)**
In theory, there should be no difference in outcome following the Fontan operation for patients with hypoplastic left heart physiology than for patients having other forms of univentricular heart. The logic behind this statement is the same as that given in the previous discussion of outcome following bidirectional superior cavopulmonary anastomosis. This has been confirmed by at least one large single-institution study.\(^{12}\) The outcomes discussed here for the Fontan operation in patients with hypoplastic heart physiology should be supplemented by the general discussion of outcomes following the Fontan procedure for all forms of univentricular heart (see Results in Chapter 41).

**Early (Hospital) Death**
In the early era, mortality after the Fontan operation for hypoplastic left heart physiology was high—8 patients in 50 (16%; CL 11%-23\%) reported by Chang and colleagues from Norwood’s group.\(^{6}\) More recent estimates of hospital mortality in larger patient cohorts from several institutions is about 5\%^{12,25} (see Fig. 49-17).

**Incremental Risk Factors for Death after Operation**
Aortic atresia with obligatory retrograde flow in the aortic arch appears to be a risk factor for death after the hybrid procedure (see Fig. 49-16).

**Hemodynamic and Morphologic Results**
About 50\% of patients undergoing the hybrid procedure require an interstage catheter-based intervention or surgical intervention before comprehensive second-stage reconstruction.\(^{14}\)

**Second-Stage Reconstruction (Bidirectional Superior Cavopulmonary Anastomosis)**
Outcome following bidirectional superior cavopulmonary anastomosis or hemi-Fontan procedure in hypoplastic left heart physiology is similar to that for patients with other forms of univentricular heart. This naturally follows from the fact that all patients with univentricular heart, including those with hypoplastic left heart physiology, are selected for bidirectional superior cavopulmonary anastomosis based on similar physiologic criteria.

Because a number of institutions with extensive experience with surgery for hypoplastic left heart physiology have reported outcomes, there are ample data on survival following each stage of operation in these patients. These data are supplemented by the more general discussion of outcome following bidirectional superior cavopulmonary anastomosis in all forms of univentricular heart (see Results in Chapter 41).

Although there is probably no difference in survival between hypoplastic left heart physiology patients and other univentricular heart patients following bidirectional superior cavopulmonary anastomosis, it is not clear whether hypoplastic left heart physiology patients are as likely as other univentricular heart patients to meet the physiologic criteria necessary to undergo bidirectional superior cavopulmonary anastomosis. Based on a number of factors, including marginal hemodynamics after first-stage reconstruction and ongoing mortality, it is likely that a smaller percentage of these patients will eventually undergo bidirectional superior cavopulmonary anastomosis.
Incremental Risk Factors for Death
Incremental risk factors for death following the Fontan operation are similar in all forms of univentricular heart (see Chapter 41).

Other Commonly Performed Operations
The two most commonly performed additional procedures performed in patients undergoing the standard three-stage protocol are repair of recurrent arch obstruction and tricuspid valve repair for regurgitation. These can be performed either at the time of the second- or third-stage procedure, or separately.

Recurrent arch obstruction can be effectively addressed in most cases with catheter-based balloon dilatation. Typically, recurrent arch obstruction is noted in infancy, and commonly in the first 6 months after the initial Norwood procedure.\(^\text{5,10,15}\) It occurs in about 20% of survivors.\(^\text{5,10,15}\) Overall risk is low, and gradient relief is excellent. Two single-institution studies revealed no mortality related to the procedure, and gradient relief in all patients, which persisted at midterm follow-up.\(^\text{5,10,15}\) One multicenter analysis showed initial success of 89%, with three deaths occurring within 48 hours of the dilatation in patients with poor ventricular function, and freedom from repeat arch intervention of 74% at 18 months.

Tricuspid valve repair can be accomplished with low mortality and midterm (mean 26 months) success (defined as less than moderate residual regurgitation) of 62%.\(^\text{13}\) Patients with poor right ventricular function after valve repair, even if the repair was initially successful, tended to do poorly, with progressive deterioration of the valve over time. Patients with an unsuccessful initial valve repair but preserved ventricular function often benefited from a second valve repair.

Cardiac Transplantation
Experience with cardiac transplantation in neonates with hypoplastic left heart physiology is small relative to the experience with reconstructive surgery and is limited to a few institutions. General information on the results of cardiac transplantation (see Results in Chapter 21) is applicable to this subpopulation. The early concept that neonates receiving cardiac transplants were “privileged hosts” does not appear to have held up. Rejection frequency and severity in neonates appears to be similar to that in the broader cardiac transplantation experience.\(^\text{16}\)

In the Loma Linda experience, 84 neonates have received cardiac transplants, with 13% (CL 7%-23%) early (30-day) mortality and 5-year survival of 82% (CL 71%-88%).\(^\text{16}\) Including patients who died while awaiting transplant, 5-year survival was 61% (CL 52%-70%).\(^\text{16}\)

A recent multicenter study shows similar midterm survival in institutions accomplished with these procedures\(^\text{12}\) (Fig. 49-18). Early in the experience, suppressive immunotherapy included cyclosporine and azathioprine without use of long-term steroid therapy. Steroids and antithymus globulin were used only for early rejection episodes. Currently, suppressive immunotherapy varies somewhat among institutions; however, in general, long-term therapy varies little relative to that given other cardiac transplant recipients (see Chapter 21).
High early survival has been the rule following neonatal cardiac transplantation for patients with hypoplastic left heart physiology, based on individual reports of several experienced institutions. Intermediate-term results have been acceptable and comparable with intermediate-term results for cardiac transplantation in general. On the other hand, surgical mortality (excluding preoperative death) for transplantation was 42% (17/40; CL 34%-52%) among a consortium of institutions infrequently performing this procedure. In contrast, the more recent report from the Pediatric Heart Transplant Study Group reports 5-year survival (also excluding preoperative death) of 72%, with most of the deaths occurring in the first 3 months after operation. When preoperative death is included, survival at 5 years falls to 54%. An important factor that is difficult to quantify is the death rate of neonates born with hypoplastic left heart physiology while awaiting an appropriate donor organ.

Because of limitations of donors heart availability, the typical neonate must wait several weeks to months before receiving a heart. The intrinsic instability of hypoplastic left heart physiology in its natural state can result in mortality during this time. Attempts have been made to quantify recipient mortality while awaiting a donor organ, but reliable information is scarce. In a multicenter study from 1998, 36 of 49 patients (73%) entered into a transplant protocol received a donor heart; the estimate of time-related interim mortality while awaiting transplant is shown in Fig. 49-7. A more recent multicenter study from the Pediatric Heart Transplant Study group analyzed 262 patients; 25% of listed patients died while awaiting transplantation (Fig. 49-19). The mean waiting period for those receiving an organ was 1.3 months.

**INDICATIONS FOR OPERATION**

Hypoplastic left heart physiology is a fatal condition; death usually occurs within 1 month of birth and certainly within 1 year (see Fig. 49-7). Surgical intervention is therefore advisable unless economic conditions or lack of institutional capability deny this possibility, or the patient’s legal guardians choose to withhold surgical therapy. Curiously, this latter practice remains relatively widespread, even though current treatment outcomes for hypoplastic left heart physiology are now comparable with outcomes for other cardiac defects for which the option to withhold support is not offered by managing physicians and other healthcare providers.

If intervention is to be accomplished, management should begin as soon as possible, preferably with prenatal arrangements for delivery at an institution capable of neonatal resuscitation and subsequent surgical management. Treatment begins at birth or as soon as diagnosis has been made, and consists initially of intensive preoperative therapy. Neonates with hypoplastic left heart physiology usually can be resuscitated and maintained in stable condition with such intervention, and the surgical procedure can be performed as an elective procedure, ideally between 2 and 5 days of life.

Whether staged reconstruction or cardiac transplantation is the treatment of choice remains controversial. Although reconstructive surgery remains the predominant method of managing patients with hypoplastic left heart physiology, there currently are no clear data to recommend reconstruction or transplantation as the procedure of choice. Equivalent outcomes, as judged by early and midterm survival, can be achieved with either treatment.

**SPECIAL SITUATIONS AND CONTROVERSIES**

**Aortic Atresia with Large Ventricular Septal Defect**

Although this lesion includes aortic atresia, it is not representative of hypoplastic left heart physiology. A two-ventricle repair is recommended because such patients commonly have a normal mitral valve and left ventricle. One approach is to perform a typical first-stage reconstruction in the neonatal period, followed by a definitive repair in which the left ventricle is baffled to the pulmonary trunk using a Rastelli-type repair (see “Rastelli Operation” under Intraventricular Repair in Chapter 52). In this repair, left ventricular outflow is baffled to the pulmonary trunk by an intracardiac patch, a
right ventricular to distal pulmonary artery conduit is placed, and takedown of the previously placed systemic–pulmonary trunk shunt is performed.

Alternatively, a one-stage complete repair in the neonate can be accomplished. Anecdotal reports of success with this procedure were reported in the 1980s and 1990s. In this procedure, the pulmonary trunk and hypoplastic aorta are reconstructed in typical fashion for first-stage reconstruction for hypoplastic left heart physiology. After completing the extracardiac portion of the procedure, the left ventricle is baffled to the pulmonary trunk with a Rastelli-type intracardiac patch. The operation is completed by placing a valved conduit from right ventricle to distal pulmonary arteries. More recently, single-institution series, reporting experience ranging from 11 to 21 cases, indicate that the operation can be performed with very low early and midterm mortality.15,22,30,31,34

Borderline Hypoplastic Left Heart Physiology

Because of the continuum of morphologic and physiologic compromise among patients with left heart anomalies, clinical decision making can be extremely difficult. Individual patients are positioned along this continuum, yet the surgeon is forced to make a dichotomous management decision. Whether to proceed with a two-ventricle repair or disregard the left-sided structures and perform a single-ventricle repair can be a difficult decision. Although a number of studies have addressed this issue, attempting to quantify the various physiologic and morphologic components of the left heart, the decision remains subjective.22,35,39,46

Pulmonary autograft aortic valve replacement (Ross procedure) in infants and neonates in recent years introduces another factor into this decision-making process (see “Autograft Pulmonary Valve” under Technique of Operation in Chapter 12, and “Repair of Tunnel Stenosis by Aortoventriculoplasty [Konno Operation]” and “Modified Konno Operation” in Section II of Chapter 47). Ability to perform the Ross procedure along with Konno enlargement of the left ventricular outflow tract, in combination with arch reconstruction and resection of left ventricular endocardial fibroelastosis, provides the opportunity to create two-ventricle repairs in patients considered to be poor candidates using older criteria.35,46

Using aggressive left heart reconstructive techniques, it is possible to physiologically normalize the entire left ventricular outflow tract and improve left ventricular cavity size and diastolic function by resecting the constricting endocardial fibroelastosis. In a small experience of one of the authors (FLH) with such borderline hypoplastic left heart patients, it has been found that the true limiting factor for successful two-ventricle repair is size and function of the mitral valve. Except for the mitral valve, it appears that all morphologic components of the left heart can be adequately addressed surgically using these techniques. Although long-term success has been achieved in a small number of patients, it remains controversial regarding when these aggressive techniques should be applied rather than opting for the single-ventricle approach.

Fetal balloon valvuloplasty provides an additional therapeutic option for patients with a borderline left heart. The sole purpose of the procedure is to convert patients to biventricular physiology who otherwise are destined for single-ventricle physiology. This procedure was first performed in 1989, but only 12 cases were performed between 1989 and 1997. Recently, McElhinney and colleagues reported their experience in 47 cases.30 After a learning curve, they currently quote 75% technical success and 10% fetal demise. Thirty percent of those undergoing a technically successful fetal procedure ultimately achieved a two-ventricle circulation. In all of these, additional postnatal, surgical, or interventional procedures were necessary. This experience convincingly demonstrates that fetal balloon valvuloplasty can be technically performed with reasonable safety in the majority of selected patients. However, it is not clear that the procedure plays a causal role in converting patients from a univentricular to a biventricular circulation. The physiologic and morphologic selection criteria for entry into the fetal treatment program were not dissimilar to those of the patients treated by one of the authors, cited earlier, who achieved biventricular repair after a postnatal Ross Konno, arch repair, and endocardial fibroelastosis resection—without fetal intervention.

Use or Avoidance of Circulatory Arrest

When performing the Norwood procedure, the decision to use either hypothermic circulatory arrest or continuous perfusion, most commonly in the form of antegrade cerebral perfusion, is made based on surgeon preference. Surgeon preference is most heavily influenced by personal experience and expert opinion, and less so by objective data.30 Hypothermic circulatory arrest techniques have been available for more than 40 years and continue to evolve. Antegrade cerebral perfusion techniques have been available for a little over a decade and are rapidly evolving as well.

Techniques are also now available for reliably performing complex neonatal cardiac surgery, including the Norwood procedure and its variants, without using total body circulatory arrest.31,44,48,53,54 Only limited evidence unequivocally demonstrates that avoiding circulatory arrest is beneficial, but a number of compelling arguments can be made supporting the position that continuous circulation, especially to the brain, should be maintained.

Although numerous maneuvers have been used to minimize unwanted sequelae of controlled cerebral ischemia that attends circulatory arrest, both clinical and animal studies indicate that profound metabolic changes take place within minutes of cessation of blood flow, regardless of temperature of the brain tissue (see Section I of Chapter 2 for details and references). Based on these studies, it is difficult to pinpoint with confidence the threshold for a safe period of circulatory arrest, although several clinical studies have attempted to define that point. The safe period concept is only valid as a tool to be applied prospectively in clinical decision making for individual patients if one assumes that all patients are equally susceptible to cerebral ischemia. There is increasing evidence that this is not the case; it is becoming recognized that genetic polymorphism can influence vulnerability of the brain to ischemic insult from individual to individual.33

Based on data showing that metabolic derangements begin immediately with circulatory arrest, and on carefully conducted animal and clinical studies demonstrating that neurologic sequelae correlate with increasing length of circulatory arrest (see “Safe Duration of Circulatory Arrest” in Section I of Chapter 2), it can be argued that clinical studies
failing to show sequelae following circulatory arrest are simply using end-point criteria that are insensitive to subtle cognitive injury that may occur with shorter arrest periods or are underpowered to demonstrate a difference. The strongest justification for using circulatory arrest has been that instrumentation, cannulae, and techniques are not available to allow repair of complex aortic arch problems in neonates using continuous perfusion. This justification, however, no longer exists.\(^{11,13,15,21}\) Although it is clear that continuous perfusion can eliminate the metabolic derangements that occur with cessation of cerebral blood flow, potential complications relating to techniques required to maintain ongoing perfusion can also occur, and these must be defined and studied.

Safeguards that are necessary to avoid perfusion-related complications, however, should be no different from those of standard CPB. There are limited data directly comparing continuous perfusion and hypothermic circulatory arrest in patients undergoing the Norwood procedure and its variants. There is a single randomized prospective study comparing it with antegrade cerebral perfusion.\(^{31}\) That study did not examine early mortality or morbidity, but focused on neurodevelopmental outcome at midterm follow-up in a single institution; no difference in outcome between the two techniques was demonstrated. This conclusion is of limited value, however, because the methodology used for the antegrade cerebral perfusion group involved periods of hypothermic circulatory arrest, multiple cannulation maneuvers, and baseline perfusion rates (20 mL · kg\(^{-1}\) · min\(^{-1}\)) that many would consider in the low flow range. The critique of this manuscript, which accompanies the publication, emphasizes these limitations and further points out that the compelling theoretical advantages of continuous perfusion must be supplemented by both developing a rigorous physiologic understanding of techniques such as antegrade cerebral perfusion, and standardizing operative techniques that minimize morbidity. The current state-of-the-art of antegrade cerebral perfusion lacks these important components.\(^{33,34}\) Several single-institution studies have established that the Norwood procedure can be performed using continuous perfusion, with early morbidity and mortality comparable with outcomes achieved using hypothermic circulatory arrest.\(^{34,35,28,29}\) Some studies indicate an early survival advantage using antegrade cerebral perfusion.\(^{31}\)

Comparison of Right Ventricle–to–Pulmonary Trunk Conduit and Systemic-to–Pulmonary Artery Shunt as Source of Pulmonary Blood Flow in First-Stage Reconstruction

For decades, a systemic–pulmonary arterial shunt has been the mainstay for providing regulated Qp to the lungs in first-stage reconstruction. The most commonly used procedure for accomplishing this is the modified Blalock-Taussig shunt using a PTFE graft. Its potential disadvantages include excessive volume load, acute thrombosis, and low diastolic blood pressure leading to coronary insufficiency. Although Norwood originally experimented with right ventricle–to–pulmonary artery conduits as the source of pulmonary blood flow in first-stage reconstruction,\(^{37}\) this was quickly abandoned.

Over the past decade, the concept of the right ventricle–to–pulmonary trunk conduit as the source of pulmonary blood flow has been reexamined.\(^{12,34}\) These techniques use either a valved or nonvalved conduit between right ventricle and central distal pulmonary trunk. They have several potential advantages, the most important of which is lack of diastolic runoff from the systemic circulation. This provides importantly elevated diastolic blood pressure in the aorta and coronary arteries compared with the systemic-pulmonary shunt, with the potential advantage of promoting more stable cardiac performance by reducing myocardial oxygen supply/demand mismatch that undoubtedly occurs in the standard Norwood operation, in which the single right ventricle has marked pressure and volume load, yet decreased coronary perfusion. Additional potential advantages include (1) improved development of the left pulmonary artery system because the source of pulmonary blood flow enters the pulmonary arteries more centrally, and (2) ability to easily perform second-stage bidirectional superior cavopulmonary anastomosis without need for CPB. The potential disadvantages of this technique are (1) a right ventriculotomy is required to place the conduit, which may lead to ventricular dysfunction and dysrhythmias; (2) damage to the pulmonary valve may occur at the time of the ventriculotomy; (3) excessive thrombosis is theoretically possible because of relative stasis during diastole; and (4) central pulmonary arterial distortion may occur.

One of the authors (FLH) has exclusively used a composite right ventricle–to–pulmonary trunk valved conduit for first-stage reconstruction since January 2002.\(^{35}\) With this technique, it is immediately apparent that postoperative diastolic blood pressure is markedly improved (Fig. 49-20) compared with both preoperative diastolic blood pressure and traditional expectations for postoperative diastolic blood pressure using a standard systemic-pulmonary shunt. Early postoperative management is simplified, and hospital mortality as low as 8% can be achieved. Others have also noted these hemodynamic advantages.\(^{12}\) Over the past decade, use of the right ventricle–to–pulmonary trunk conduit has increased

---

**Figure 49-20** Difference in preoperative and early postoperative diastolic blood pressure (Δ diastolic pressure) in five patients undergoing first-stage reconstruction utilizing a valved right ventricle–to–pulmonary artery composite graft. Note marked improvement in diastolic blood pressure in all cases.
steadily, and currently it is chosen about as frequently as the systemic-to-pulmonary artery shunt.

Superiority of one technique over the other has not been unequivocally demonstrated, but a number of studies address this question. Many of these are retrospective single-institution studies and are not randomized; important reports are cited and discussed here. Mair and colleagues retrospectively evaluated 32 patients, 18 with a shunt and 14 with a right ventricle-to-pulmonary artery conduit.\textsuperscript{345} They demonstrated better diastolic blood pressure, lower hospital and interstage mortality, and better ventricular function by catheterization at 3 months in the conduit group. There were no thrombotic events. One concern with this study is that the first 18 patients received shunts, and the last 14 conduits.

In another nonrandomized single-institution study of 66 patients, Cua and colleagues showed no difference in morbidity or mortality in 37 shunt patients and 29 conduit patients.\textsuperscript{G11} The conduit group had higher diastolic blood pressure, faster recovery, and shorter hospital stay. Ruffer and colleagues retrospectively analyzed 54 patients, 31 receiving a shunt and 23 a conduit.\textsuperscript{R8} Diastolic blood pressure was higher in the conduit group, and mortality was lower (8.7% vs. 19%, \(P = .12\)). Hospital length of stay and interstage mortality were similar. Pruett and colleagues retrospectively report 159 cases, 103 receiving a shunt and 56 a conduit.\textsuperscript{P9} Mortality was 42% prior to second-stage surgery in the shunt group, compared with 23% in the conduit group. The left pulmonary artery grew more in the conduit group, but the pulmonary trunk was more likely to be hypoplastic. The conduit group was more likely to need reintervention prior to standard second-stage intervention. Caspi and colleagues showed that the Nakata index for conduit patients was greater (240 ± 18 mm\(^2\) · m\(^{-2}\) vs. 190 ± 10 mm\(^2\) · m\(^{-2}\), \(P = .03\)), and branch pulmonary arteries were more equal in size than those in shunt patients.\textsuperscript{C3}

Graham and colleagues reported similar findings as well as higher diastolic blood pressure and lower right ventricular end-diastolic pressure in conduit patients at catheterization in preparation for second-stage intervention.\textsuperscript{G12} Pizzaro and colleagues demonstrated lower operative mortality in the conduit group compared with the shunt group (8% vs. 30%, \(P = .05\)) as well as less need for ventilator manipulation, extracorporeal membrane oxygenation, and delayed sternal closure.\textsuperscript{P5} Tanoue and colleagues demonstrated that overall ventricular performance was comparable at midterm follow-up in both shunt and conduit groups.\textsuperscript{T2} Griselli and colleagues retrospectively evaluated 367 patients and showed lower hospital (15% vs. 31%, \(P < .05\)) and midterm (22% vs. 41%, \(P < .05\)) mortality in the conduit group.\textsuperscript{G13}

Atallah and colleagues showed lower hospital and 2-year mortality in conduit patients compared with shunt patients, as well as improved psychomotor development; however, shunt patients underwent initial surgery between 1996 and 2002, whereas conduit patients underwent surgery between 2002 and 2005.\textsuperscript{A4} In contrast, Tabbutt and colleagues showed similar hospital and midterm survival and hospital length of stay in 149 patients (95 shunts, 54 conduits) but also an increased need for early reintervention in the conduit group.\textsuperscript{T1} Lai and colleagues reviewed 80 patients and showed similar early mortality in the conduit and shunt groups, but noted that six of 41 shunt survivors died before second-stage intervention, whereas none of the 29 conduit patients died.

Morbidity and mortality associated with second-stage intervention were similar.\textsuperscript{L11}

Several studies note the requirement for reintervention for inadequate Qp prior to standard second-stage intervention in patients who receive the right ventricle-to-pulmonary trunk conduit.\textsuperscript{D3,P7,R5,T1} Whether this is an intrinsic problem with the conduit procedure or part of the learning curve related to a relatively new technique is unclear at this time. When this problem occurs, it can be managed either by surgical or interventional revision of the conduit\textsuperscript{D3,P7,T1} or by placing a systemic-to-pulmonary artery shunt, preferably with take-down of the conduit.\textsuperscript{H6} The question is whether or not right ventricular function is impaired as a result of the right ventriculotomy or other factors related to the conduit procedure.

Although there are currently no definitive answers, several studies\textsuperscript{G12,R3,T2} and the literature review by Raja and colleagues\textsuperscript{R1} indicate that there is no evidence that right ventricular function is impaired either early or at midterm follow-up. A single randomized prospective multicenter study comparing the right ventricle-to-pulmonary trunk conduit with the systemic artery-to-pulmonary artery shunt has been performed.\textsuperscript{T35} Fifteen institutions enrolled 549 patients. Transplantation-free 1-year survival was higher in the conduit group (74% vs. 64%, \(P = .01\)). The hazard function for death is higher for shunt patients from month 1 to month 12 after operation, becomes equal to that for conduit patients from months 13 to 36, then again rises above the hazard for conduit patients from months 36 to 48 (see Fig. 49-13). Unintended reinterventions were higher in the conduit group. Ventricular function was similar in both groups.

To summarize, current evidence suggests that the right ventricle-to-pulmonary trunk conduit is associated with improved early and midterm survival and more favorable early hemodynamics, including diastolic blood pressure and shorter hospital length of stay, and does not negatively affect right ventricular performance at midterm follow-up. Branch pulmonary artery development may be improved. An increased number of unintended procedures have been documented using this technique, but it is likely these will decrease as experience with the technique grows.

\caption{Survival according to hybrid and Norwood management strategies in high-risk patients with hypoplastic left heart physiology. (From Pizarro and colleagues.\textsuperscript{G4})}
\end{figure}
Hybrid versus Norwood Procedure

It is difficult to compare these two procedures, mainly because hybrid procedures are usually performed in higher-risk patients. Despite this, a direct comparison of early mortality after neonatal surgery suggests that hybrid outcomes are at least as good as Norwood outcomes. Interstage and second-stage mortality, however, appear to be higher. The only study that examines outcomes following the Norwood procedure and the hybrid procedure in matched high-risk patient cohorts suggests that survival is similar p4 (Fig. 49.21).

Congenital mitral valve disease is a developmental malformation of one or more of the components of the mitral valve apparatus, including that portion of left atrial wall immediately adjacent to the mitral anulus that produces stenosis or regurgitation or, occasionally, a combined lesion. It often coexists with other cardiac anomalies, particularly those involving the left-sided cardiac chambers and aorta.

Left atrioventricular valve (AV) anomalies associated with AV septal defects (see Chapter 34), aortic atresia and other forms of hypoplastic left heart physiology (see Chapter 49), various forms of AV discordant connection (see Chapter 55), or transposition of the great arteries (see Chapter 52) are special situations discussed in the chapters describing these conditions. Mitral valve anomalies associated with straddling or univentricular AV connections are described in Chapters 35 and 56, respectively. Regurgitation from mitral valve prolapse as part of the syndrome of myxomatous degeneration is described in Chapter 11.

**HISTORICAL NOTE**

Heterogeneity of congenital mitral valve disease and frequency of its association with other cardiac anomalies make it difficult to trace the historical evolution of knowledge about this entity. However, as early as 1902, Fisher described two cases of congenital disease of the left side of the heart, one of which was a stenotic supravalvar ring. In 1961, parachute mitral valve, another entity in this spectrum, was not described until 1963. In 1962, Creech and colleagues reported repairing congenital mitral regurgitation resulting from a cleft in the posterior leaflet in a 2-year-old girl. Although the child’s condition was
improved by suturing the cleft, moderate mitral regurgitation persisted.\textsuperscript{c10}

**MORPHOLOGY**

The congenital anomaly may involve any component of the mitral apparatus and may result in stenosis with or without regurgitation or in pure regurgitation. Although only one component may be involved, more often the entire valve is affected.\textsuperscript{c2} Congenital mitral stenosis without or with regurgitation may result from supravalvar, anular, or valvar narrowing and may be accentuated by subvalvar obstruction produced by hypertrophied and misplaced papillary muscles or sheets of fused chordae.\textsuperscript{c3} Frequently, stenosis is a result of abnormalities at multiple levels. Although embryologic origins of these complex anomalies are poorly understood, recent studies suggest that abnormal development of a transient left ventricular (LV) structure, a horseshoe-shaped ventricular myocardial ridge, results in various obstructive mitral valve lesions, including parachute mitral valve and formation of asymmetric mitral valves.\textsuperscript{c51} Congenital mitral regurgitation may result from anular dilatation secondary to anterior or posterior leaflet prolapse or to posterior leaflet hypoplasia with chordal shortening. Chordal elongation and valve prolapse may be so severe that chordal rupture can develop even in young children, producing severe regurgitation. Congenital mitral regurgitation may also be produced by clefts, gaps, or perforations in the anterior mitral leaflet, by accessory commissures, or by leaflet hypoplasia at medial or lateral commissures.

**Supravalvar Ring**

A tough fibrous ring may be situated just on the left atrial side of the mitral anulus.\textsuperscript{A4} The pulmonary veins and left atrial appendage enter the left atrium above (proximal to) the ring, in contrast to the situation in cor triatriatum (see Chapter 32). The supravalvar ring may be nonobstructive and an incidental finding, or it may protrude into the orifice, producing a variable degree of obstruction.\textsuperscript{A4,D2} A ring may also occur on the left atrial aspect of the mitral valve leaflets that, when circumferential, prevents their adequate opening, causing obstruction. This lesion may be particularly difficult to identify echocardiographically.

A supravalvar ring is an isolated lesion in about half the cases in which it contributes importantly to death in the first year of life\textsuperscript{D2,S14} (Fig. 50–1). In the other half, it coexists with other cardiac anomalies, particularly with other mitral valve anomalies and with LV outflow tract obstruction.\textsuperscript{S6}

**Mitral Anulus**

The mitral anulus uncommonly is small and obstructive in the absence of severe LV hypoplasia or other valvar abnormalities.\textsuperscript{C3} It may be small but not obviously obstructive, particularly in hearts with coarctation of the aorta.\textsuperscript{R2} The anulus may be enlarged, usually secondary to mitral regurgitation resulting from some other deformity of the valve. However, the basic valvar anomaly leading to regurgitation may be subtle and difficult to identify. Carpentier and colleagues found essentially isolated anular dilatation in 8 (17%) of 47 cases with congenital mitral valve disease, although some deficiency of commissural tissue is implied by their description.\textsuperscript{C3}

**Leaflet Anomalies**

The orifice through the mitral valve is frequently narrowed by congenital absence of one or both commissures, which are replaced by a continuous sheet of leaflet tissue. Small perforations may be present at what is usually a commissure (Fig. 50–2). The leaflets often then take the form of an inverted
Chapter 50  Congenital Mitral Valve Disease

...none. Chordae tendineae may pass from the edges of an accessory commissure to ventricular septum or rudimentary papillary muscles (as was the case in two of five cases reported by Carpentier and colleagues\textsuperscript{C3}), or the cleft may simply represent leaflet deficiency in that area (Fig. 50-4) without chordal support.\textsuperscript{B4,F3}

Rarely, there may be a hole in the anter...
Papillary Muscle Anomalies

There may be a single large papillary muscle with all chordae attaching to it, the so-called parachute valve described first by Schiebler and colleagues and emphasized by Shone and colleagues\(^2,6\) (Figs. 50-6 and 50-7). Usually the chordae are short and thick and limit leaflet movement. This restricts the primary orifice through the opened valve as well as secondary orifices between chordae, resulting in mitral stenosis. In other cases, there is a single large papillary muscle, and near it is a hypoplastic one with only a few chordae attached; the valve orifice is narrowed by the same mechanisms. A parachute valve usually produces only severe stenosis, but it may also produce mitral regurgitation.\(^3\)

Two hypertrophied and abnormally placed contiguous papillary muscles, usually situated posteriorly, are also a cause of subvalvar obstruction.\(^3,4,12\) Obstruction is often further aggravated by coexistence of short, thick chordae and anomalous thick muscular bands.\(^5\) In other cases, there are three or more closely placed and hypoplastic or bulky papillary muscles, a situation in which short, thick chordae are often also present and contribute to stenosis. In all these cases, absence of the normal wide interpapillary distance contributes to obstruction in the mitral pathway.

An anomalous papillary muscle arcade (mitral arcade) formed by a bridge of fibrous tissue running through the free aspect of the anterior mitral leaflet, between the anterolateral and posteromedial papillary muscles, may produce mitral regurgitation\(^3,2,1\) (Fig. 50-8).

Coexisting Cardiac Anomalies

Patients with congenital mitral regurgitation often have coexisting cardiac anomalies, but they tend to be less severe than in congenital mitral stenosis (Table 50-1).

Congenital mitral stenosis is rarely an isolated malformation. In about 30% of cases, it coexists with ventricular septal defect (VSD). In more than 50%, it coexists with one or
of patients demonstrate congenital mitral valve disease.\textsuperscript{3} All of this supports considering congenital mitral valve disease as an important component in the entity known as hypoplastic left heart physiology (see Chapter 49).

RARE COEXISTENCE OF A STENOSONG SUPRAVALVAR RING WITH TETRALOGY OF FALLOT IS NOTEWORTHY BECAUSE, IF UNDETECTED, IT MAY CAUSE DEATH AFTER TETRALOGY REPAIR.\textsuperscript{5,6} Congenital mitral valve disease and subaortic stenosis may rarely coexist with subpulmonary stenosis and intact ventricular septum, subpulmonary stenosis and VSD, or valvar pulmonary stenosis.\textsuperscript{15,23}

### CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

#### Symptoms and Signs

**Isolated Mitral Valve Disease**

Symptoms and clinical signs are identical to those of acquired mitral valve disease, the congenital etiology being apparent only when presentation is in infancy or early childhood and there is no rheumatic history (see Clinical Features and Diagnostic Criteria in Section I of Chapter 11). Symptoms of pulmonary venous hypertension include dyspnea, orthopnea or paroxysmal nocturnal dyspnea, and recurrent pulmonary infection.\textsuperscript{15} Pulmonary hypertension is usually present in severe lesions, terminating in heart failure, often with peripheral and central cyanosis.\textsuperscript{18}

Mitral stenosis is associated with a prominent apical mid-diastolic murmur, sometimes with presystolic accentuation, and there may be an opening snap, although the morphologic features commonly resulting in limitation of leaflet movement make this less common than in acquired mitral stenosis.\textsuperscript{14,21} Mitral regurgitation is evidenced by an apical pansystolic murmur radiating to the axilla, frequently with a third heart sound or a short mid-diastolic murmur and LV overactivity. When there is pulmonary hypertension, the second heart sound is accentuated and there is a right ventricular lift.

**Mitral Valve Disease and Left Ventricular Outflow Tract Obstruction**

Unless a VSD or patent ductus arteriosus is also present, the mitral signs are usually clinically diagnostic, particularly when the only additional important site of obstruction is a

coarctation. When there is severe congenital aortic stenosis, the mitral lesion, unless also severe, may not be clinically obvious, although it worsens the clinical presentation.

Electrocardiography

Electrocardiographic (ECG) evidence of left atrial hypertrophy of greater degree than is usually found in the coexisting cardiac anomaly suggests associated congenital mitral valve disease. Right ventricular hypertrophy is evident on the ECG when there is the usual raised pulmonary vascular resistance and right atrial enlargement, whereas LV hypertrophy is evident on the ECG when there is severe mitral regurgitation or associated LV outflow tract obstruction. Atrial fibrillation is rare.

Chest Radiography

Left atrial enlargement out of proportion to that usually present in any coexisting cardiac anomaly is the most important clue in the chest radiograph of the possible presence of congenital mitral valve disease. There is cardiac enlargement regardless of whether the disease is isolated or complex. Signs of pulmonary venous hypertension and occasionally overt pulmonary edema may be present in severe cases, but pulmonary plethora from a coexisting left-to-right shunt may obscure these signs.

Two-Dimensional Echocardiography

Two-dimensional echocardiography combined with Doppler interrogation can provide a complete analysis of the morphology and function of congenitally abnormal mitral valves \(^{35,64,89,74,72}\) (Fig. 50-9, A-F). However, diagnosis by echocardiography of some forms of congenital mitral valve disease, especially supravalvar ring and double orifice mitral valve, requires considerable care and can easily be missed. \(^{35,54}\) Three-dimensional echocardiography can provide important morphologic details that may not be visible with standard imaging (see Fig. 50-2).

Cardiac Catheterization and Cineangiographic Studies

Cardiac catheterization and cineangiographic studies are often performed to evaluate possible associated lesions and define the degree of pulmonary vascular disease. \(^{2}\) Morphology of the congenitally abnormal valve can be further evaluated by its cineangiographic appearance. \(^{34}\)

Computed Tomography and Magnetic Resonance Imaging

Computed tomography (CT) plays a limited role in evaluating the congenitally abnormal mitral valve, but magnetic resonance imaging (MRI) can provide important morphologic information that may supplement that provided by echocardiography (see Figs. 50-5 and 50-7). In addition, MRI can provide functional information such as quantification of mitral regurgitant fraction and valve area in diastole (Fig. 50-10).

NATURAL HISTORY

Congenital mitral valve disease is a rare congenital cardiac anomaly, occurring in 0.6% of autopsied patients with congenital heart disease and 0.21% to 0.42% of clinical cases of congenital heart disease. \(^{2}\)

Natural history is highly variable and depends most importantly on severity of resultant stenosis or regurgitation and on type and severity of coexisting lesions, rather than on the particular morphologic mitral valve lesion itself. For example,
in one study, parachute mitral valve was associated with 95% freedom from mitral valve surgery at 6 months and 80% freedom at 10 years. However, associated cardiac defects were present in essentially all cases, particularly LV outflow tract abnormalities, atrial septal defect, VSD, coarctation, and hypoplastic LV; these strongly influence natural history. In another study, only 4% of patients with parachute mitral valve required a procedure on the valve, with intervention dominated by associated cardiac anomalies. Parachute mitral valve presenting in the adult is rare but does occur and is more likely to be an isolated anomaly than when diagnosed in infants and children. Nine patients have been identified in the literature over the past 50 years; three were asymptomatic without important hemodynamic abnormalities, three presented with stenosis, and three with regurgitation.

Isolated congenital mitral stenosis usually is severe and often produces symptoms and death if untreated during the first 4 to 5 years of life. When congenital mitral stenosis coexists with other important cardiac anomalies, symptoms occur even earlier. When it is associated with other components of hypoplastic left heart physiology, severe symptoms often develop during the first year of life.

Isolated congenital mitral regurgitation is often only moderate in severity in early life, and about half the patients with it do not show development of important symptoms. Symptoms and need for intervention usually come earlier when it coexists with other important cardiac anomalies.

**TECHNIQUE OF OPERATION**

The overall approach to the neonate, infant, and young child is different from that for older patients. Preservation of the native valve is of paramount importance, even if it means accepting residual valve disease that might otherwise not be
considered acceptable in a fully grown patient. The valve must be carefully studied preoperatively and at operation, seeking ways in which it can be repaired rather than replaced. Specific techniques such as rectangular resection, which if unsuccessful will result in obligatory valve replacement as a fallback option, should generally be avoided. Some techniques used for congenital mitral valve disease are the same as those used for older patients with acquired disease, and these are described for both mitral stenosis and regurgitation under Technique of Operation in Section I of Chapter 11. However, many techniques are specific for congenital abnormalities such as supramitral ring (Fig. 50-11), mitral arcade (Fig. 50-12), and single papillary muscle (Fig. 50-13). In general, repair is possible in 50% to 80% of patients. Additional comments specific to congenital mitral valve disease follow.

Repair of Congenital Mitral Stenosis

When the valve leaflets are fused into one and are stenotic, leaflet incisions may be made in the areas in which commissures would be expected to have developed. Consideration is given to inserting polyester or polytetrafluoroethylene (PTFE) chordae (see “Repair of Chordae” later in this chapter). At times, fused papillary muscles or chordae may be split or partly excised in an attempt to enlarge the orifice (see Fig. 11-7 in Chapter 11).

Because these maneuvers may result in regurgitation, immediately after discontinuing cardiopulmonary bypass (CPB), a regurgitant mitral jet may first be detected by palpating the posterior left atrial wall and then the superior left atrial wall beneath the aorta. Intraoperative transesophageal echocardiography (TEE) is invaluable at this stage in determining that mitral valve function is sufficiently good to avoid valve replacement. If TEE documents important regurgitation accompanied by high left atrial pressure and a suboptimal hemodynamic state, CPB is reestablished and the valve repaired further or replaced; otherwise, early and late results are unsatisfactory. If hemodynamics are acceptable but regurgitation is moderate to severe, the decision to replace the valve is complex. Importantly, the smaller the patient and mitral anulus, the more likely will be the tendency to

---

**Figure 50-10** Short-axis view at level of mitral valve orifice during diastole: high-velocity mitral inflow is seen as white. During systole, regurgitant jet can be visualized and analyzed, and a regurgitant fraction can be calculated as a percentage of inflow. Mitral orifice area in diastole can be calculated by planimetry and is expressed in square centimeters. Two papillary muscles are demonstrated. (From Hamilton-Craig and colleagues.)

---

**Figure 50-11** Repair of supramitral ring. A, Long-axis depiction of left heart showing left atrium, left ventricle, and mitral and aortic valves. A supramitral ring (SMR) is present on mitral valve. B, Close-up cutaway view of mitral valve and anulus showing SMR. Ring can be cut away circumferentially using sharp dissection as shown here, but in some cases, it can be peeled away bluntly once the plane between underlying endocardium and ring tissue is established. Ring may be discrete (as shown here) but may also extend to a variable degree onto mitral leaflets, sometimes extending across length of leaflet onto chordal structures, causing thickening, contraction, and immobility. In this case, using both sharp and blunt dissection, as much of the abnormal tissue as possible is removed from leaflet without damaging underlying leaflet tissue. (From Chauvaud.)
accept the result, recognizing that this will be a temporary solution.

Repair of Congenital Mitral Regurgitation

The mitral valve is carefully examined with the possible pathologic bases for congenital mitral regurgitation clearly in mind, because these determine the most appropriate type of operation. Repair based on pathology is performed whenever possible. Specific maneuvers include anuloplasty, repair of cleft leaflet, various forms of chordal repair including shortening, lengthening, and resuspension of ruptured chords, partial leaflet resection, chordal replacement, and partial commissural closure (see Technique of Operation in Section I of Chapter 11).

Anuloplasty

Occasionally, anular dilatation is the dominant pathology even in young children, but it is usually associated with some abnormal thickening and prolapse of a billowing anterior leaflet. If a reasonable anterior leaflet without ruptured chordae is present, anuloplasty is indicated. Anuloplasty is also appropriate when there is marked hypoplasia or near absence of the posterior leaflet, which probably initially was responsible for the regurgitation and subsequent anular

Figure 50-12  Repair of mitral arcade. A, En face view of mitral valve with arcade formation of subvalvar mechanism. PART VII  Congenital Heart Disease

1822

competence. If there is insufficient leaflet tissue, the cleft closure can be augmented with a patch (Fig. 50-15). A posteromedial (Wooler type) anuloplasty using interrupted simple sutures of monofilament nonabsorbable material, or a Reed anuloplasty, may be helpful.

Mitral Valve Replacement

When repair is not possible, mitral valve replacement is performed (see “Mitral Valve Replacement” under Technique of Operation in Section I of Chapter 11). Stent-mounted glutaraldehyde-preserved porcine xenografts are not appropriate in infants and children because of their rapid degeneration and bulk (see “Reoperation,” later). The favorable orifice-to-anulus ratio of the St. Jude Medical valve (see “Choice of Device for Valve Replacement” under Indications for Operation, Selection of Technique, and Choice of Device
dilatation. Following anuloplasty, the mitral valve is essentially converted to a monoleaflet valve.

Although use of an anuloplasty ring is optimal in adults, it is not used in infants and children because it precludes growth of the anulus. Thus, a technique such as the Reed asymmetric measured anuloplasty is chosen (see Fig. 11-15 in Chapter 11).

Repair of Chordae

When regurgitation is caused by ruptured chordae to less than half the posterior leaflet, a rectangular excision and leaflet repair, usually combined with anuloplasty, may be indicated (see Figs. 11-9 and 11-10 in Chapter 11). A result similar to that obtained with rectangular excision can be achieved by simply folding the unsupported component of the leaflet on itself and securing the folds with sutures, rather than excising the leaflet tissue. If the repair attempt is unsuccessful, the folded leaflet tissue can be taken down or unfolded, allowing further valve-sparing reparative maneuvers to be attempted.

A sliding plasty has been used by Carpentier and colleagues to correct congenital elongation of chordae to part of a papillary muscle. The papillary muscle is incised longitudinally and reconstructed by suturing the halves together asymmetrically, with the part attached to the elongated chordae fixed at a lower level. Elongation of all chordae to a papillary muscle may be treated by chordal shortening (Fig. 50-14). The extremity of the papillary muscle is incised longitudinally, redundant chordae buried in the trench thus created, and the papillary muscle closed firmly around them by sutures. In these situations, placement of polyester or PTFE chordae can also be useful (see “Repair of Mitral Regurgitation” under Technique of Operation in Section I of Chapter 11).

Chordal repair often involves splitting or separating papillary muscles as well as leaflet commissures. An approach through the LV apex has been described but is not recommended. Use of artificial chordae for mitral valve reconstruction in children has been described; expanded PTFE sutures are employed in the technique, and early and midterm results have been encouraging.

Repair of Cleft Mitral Leaflet

When sufficient anterior or posterior mitral leaflet tissue is present on both sides of a cleft leaflet, the cleft is sutured closed with interrupted simple sutures to achieve competence. If there is insufficient leaflet tissue, the cleft closure can be augmented with a patch (Fig. 50-15). A posteromedial (Wooler type) anuloplasty using interrupted simple sutures of monofilament nonabsorbable material, or a Reed anuloplasty, may be helpful.

Mitral Valve Replacement

When repair is not possible, mitral valve replacement is performed (see “Mitral Valve Replacement” under Technique of Operation in Section I of Chapter 11). Stent-mounted glutaraldehyde-preserved porcine xenografts are not appropriate in infants and children because of their rapid degeneration and bulk (see “Reoperation,” later). The favorable orifice-to-anulus ratio of the St. Jude Medical valve (see “Choice of Device for Valve Replacement” under Indications for Operation, Selection of Technique, and Choice of Device

Figure 50-14  Repair of elongated chordae by chordal shortening. A, Papillary muscle is split along its length between elongated chord and normal chords. B-C, Tip of papillary muscle attached to elongated chord is buried into base of papillary muscle, using a pledgeted suture such that chord is now of proper length. D, Papillary muscle is sutured closed. (From Chauvaud.)

Figure 50-15  Repair of mitral valve cleft. A, Cleft is identified over its full extent, with its central limit defined by the first chordal attachments on the leaflet normal edge. A simple suture is placed precisely at this point to appropriately align cleft. B, Simple sutures are placed to close remainder of cleft. C, If leaflet deficiency is present (as shown here), a patch is used. D, Patch has been secured in place using multiple interrupted sutures, again paying close attention to alignment of edges. (From Chauvaud.)
SPECIAL FEATURES OF POSTOPERATIVE CARE

The usual practices and protocols are used (see Chapter 5). Patients, even infants, who receive mitral valve replacement with prosthetic valves are maintained on anticoagulation with warfarin using the same general protocols as in adults (see “Special Features of Postoperative Care” in Section I of Chapter 11). Small valves in infants may be prone to dysfunction, either because of thrombosis or leaflet immobility caused by adjacent tissue at or near the small anulus. Placing a left atrial pressure catheter at the time of operation is mandatory, and using intraoperative and postoperative echocardiography to document normal movement of both valve leaflets is important in managing these patients.

RESULTS

Survival

Early (Hospital) Death

In the past, early mortality after operation for mitral valve disease in the pediatric age range was highly variable, ranging between 1% and 50%. In most reports after 1990, mitral valve surgery in infants and children has a consistently low mortality (0%-10%) for both repair and replacement (Table 50-3).

Despite these encouraging reports, the role of patient selection in determining early outcome remains unclear in these complex anomalies. In a series of 31 severely symptomatic patients with mitral stenosis requiring intervention within the first 2 years of life, 18 underwent balloon dilatation and 13 surgical intervention. Early mortality for the surgical patients was 31% (CL 16%-49%). In a series of seven patients presenting within the first year of life with mitral regurgitation, four required surgical intervention, and three were managed medically. Two of the four surgical patients died in hospital; both required urgent operation. The two survivors underwent elective operation. Yet, in another study of 17 patients presenting with mitral regurgitation, mitral valve repair was performed in all, and there was no early or late mortality. Mean age was 11 months, with 10 patients younger than age 1 year and 15 in heart failure (5 of whom required preoperative mechanical ventilation).[316]

Time-Related Survival

In the early surgical era, only about 50% of patients receiving valve repair or replacement for congenital mitral valve disease were alive 10 years later. Many deaths were related to coexisting cardiac anomalies and reoperation. Current results are better. In reports after 1990, 5- and 10-year survival appears to be between 80% and 100% (Table 50-4). Notably, there has been little or no further improvement in late survival during the last 2 decades.

Incremental Risk Factors for Premature Death

Incremental risk factors have been identified in many individual series, but there is little consistency among studies, other than younger age, era of surgery, and coexisting cardiac anomalies—all of which appear in multiple analyses. In the analysis of 79 children undergoing mitral valve repair by Aharon and colleagues, no incremental risk factors for early or late death could be identified. Incremental risk factors for early death have also been identified in one study involving predominantly surgical valve replacement. Schaverien and colleagues and Marino and colleagues both report that associated cardiac anomalies are a risk factor for death in patients with parachute mitral valve, even when no surgical procedure on the valve itself is performed. Calderone and colleagues, reporting a multicenter study of 139 patients undergoing valve replacement, identified AV septal defect and Shone’s complex as risk factors. Calderone and colleagues, reporting a multicenter study of 139 patients undergoing valve replacement, identified AV septal defect and Shone’s complex as risk factors. Calderone and colleagues, reporting a multicenter study of 139 patients undergoing valve replacement, identified AV septal defect and Shone’s complex as risk factors. Calderone and colleagues, reporting a multicenter study of 139 patients undergoing valve replacement, identified AV septal defect and Shone’s complex as risk factors.

Preoperative Functional Class

Patients in higher New York Heart Association (NYHA) functional classes are at a considerably greater risk of dying after operation, particularly early postoperatively (Table 50-5). Preoperative cardiothoracic ratio > 0.6 has also been identified as a risk for midterm death after valve repair. This is likely a surrogate for lower functional class.

Age

A number of studies identify younger age as a risk factor for death after either valve repair or replacement. Most studies categorize age groups into younger than 2 years or younger than 1 year. Age younger than 2 years was identified as a risk in one study involving predominantly surgical repair and balloon valvotomy. Age younger than 2 has also been identified as a risk factor following mitral valve replacement. Prifti and colleagues and Selamet Tierney and colleagues identified age younger than 1 year as a risk for midterm death after valve repair. This is likely a surrogate for lower functional class.

Coexisting Cardiac Anomalies

Hypoplastic left heart syndrome has a large influence on survival. However, Bolling and colleagues report no deaths (0%; CL 0%-6%) among 30 patients undergoing their first operation for Shone syndrome, although among 17 undergoing a second operation, 4 (24%; CL 12%-39%) died. Prifti and colleagues report that associated cardiac anomalies are a risk for both reoperation and midterm death after valve repair.

Mitrval Regurgitation versus Stenosis; Repair versus Replacement

Neither of these factors can be definitively related to the probability of death early or late postoperatively.
There is conflicting evidence regarding whether survival is worse after mitral valve replacement than after repair; furthermore, the evidence that can be cited to address this question is indirect. This is understandable for several reasons. First, there are no reports randomizing the two techniques, and second, it is generally acknowledged that repair is preferable to replacement in small patients because of growth reasons, thereby introducing a strong selection bias. One report shows 10-year survival of only 51% (Fig. 50-16) for patients undergoing mitral valve replacement when the primary diagnosis was mitral regurgitation; however, only 7 of the 145 patients underwent initial mitral valve replacement. The study by McElhinney and colleagues was similar, with only 11 of 108 patients undergoing initial valve replacement; replacement carried a higher mortality. Another report shows that for a primary diagnosis of mitral stenosis, initial mitral valve replacement was an independent predictor of worse survival over time. However, another study examining patients with primary diagnoses of either stenosis or regurgitation showed no difference between repair and replacement (Fig. 50-17). Other studies with larger numbers of patients undergoing mitral valve replacement have shown that replacement, relative to repair, is not an incremental risk factor for death. There are several large series reporting outcomes exclusively for mitral valve repair or replacement. Repair series tend to show better outcome than replacement series. This is not surprising, for the same reasons stated in the previous paragraph. In one report of 71 repairs, outstanding early and midterm outcome (4.2% early mortality [CL 1.9%-8.3%] and 94% 5-year survival) was demonstrated. In another report of 94 patients, early mortality was 8.5% (CL 5.5%-13%) and 5-year survival 89%. Two separate series of mitral repair exclusively for mitral regurgitation showed no early or late mortality. Both series have fewer associated cardiac anomalies and simpler anomalies than most series with a mixture of stenosis and regurgitation patients.

A number of studies exclusively examine valve replacement. Early mortality ranges from 11% to 36% according to a review by Alsoufi and colleagues, which examined 13 recent institutional series. Furthermore, from the same review, early mortality is even higher in patients younger than age 2: up to 52%. In a multicenter study of 139 patients undergoing replacement, 5-year survival was 75% overall, but survival was strongly affected by the ratio of valve size to patient weight, with higher size/weight ratio associated with decreased survival (Fig. 50-18). In a single-institution study of valve replacement in 25 patients between 1996 and 2006, 5-year survival was 83%.

**Figure 50-16** Survival after operation for mitral valve regurgitation in children, stratified by type of operation. Patient cohort in replacement group is small. Numbers along horizontal axis are patients at risk. (From Chauvaud and colleagues)

There is conflicting evidence regarding whether survival is worse after mitral valve replacement than after repair; furthermore, the evidence that can be cited to address this question is indirect. This is understandable for several reasons. First, there are no reports randomizing the two techniques, and second, it is generally acknowledged that repair is preferable to replacement in small patients because of growth reasons, thereby introducing a strong selection bias.
Reoperation Following Mitral Valve Repair

Early and midterm freedom from reoperation following mitral valve repair in the current era is high but decreases substantially over time. In one study, freedom from reoperation was 97% at 2 years and 83% at 8 years\(^1\) (Fig. 50-19). In another, it was 95% (95% CL 90%-98%) at 1 year, 80% (95% CL 71%-87%) at 10 years, and 67% (95% CL 52%-80%) at 15 years.\(^6\) In still another, it was 76% (CL 70%-82%) after 5 years.\(^2\)

Masuda and colleagues, however, reported no early mortality (0%; CL 0%-5.0%) and 5 late deaths in 37 patients undergoing valve replacement.\(^3\)

Similarly, for patients undergoing valve replacement after 1990, Alexiou and colleagues reported an early mortality of 3.6% (1 of 28; CL 0.6%-12%) and 10-year survival of 86%.\(^2\)

Reoperation

In the past, many reoperations were required because of degeneration of bioprostheses. This is part of the incremental risk of young age on bioprosthesis degeneration, particularly in older children who have little remaining growth potential—first, because mechanical prostheses rather than bioprostheses are used when replacement is necessary; and second, because less-than-perfect repairs are now considered unacceptable.

Reoperation may take one of several forms: repeat repair of a previously repaired valve, replacement of a previously repaired valve, replacement of a previously placed prosthesis, or revision and salvage of a previously placed prosthesis.
Other series examining patients undergoing first valve-replacement surgery at younger than 6 years of age show freedom from re-replacement at 5 years in the range of 70% to 80%, and at 10 years in the range of 25% to 60%.82,1,94

Reoperation generally suffices because a prosthesis two to three times larger can usually be inserted.2 In older children receiving larger initial valves (≥23 mm), 10- and 15-year freedom from re-replacement is 83% and 83%, respectively.2

**Influence of Young Age at Operation**

Reoperation was more frequent in a series of 20 patients with mitral valve disease undergoing operation before age 1 year.107

Six early reoperations were performed in five patients, with mitral valve replacement in four, a second valve repair in one, and a mechanical prosthesis thrombectomy in one. Late reoperations on the mitral valve were performed five times, with mitral valve repair in two and replacement in three. Overall freedom from reoperation was 58% (CL 47%-69%) at 7 years, and was similar for patients with an original diagnosis of mitral regurgitation and stenosis (Fig. 50-21). As noted under “Reoperation Following Mitral Valve Replacement,” in a multicenter study of mechanical prostheses in a cohort of patients younger than age 5, younger age at first valve placement predicted shorter prosthesis longevity.101

![Figure 50-21](image-url) **Figure 50-21** Freedom from reoperation among 20 patients (10 with mitral regurgitation and 10 with mitral stenosis) undergoing surgical correction within first year of life. (From Uva and colleagues.101)

**Reoperation and Use of Artificial Chordae Tendineae**

In 16 patients undergoing mitral valve repair using artificial chordae tendineae, no reoperations were required during follow-up of up to 26 months.44

**Functional Result**

Most patients who have had a reoperative operation for congenital mitral stenosis have a lessened diastolic gradient after repair but continue to have a residual gradient up to about 10 mmHg.68 An exception is isolated supravalvar ring, in which complete relief of the diastolic gradient may be obtained.69,81,101

Most patients with either congenital mitral stenosis or regurgitation have at least some regurgitation after repair. Carpentier and colleagues reported that in 22 of 34 such patients, there was an apical systolic murmur late postoperatively, and only 7 of the 34 showed important decrease in heart size.68 Of 12 patients recatheterized, 7 had moderate or severe regurgitation. Flege and colleagues reported a virtually complete repair in only 4 of 13 patients with congenital mitral regurgitation.107

At follow-up to 15 years, 85% to 100% of patients are in NYHA functional class I81,9,68,103,101,1 (Table 50-6). Among patients undergoing repair for mitral valve regurgitation, follow-up echocardiography commonly reveals some regurgitation of mild to moderate degree68,101 (see Table 50-6). However, more recent reports suggest improving functional results (see Table 50-6). Among those undergoing mitral valve repair for stenosis, important residual stenosis is uncommon.81,11

In the series of 33 late-surviving patients following mitral valve repair in whom no reoperation was performed, Yoshimura and colleagues found that eight patients had grade 1+/6+ or 2+/6+ systolic murmurs with echocardiographic findings of trivial or mild mitral regurgitation.107

The hemodynamic state after replacement of a congenitally abnormal mitral valve depends on type and size of the replacement device used (see Table 11-9 in Chapter 11). In general, hemodynamic state and valve function are satisfactory unless a device complication develops. In echocardiographic studies by Uva and colleagues, among patients receiving prosthetic mitral valves, transprosthesis gradient was 6.2 ± 3.7 mmHg.56

Prosthetic valves in children have resulted in no higher incidence of thromboembolism and complications from anticoagulation with warfarin than in adults.66,102 The possible exception to this may be with use of very small mechanical

prostheses (15 - to 17-mm diameter) placed in the supraanular position in infants. Information regarding this observation is, however, anecdotal.

**INDICATIONS FOR OPERATION**

In view of its natural history, severe symptoms and signs of important pulmonary venous hypertension are an indication for prompt operation in infants with congenital mitral valve disease. A reparative operation is indicated if feasible. These same indications prevail in children and young adults. When symptoms are mild or even moderate, operation is delayed in the hope that when it becomes necessary, and if valve replacement is required, an adult-sized device can be used. Operation is indicated even in the absence of marked symptoms when pulmonary hypertension is severe; in this situation, there may be right-to-left shunting across a patent ductus arteriosus or foramen ovale.

Surgery may be indicated in asymptomatic patients with moderate or worse mitral regurgitation in whom a simple and reliable reparative procedure is anticipated, such as closure of a regurgitant cleft. Delay in repair may lead to progressive damage to the valve, increasing the chance that repair will not be effective.

When repair is performed, long-term follow-up is indicated because of need in some patients for reoperation. When valve replacement is performed in infants, children, and young adults, a bioprosthesis is contraindicated because of its rapid degeneration in these age groups. A mechanical prosthesis is currently the device of choice, with long-term warfarin anticoagulation.

It is important to identify coexisting congenital mitral valve disease in patients being considered for repair of LV outflow tract obstruction, VSD, tetralogy of Fallot, or double outlet right ventricle. When mitral disease is present and is moderate or severe, the mitral disease must also be treated operatively.

**SPECIAL SITUATIONS AND CONTROVERSIES**

Valved Conduit Bypass of the Mitral Valve

When the mitral anulus is very small, a valved conduit (similar to that used for right ventricular–pulmonary trunk reconstruction) may be placed between the left atrium and LV. Laks and colleagues reported such a procedure (which was unsuccessful) in 1980, and Lansing and colleagues reported a successful case in a 10-year-old girl in 1983. Others have used this technique with good early results. Late results are not available.

Pulmonary Autograft Mitral Valve Replacement

Replacing the mitral valve with a pulmonary autograft, sometimes known as the Ross II operation, was initially described in 1967. It is only in the last decade that this procedure has been widely used, primarily in countries with a high prevalence of rheumatic disease, limited financial resources, and poor programs for follow-up anticoagulation monitoring. A 2004 review of worldwide use of the procedure identified 103 cases from 14 reports, with one report accounting for 80 patients. In that series, 78 of 80 patients had rheumatic disease, and 2 had congenital mitral valve disease; ages of the latter two patients were 4 years (primary mitral stenosis) and 6 years (primary mitral regurgitation). Overall early mortality was 5.0% (4 of 80; CI 2.6%-8.9%), and late mortality 6.25%, but no follow-up specific to the two congenital patients was reported, other than that the 6-year-old developed stenosis of the right ventricle–pulmonary artery trunk conduit at 1 year.

Brown and colleagues reported eight patients, four of whom had congenital mitral valve disease; two of the four had previously placed prosthetic valves that required re-replacement, and two had previously repaired atrioventricular septal defects. Ages of the four ranged from 12 to 22 years at autograft mitral valve replacement. There was no early or late mortality at a mean follow-up of 6.2 months, although one patient required autograft replacement owing to stenosis.

Four other case reports, totaling five patients, describe use of a pulmonary autograft for congenital mitral valve disease in infants ranging from age 2 to 11 months; among these, one died (20%; CI 3.2%-53%), one required immediate reoperation, and three survived with no more than short-term follow-up. One other case report describes emergency pulmonary autograft mitral valve replacement in a 36-month-old with a thrombosed mechanical valve originally placed for endocarditis. Again there was no mid- or long-term follow-up. A pulmonary autograft currently cannot be recommended for congenital mitral valve disease, especially in infants. The experience is limited, and important problems have been demonstrated upon early assessment, with no long-term follow-up available.

**Section I  Vascular Ring**

**DEFINITION**

Vascular ring is a congenital anomaly in which the aortic arch and its branches completely or incompletely encircle and compress the trachea or esophagus or both.

**HISTORICAL NOTE**

Double aortic arch was apparently first described by Hommel in 1737 (cited by Turner) and a century later by Von Siebold. Wolman is credited with describing the syndrome of tracheal and esophageal compression produced by a double arch in 1939. A description of a patient with dysphagia thought to be due to a retroesophageal right subclavian artery was published in 1794 by Bayford, although the vessel was illustrated to pass between the esophagus and trachea rather than in its actual position posterior to the esophagus.

Modern interest in these anomalies was prompted by the first surgical correction of a double aortic arch by Gross in 1945. Subsequently, he pioneered surgical treatment of most other forms of vascular ring. The basis for radiologic diagnosis was initially described by Neuhauser.

The complex development and regression of the aortic arches during fetal development was elucidated by Congdon in 1922, but until Gross's pioneering surgical work, this information was little used by clinicians. In 1948, Edwards introduced the hypothetical double aortic arch scheme to conceptualize the numerous anomalies of the arch complex. This was further elaborated by Kirklin and Clagett in 1950 and by Stewart, Kincaid, and Edwards in 1964. In 1951, Barry provided a clear anatomic summary and review of Congdon’s basic work. In 1999, Momma and colleagues, followed by McElhinney and colleagues, identified chromosome 22q11 deletions associated with isolated anomalies of laterality or branching of the aortic arch.

**MORPHOLOGY**

Variations in arrangement of the ascending, transverse, and descending aorta and its branches are numerous in patients with vascular rings. Several of these may produce compression of the trachea or esophagus, or both, and are of surgical importance. They may be grouped as (1) complete or (2) incomplete vascular rings, including compression by the brachiocephalic artery or left common carotid artery (Box 51-1).

Of 301 patients with vascular ring or sling reported by Backer and Mavroudis, 84% fit into the categories of double aortic arch (30%), right arch with retroesophageal component (27%), and brachiocephalic artery compression syndrome (27%).

**Complete Vascular Ring**

**Double Aortic Arch**

In patients with double aortic arch, the ascending aorta arises normally, but as it leaves the pericardium it divides into two branches, a left and right aortic arch, that join posteriorly to form the descending aorta. The left arch passes anteriorly and to the left of the trachea in the usual position and is joined by the ductus arteriosus (or more often a ligamentum arteriosum), where it becomes the descending aorta. The right aortic arch passes to the right and then posterior to the esophagus to join the left-sided descending aorta, thus completing the vascular ring (Fig. 51-1). Occasionally the descending aorta is right sided, in which case the left arch (or its remnant) passes behind the esophagus. This was the case in 13 of 19 cases reported by Lincoln and colleagues. Alternatively, the descending aorta may be essentially a midline structure.

The right arch gives origin to two vessels, the right common carotid and right subclavian arteries, and the left arch gives origin to the left common carotid and left subclavian arteries in that order. The right aortic arch is most often...
PART VII Congenital Heart Disease

This fibrous chord, at its origin from the base of the left subclavian artery, lies close to the ligamentum arteriosum. The latter structure passes from this point to the adjacent proximal part of the left pulmonary artery (Fig. 51-3; double arch, left dominant). Less commonly (20% of cases) the left aortic arch is larger (left dominant) than the right, which although smaller in its distal part after the origin of the right subclavian artery, is rarely atretic (Fig. 51-4; see also Fig. 51-3). Size of the right and left aortic arches is nearly equal (balanced) in about 5% of cases.

Associated cardiovascular anomalies are uncommon but include tetralogy of Fallot and transposition of the great arteries.

**Right Aortic Arch with Retroesophageal Component**

In the situation of right aortic arch with a retroesophageal vascular or ligamentous component, a vascular ring is usually present, but the anatomic details vary depending on site of regression (interruption) of the embryonic left arch.

In the common situation of right aortic arch without retroesophageal segment, no vascular ring is present. The arch branches arise in mirror image of the normal (Fig. 51-5). This arrangement is the result of interruption of the embryonic left arch distal to the ductus arteriosus, in which the anterior ligamentum courses from the brachiocephalic artery to the proximal left pulmonary artery (Fig. 51-6, A, type 1 right aortic arch). This type is particularly common in tetralogy of Fallot (see Chapter 38) and truncus arteriosus (see Chapter 43).

**Mirror-Image Branching and Retroesophageal Ligamentum Arteriosum**

 Interruption of the left arch is proximal (upstream) to the ductus arteriosus (Fig. 51-6, B, type 2 right aortic arch). The left-sided ligamentum arteriosum extends from a diverticulum (Kommerell) on the upper descending thoracic aorta, behind the esophagus, forward to the left pulmonary artery. The vascular ring is formed by the ascending portion of the right arch and brachiocephalic artery anteriorly, by the aortic diverticulum posteriorly, and by the ligamentum arteriosum laterally. In the surgical series reported by Backer and colleagues, this anomaly represented about one third of right arch vascular rings.
carotid artery, and the descending aorta gives origin to the retroesophageal left subclavian artery as the fourth branch. The ductus or ligament arises with the left subclavian artery from an aortic diverticulum or from the left subclavian artery itself near its origin, where the subclavian artery may be narrowed. The descending aorta can be left or right sided. This is the most common type of vascular ring associated with right arch (see Fig. 51-6, C), accounting for about two thirds of right arch vascular rings. It is usually loose, so compression of either the esophagus or trachea is uncommon. Associated cardiac anomalies are rare.

Retroesophageal Left Brachiocephalic Artery

Here interruption occurs between the left common carotid and the right arch (Fig. 51-6, D, type 4 right aortic arch). A vascular ring is present, but the anomaly is rare. Bein and colleagues reported a case of long-segment coarctation with this anomaly.

Left Aortic Arch and Right Descending Aorta

Vascular rings are likely in the uncommon combination of left aortic arch and right descending aorta. The left arch crosses behind the esophagus. In combination with right patent ductus arteriosus or ligamentum arteriosum, a vascular ring is formed.

Cervical Aortic Arch Complex

Cervical aortic arch is a developmental entity consisting of persistence of the right or left third branchial arch and regression of the fourth branchial arch. The cervical aortic arch complex consists of a cervical position of the apex of the aortic arch with separate origin of the contralateral carotid artery, a retroesophageal descending aorta coursing contralaterally to the arch, and anomalous origin of the subclavian artery from the descending aorta. The cervical arch usually
Figure 51-6  Vascular ring associated with right aortic arch. Center drawing depicts a double aortic arch with descending thoracic aorta as a midline or left-sided structure. Ligamentum arteriosum (dashed line) is shown originating from junction of right or left arch and descending aorta. Right-sided ligamentum arteriosum to right pulmonary artery usually forms in association with a right-sided descending aorta. Left-sided ligamentum arteriosum is the common configuration connecting midline or left descending thoracic aorta to left pulmonary artery near bifurcation. The four possible sites (dotted lines) of regression (interruption) of left arch during fetal development are shown. Various types of right aortic arch are depicted depending on site of interruption. Vascular ring results from a retroesophageal component of left arch giving rise to the ligamentum. A, Type 1 right aortic arch. Aortic arch branches arise in mirror image of normal. Anterior ligamentum arteriosum courses from brachiocephalic artery to proximal left pulmonary artery (see Fig. 51-5). There is no vascular ring. B, Type 2 right aortic arch. Left arch regresses just distal to left subclavian artery, leaving a retroesophageal aortic diverticulum. Ligamentum (ductus) arteriosum arises posteriorly from descending aorta and courses to left pulmonary artery, completing a vascular ring. C, Type 3 right aortic arch. Left arch regresses between left common carotid and left subclavian arteries, leaving a retroesophageal subclavian artery, with ligamentum (ductus) arteriosum forming a complete vascular ring. D, Type 4 right aortic arch. Left arch regresses between right arch and left common carotid artery. Complete vascular ring is present in this rare anomaly.
is right sided. The aorta is usually redundant and crosses to the opposite side posterior to the esophagus. The retro-esophageal segment of the aorta may be tortuous and severely narrowed.\(^{14}\) A vascular ring is formed when there is an aberrant subclavian artery on the side contralateral to the aortic arch and a ligamentum arteriosum. There is considerable variability in anatomic configuration of the aortic arch and its branches.\(^{37}\) Abnormalities of brachiocephalic arterial branching and arch laterality are common in patients with cervical aortic arch.\(^{84}\) Vascular ring is frequently present, usually formed by the right aortic arch and aberrant left subclavian artery, but occasionally by double aortic arch. Rarely, a left cervical aortic arch, right ligamentum arteriosum, and right descending aorta form the vascular ring (see also discussion under “Left Aortic Arch and Right Descending Aorta”).\(^{93}\)

### Incomplete Vascular Ring

#### Left Aortic Arch and Retroesophageal Right Subclavian Artery

The relatively common (0.5% of the general population\(^{31}\)) retroesophageal right subclavian artery arising as the fourth branch of an otherwise normal aortic arch and passing upward and to the right behind the esophagus was once thought to be a cause of dysphagia (dysphagia lusoria, or “difficulty swallowing due to a trick of nature”).\(^{84,1,3,10}\) This condition does not form a complete ring and is generally not considered the true cause of vague symptoms related to swallowing. Rarely, a right ligamentum arteriosum passing from the retroesophageal right subclavian artery to the right pulmonary artery forms a vascular ring that is symptomatic.

#### Tracheal Compression by Brachiocephalic or Left Common Carotid Artery

The brachiocephalic or left common carotid artery may be drawn taut across the anterior wall of the trachea, a potential but uncommon cause of respiratory obstruction.\(^{2,2,3,3,1,3,4}\) It is not known why they occasionally compress the trachea. Presumably, the brachiocephalic artery originates more posteriorly from the aortic arch than usual, so it crosses the trachea more posteriorly.\(^{44}\)

#### Ductus Arteriosus Sling

Binet and colleagues described an infant with respiratory obstruction in which an anomalous vessel (presumed to be the ductus arteriosus) originated from the right pulmonary artery, crossed to the left between the esophagus and trachea, and joined the descending aorta adjacent to the origin of a retroesophageal right subclavian artery.\(^{81}\)

#### Severe Malrotation of Heart with Patent Ductus Arteriosus

Compression of the lower trachea can occur with a normal left arch when there is severe malrotation of the heart into the right chest in association with aegesis or hypoplasia of the right lung.\(^{81,92}\) Scherer and Westcott described a patient with dextrocardia and normal lungs in whom the pulmonary trunk lay anterior to the trachea and somewhat to the right. The patent ductus arteriosus connecting with a normally positioned descending aorta pulled the pulmonary trunk backward, compressing the front of the trachea. Compression was relieved by dividing the patent ductus arteriosus.\(^{93}\)

### CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

#### Symptoms and Signs

Symptoms of vascular ring relate to the consequences of tracheal and esophageal compression.\(^{34,41,30}\) Presentation is usually within the first 6 months of life and often within the first month. Inspiratory stridor may be present at birth, often in association with an expiratory wheeze and tachypnea. Stridor may be worse in various positions—for example, when the baby is lying on his or her back rather than side. Often, stridor is relieved by extending the neck. The baby’s cry may be hoarse and, in the absence of frank stridor, the breathing noisy. Persistent barking cough is frequently present. There may be episodes of apnea, severe cyanosis, and unconsciousness. When obstruction is severe, subcostal retraction is obvious. Recurrent respiratory infections are common and aggravate the respiratory obstruction; when obstruction is less severe, obstructive symptoms may be apparent only at such times.

The baby often feeds poorly, and there may be obvious difficulty in swallowing liquids, with episodes of choking and increased respiratory obstruction at these times. Dysphagia for solids is common (most severe cases are operated on before the babies are old enough to be offered solid food), with the baby refusing to swallow them or choking and regurgitating.

Dysphagia lusoria is often attributed to retroesophageal origin of the right subclavian artery from the upper descending thoracic aorta.\(^{84,1,3,10}\) The artery courses to the right, posterior to the esophagus, producing an indentation of the esophagus that has been blamed for vague symptoms in children, but that is usually not the cause. Should it become ectatic or aneurysmal later in life, difficulty swallowing is more likely.

Symptomatic vascular rings manifesting in adults are rare, and reports often emphasize dysphagia as the predominant symptom. Grathwohl and colleagues\(^{81}\) reviewed case reports of 24 adults with vascular rings. Two thirds had symptoms, 63% respiratory. Dysphagia was less prominent, occurring in 33%. Vascular rings occurring in adults may mimic chronic asthma.\(^{81,92}\)

#### Chest Radiography

Plain chest radiograph in the frontal view is either normal (10%) or shows a right aortic arch (85%).\(^{75}\) Anterior tracheal bowing is present on 92% of lateral views, and tracheal narrowing on 77%.

#### Esophagography

The esophagram is a useful diagnostic measure.\(^{34,1,3}\) Video esophagography at the time of cineangiography is optimal because it permits a detailed study showing the pulsatile nature of the obstruction and trachea.

With double aortic arch, the esophagram shows left- and right-sided indentations, with that for the right arch usually higher and deeper (Fig. 51-7, A). In addition, the retro-esophageal component produces a prominent posterior indentation that courses downward and to the left. In contrast, a retroesophageal left subclavian artery arising from the right arch produces a narrower esophageal impression that
courses upward and rightward. Right arch and left ligamentum arteriosum show more marked right-sided than left-sided indentation (Fig. 51-7, B).

Bronchoscopy

Bronchoscopy is rarely done, although it does identify sites of tracheal compression and shows its pulsatile nature.\textsuperscript{10}

Two-Dimensional Echocardiography

Two-dimensional echocardiography is useful in diagnosing vascular ring, at least in neonates and infants, and is critically important for identifying associated cardiac anomalies.\textsuperscript{17} However, it is inferior to computed tomography (CT) in demonstrating details of arch anatomy.

Computed Tomography

CT with contrast usually provides an excellent image of the structures and complements two-dimensional echocardiography. Ultrafast CT with three-dimensional reconstruction provides even greater anatomic detail.\textsuperscript{14} In many institutions, CT has become the standard modality for delineating details of vascular ring anatomy.\textsuperscript{87}
B, Right aortic arch with retroesophageal aortic diverticulum giving origin to a retroesophageal left subclavian artery and ligamentum arteriosum. AP views show typical bilateral indentations, lateral views a posterior indentation. Key: ANT, Anterior aspect of patient; L, left side of patient; POST, posterior aspect of patient; R, right side of patient.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is diagnostic and delineates severity of tracheal narrowing.\(^{54}\)

Aortography

Because of the accuracy of noninvasive imaging, aortography is rarely necessary. Aortography may be performed via a catheter positioned in the ascending aorta and is usually combined with cineangiography to assess associated congenital cardiac anomalies. Using biplane techniques, the first injection depicts both lateral and anteroposterior views, and the second both left and right oblique views. A degree of cranial tilt may separate the arches better in oblique views.\(^{51}\) Aortography can establish that the anomaly is a complete double aortic arch and show sites of narrowing in the left or (rarely) right arch (see Figs. 51-2 and 51-4). It cannot distinguish between a double arch with an atretic segment and a right aortic arch with a retroesophageal component. Sharp angulation of one of the brachiocephalic arteries may indicate the site of an atretic segment in a double arch or a constricting ligamentum arteriosum in a right arch with retroesophageal component (Fig. 51-8).

NATURAL HISTORY

Vascular rings of aortic arch origin account for 1% to 2% of cases of congenital heart disease.\(^{51}\) Only fragmentary information exists concerning the natural history of these anomalies. Untreated severe respiratory obstruction in the first 6 months of life is presumably fatal before age 1 year, particularly when symptoms are present from birth. Symptoms first appearing after age 6 months are less severe and rarely progressive, except at times of respiratory infection or regurgitation and choking.

When symptoms are of borderline severity, they usually disappear as the child grows. Godtfredsen and colleagues followed 11 patients with symptoms not severe enough to justify surgery.\(^{63}\) Of the six who had either double aortic arch or right arch with retroesophageal component, four outgrew their symptoms by age 4 years, and two with persistent symptoms had other anomalies to explain them.
Figure 51-8  Aortogram of right aortic arch with retroesophageal left subclavian artery and ligamentum arteriosum arising from a retroesophageal aortic diverticulum. Frontal views (A-B) and right anterior oblique views (C-D) are at different phases in cardiac cycle. Angulation at origin of left subclavian artery from diverticulum suggests presence of a ligamentum arteriosum under tension passing forward to left pulmonary artery (as was the case at operation). Angulation is downward in frontal view and anterior in right anterior oblique view. Absence of a similar angulation along course of left common carotid artery suggests that this artery is not connected to the diverticulum by an atretic ligament that forms part of a complete left aortic arch.
oversewn with two rows of 4-0 or 5-0 polypropylene sutures. Its mediastinal surface is then dissected further to free it and allow the divided ends to separate. The descending aorta is also mobilized and sometimes sutured to the rib periosteum to keep it away from the esophagus. In this and other operations for relief of vascular rings, “all strands or bands of tissue which form a part of the constricting mechanism” must be dissected away from the trachea or esophagus. Operation is completed by closing the chest wound in layers after inserting a single intercostal tube for drainage.

More often, the distal left arch is narrowed, and approach is made from the left side. The vascular structures and ligamentum arteriosum are dissected out and separated thoroughly from surrounding tissues (Fig. 51-9, A). The ligamentum arteriosum is divided, taking care to avoid injury to the recurrent laryngeal nerve. The junction of the left arch with the descending aorta is divided between vascular clamps and the ends oversewn (Fig. 51-9, B). The end of the left arch is then further dissected from underlying mediastinal tissues to allow it to retract forward. The medial surface of the descending aorta and distal divided end are also dissected.

Figure 51-9 Operative repair of vascular ring caused by right dominant double aortic arch. A, Surgeon’s view of anomaly through left posterolateral thoracotomy. Both arches, their branches, and ligamentum arteriosum are dissected and separated thoroughly from surrounding tissues. Site of division of smaller left arch is shown by dashed line. B, Ligamentum arteriosum is divided between surgical clips. Aortic arch is divided and ends ligated or oversewn. Anteromedial surface of aorta is dissected away from esophagus. Adventitia of lateral wall of aorta is sutured to periosteum of an adjacent rib to pull aorta laterally and posteriorly away from esophagus.

Generally, symptoms are milder and of later onset, and dysphagia is less prominent, in patients having right aortic arch with retroesophageal component than in those with double aortic arch.

TECHNIQUE OF OPERATION

Double Aortic Arch

In all cases of double aortic arch with a left-sided ligamentum, the repair may be approached through a left thoracotomy via the fourth interspace or bed of the nonresected fifth rib, as in the operation for patent ductus arteriosus (see Chapter 37, Fig. 37-3) or coarctation (see Chapter 48, Fig. 48-15). However, a similar approach from the right side may also be used when the left arch is dominant. Median sternotomy may be used when coexisting cardiac anomalies require repair.

When the left arch is dominant, the right arch can be dissected out via a left-sided approach, including the part passing behind the esophagus, and is divided between clamps close to its junction with the descending aorta. Its ends are oversewn with two rows of 4-0 or 5-0 polypropylene sutures. Its mediastinal surface is then dissected further to free it and allow the divided ends to separate. The descending aorta is also mobilized and sometimes sutured to the rib periosteum to keep it away from the esophagus. In this and other operations for relief of vascular rings, “all strands or bands of tissue which form a part of the constricting mechanism” must be dissected away from the trachea or esophagus. Operation is completed by closing the chest wound in layers after inserting a single intercostal tube for drainage.

More often, the distal left arch is narrowed, and approach is made from the left side. The vascular structures and ligamentum arteriosum are dissected out and separated thoroughly from surrounding structures (Fig. 51-9, A). The ligamentum arteriosum is divided, taking care to avoid injury to the recurrent laryngeal nerve. The junction of the left arch with the descending aorta is divided between vascular clamps and the ends oversewn (Fig. 51-9, B). The end of the left arch is then further dissected from underlying mediastinal tissues to allow it to retract forward. The medial surface of the descending aorta and distal divided end are also dissected.
aorta is dissected away from the esophagus and sutured to the adjacent rib periosteum to pull it laterally and posteriorly away from the esophagus.

Techniques have been developed to divide vascular rings using video-assisted thoracoscopy. Compared with standard thoracotomy techniques, it is equally safe (no mortality), and length of stay in the intensive care unit or hospital, duration of intubation, and hospital charges are similar.

Right Aortic Arch with Retroesophageal Component

Right arch with retroesophageal component is generally approached from the left side. After dissection is completed, the ligamentum arteriosum is divided. The aortic diverticulum (Kommerell) is resected when it is large enough to independently compress the esophagus or trachea. Backer and colleagues recommend routine reimplantation of the left subclavian artery into the left common carotid artery if it arises from the diverticulum (Fig. 51-10). The descending aorta is dissected away from the esophagus and sutured to the periosteum of the rib if necessary to keep it away from the esophagus.

A robotic approach for dividing a left-sided ligamentum has been reported in a type 4 right aortic arch vascular ring.

Left Aortic Arch

Right-sided thoracotomy is used for left aortic arch and right-sided ligamentum arteriosum with or without a retroesophageal right subclavian artery (Fig. 51-11). The ligamentum is dissected and divided in the same fashion as for right arch with retroesophageal component.

Tracheal Compression by Brachiocephalic or Left Common Carotid Artery

When the lower trachea is compressed by an anomalous brachiocephalic artery (Fig. 51-12) or a malrotated left aortic

Figure 51-10  Repair of right aortic arch with retroesophageal component. A, Anatomy of patient with right aortic arch, retroesophageal left subclavian artery (LSA), and large Kommerell diverticulum (embryologic remnant of left fourth aortic arch). Diameter of Kommerell diverticulum is usually equal to size of descending aorta. Ligamentum arteriosum is not illustrated. B, Resection of Kommerell diverticulum through left thoracotomy. Vascular clamp partially occludes descending thoracic aorta at origin of Kommerell diverticulum. Clamp on LSA is not illustrated. Kommerell diverticulum has been completely resected. C, Completed repair. Orifice at which Kommerell diverticulum was resected is usually closed primarily or (inset) can be patched with polytetrafluoroethylene if necessary. LSA has been implanted into side of left common carotid artery (LCAA) with fine running polypropylene sutures. Key: RCCA, right common carotid artery; RSA, right subclavian artery. (Redrawn from Backer and colleagues.)
arch associated with severe rightward malrotation of the heart, approach may be through a median sternotomy. A short left anterolateral thoracotomy also works well and leaves the sternum intact; the suspending sutures may be passed through the sternum. The anomalous vessel is fully dissected, then suspended from the posterior aspect of the sternum or adjacent ribs with 3-0 or 4-0 polypropylene pledgeted mattress sutures that pick up the adventitia of the vessel.

Hawkins and colleagues have proposed an alternative midline approach in which the brachiocephalic artery is reimplanted more proximally on the ascending aorta and to the right of the trachea. Hawkins and colleagues have proposed an alternative midline approach in which the brachiocephalic artery is reimplanted more proximally on the ascending aorta and to the right of the trachea. Hawkins and colleagues have proposed an alternative midline approach in which the brachiocephalic artery is reimplanted more proximally on the ascending aorta and to the right of the trachea. Hawkins and colleagues have proposed an alternative midline approach in which the brachiocephalic artery is reimplanted more proximally on the ascending aorta and to the right of the trachea.

RESULTS

Complete Vascular Ring

In the current era, hospital mortality after repair of vascular ring without major associated lesions should approach zero. Good functional results are obtained in 90% of surviving patients. In a 45-year analysis by Backer and colleagues, early mortality was primarily related to major associated cardiac or respiratory anomalies.

Late outcomes after repair of complete vascular ring are generally good, but persistent respiratory symptoms are frequent—54% after repair of double aortic arch in a longitudinal study by Alsenaidi and colleagues, possibly associated with previous compression-related tracheobronchial damage or maldevelopment. Gastrointestinal symptoms are uncommon.

Incomplete Vascular Ring

Results are also good in about 90% of patients with incomplete vascular ring.

Tracheal Compression by Brachiocephalic or Left Common Carotid Artery

Results of arteriopexy for tracheal compression by the brachiocephalic or left common carotid artery were excellent in 93% of a group of 76 patients. Death occurred in 3 of 79 (3%; CI 1.7%-7.5%) patients. Similar results have been achieved by the reimplantation technique.

INDICATIONS FOR OPERATION

Operation is indicated in all patients with important obstructed airway symptoms. Treatment should not be delayed, because hypoxic and apneic spells may occur, as well as further damage to the trachea and bronchi. Operation is not indicated if symptoms are mild or absent.

SPECIAL SITUATIONS AND CONTROVERSIES

Resection of Kommerell Diverticulum

Most surgeons have routinely left alone a Kommerell diverticulum or performed an aortopexy in the vicinity of the diverticulum by tacking it to the adjacent chest wall. However, Backer and colleagues recommend its routine excision because of the occasional need to reoperate for symptom recurrence secondary to tracheoesophageal compression by the diverticulum. Further longitudinal studies are needed to clarify the role of routine diverticular resection.

DEFINITION

Vascular sling is a congenital anomaly in which the left pulmonary artery (LPA) arises from the right pulmonary artery (RPA) extrapericardially (anomalous LPA), courses to the left...
Figure 51-12  Operative repair of tracheal compression by brachiocephalic artery. A, Brachiocephalic artery originates from aortic arch more distally than usual, causing compression of trachea. It is shown in midline exposure. B, Brachiocephalic artery is disconnected from aorta and its origin closed by suture and reimplanted more proximally on ascending aorta. C, Anomaly is approached through a left anterior thoracotomy. Anomalous vessel is completely separated from trachea and attached (D) by suture to periosteum of posterior aspect of sternum.
behind the tracheal bifurcation and in front of the esophagus to reach the left lung hilum, and forms a sling around the trachea.

**HISTORICAL NOTE**

Anomalous LPA was first recognized by Glave and Doehle in 1897 during an autopsy performed on a 7-month-old child who died of asphyxia. The next report was that of Scheid in 1938, again in the German literature and again from autopsy findings, this time in a 7-month-old child who died of respiratory obstruction. Description of the anomalous origin and course of the artery is accurate in both reports, but Scheid also described in detail an associated diffuse tracheal stenosis caused by presence of complete cartilaginous rings. This latter condition was again accurately described by Wolman 3 years later.

Quist-Hanssen from Norway detailed the clinical findings of pulmonary artery sling premortem in 1949, although exact diagnosis was not made until autopsy. Welsh and Munro first suggested, based on their autopsy findings, that in this anomaly the barium swallow should show an anterior esophageal indentation; Wittenborg and colleagues soon after accurately defined these features on an esophagram. In 1980, Stone and colleagues described diagnosis by CT, and in 1988, Malmgren and colleagues by MRI.

In 1958, Contro and colleagues coined the term *vascular sling* to distinguish the condition from vascular ring. Much later, Berdon and colleagues introduced the phrase *ring-sling complex* to emphasize the often coexisting tracheal anomaly.

In 1954, Potts and colleagues were the first to report successful operation in a patient in whom the anatomy of the malformation was not established before operation. Potts divided the LPA at its origin from the RPA, transferred the vessel in front of the trachea, and reanastomosed it to the proximal stump. Soon after, Morse and Gladding reported a case diagnosed at right thoracotomy and confirmed at autopsy, in which the anomalous LPA was dissected away (but not divided) from the trachea in an attempt to relieve compression.

Hiller and Maclean operated successfully on a patient correctly diagnosed by barium swallow and angiography in 1955; after mobilizing and dividing the anomalous LPA, they anastomosed it to the side of the pulmonary trunk (the operation currently practiced). The patient’s stridor was relieved completely, and the chest radiograph was normal. However, angiogram 3 weeks later showed LPA occlusion. In 1962, Mustard and colleagues reported relief of respiratory obstruction following division of the ligamentum arteriosum only. One year later, Lochlor and colleagues reported a case in which the right mainstem bronchus was successfully resected in front of the anomalous LPA. Neither of the latter two procedures is practiced currently.

MORPHOLOGY

**Anomalous Left Pulmonary Artery**

The anomalous LPA arises extrapericardially from the posterosexterior wall of a normally positioned RPA lying in front of the proximal right main bronchus. The RPA is a direct continuation of the pulmonary trunk, the junction between them marked by attachment of the ligamentum arteriosum (or ductus arteriosus). From its point of origin, the LPA curves upward and backward over the proximal right main bronchus, then to the left behind the lower trachea and its bifurcation at or slightly above the carina (Fig. 51-13). It courses slightly inferior to lie behind the proximal left mainstem bronchus, then appears immediately superior to it to enter the left lung, and then divides. The left lung hilum is lower than normal in relation to the pulmonary trunk.

The LPA usually indents the posterior wall of the trachea and left main bronchus as it passes behind them and displaces (bows) the distal trachea and carina toward the left. The right main bronchus is bowed anteriorly. The LPA passes in front of the esophagus, which is usually indented across its entire anterior aspect or, less often, on its leftward anterior surface only.

The anomalous LPA is frequently slightly smaller than normal (see Chapter 1). Rarely, the right upper lobe artery comes off the LPA near its origin. Bamman and colleagues described one case in which the left lung was partly supplied by an LPA in normal position; the anomalous LPA supplied only the left lower lobe and crossed behind the left atrium rather than behind the tracheal bifurcation.

The ligamentum arteriosum (or ductus arteriosus) follows a normal course from the junction of the pulmonary trunk RPA, passing backward directly superior to the left main bronchus and anomalous LPA (not between them as depicted by Williams and colleagues) to join the descending aorta. It may participate with the anomalous LPA in forming a vascular ring.

**Tracheobronchial and Pulmonary Abnormalities**

The trachea near the bifurcation is usually narrowed as a result of posterior compression by the anomalous LPA. This mainly affects the origin of the right main bronchus and trachea just above the carina. Rarely, the left main bronchus may be narrowed by a similar mechanism.

In about 50% of patients, narrowing of the trachea or proximal main bronchi is secondary to presence of complete ring cartilages (ring-sling complex), which often are more numerous than normal. In these areas, the pars membranacea is absent and the lumen is usually severely narrowed. This process may involve the entire length of the trachea or only its proximal or distal portions. The major bronchi may be similarly involved, or their cartilaginous rings may be wide and irregular and the bronchi variable in diameter and length.

The so-called bronchus suis, consisting of separate high origin from the trachea of the right superior lobar bronchus to the right upper lobe, is more frequent than normal. It is not itself a cause of obstruction.

When the right main bronchus is selectively narrowed, there is hyperinflation of the right lung (not affecting the right upper lobe when there is a bronchus suis present); when
the left main bronchus is narrowed, there is hyperinflation of the left lung. More complete obstruction leads to atelectasis. When obstruction of the right main bronchus is important in utero, there may be retention of fetal fluid in the right lung at birth.

Either the left or right lung may be unilobar. Rarely, the right lung may be hypoplastic. The lung hypoplasia may be part of scimitar syndrome.

Other Cardiovascular Anomalies
Other cardiovascular anomalies coexist with half the cases of anomalous LPA. Most common are left superior vena cava, atrial septal defect, patent ductus arteriosus, and ventricular septal defect. There may also be tetralogy of Fallot, single ventricle, transposition of the great arteries, tricuspid atresia, or aortic arch anomalies.

Noncardiovascular Developmental Anomalies
A variety of noncardiovascular developmental anomalies coexist relatively frequently.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA
Symptoms and Signs
Symptoms of vascular sling relate to the consequences of tracheal and esophageal compression. Up to 90% of patients have important and usually severe symptoms that develop soon after birth.

The most common presentation is with wheezing and stridor, often with prolongation of the expiratory phase, suggesting asthma, and with a harsh cough and intercostal indrawing. In addition, there may be choking and rapid breathing or apneic spells and associated episodes of cyanosis. Symptoms are episodic, but acute episodes of dyspnea and cyanosis or severe exacerbations of respiratory obstruction are common and may result in unconsciousness, convulsions, or even death. In severe cases, hypercapnia and right lung emphysema requiring mechanical ventilation may be present from birth.

Symptoms may be precipitated by respiratory infections and are occasionally altered by changes in posture of the infant. They may be made worse by feeding, with or without regurgitation and choking. Dysphagia, however, is uncommon.

Chest Radiography
Plain chest radiograph gives important clues to correct diagnosis. It shows anterior bowing of the right main bronchus and deviation of the lower trachea and carina to the left. In addition, the left lung hilum is lower than normal in relation to position of the pulmonary trunk, and unequal aeration of the lungs frequently is present. Usually the right lung is overinflated, but sometimes the left may be. When obstruction is more complete, there may be areas of atelectasis. There is mediastinal density between the trachea and esophagus on the lateral view and, in older patients in particular, right-sided mediastinal density opposite the carina in the posteroanterior view.

In newborns, the initial chest radiograph may show retention of fetal fluid in the right lung, evidenced by a uniform opacity without loss of volume (this is in fact increased) and without an air bronchogram. Once the fetal fluid has been resorbed or suctioned off, the lung will appear hyperinflated.
Bronchoscopy

Bronchoscopy is required in all patients to evaluate tracheal abnormalities (complete tracheal rings) and identify areas of stenosis that may need surgical repair and affect airway and ventilatory management.

Cardiac Catheterization and Angiography

Cardiac catheterization and angiography display the anomaly well, can confirm diagnosis (Fig. 51-15), and demonstrate

**Figure 51-14** Esophagram (lateral) of anomalous left pulmonary artery. Prominent indentation of anterior wall of esophagus is seen immediately above tracheal bifurcation.

**Figure 51-15** Cineangiogram of vascular sling (anomalous left pulmonary artery). A, Preoperative study showing left pulmonary artery originating from right pulmonary artery. Small patent ductus arteriosus (arrow) is present between distal left pulmonary artery and pulmonary trunk. Concavity apparent in upper surface of left pulmonary artery just lateral to the ductus is impression of descending aorta. B, Late postoperative study showing stenosis at anastomosis of left pulmonary artery to pulmonary trunk. This was successfully treated by percutaneous balloon dilatation.
associated cardiovascular anomalies. The LPA is visualized best in a cranially tilted frontal view.

**NATURAL HISTORY**

Vascular sling is a rare condition. The largest series includes 15 patients accumulated over 45 years in a high-volume children’s hospital. Therefore, information about natural history is incomplete.

**TECHNIQUE OF OPERATION**

Repair is advantageously performed through a median sternotomy using CPB, although it can be done through a left thoracotomy. **Reimplantation of Left Pulmonary Artery**

*With Cardiopulmonary Bypass*

After usual preparations and bronchoscopy (if not previously performed) and median sternotomy, the pericardium is opened and retraction sutures applied. The aorta is dissected completely away from both pulmonary arteries. The ligamentum arteriosum, which is often stretched tightly across the carina and is part of the vascular sling, is dissected and divided between ligatures. The decision is then made either to reimplant the LPA or excise a tracheal stenosis (if this exists), move the dissected but undivided LPA anteriorly, and reconstruct the trachea end to end.

When the tracheal rings are normal and no tracheal stenosis or softening is demonstrated, CPB is established using a single venous cannula and a perfusate temperature of about 32°C (see Chapter 2). The left pleural space is opened widely, either then or later. The LPA is identified coming off the RPA. It is dissected out well distally, completely separating it from surrounding structures, including the trachea anteriorly and the esophagus posteriorly. The plane of dissection must be on the adventitia of the LPA to avoid damage to the membranous portion of the trachea (Fig. 51-16, A). The LPA is cut away from the RPA, and the defect in the latter is closed with two rows of 5-0 or 6-0 polypropylene sutures. The LPA is then pulled out into the left pleural space. A large window is made in the pericardium behind the phrenic nerve and alongside the pulmonary trunk, and the LPA is brought into the pericardial space through it. An incision is made in the left lateral aspect of the pulmonary trunk. Taking care that the LPA lies nicely without kinking or rotation, its proximal end is anastomosed to the side of the pulmonary trunk with continuous 6-0 or 7-0 polypropylene suture (Fig. 51-16, B).

After rewarming the patient, CPB is discontinued and cannulae removed. A polyvinyl pressure-recording catheter may be brought out from the pulmonary trunk via the right ventricle. The remainder of the operation is completed as usual.

*Without Cardiopulmonary Bypass*

A left posterolateral thoracotomy is made, entering the chest via the fourth interspace or fifth rib bed. Alternatively, some have preferred median sternotomy. The anomalous LPA is identified by dissecting the superior part of the left lung hilum (Fig. 51-17, A). The ligamentum arteriosum is divided because this improves exposure and may possibly relieve compression of the left main bronchus. Dissection of the LPA is continued medially (centrally) and behind the proximal left main bronchus and tracheal bifurcation. The artery is freed completely from the posterior wall of these structures and followed as far as possible into the mediastinum to gain adequate length. Care is taken not to obstruct flow into the RPA by undue tension on the LPA. The patient is given heparin (1.5 mg · kg⁻¹) to obtain systemic anticoagulant effect. The LPA is then divided between vascular clamps, its proximal end on the RPA oversewn with continuous 6-0 or 7-0 polypropylene suture, and the clamp removed (Fig. 51-17, B).
The pericardium is opened with a vertical incision anterior to the phrenic nerve to expose the pulmonary trunk, and a second similar incision is made posterior to this structure, through which the distal end of the anomalous LPA is passed. The tip of the left atrial appendage is retracted by a ligature tied to it, and the left wall of the pulmonary trunk is excluded in a curved vascular clamp. The clamp is positioned to allow the LPA to reach the pulmonary trunk without kinking or tension. The excluded portion of the pulmonary trunk is opened and an end-to-side anastomosis performed between it and the LPA (see Fig. 51-17, B), refashioning the LPA end obliquely to increase the diameter of the anastomosis. The posterior layer of the anastomosis is performed from within the vessels, using continuous 6-0 or 7-0 polypropylene suture and the anterior layer from outside. Clamps are then removed. Heparin is not reversed.

The pericardium is left open and the chest closed, leaving one intercostal tube for drainage.

**Tracheal Resection and Relocation of Left Pulmonary Artery**

When there is a localized area of tracheal stenosis, the trachea is minimally mobilized, and the tip of the endotracheal tube is ascertained to lie proximal to the proposed resection. A median sternotomy is performed and CPB established in the manner just described. The anomalous LPA is completely freed from surrounding structures and the stenotic area of
trachea excised (Fig. 51-18, A). The LPA is brought through the tracheal gap and positioned anterior to the trachea. The patient’s neck is flexed if necessary, and an end-to-end tracheal anastomosis is performed (Fig. 51-18, B and C) using continuous 5-0 or 6-0 polydioxanone suture. CPB is discontinued after the patient has been rewarmed, and the remainder of the operation is completed in the usual manner (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2). Before muscle relaxants are discontinued in the intensive care unit, the patient is fitted with a back brace to prevent cervical extension.

If tracheal disease is of considerable length and associated with complete tracheal rings, local excision may not be corrective. These longer segments of tracheal stenosis are treated by tracheoplasty. Using CPB, either a slide tracheoplasty or a long tracheoplasty with pericardium is performed. For pericardial reconstruction, a vertical anterior incision is made in the trachea through the complete

Figure 51-18 Repair of anomalous left pulmonary artery (LPA) with tracheal stenosis caused by complete tracheal rings (tracheomalacia). Operation is performed through median sternotomy with cardiopulmonary bypass. A, Anomalous LPA is freed from surrounding structures. Trachea is divided (dotted lines) above and below stenotic area. Excision of stenotic trachea leaves a gap through which anomalous pulmonary artery is pulled and positioned anterior to trachea. B, End-to-end anastomosis of trachea is constructed using absorbable suture. LPA is shown positioned anterior to trachea. C, Completed repair shows LPA still attached anomalously to right pulmonary artery but positioned anterior to trachea to avoid tracheal compression.
rings under bronchoscopic guidance. A pericardial patch is inserted with polydioxanone suture to widen the trachea. The patch appears to be adequate for enlarging the trachea but does not provide support to it and may collapse during inspiration, partially obstructing the trachea and resulting in noisy respiration for months to a year. Options that do provide support are a tracheal insert fashioned from costal cartilage or a prosthesis constructed from prosthetic mesh hardened with cyanoacrylate to which the pericardium is attached with biological glue.

The LPA is transected at its origin, repositioned, and anastomosed to the side of the distal pulmonary trunk to complete the operation. When major associated cardiac anomalies are present, they can be repaired along with LPA reimplantation on CPB. Tracheal reconstruction, if needed, can be deferred for 2 to 4 days and performed as a separate procedure.

Because of the unavoidable mediastinal contamination from an open trachea, Konstantinov and colleagues recommend placing a pericardial flap between the great vessels and anterior tracheal suture lines.

SPECIAL FEATURES OF POSTOPERATIVE CARE

Care is as described in Section I. Special attention is required for tracheal care and secretion management if the trachea has been reconstructed.

RESULTS

Survival

Percent survival is not meaningful when derived from the small number of patients known to have been treated surgically. In the series reported by Backer and colleagues, there were no hospital deaths among 12 patients (0%; CL 0%-15%), but two (17%) patients died during the first postoperative year.

Mode of death is usually respiratory and related to tracheal abnormalities. When these abnormalities are not present, prognosis is excellent.

Left Pulmonary Artery Patency

In many groups of patients operated on in an earlier era, usually through a left thoracotomy, the LPA anastomosis frequently was not patent late postoperatively. With currently used methods, the anastomosis usually remains patent.

Freedom from Postoperative Respiratory Obstruction

When respiratory obstruction is due only to compression of the trachea by an anomalous LPA, relief is virtually always complete after simple reimplantation of the artery. Relief of symptoms has been obtained in a few such patients in whom only the ligamentum arteriosum or a patent ductus arteriosus has been divided. When tracheal stenosis is a component of respiratory obstruction, tracheal resection and relocation of the LPA aided by CPB has provided complete relief of symptoms. When there is diffuse anatomic tracheal stenosis associated with complete cartilaginous rings, relief of respiratory obstruction has been variable, but results after pericardial patch tracheoplasty can be good.

INDICATIONS FOR OPERATION

When anomalous LPA is present and there are symptoms and radiologic signs of important respiratory obstruction, operation is indicated. When respiratory symptoms are due to tracheal compression without fixed stenosis and without complete tracheal rings, either relocation and reimplantation of the LPA (preferably with CPB) or relocation after tracheal transection and reanastomosis is indicated. When a localized tracheal stenosis is present, resection of the stenosis, relocation of the LPA, and end-to-end anastomosis of the trachea are indicated.

When there is severe diffuse tracheal stenosis with complete cartilaginous rings, the surgical problem is more difficult. Correction of the left pulmonary arterial problem and simultaneous tracheal reconstruction of some type are indicated, but the outcome has been unpredictable.

DEFINITION

Complete transposition of the great arteries (TGA) is a congenital cardiac anomaly in which the aorta arises entirely or largely from the right ventricle (RV) and in which the pulmonary trunk arises entirely or largely from the left ventricle (LV), known as ventriculoarterial discordant connection. Although the phrase complete transposition of the great arteries may properly be applied whenever this situation exists, this chapter uses TGA to denote a cardiac anomaly with atrioventricular concordant connection as well as ventriculoarterial discordant connection. Thus, the term TGA is not applicable to patients with transposed great arteries and tricuspid or mitral atresia or double inlet left or right ventricle (see Chapters 41 and 56) or atrioventricular discordant connection (congenitally corrected transposition of the great arteries; see Chapter 55).

HISTORICAL NOTE

The first morphologic description of TGA is attributed to Baillie in 1797. The term transposition of the aorta and...
pulmonary artery was coined by Farre when he described the third known case of this anomaly in 1814 using the word transposition (trans, “across”; ponere, “to place”), meaning that the aorta and pulmonary trunk were displaced across the ventricular septum. In subsequent pathologic descriptions that included attempts to explain its embryologic basis, the word transposition was used to describe an anterior position of the aorta relative to the pulmonary trunk, and by the early 1900s, it had become accepted practice to include any abnormal position of the aorta, regardless of its ventricular origin, under this heading. This broad confusing definition was clarified by Van Praagh and colleagues in 1971, when they strongly advocated return to Farre’s original definition of transposition, and introduced the useful term malposition to describe those abnormal positions of the aorta in which both great arteries fail to be displaced across the ventricular septum. This literal meaning of transposition is now accepted by most pathologists and surgeons.

Recognition of TGA during life resulted from observations of Fanconi in 1932 and Taussig in 1938. Importance of the early appearance of pulmonary vascular disease, even when the ventricular septum was intact, was described by Ferguson and colleagues in 1960 and Ferencz in 1966.

Surgery for TGA commenced in 1950 when Blalock and Hanlon at Johns Hopkins Hospital described a closed method of atrial septectomy designed to provide mixing of pulmonary and systemic venous return at the atrial level. Edwards, Barger, and Lyons modified the Blalock-Hanlon procedure in 1964 by resuturing the septum so as to connect the right pulmonary veins to the right atrium.

In 1953, Lillehei and Varco described a “partial physiologic correction” (or atrial switch) consisting of anastomosis of right pulmonary veins to right atrium, and inferior vena cava (IVC) to left atrium, a technique that became known as the “Baffes operation.” Baffes incorporated use of an allograft aortic tube to connect the IVC to the left atrium.

Palliation of TGA was revolutionized when Raskind and Miller in Philadelphia introduced balloon atrial septostomy (BAS) in 1966. However, in 1971 at Great Ormond Street Hospital in London, Tynan showed that BAS did not allow all babies with TGA to survive until repair. A modification of this procedure was introduced in 1975 by Park and colleagues with their substitution of a blade rather than a balloon at the end of the catheter.

Throughout the 1950s there were attempts to correct TGA surgically either at the atrial or the great artery levels. The concept of a physiologic correction at the atrial level by switching the atrial septum so that systemic venous return is directed to the LV and pulmonary venous return to the RV was first proposed by Albert at a meeting of the American College of Surgeons in 1954. This concept was amplified by Merendino and colleagues in 1957. The first successful operation of this type was accomplished by Senning in 1959, who refashioned the walls of the right atrium and the atrial septum to accomplish atrial-level transposition of venous return. Modifications were suggested by many, including Schumaker in 1961 and Bernard and colleagues in 1962. At the Mayo Clinic the Senning procedure was used between 1960 and 1964 with some successes (a few of these patients were still alive and well 30 years later) but with many disappointing results, related in part to the fact that most of the infants and children had a large ventricular septal defect (VSD) and varying degrees of pulmonary vascular disease.

The Mustard procedure, in which the atrial septum is excised and a pericardial baffle used to redirect systemic and pulmonary venous flow, was devised in an attempt to create larger atra than were produced by the Senning procedure and was successfully introduced at the Toronto Sick Children’s Hospital in 1963 and reported in 1964. (Actually, Wilson and colleagues described essentially the same operation in 1962. Mustard’s initial results were better than had been achieved with the Senning procedure, at least in part because he had access to a reservoir of young children with TGA and intact ventricular septum who had been palliated by a Blalock-Hanlon operation.

The Mustard technique soon was adopted in almost all cardiac surgical centers. However, a slightly modified Senning repair was reintroduced by Quaegebeur, Rohmer, and Brom in 1977, mainly because of persisting problems with baffle obstruction and arrhythmia after the Mustard procedure.

It became conventional to delay this atrial switch definitive procedure for 12 to 24 months after BAS. In occasional patients the Mustard procedure was extended to smaller infants by Dillard and colleagues in 1969, Bonchek and Starr in 1972, and Subramanian and Wagner in 1975. The first substantiated proposal that repair was necessary and possible in the first 3 months to avoid considerable pre-repair mortality was by Barratt-Boyces and colleagues.

TGA with large VSD remained a difficult problem throughout this early era because of high hospital mortality after repair and rapid development of pulmonary vascular disease in many patients. However, enough successes were obtained with the atrial switch procedures to demonstrate the value of continuing to treat patients in this subset surgically. In 1972, Lindesmith and colleagues introduced the use of a palliative Mustard procedure in which the VSD was left unclosed for patients with high pulmonary vascular resistance. The modification in which a large VSD was created in TGA with intact ventricular septum was used by Stark and colleagues in 1976.

Successes were few in patients with TGA, VSD, and important left ventricular outflow tract obstruction (LVOTO) in this early period of intracardiac surgery for TGA. Daicoff and colleagues in 1969 reported a few successful repairs by direct relief of the LVOTO associated with an atrial switch by Mustard’s technique. Later, in 1969, Rastelli and colleagues combined intraventricular tunnel repair (LV to aorta) of the double outlet RV operation (see “Intraventricular Tunnel Repair of Simple Double Outlet Right Ventricle” under Technique of Operation in Chapter 53) with a rerouting valved extracardiac conduit (RV to pulmonary trunk) and closure of the origin of the pulmonary trunk from the LV to produce an anatomic repair of TGA, VSD, and LVOTO.

Somewhat disappointing results of the atrial switch operation for TGA and large VSD continued to be a stimulus for developing an arterial switch operation, particularly because the right (systemic) ventricle sometimes failed late postoperatively in these patients. Much earlier, in 1954, Mustard and colleagues had described unsuccessful attempts to perform an arterial switch operation in seven patients, with transfer of the left coronary ostium to the pulmonary trunk and use of a monkey lung as the oxygenator. Other reports of unsuccessful operations of this general type were those of Bailey and colleagues in 1954 and Kay and Cross in 1955.
and colleagues attempted such a procedure in two patients with an intact ventricular septum in 1961 using cardiopulmonary bypass (CPB), transferring the great arteries and a ring of aorta carrying the coronary arteries. Interest then lagged in many centers, but a few groups persisted with efforts to perfect this approach. Jatene and colleagues in Brazil achieved a major breakthrough in 1975 with the first successful use of an arterial switch procedure (Jatene procedure), applying it in infants with TGA and VSD. Soon after, Yacoub and colleagues reported successful cases. An important technical modification of the original Jatene procedure was the demonstration by Lecompte and colleagues that direct anastomosis of both great arteries without interposition of a tube graft is possible when the pulmonary bifurcation is transferred in front of the distal ascending aortic arch. Aubert and colleagues successfully used intraarterial baffling and creation of an aortopulmonary tunnel to correct simple TGA by an arterial switch in 1978.

Yacoub’s attempts in London to perform an arterial switch procedure in three infants with TGA and intact ventricular septum were unsuccessful in 1972, but reports by Mauck in 1977 and Abe in 1978 with their colleagues indicated that such a repair was possible in infancy. However, most infants with TGA and intact ventricular septum did not survive arterial switching. Yacoub approached this problem of the low-pressure LV not being prepared for sustaining systemic pressure by performing pulmonary artery banding as a first stage. The matter was resolved when Radley-Smith and Yacoub in London, Quegebeur in Holland, and Castaneda in Boston with their colleagues demonstrated feasibility and safety of repair of simple TGA in the first few days of life by an arterial switch operation.

**MORPHOLOGY AND MORPHOGENESIS**

**Right Ventricle**

The RV is normally positioned, hypertrophied, and large in TGA. Its inflow and sinus portions are essentially normal in architecture. In about 90% of cases, there is a subaortic conus, and the aorta is rightward and anterior and ascends parallel to the posterior and leftward pulmonary trunk (Fig. 52-1). Such hearts also have an infundibular septum, which in the absence of a VSD, joins normally with the ventricular septum between the limbs of the trabecula septomarginalis (septal band; TSM). The infundibulum does not deviate to the left as in the normal heart, but projects directly superiorly from the sinus portion of the ventricle (Fig. 52-2).

There is less wedging of the pulmonary trunk between the mitral and tricuspid valves than in the aorta of normal hearts. As a result, a larger area of contiguity exists between the mitral and tricuspid valves than normally. These atrioventricular (AV) valves may be at virtually the same level, and the AV septum and membranous interventricular septum are then smaller than usual or (rarely) absent. The right fibrous trigone of the central fibrous body is abnormally shaped and attenuated.

In about 10% of hearts with TGA and intact ventricular septum, the subaortic conus in the RV is absent or very hypoplastic. Then the aorta is either directly anterior or anterior and to the left of the pulmonary trunk origin or (rarely) posterior. In a few cases, however, a posteriorly placed aorta is associated with a subaortic conus.

**Left Ventricle**

The LV infrequently contains a conus; typically pulmonary-mitral fibrous continuity exists, comparable with aortic-mitral fibrous continuity in the normal heart (Fig. 52-3). In about 8% of hearts with TGA, and most often in those with a VSD, a subpulmonary conus is present in the LV. The subpulmonary conus is frequently stenotic. In most of these cases, the aorta still lies anteriorly and to the right but it may be leftward or posterior.

**Ventricular Wall Thickness, Cavity Shape, and Function**

In the normal heart, the LV wall is thicker than the RV wall in utero. After birth, LV wall thickness increases progressively, whereas the RV wall becomes relatively thinner. In TGA, the RV wall is considerably thicker than normal at birth and increases in thickness with age. When the ventricular septum is intact and no important pulmonary stenosis
is present, the LV wall is of normal thickness at birth. Wall thickness remains static, however, leading to less-than-normal thickness within a few weeks of birth and a relatively thin wall by age 2 to 4 months.\textsuperscript{36,37,39,410} When a VSD is present, LV wall thickness increases slightly less than in the normal heart, but remains well within the normal range during the first year of life.\textsuperscript{318,520} With LVOTO (pulmonary stenosis) the evolution is similar, although when obstruction is severe and the ventricular septum is intact, LV wall thickness eventually exceeds RV wall thickness.\textsuperscript{6} Although not equivalent to LV work potential, LV wall thickness reflects the ventricle’s functional capacity.

In infants with TGA, the LV cavity is the usual ellipsoid in shape at birth but soon becomes banana shaped.\textsuperscript{819} Alteration in LV function accompanies this geometric change.

RV function is usually normal in TGA in the perinatal period. Thereafter, when the ventricular septum is intact, RV end-diastolic volume is increased and RV ejection fraction decreased.\textsuperscript{615,13} Depressed RV ejection fraction is unlikely to be caused by increased afterload or decreased preload and probably results from depressed RV function from relative myocardial hypoxia or the geometry of the chamber.\textsuperscript{615}

LV end-diastolic volume is increased in TGA, and LV ejection fraction is normal. RV/LV end-diastolic volume ratio, normally 1.0, is increased to 1.5 ± 0.33.

Atria

The atria are normally formed in TGA. Right atrial size is usually larger than normal, particularly when the ventricular septum is intact.

Conduction System

The AV node and bundle of His lie in a normal position, although the AV node is abnormally shaped and may be partly engulfed in the right trigone. The left bundle branch originates more distally from the bundle of His than usual and arises as a single cord rather than a sheath. Therefore, damage to the bifurcation of the bundle at VSD closure is
Great Arteries

The aorta is most often directly anterior or slightly to the right (Table 52-1). In the Taussig-Bing heart, great arteries may be side by side, with the aorta to the right (see “Taussig-Bing Heart” under Morphology in Chapter 53). Rarely the aorta is directly posterior.

Some refer to the aortic sinuses of Valsalva as “left posterior-facing” or “right posterior-facing” sinuses and “nonfacing” sinus. This becomes awkward, however, in the 25% of cases in which positions of the great arteries are different from the usual anteroposterior locations. A more universally applicable scheme is the Leiden convention, in which sinus I is on the right of an imagined observer standing in the nonfacing noncoronary aortic sinus of Valsalva looking toward the pulmonary trunk. Proceeding counterclockwise, the next sinus is sinus 2.

In 13% to 30% of patients with TGA, aortic and pulmonary commissures are not precisely aligned because of malalignment of either the aortic or mitral valve. In one study, commissural malalignment was found in nearly 40% of patients undergoing an arterial switch procedure. Recognition of commissural malalignment is important in planning the coronary transfer as well as preventing neo-aortic valve regurgitation.

Coronary Arteries

Coronary arteries in TGA usually arise from the aortic sinuses that face the pulmonary trunk, regardless of the interrelationships of the great arteries. Thus, the noncoronary sinus is usually the anterior one. Most often the left anterior descending (LAD) and circumflex (Cx) coronary arteries arise as a single trunk (left main coronary artery [LCA]) from aortic sinus 1 and distribute in a normal manner, although the Cx system is often small (Table 52-2). The right coronary artery (RCA) arises from sinus 2 and follows this artery’s usual course.

Data from Kirklin and colleagues.

*Data based on 513 neonates with simple transposition of the great arteries (TGA) or TGA with ventricular septal defect undergoing arterial switch operation, 1985 to March 1, 1989, Congenital Heart Surgeons Society multinational study.

Key: Ao, aorta; L, left; PT, pulmonary trunk; R, right.

An almost infinite number of deviations from this usual pattern exist. Typical patterns are observed when both sinuses 1 and sinuses 2 give rise to a major coronary artery (Fig. 52-4). Patterns in which the Cx or LCA passes behind the pulmonary trunk deserve special attention by the surgeon (see “Arterial Switch Operation” under Technique of Operation later in this chapter).

All three main coronary arteries may arise from a single sinus (single coronary artery), most frequently, and of utmost concern to the surgeon, from sinus 2. Usually the arteries all arise from a single ostium in the center of the sinus (see Table 52-2). Alternatively, they may arise from a double-barreled ostium consisting of two ostia immediately adjacent to each other and constituting essentially a single ostium. Regardless, often these patients have an infundibular branch arising from sinus 1, making true single RCA uncommon. Coronary artery distribution in this situation has a typical pattern (Fig. 52-5). At times, however (in a pattern not shown in Fig. 52-5), the LCA or LAD passes forward between aorta and pulmonary trunk in an intramural course to emerge anteriorly. In this situation, instead of all three main coronary arteries arising from an essentially single, more or less centrally positioned, ostium, the LCA or LAD alone nearly always arises from an entirely separate ostium far to the left of the RCA ostium, adjacent to or just above the valvar commissure between sinuses 2 and sinus 1 (Fig. 52-6). An LCA or LAD arising in this
Figure 52-4  Most common patterns of circumflex coronary system when each facing sinus of Valsalva (sinuses 1 and 2) gives origin to a major coronary artery in hearts with transposition of great arteries. Key: Cx, Circumflex; L, left anterior descending coronary artery; R, right coronary artery. (From Quaegebeur.\textsuperscript{92})

Figure 52-5  Origin of all three major coronary arteries from a single ostium (or a double-barreled ostium) in sinus 2 or sinus 1 in hearts with transposition of great arteries. Key: Cx, Circumflex; L, left anterior descending coronary artery; R, right coronary artery. (From Quaegebeur.\textsuperscript{92})

location passes forward in an \textit{intramural course} (see Fig. 52-6) and entirely within the aortic wall (Fig. 52-7). It emerges from the aorta anteriorly and has the same appearance externally as when the artery originates from sinus 1.

In patients with situs inversus, the coronary arteries are a mirror image of situs solitus but seem to have a predilection for all coronary arteries to arise from a single sinus.\textsuperscript{112} Rarely the RCA may be intramural as it passes to the right and forward from its usual origin from sinus 2 in an otherwise typical pattern of “sinus 1: LAD, Cx; sinus 2: RCA” (or 1LCx-2R).

In 88 autopsy specimens, origins of coronary arteries were at or above the level of the sinutubular junction in 20%, paracommissural origin occurred in 3%, and angle of exit from the aortic wall was not orthogonal but tangential in 7%.\textsuperscript{112} Those with high takeoff were all intramural.

A \textit{conus artery} frequently arises separately and from its own ostium in sinus 1. It may supply at least a considerable part of the anterior wall of the infundibulum of the RV.

The course of the \textit{sinus node artery} may be important in the atrial switch (Mustard or Senning) operation. This artery usually arises from the RCA close to its origin and passes superiorly and rightward, usually partly embedded in the most superior portion of the limbus of the atrial septum, where it can be damaged if this portion of the atrial septum is widely excised.\textsuperscript{113} Then the sinus node artery usually passes behind or branches to form an arterial circle around the cavoatrial junction.\textsuperscript{49}
PART VII Congenital Heart Disease

Pulmonary Vascular Disease

Now that repair of simple TGA is usually performed in the first week or two of life, and repair of TGA with VSD is usually performed in the first month or two of life, pulmonary vascular disease has almost disappeared (see Natural History and Results later in this chapter), just as it has in many other types of congenital heart disease. However, it becomes important in many patients with TGA when early surgical treatment is not performed (Table 52-3). C16,F3,F4,F8,N7,V10

When pulmonary vascular disease develops in TGA, histologic changes in the pulmonary arteries are comparable with those found in isolated large VSD and can be similarly graded by the Heath-Edwards or Reid criteria (see “Pulmonary Vascular Disease” under Morphology in Section I of Chapter 35). In addition, however, pulmonary microthrombi are present in about 25% of lungs examined at autopsy N8 or on lung biopsy. W1 Pulmonary microthrombi produce a variety of intimal lesions, including eccentric cushion lesions and occlusion with recanalization of nonlamellar intimal fibrosis that can result in irregular fibrous septa within vessel lumens. These changes occur with and without laminar and circumferential changes secondary to hypertensive pulmonary vascular disease and are of uncertain etiology and importance. The changes are seldom severe enough to cause an increase in pulmonary vascular resistance (Rp) and occur with equal frequency in TGA with intact ventricular septum, large VSD, and large VSD and LVOTO N8. Using lung biopsy specimens, Wagenvoort and colleagues have also described wall thinning and dilatation of pulmonary arteries and, to a lesser extent, pulmonary veins in TGA with intact ventricular septum, particularly when the hematocrit is high. W1

Coexisting Cardiac Anomalies

About 75% of neonates presenting with TGA have no important coexisting cardiac anomaly other than a patent foramen ovale or an atrial septal defect. About 25% to 40% have a large or small VSD. Only about 5% have associated LVOTO. Some VSDs close spontaneously in the first few weeks or months of life, and some patients without LVOTO during the first few weeks of life develop obstruction later. Also, some with TGA, VSD, and LVOTO are asymptomatic as neonates and present later in life.

*Data are based on GLH autopsy study.
+These VSDs were also juxta-tricuspid.
In 6 of the 22 hearts, VSDs were multiple.

Key: AV, Atrioventricular; VSD, ventricular septal defect.

Ventricular Septal Defect

The same types of VSD occur with TGA, and with the same definitions, as occur in hearts with a primary VSD, and they occur in about the same proportions (Table 52-4) (see “Location in Septum and Relationship to Conduction System” in Morphology in Section I of Chapter 35). Conoventricular defects of the several different varieties are most common and may not necessarily be juxtapulmonary (on LV side) (Fig. 52-8). In some hearts with conoventricular VSDs, the infundibular septum is malaligned and fails to insert within the Y of the TSM. The septum may be displaced leftward, resulting in a variable degree of LVOTO (Figs. 52-9 and 52-10), or rightward, tending to result in RV (subaortic) obstruction (Fig. 52-11). VSD with malalignment may not be juxta-tricuspid, as in tetralogy of Fallot, but the malaligned infundibular septum may be hypoplastic, varying from the usual tetralogy of Fallot (see Morphology in Section I of Chapter 38).

When the infundibular septum is displaced to the right, the pulmonary trunk may be biventricular in origin and over a juxtapulmonary VSD. Hearts with this arrangement are similar to those with double outlet right ventricle and juxtapulmonary VSD (see “Taussig-Bing Heart” under Morphology in Chapter 53) and may be associated with subaortic stenosis or aortic arch obstruction (arch hypoplasia, coarctation, or interruption). Occasionally the VSD is juxta-arterial and associated with a malaligned but nondisplaced infundibular septum. The infundibular septum may be absent or almost gone, and the VSD is then juxta-arterial (doubly committed) (Fig. 52-12).

Inlet septal defects that are also juxta-tricuspid are slightly more common in hearts with TGA than in those with a concomitant ventriculoarterial connection, in which the bundle of His passes from the AV node along the posteroinferior margin of the VSD. The juxta-aortic type of inlet septal defect, with its characteristic tricuspid straddling and abnormal AV node position, probably also occurs more often in hearts with TGA than other defects (see “Inlet Septal Ventricular Septal Defect” in Morphology in Section I of Chapter 35).

Most muscular VSDs are in the midseptum but may occur in other areas (Fig. 52-12).

Left Ventricular Outflow Tract Obstruction

Development of LVOTO, which produces subpulmonary obstruction, is part of the natural history of many patients with TGA. The obstruction may be dynamic or anatomic. LVOTO occurs in an important way at birth or within a few days in only 0.7% of patients with TGA and intact ventricular septum. Obstruction is present in about 20% of patients born with TGA and VSD. LVOTO may become apparent or develop after birth in other patients, thus reaching an overall prevalence of 30% to 35%.

Dynamic type of LVOTO, developing in patients with TGA and intact ventricular septum, is the result of leftward bulging of the muscular ventricular septum secondary to higher RV than LV pressure. Dynamic LVOTO is particularly likely to occur if the aorta lies anterior and more to the left than usual, with increased wedging of the subpulmonary area. The septum impinges against the anterior mitral leaflet in combination with abnormal systolic anterior leaflet motion (SAM). Thus, the mechanism is similar to that present.
**Figure 52-8** Specimen of transposition of great arteries with large conoventricular ventricular septal defect (VSD). A, From right ventricular side, VSD is seen to be adjacent to tricuspid valve anulus and extends inferiorly beneath it. Infundibular septum is normally aligned with trabecula septomarginalis. B, From left ventricular side, VSD is separated from pulmonary valve in part by an anomalous bulky fibrous pouch (arrow) that originates from left side of septal tricuspid leaflet and is a cause of left ventricular outflow tract obstruction. There is mitral-tricuspid continuity across floor of defect. Key: AoV, aortic valve; IS, infundibular septum; LV, left ventricle; MV, mitral valve; PV, pulmonary valve; RV, right ventricle; TSM, trabecula septomarginalis; TV, tricuspid valve.

**Figure 52-9** Specimen of transposition of great arteries with large conoventricular ventricular septal defect with leftward displacement of infundibular septum. A, From right ventricular side. B, From left ventricular side, conal septum is fused with left ventricular anterior free wall, with left ventricular outflow tract obstruction only moderate. Key: Ao, Aorta; AoV, aortic valve; IS, infundibular septum; D, ventricular septal defect; LV, left ventricle; MV, mitral valve; PV, pulmonary valve; RV, right ventricle; TSM, trabecula septomarginalis; TV, tricuspid valve.
Figure 52-10  Specimen of transposition of great arteries with large conoventricular ventricular septal defect (VSD) and leftward displacement of relatively small conal septum. A, From right ventricular side, fibrous tag (arrow), which also contributes to left ventricular outflow tract obstruction, is seen through VSD. B, From left ventricular side. Key: AoV, Aortic valve; IS, infundibular septum; LV, left ventricle; MV, mitral valve; PV, pulmonary valve; RV, right ventricle; TV, tricuspid valve; VSD, ventricular septal defect.
in hypertrophic obstructive cardiomyopathy (HOCM), but there is no asymmetric septal hypertrophy (see “Dynamic Morphology of Septum and Mitral Valve” under Morphology in Chapter 19). The gradient may be contributed to by the high velocity of blood flow produced by the usually large pulmonary-to-systemic blood flow ratio and the deformation of the LV outflow tract. When dynamic obstruction is severe, a ridge of endocardial thickening is produced on the septum at its point of contact with the mitral leaflet (Fig. 52-14). In patients with TGA and intact ventricular septum, rarely a subvalvar fibrous ridge may produce LVOTO. The ridge extends onto the anterior mitral leaflet near its hinge. This lesion is analogous to discrete subvalvar aortic stenosis occurring in otherwise normal hearts with ventriculoarterial concordant connection; it is usually localized but may be the tunnel type (see “Tunnel Subvalvar Aortic Stenosis” under Morphology in Section II of Chapter 47). LVOTO in these patients rarely may be caused by fibrous tags arising from the mitral apparatus or membranous septum. Valvar stenosis occurs infrequently in this situation, and anular hypoplasia is even less common. 

In patients with TGA and VSD, stenosis is usually subvalvar and valvar. Subvalvar stenosis is in the form of a localized fibrous ring, long tunnel-type fibromuscular narrowing, or muscular obstruction related to protrusion of the infundibular septum into the medial or anterior aspect of the LV outflow tract (Figs. 52-15 and 52-16). An important but fortunately rare form of subvalvar stenosis is attachment of the anterior mitral leaflet to the muscular outflow septum by anomalous fibrous or chordal tissue (Fig. 52-17). Other rare causes of subvalvar pulmonary stenosis are parachute mitral valve, accessory mitral leaflet tissue, and aneurysm of the membranous ventricular septum. An aneurysm may bulge as a windsock into the LV outflow tract. Its walls are thick, and the VSD is either below the aneurysm or within its sac. However, most of these “aneurysms” are examples of redundant fibrous tissue prolapsing through the VSD from the tricuspid valve (see Fig. 52-8) or accessory fibrous tags (see Fig. 52-10) in association with the anterior mitral valve leaflet.
Figure 52-12 Specimen of transposition of great arteries with large juxta-arterial ventricular septal defect (VSD). Infundibular septum is absent, and confluent aortic and pulmonary valves form upper margin of VSD. Defect is thus doubly committed. There is mild overriding of pulmonary artery and valve into right ventricle. A, From right ventricular side. B, From left ventricular side, there is pulmonary-mitral continuity. Key: Ao, Aorta; AoV, aortic valve; LV, left ventricle; MV, mitral valve; PT, pulmonary trunk; PV, pulmonary valve; TV, tricuspid valve.

Figure 52-13 Specimen of transposition of great arteries with large inlet muscular ventricular septal defect. This defect could be termed a conoventricular ventricular septal defect that is not juxtratricuspid because of a band of muscle separating it from membranous septum and tricuspid ring. A, From right ventricular side, muscle band is poorly seen (arrow). B, From left ventricular side. Key: AoV, Aortic valve; D, ventricular septal defect; LV, left ventricle; MV, mitral valve; PV, pulmonary valve; RV, right ventricle; TV, tricuspid valve.
Figure 52-14  Specimen of transposition of great arteries with essentially intact ventricular septum and dynamic muscular form of left ventricular outflow tract obstruction. Arrow points to ridge of endocardial thickening that forms at the point at which mitral leaflet touches septum during diastole. Key: LV, left ventricle; MV, mitral valve; PV, pulmonary valve.

Figure 52-15  Specimen of transposition of great arteries, ventricular septal defect (VSD), and left ventricular outflow tract obstruction. VSD is associated with infundibular septal malalignment and leftward displacement into left ventricular outflow tract. A, From right ventricular side. B, From left ventricular side, infundibular septum has fused with base of anterior mitral valve leaflet, which is cleft (arrow). Pulmonary valve ostium is displaced posteriorly and is severely stenotic. Key: AoV, aortic valve; IS, infundibular septum; MV, mitral valve; PV, pulmonary valve ostium; RV, right ventricle; TV, tricuspid valve.
Chapter 52  Complete Transposition of the Great Arteries

Valvar stenosis is caused by anular hypoplasia and when present is typically associated with subvalvar lesions. The pulmonay valve may be bicuspid. Rarely, there is a stenotic muscular subpulmonary infundibulum.

Patent Ductus Arteriosus
Patent ductus arteriosus (PDA) is more common in hearts with TGA than in hearts with ventriculoarterial concordant connection. At initial cardiac catheterization at an average age of 2 weeks, Waldman and colleagues found a PDA present in almost half the cases but it was functionally (although not necessarily anatomically) closed at 1 month. Persistence of a large PDA for more than a few months is associated with an increased prevalence of pulmonary vascular disease.

Tricuspid Valve Anomalies
The tricuspid to mitral anulus circumference ratio, normally greater than 1, is less than 1 in 46% of patients (Calder L: personal communication; 1984). This reduced ratio is most marked in hearts with associated coarctation (Fig. 52-18). Functionally important tricuspid valve anomalies are present in only about 4% of surgical patients (Table 52-5). In autopsy studies, however, a considerably higher proportion are found, particularly when there is a VSD.

Rarely, in hearts with intact ventricular septum, minor tricuspid valve anomalies may lead to severe regurgitation early in life. In hearts with TGA and VSD, anomalous chordal attachments around the edges of conoventricular VSDs are more common than in isolated VSD. These may complicate transatrial VSD closure and the construction of an intraventricular tunnel in the Rastelli operation.

The tricuspid leaflets can be redundant and dysplastic in TGA. Accessory tricuspid tissue may prolapse through the VSD and produce LVOTO (see “Left Ventricular Outflow Tract Obstruction” in previous text).

The tricuspid anulus may be dilated, resulting in some regurgitation, or in other cases the valve may be hypoplastic in association with underdevelopment of the RV sinus. Anular overriding or tensor straddling or both can occur, the latter being more common.
Figure 52-18  Ratio of tricuspid to mitral valve circumference in a series of autopsy hearts with transposition of great arteries (TGA) compared with 17 normal hearts. “Control” TGA specimens were those with a completely intact ventricular septum, with or without a small patent ductus arteriosus, atrial septal defect, or patent foramen ovale. Only unoperated specimens and those obtained within 30 days of an intracardiac repair are included. Vertical bars indicate one standard deviation. Individual P values are noted. Key: Coarct, Coarctation; PS, pulmonary stenosis; TV/MV, tricuspid to mitral valve; VSD, ventricular septal defect. (From Calder L: personal communication; 1984.)

*dMild in 16, moderate in 20, severe in 31.
*eRequiring closure.

Mitral Valve Anomalies

Important structural anomalies of the mitral valve are present in 20% to 30% of hearts with TGA, mostly in combination with a VSD, but the majority are not functionally important. There may be slight hypoplasia of the valve ring, often with clockwise rotation (viewed from LV apex). Mitral valve anomalies can be categorized into four groups as those affecting the:

1. Leaflets
2. Commissures
3. Chordae tendineae
4. Papillary muscles

The most important from a surgical standpoint are those of mitral valve overriding or straddling, in which the mitral valve leaflet is frequently also cleft.

Aortic Obstruction

Coexisting aortic obstruction can be discrete (coarctation or less often, interrupted aortic arch) or caused by distal arch hypoplasia. Rarely, it occurs when the ventricular septum is essentially intact, but it occurs in 7% to 10% of patients with TGA and VSD. This coexistence is more frequent when the VSD is juxtapulmonary and the pulmonary trunk is partly over the RV in association with rightward and anterior displacement of the infundibular septum and with some subaortic narrowing. (Coarctation is also common in the Taussig-Bing type of double outlet right ventricle; see “Taussig-Bing Heart” under Morphology in Chapter 53.) The ductus usually also remains patent to the aorta below the coarctation (pruductal coarctation).

When there is associated coarctation, underdevelopment of the RV sinus is more common and, as noted earlier, tricuspid to-mitral annulus circumference is less than in other TGA subsets.

Right Aortic Arch

Right aortic arch occurs in about 5% of patients with TGA. It is more common when there is an associated VSD than when the ventricular septum is intact and when there is associated leftward juxtaposition of the atrial appendages.

Leftward Juxtaposition of Atrial Appendages

Leftward juxtaposition of the atrial appendages occurs in about 2.5% of patients with TGA coming to repair. It is associated with a higher than usual prevalence of important underdevelopment of the RV sinus. Bilateral conus and dextrocardia seem more common in TGA associated with leftward juxtaposition than in TGA generally.

Right Ventricular Hypoplasia

RV hypoplasia was found to some degree in 17% of the autopsy series of TGA reported by Riemenschneider and colleagues.
Other Anomalies
Rarely, TGA coexists with congenital valvar aortic stenosis, and very rarely with total anomalous pulmonary venous connection. TGA can also coexist with complete AV septal defect (see “Complete Atroventricular Septal Defect” under Morphology in Chapter 34).

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

When the great arteries are transposed in hearts with AV concordant connection, systemic and pulmonary circulations are in parallel. Unless there is shunting between the two, this defect is incompatible with life for more than a short time. With this arrangement, pulmonary (Qp) and systemic (Qs) blood flow can vary independently, and shunting between the two circulations over more than very short periods must be equal in both directions, or eventually all the blood will be in one or the other circulation. Magnitude of bidirectional shunting is highly variable and is referred to as degree of mixing.

Symptoms and clinical presentation also depend in part on left atrial and pulmonary venous pressure. When Qp is even moderately elevated, these pressures tend to become elevated and produce symptoms. Both LV and RV failure usually result.

Clinical features and diagnostic criteria of patients with TGA fall into three groups based on these criteria, as discussed in the text that follows.

Essentially Intact Ventricular Septum (Poor Mixing)

TGA with essentially intact ventricular septum includes infants without a VSD or with a VSD 3 mm or less in diameter. A patent foramen ovale or naturally occurring atrial septal defect (ASD) is usually present. Cyanosis is apparent in half these infants within the first hour of life and in 90% within the first day and is rapidly progressive. Qp is usually increased to a pulmonary-systemic blood flow ratio (Qp/Qs) of about 2, but because of poor mixing across the small communication, this does not alleviate hypoxia. The baby becomes critically ill with tachypnea and tachycardia and dies from hypoxia and acidosis without appearance of frank heart failure. This rapid downhill course is usually obviated with a naturally occurring ASD of adequate size, because cyanosis is less severe. In surviving infants, appearance of moderate or severe dynamic LVOTO is associated with increasing cyanosis and hypoxic spells even after an adequate atrial septostomy.

Clinical signs in most newborns are unimpressive. Generally, patients are of average birth weight and in good general condition, although with severe cyanosis. Clubbing of fingers and toes is absent and generally does not appear unless the infant survives to about age 6 months. There is mild increase in heart and respiratory rates. The heart is not hyperactive, and the liver is barely palpable. A faint mid-systolic ejection-type murmur is present along the midleft sternal edge in less than half these infants. This murmur is more prominent with organic or dynamic LVOTO, first appearing at age 1 or 2 months with the dynamic form and then gradually increasing in intensity. The second heart sound is unremarkable (often apparently single or narrowly split), and the third heart sound and apical mid-diastolic flow murmur are both rare.

Chest radiography (Fig. 52-19) has three characteristic features:

1. An oval- or egg-shaped cardiac silhouette with a narrow superior mediastinum
2. Mild cardiac enlargement
3. Moderate pulmonary plethora

In the first week of life, however, the chest radiograph may be normal; occasionally cardiac enlargement may be more marked. The narrow mediastinum is caused in part by the great artery positions and by shrinkage of the thymus, usually associated with stress, and the plethora is caused by the increase in Qp. Plethora is less marked when there is important LVOTO.

The electrocardiogram (ECG) is often normal at birth, with the usual neonatal RV pattern. By the end of the first week, persistence of an upright T wave in the right precordial leads indicates abnormal RV hypertrophy, and right-axis deviation predominates. The vectorcardiogram shows a clockwise horizontal plane loop indicative of a near-normal LV systolic pressure and a dominant RV mass. When important
LVOTO is present or Rp is elevated, ECG evidence indicates biventricular hypertrophy.

Large Ventricular Septal Defect, Large Patent Ductus Arteriosus, or Both (Good Mixing)

Presentation in this TGA group generally occurs in the latter half of the first month, with mild cyanosis and signs of heart failure resulting from pulmonary venous hypertension and myocardial failure. Tachycardia, tachypnea, important liver enlargement, and moist lung bases are present. The heart is more active and usually larger than in the poor-mixing group.

A large VSD is associated with a moderate-intensity pansystolic murmur along the lower left sternal edge that may not be present initially. There is usually an apical mid-diastolic murmur or gallop rhythm and narrow splitting of the second heart sound with accentuation of the pulmonary component. With a large PDA, a continuous murmur, bounding pulses, and an apical mid-diastolic murmur are present in less than half the patients, even when the ventricular septum is intact. Sudden spontaneous closure of a large PDA when there is no VSD results in an increase in cyanosis (see Natural History later in this chapter).

Chest radiography may show more cardiomegaly, more plethora, and a wider superior mediastinum than in the poor-mixing group. Development of pulmonary vascular disease is associated with reduction in Qp and less plethora, particularly in the peripheral lung fields, as well as reduced heart size, but these features generally appear after the neonatal period.

The ECG shows biventricular hypertrophy and, when there is a persistent large VSD, a Q wave in V6. Isolated LV hypertrophy is rare and suggests RV hypoplasia with tricuspid valve overriding.

When coarctation of the aorta coexists with VSD and PDA, femoral pulses are usually normal because the coarctation is preductal and ductus arteriosus large. Rarely, differential cyanosis can occur, with cyanosis confined to the upper torso. All patients with this combination present early in life in heart failure and respond poorly to decongestive treatment. Isolated LV hypertrophy may be present on ECG because of frequent association of coarctation with RV hypoplasia.

Large Ventricular Septal Defect and Left Ventricular Outflow Tract Obstruction (Poor Mixing without High Pulmonary Blood Flow)

Large VSD with LVOTO is the least common of the three TGA groups. LVOTO is associated with a decreased Qp and poor mixing, but pulmonary venous hypertension and associated symptoms and signs do not develop because of lack of increase in Qp. Heart failure is therefore not present. Clinical findings are similar to those of tetralogy of Fallot with severe pulmonary stenosis or pulmonary atresia (see Clinical Features and Diagnostic Criteria in Section I of Chapter 38), and cyanosis is severe from birth. The heart is not overactive, and there is a pulmonary ejection murmur and often a single heart sound without an apical gallop or mid-diastolic murmur. Chest radiography shows a near normal–sized heart with normal or ischemic lung fields, and ECG shows biventricular hypertrophy.

Echocardiography

Definitive diagnosis of TGA can be made using two-dimensional (2D) echocardiography. Two-dimensional echocardiography is also particularly valuable in detecting tricuspid valve abnormalities, including overriding and straddling, and the varieties of subpulmonary stenosis, including dynamic obstruction. Echocardiographic features of dynamic LVOTO include leftward deviation of the ventricular septum, abnormal fluttering and premature closure of the pulmonary valve, SAM of the mitral leaflet (about 50% of cases), and prolonged diastolic apposition of the anterior mitral valve leaflet to the septum.

Echocardiography can also define with reasonable accuracy morphology of the coronary arteries, including number, origin, major branching pattern, and other features such as intramural course (Fig. 52-20). With two-reader methodology, the sensitivity of echocardiography to detect coronary variants is 86%, with a negative predictive value of 91% (Fig. 52-21).

Fetal echocardiography may be helpful in identifying abnormalities of the foramen ovale or ductus arteriosus, which is associated with neonatal hypoxia and death, and of the ventricular septum. Fetal diagnosis may improve perinatal care and reduce perinatal mortality and postoperative morbidity.

Cardiac Catheterization

Cardiac catheterization and cineangiography are not performed routinely, particularly in neonates, with major reliance for diagnosis placed on echocardiography. Nonetheless, knowledge of the information from these studies remains important.

A full study includes calculation of Qp and Qs and pressures, including those across the LV outflow tract. Because of intracardiac communications in patients with TGA, the Fick method is usually the only practical way of measuring Qp and Qs. Despite complexity of the circulation, standard calculations apply. Meticulous care is required in measuring oxygen consumption using a closed-box technique in infants. Equations are as follows:

\[
Q_p = \frac{V_O}{C_pO_2 - C_pO_2} \\
Q_s = \frac{V_O}{C_aO_2 - C_VO_2} \\
Q_ep = \frac{V_O}{C_pO_2 - C_VO_2}
\]

where

- \(Q_p\) = Pulmonary blood flow
- \(V_O\) = Oxygen consumption, mL · min\(^{-1}\)
- \(C_pO_2\) = Pulmonary venous oxygen content, mL · L\(^{-1}\)
- \(C_pO_2\) = Pulmonary arterial oxygen content, mL · L\(^{-1}\)
- \(Q_s\) = Systemic blood flow
- \(C_aO_2\) = Systemic arterial oxygen content, mL · L\(^{-1}\)
- \(C_VO_2\) = Mixed venous oxygen content, mL · L\(^{-1}\)
- \(Q_ep\) = Effective pulmonary blood flow

\(Q_ep\) represents flow of blood from the systemic to the pulmonary circuit at atrial, ventricular, and great arterial levels.
Flow must be equal in the opposite direction (anatomic left-to-right shunt or effective systemic blood flow), or over time one circuit would be deprived of blood.

Inherent errors occur in measuring these flows. When $Q_p$ is high and therefore pulmonary arterial oxygen saturation ($Sp_{aO_2}$) is high, the Fick calculation tends to be inaccurate. This error may be compounded by difficulties in recovering a truly mixed $Sp_{aO_2}$. Fortunately, these errors are greatest in patients with a very high $Q_p$, when concern is minimal about a high $R_p$. Calculations are more accurate when the $Q_p$ is low and $R_p$ correspondingly high. Potential for error exists if pulmonary arterial sampling is made proximal to site of entry of sizable systemic (bronchial) collaterals. Truly mixed $Sp_{aO_2}$ would then be lower than that measured, and $Q_p$ correspondingly lower, but in practice this situation is uncommon.

Thus, with careful technique, $R_p$ in patients with TGA can be calculated with reasonable accuracy. A specific problem arises, however, if hematocrit is particularly high; viscosity of the blood increases sharply when hematocrit is greater than
60%. The effect of viscosity on \( Q_p \) may then become important, and calculated \( R_p \) may be higher than that dictated by the pulmonary vascular bed alone.\(^{31}\) The only solution to this is to repeat the measurements after lowering the hematocrit by venesection.

\( Q_p \) is the flow upon which life depends. This flow is relatively fixed, typically only about 1.0 to 1.5 L \( \cdot \) min\(^{-1} \) \( \cdot \) m\(^{-2} \). This places a major constraint on oxygen supply to the patient. These relationships become evident in rewriting the Fick equation as follows:

\[
V_O_2 = Q_p (C_pO_2 - C_VO_2) = Q_p (SpvO_2 - SvO_2) \times Hb \times C_{max}O_2
\]

where

\( SpvO_2 = \) Pulmonary venous oxygen saturation
\( SvO_2 = \) Mixed-venous oxygen saturation
\( C_{max}O_2 = \) Oxygen capacity per gram of Hb
\( Hb = \) Hemoglobin concentration, g \( \cdot \) L\(^{-1} \)

On this basis, any reduction in hemoglobin will reduce oxygen uptake, and compensation for it is not possible in patients with TGA.\(^{39}\) If stress or exercise increases oxygen requirement, the difference in \( C_p \) and \( C_V \) must widen, and because \( C_p \) cannot increase, \( C_V \) (and thus tissue \( P_O_2 \)) must fall.

Cineangiography

Using appropriate views, cineangiography demonstrates the cardiac connections and great artery positions (Fig. 52-22), position and number of VSDs (Fig. 52-23), site of any LVOTO (Fig. 52-24), size and function of AV valves, size and function of both ventricles, pattern of the coronary arteries, and presence of other cardiac anomalies.

Computed Tomography and Magnetic Resonance Imaging

Although these newer modalities are more accurate than echocardiography in evaluating anatomy, particularly coronary anatomy, they are not routinely used in the neonate. Cardiac computed tomographic angiography (CTA) and image postprocessing with volume rendering can give an accurate diagnosis of the coronary pattern, even in neonates (Fig. 52-25). These modalities are used more frequently in postoperative patients in whom coronary imaging is indicated.

**NATURAL HISTORY**

Prevalence

TGA is a common form of congenital heart disease, occurring in 1:2100 to 1:4500 births\(^{1,12,14}\) and accounting for 7% to 8% of all congenital heart disease. Prevalence might be reduced more than 50% by maternal preconceptional multi-vitamin use\(^{39}\) or may be reduced by avoiding pesticides during the first trimester.\(^{1,12}\) In the Auckland area of New Zealand, prevalence over a 10-year period was 1:2400, whereas in New England (U.S.), it was 1:4000\(^{112}\) (\( P < .005 \)). Before the advent of effective treatment, at least 16% of deaths from congenital heart disease during childhood were caused by TGA.\(^{1,14}\)

Male-to-female ratio is 2:1. Male predominance increases to 3:3:1 when the ventricular septum is essentially intact and disappears in complex forms.\(^{1,14}\)

Survival

When patients with all varieties of TGA are considered, 55% survive 1 month, 15% survive 6 months, and only 10% survive 1 year (Fig. 52-26).\(^{5,8,7,8,1,12,14,7}\) Mean life expectancy is 0.65 year, rising to 4 years for those who survive to 12 months and to 6 years for the few who survive for 10 years. Thereafter, life expectancy declines rapidly (see Fig. 52-26).

Survival without treatment is different among subsets. It is particularly poor in untreated patients with *TGA and essentially intact ventricular septum*: 80% at 1 week but only 17% at 2 months and 4% at 1 year.\(^{1,14}\) Survival in this group is better when there is a true ASD (Fig. 52-27).

In patients with *TGA and important VSD*, early survival is higher: 91% at 1 month, 43% at 5 months, and 32% at 1 year.\(^{1,14}\) It is lower when the patient has a very large \( Q_p \) (see Fig. 52-27). The combination of large VSD and aortic obstruction (coarctation, interrupted arch) is particularly lethal; all patients die within a few months of birth with severe heart failure. Paradoxically, obstructive pulmonary vascular disease in patients with TGA and VSD improves early survival to 40% at 1 year, but with rapid decline thereafter and none alive by age 5 years.

In patients with *TGA, VSD, and LVOTO*, early survival is still better, reaching 70% at 1 year and 29% at 5 years, because in many patients LVOTO is only moderate initially.

Leibman and colleagues found that PDA increased risk of early death in all subsets of patients.\(^{1,14}\) This is particularly the case when the ductus is large.

Modes of Death

Poor survival in patients with *TGA and essentially intact ventricular septum* is related primarily to hypoxia. Intercurrent pulmonary infections may develop and are particularly lethal because they reduce \( Q_p \) and lead rapidly to increasing hypoxia, acidemia, and death. Death in this group may also result from cerebrovascular events, usually caused by the polycythemia and increased blood viscosity secondary to severe cyanosis, particularly in association with dehydration. However, hypoxia plus hypochromic microcytic anemia has also been implicated in the etiology of these events.\(^{116}\) Nonfatal cerebrovascular events occur in about 6% of patients treated by BAS\(^{112}\) and include cerebral abscess.

Patients with *TGA and important VSD* usually die with heart failure. Modes of death described for patients with simple transposition sometimes pertain to this group as well and include frequent intercurrent pulmonary infections.

Hypoxia is the primary cause of morbidity and mortality in patients with *TGA, VSD, and LVOTO*.

Patent Ductus Arteriosus

PDA is present at age 1 week in about half the patients with TGA, but thereafter the prevalence falls rapidly.\(^{219}\) When patent, the ductus is small (<3 mm in diameter) in about two
Figure 52-22  Cineangiograms of simple transposition of great arteries. **A-B**, Left ventricular injection, long axial view, in diastole and systole. Left ventricular outflow tract is widely open. Apparent narrowing at origin of left pulmonary artery is frequently seen and, as here, usually disappears during systole. **C-D**, Left ventricular injection, similar views and position, in another infant. Left ventricle gives origin to pulmonary trunk, and there is a long area of subpulmonary left ventricular outflow tract obstruction.
Figure 52-23  Cineangiograms of transposition of great arteries and ventricular septal defect (VSD). A, Small midmuscular VSD is demonstrated by right ventricular injection in long axial view. B, Large VSD in inflow portion of septum is demonstrated by right ventricular injection in four-chamber position. C, Large conoventricular VSD is shown with left ventricular ejection in long axial view. D, Multiple muscular VSDs are demonstrated with a right ventricular injection in long axial view. Key: Ao, Aorta; LV, left ventricle; PT, pulmonary trunk; RV, right ventricle.
Figure 52-24  Cineangiograms of transposition of great arteries, ventricular septal defect (VSD), and left ventricular outflow tract obstruction (LVOTO). A, Subvalvar LVOTO is associated with large conoventricular VSD, as shown by left ventricular injection and four-chamber view. B, Long subvalvar LVOTO is associated with large conoventricular VSD, as shown by left ventricular injection and four-chamber view. C, Discrete subvalvar LVOTO with large VSD and mild overriding of aorta onto left ventricle, as shown by left ventricular injection and four-chamber view. Key: Ao, Aorta; IS, infundibular septum; LV, left ventricle; PT, pulmonary trunk; PV, pulmonary valve; RV, right ventricle.

Figure 52-25  Computed tomography volume-rendered image showing left main coronary artery with left anterior descending and circumflex branches arising from left-facing sinus of Valsalva in infant with unrepaired S,D,D transposition of great arteries. Key: Ao, Aorta; Cx, circumflex coronary artery; L Main, left main coronary artery; LAD, left anterior descending coronary artery; LV, left ventricle PT, pulmonary trunk; RV, right ventricle.

Figure 52-26  Survival and life expectancy of 655 children with transposition of great arteries (TGA) of all types, all of whom died between 1957 and 1964; 73 living children and 14 miscellaneous deaths are excluded. Group is impure in that about 15% of the total had either single ventricle, hypoplasia of left ventricle with mitral stenosis or atresia, or hypoplasia of right ventricle with tricuspid stenosis or atresia. However, trends are representative of patients with TGA. (From Liebman and colleagues.)

1877
thirds of patients and seems to have little influence on natural history.\textsuperscript{1,14} When it is large, LV output is increased and hypoxia lessens, but heart failure becomes more severe. Under these circumstances, acute and often early closure of the ductus results in sudden increase in hypoxia and clinical deterioration.\textsuperscript{18,\textsuperscript{W2}} This is related not only to decreased mixing at the ductus level but also at the atrial level because of the fall in left atrial pressure that results from decreased pulmonary venous return.\textsuperscript{W2}

Atrial Septal Defects

In patients with TGA, the patent foramen ovale tends to close at the usual rate. This is the major cause of the time-related increase in hypoxia and death in patients with TGA and essentially intact ventricular septum without an important PDA. A true ASD, on the other hand, remains unchanged in size and palliates the patient longer.\textsuperscript{18} The same is true for those rare examples of coexisting partial anomalous pulmonary venous connections.

Ventricular Septal Defects

Large VSDs close or narrow in probably a smaller proportion (≈20\%) of patients with TGA than in patients with isolated VSD (see “Spontaneous Closure” under Natural History in Section I of Chapter 35). In most cases, however, the closing VSD is initially small and often muscular, and spontaneous closure has been documented to occur as late as the last part of the first decade of life.\textsuperscript{18} This process was rarely documented before the era of BAS, because so few patients survived beyond the first few months of life.\textsuperscript{3,13}

Left Ventricular Outflow Tract Obstruction

Dynamic LVOTO is not present at birth but can appear within several weeks. It gradually progresses in severity. Awareness of this tendency has increased since the era of BAS, after which LVOTO frequently develops. When dynamic LVOTO becomes important, hypoxia returns and life expectancy is shortened. LVOTO develops infrequently in patients with TGA and important VSD.

Pulmonary Vascular Disease

When TGA occurs as an isolated lesion (simple TGA), pulmonary vascular disease rarely develops in the first few months of life. After about 6 to 24 months, however, its prevalence increases to 10\% to 30\%.\textsuperscript{16,3,\textsuperscript{F1},\textsuperscript{F4},\textsuperscript{L3},\textsuperscript{N8}} Its development reduces Qp and increases hypoxia.

In patients with TGA and moderate or large VSD, pulmonary vascular disease develops more rapidly than in patients with simple TGA, as it does in those with persistently large PDA. Among those dying at about age 6 months, 25\% have developed severe pulmonary vascular disease (2grade 3), and 50\% of infants dying by age 12 months have developed it. These prevalences are much higher than in patients with primary VSD, and mechanisms may include hypoxemia and a prominent bronchopulmonary collateral circulation.\textsuperscript{2,\textsuperscript{F3},\textsuperscript{F4},\textsuperscript{N7},\textsuperscript{W1},\textsuperscript{W2}}

Increased Blood Flow to Right Lung

At birth in TGA, as in normal patients, slightly more blood flows to the right lung than to the left. In contrast to normal flow, however, flow to the right lung in TGA increases as age increases.\textsuperscript{4,\textsuperscript{R1},\textsuperscript{Y8}} In addition to age, magnitude of the increase is affected by the angle between takeoff of the right pulmonary artery and pulmonary trunk; the wider this angle (and thus the more the pulmonary trunk faces directly into the right pulmonary artery), the greater the blood flow to the right lung. The tendency of infants with intact ventricular septum to develop dynamic LVOTO after the first few months increases the velocity of flow, which increases the momentum effect toward the more directly aligned vessel.

Once right lung flow increases, the right vascular bed grows more and there is a relative increase in Rp and reduced compliance in the left lung, which further reduces left lung flow. It is unlikely that this phenomenon importantly affects the natural history of untreated TGA.

TECHNIQUE OF OPERATION

Currently, the arterial switch operation is advised for most patients with TGA except those with important fixed LVOTO.
An atrial switch operation (Mustard or Senning type) may be appropriate rarely, and in highly selected patients. Patients with poor mixing, typically those with intact ventricular septum and a small ASD, come to the operating room receiving an infusion of prostaglandin E2 and usually having had BAS. In current cardiology practice, septostomy is performed through transvenous access using echocardiographic guidance. These preoperative maneuvers usually result in adequate mixing and a stable patient.

Arterial Switch Operation

Simple Transposition of the Great Arteries with Usual Great Artery and Coronary Patterns

Preparation of the patient for operation, anesthesia, placement of monitoring devices, and details of the median sternotomy and initial dissection are the same as in other operations in neonates and young infants (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2). Positioning of the baby with extension of the neck is particularly important for exposure of the great arteries. Three general types of support systems are in use for arterial switch operation:

1. Continuous CPB, usually at 18° to 25°C, with reduced flow rate after reaching the target temperature. In some centers, mild hypothermia or normothermia is used. The IVC and superior venae cavae (SVC) are cannulated directly for venous return.

2. Near-continuous CPB at 18° to 20°C and with reduced flow rates (0.5 to 10 L·min⁻¹·m⁻²), but with a single venous cannula inserted through the right atrial appendage (see Sections III and IV in Chapter 2). Hypothermic circulatory arrest is established only for closure of the ASD, which is done through the opening in the tip of the right atrium or a small right atriotomy after removing the venous cannula. After this closure, the venous cannula is reinserted, CPB reinstituted, and full flow restored for rewarming of the patient.

3. Operation primarily is performed during hypothermic circulatory arrest after the patient has been cooled to 18°C by CPB, with rewarming also accomplished by CPB.

Preference for these methods is in the order presented.

Myocardial management is also variable among institutions achieving good results. A prevalent method is infusion into the aortic root through a large-bore needle of a cold, hyperkalemic, sanguineous solution just after clamping the ascending aorta, and no more. Another method is use of the same protocol but with an asanguineous cardioplegic solution.

The aorta and pulmonary trunk must be dissected apart and the ductus arteriosus dissected. The right and left pulmonary arteries are extensively mobilized to their lobar branches and beyond if needed. As much of this as convenient is performed before CPB, but it may be necessary to complete these steps after CPB is established. The aortic purse-string stitch is placed as far downstream as possible to facilitate work on the aortic root and ascending aorta (Fig. 52-28, A). When using two venous cannulae, purse-string sutures are placed in the superior and inferior venae cavae as they enter the right atrium. A suture ligature is placed around the aortic end of the ductus (see Fig. 52-28, A) Another purse-string stitch is placed in the right superior pulmonary vein as it enters the left atrium (not shown in Fig. 52-28, A).

After cannulation is completed, CPB is established and cooling begun. Another suture ligature is placed around the pulmonary end of the ductus and the ductus divided. If the two venae cavae have been directly cannulated, adjustable snares are placed around them and tightened, and a small (13F) angled vent catheter is placed through the purse string in the right superior pulmonary vein, positioning its tip across the mitral valve into the LV. The cardioplegic infusion needle is inserted, the aorta clamped, and infusion given.

The aorta is transected and better exposure is obtained by turning back the proximal segment to facilitate further dissecting apart the great arteries (Fig. 52-28, B). The pulmonary trunk is transected just proximal to its bifurcation (Fig. 52-28, C). The aortic button around the orifice of the LCA is excised from its sinus, and this is inserted into the left-facing sinus of the neoaorta (originally, pulmonary trunk). The aortic button around the orifice of the right coronary artery is excised and inserted into the right-facing sinus of the neoaorta (Fig. 52-28, B-D).

After the Lecompte maneuver (Fig. 52-28, E), the neoaorta is constructed by anastomosing the proximal segment of the original pulmonary trunk to the distal aortic segment. The stretched or torn foramen ovale (or ASD) is closed through an incision in the right atrium, usually with a running stitch. A patch may be used if the ASD is large. The right atrium is closed.

Separate autologous pericardial patches are used to fill in the defects in the proximal neopulmonary trunk. The neopulmonary trunk is then constructed (Fig. 52-28, F). All the latter steps involving pulmonary trunk reconstruction may be completed before removing the aortic clamp and beginning reperfusion of the heart, or reperfusion may be started at any point along the way.

A polyvinyl catheter is brought out from the left atrium through the right superior pulmonary vein or left atrial appendage if not already placed, and later, one is brought out from the right atrium. After the neonate has been rewarmed by the perfusate and proper conditions are in place, CPB is discontinued, and the remainder of operation is performed as detailed earlier (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2). Use of intraoperative echocardiography to assess global and, especially, regional ventricular function is helpful in assessing adequacy of coronary translocation.

Simple Transposition of the Great Arteries with Origin of Circumflex Coronary Artery from Sinus 2

At times, the CX coronary artery arises as a branch of the RCA, the ostium of which is in sinus 2 (right-facing sinus). The CX artery then passes leftward behind the pulmonary trunk and arborizes in the usual fashion (Fig. 52-29, A). Less often the LCA arises from sinus 2 (an RCA from sinus 1) and passes leftward behind the pulmonary trunk to bifurcate in the usual manner. In both situations, particular care is required in the transfer of this coronary button from sinus 2.

Operation proceeds in the manner just described until the button of aorta containing the ostium of RCA and CX has been excised from sinus 2. A trap door opening is made in the right-facing sinus of the proximal neoaorta, cutting this
Figure 52-28  Arterial switch operation for transposition of great arteries, with aorta anterior and rightward, and usual coronary artery pattern (1LCx-2R). A, Placement of cardiopulmonary bypass (CPB) purse strings is shown in a patient who will undergo operation using continuous bypass and bicaval cannulation. Note that aortic purse string is placed as high on ascending aorta as possible to provide room for great artery manipulation. Venous purse strings are placed directly into superior and inferior venae cavae. A suture ligature has been placed around aortic end of ductus arteriosus. Tissue between great arteries is dissected prior to establishing CPB. A helpful maneuver is to place marking sutures on neoaorta for identifying sites of coronary implantation. Left and right branch pulmonary arteries are mobilized into first-order branching vessels. Cannulation proceeds in standard fashion and ductus arteriosus is immediately ligated. A separate suture ligature is placed on pulmonary artery end of ductus arteriosus and tied, and ductus is transected. A separate purse-string suture is placed in right upper pulmonary vein as it enters left atrium, and a vent catheter is introduced through purse string into left atrium, across mitral valve, and positioned into left ventricle (vent is not shown in this figure). B, After target core temperature is achieved, aorta is clamped and cardioplegia introduced into aortic root by one of standard methods. The aorta is transected just above sinutubular junction, and coronary arteries are carefully examined to confirm their positions and to rule out possibility of any unusual variations, such as eccentric coronary ostia or intramural coronary arteries. Using sharp dissection with fine scissors, coronary arteries are removed from their sinuses with at least a 1- to 2-mm cuff of sinus tissue surrounding ostia. Ligated and divided ductus arteriosus is also shown.
Coronary buttons have been completely mobilized. Pulmonary trunk is transected at its midportion and sites of coronary implantation (with help of marking sutures, if present) are identified on proximal neoaorta (dashed lines). Various techniques can be used to prepare implantation sites. Most common variation is shown here, in which implantation site is prepared by removing a horseshoe-shaped segment of pulmonary trunk wall. Implantation sites can also be prepared with a simple incision (slit) without resection of any proximal neoaortic tissue. Coronary implantation is performed sequentially using a running 8-0 or 7-0 monofilament suture. Following implantation, it is important to visualize course of coronary artery and, if any doubt remains as to its patency, a 1- to 1.5-mm probe is passed into its proximal portion to demonstrate patency.

Continued
Coronary arteries are fully implanted. Lecompte maneuver has been performed, as indicated by branch pulmonary arteries now located anterior to aorta. Anastomosis between proximal neoaorta and ascending aorta is performed end to end using a running 7-0 monofilament suture technique. After completing aortic anastomosis, coronary explantation sites on proximal neopulmonary trunk are reconstructed with individual patches of glutaraldehyde-treated autologous pericardium. Individual pericardial patches are tailored to be slightly larger than defects that resulted from coronary explantations. Proximal neopulmonary trunk is then connected to distal pulmonary trunk, end to end, using a running monofilament 7-0 suture technique. Completed great artery reconstruction is shown, along with closed CPB cannulation sites. Careful examination of proximal coronary arteries and their relation to anteriorly positioned pulmonary trunk and pericardial patches is routinely performed to ensure coronary arteries are not distorted or compressed. (Atrial septal defect [ASD] is closed using standard technique as described in text. ASD can be closed at any point in procedure. The common technique used with continuous CPB is to close ASD after aortic reconstruction is complete, but before embarking on pulmonary trunk reconstruction. In this way, ASD is closed with the aortic clamp still in place, aiding intracardiac visualization. Aortic clamp is then removed prior to performing pulmonary trunk reconstruction, minimizing myocardial ischemia time.)
Figure 52-29  Arterial switch operation for transposition of great arteries in patients with second most common coronary artery pattern (1L-2RCx). A, Aorta is anterior and slightly to right, as in the usual case. Proposed site of pulmonary trunk transection is as far distal as possible, just before bifurcation, to provide a proper implantation site on proximal neoaorta (native pulmonary trunk) for coronary button from sinus 2. Proposed aortic transection site is slightly more distal than in the case with most common coronary pattern (see Fig. 52-28), to accommodate slightly shorter distal pulmonary trunk segment at time of pulmonary reconstruction. Dashed lines show proposed transected sites of great arteries. Note circumflex coronary artery passing posterior and to left behind great arteries to distribute to its normal myocardial area. B, Using standard cardiopulmonary bypass and myocardial protection techniques, operation proceeds in standard fashion until it is necessary to reimplant coronary button from sinus 2. Coronary from sinus 1 has been reimplanted in standard fashion (see Fig. 52-28). Proximal neopulmonary trunk is retracted anteriorly, and tissue between the two great arteries at their bases is fully dissected. Dashed line shows proposed incision to create “trapdoor” flap that serves to orient sinus 2 coronary button after reimplantation such that circumflex artery is neither kinked nor stretched. Because pulmonary trunk was transected as distally as possible, reimplanted coronary also is positioned more cephalad than in usual case. This also minimizes chance of circumflex artery kinking.

Simple Transposition of the Great Arteries with Origin of All Coronary Arteries from Sinus 2

When all three major coronary arteries arise from sinus 2, they usually do so from a single ostium (see “Coronary Arteries” under Morphology earlier in this chapter). Operation is performed in the same general manner as described in the preceding text for patients in whom the Cx arises as a branch from the RCA arising from sinus 2.

When all three branches pass to the right and none passes leftward behind the pulmonary trunk, implantation can be into a simple incision in the center of the right-facing sinus.
When all three major coronary arteries arise from sinus 2, they may arise infrequently from two ostia, one of which is eccentrically located very near the valve commissure between sinus 2 and sinus 1 (Fig. 52-30, A). The LCA or only the LAD typically passes directly forward intramurally within the wall of the aorta. Unless forewarned, the surgeon may not recognize this from external examination after sternotomy, identifying it only after transecting the aorta and examining the interior of the aortic sinuses.

Several techniques have been used successfully to manage this problem.\textsuperscript{A15,A16,T2} One involves taking down the adjacent aortic (neopulmonary) valvar commissure (Fig. 52-30, B), which is resuspended subsequently on the pericardial patch used for neopulmonary trunk reconstruction. Separate aortic buttons are excised around each orifice, taking pains to include the entire intramural course of the LCA (Fig. 52-30, B and C). The buttons are inserted into the proximal neo-aortic segment in more or less the usual manner. In another technique (Fig. 52-30, D-F), both orifices are included in a single aortic button, which is inserted into the proximal neo-aortic segment by a special technique that minimizes rotation of the button.

Suzuki provides an excellent summary of different techniques of coronary transfer during the arterial switch operation.\textsuperscript{S30}

Transposition of the Great Arteries with More or Less Side-by-Side Great Arteries

The great arteries may be more or less side by side with the aorta to the right, and usually a VSD is present or the cardiac malformation is double outlet right ventricle with juxtapulmonary VSD (Taussig-Bing heart; see “Taussig-Bing Heart” under Morphology in Chapter 53). Prevalence of the various coronary artery patterns is different in this setting, one of the most common being sinus ILR-2Cx.

Operation is conveniently performed in a somewhat different manner and without the Lecompte maneuver (Fig. 52-31), although some perform the Lecompte maneuver even in this setting. Exact details of configuration and sizes of the great arteries and coronary artery positions may determine advisability of the Lecompte maneuver when more or less side-by-side great arteries are present.

Repair of Coexisting Ventricular Septal Defect

The VSD is repaired with a patch of polyester, polytetrafluoroethylene (PTFE), or autologous pericardium, with due regard for location of the conduction system (see Technique of Operation in Section I of Chapter 35). Approach may be through the right atrium, although for some VSDs access is easier through the proximal aortic (neopulmonary) segment or pulmonary (neoarterial) segment (see “Repair of Taussig-Bing Heart by Arterial Switch Repair” under Technique of Operation in Chapter 53).

Other Techniques

As in most procedures, other techniques are suitable for performing all or parts of the arterial switch operation. In one approach, after transecting the great arteries, the aortic buttons containing the coronary ostia are excised from the proximal aortic segment. Three fine sutures are placed externally on the proximal segment of the neo-arterial to mark the site of each valve commissure. The Lecompte maneuver is performed, and the two aortic segments are anastomosed to each other to construct the neo-arterial.\textsuperscript{B40,P1} The aortic clamp is released momentarily and hemostasis secured. With the clamp open and with due regard for position of commissural marking sutures, sites for implanting the coronary arteries are selected. With aorta again clamped, incisions are made, and the coronary buttons are transferred to the neo-arterial. The final steps are closure of the sites from which the coronary buttons were excised and construction of the neopulmonary artery. This method facilitates obtaining hemostasis of the neoarterial anastomosis by examining the suture line after releasing the aortic clamp momentarily and placing any needed additional stitches at that time. Also, the proximal neo-arterial is distended, facilitating selection of the site for
implanting the coronary arteries and creating incisions for receiving them.

In another alternative, the coronary buttons are implanted into incisions made proximal to the transection site. Before creating the neoaortic-aortic anastomosis, incisions into which the coronary buttons will be transferred are made, and the lower halves of the circumference of the buttons are anastomosed into this incision. The upper half is incorporated into the neoaortic-aortic anastomosis, which is made as the next step. This method puts sites of

---

**Figure 52-30** Arterial switch operation for transposition of great arteries when all three major coronary arteries arise from sinus 2. In this figure, there are two separate ostia within sinus 2, with an eccentrically placed left main coronary ostium with an intramural left main coronary artery (LCA) course. **A**, Although LCA gives rise to left anterior descending (LAD) and circumflex (Cx) coronary arteries and appears from exterior inspection to be arising from sinus 1, it actually arises from sinus 2 from an eccentrically placed orifice that is distinct from nearby right coronary orifice. LCA orifice is positioned close to commissure between cusps of the two facing sinuses. Proximal aspect of LCA travels circumferentially within wall (intramurally) of neoaorta before emerging from aortic wall to become distinctly separate from it in region of left-facing sinus. Intramural component involves region of commissure between the two cusps of facing sinuses. Several important judgments must be made with this coronary pattern. First, it must be decided whether there is enough tissue separating the two ostia to be able to mobilize coronaries separately. If so, preferred method of management is to mobilize the two coronary buttons separately as shown here. **B**, The second important judgment involves managing intramural component of LCA. Right coronary button is mobilized in standard fashion. If commissure between cusps of two facing sinuses is involved with the intramural component of the LCA, then commissure is stripped away from internal aspect of sinus as shown here, leaving cusps and commissure intact. This then allows for complete mobilization of eccentrically shaped left coronary button. Eccentric shape is necessary for button to contain entire intramural component of LCA. **C**, Two completely mobilized coronary buttons are shown with remnants of commissure present on left coronary button. Each button is then reimplanted in the usual fashion. **D**, If it is determined that the bridge of tissue between the two coronary ostia is either too narrow to allow separating them or is nonexistent (true single ostium), an alternative technique of coronary implantation must be used. Shown here are separate ostia too close together to allow safe mobilization of separate buttons. Also, neither ostia shows an intramural course. In this setting, a single large button encompassing both ostia is mobilized. Proximal neoaorta is prepared for reimplantation by removing an appropriately sized segment of neoaorta wall. Distal aspect of coronary button is then sutured to implantation site. Note that coronary button is rotated minimally. **E**, Proximal neoaorta to ascending aorta anastomosis is performed, completing entire circumference except for that portion that contains coronary button. A small hemisphere-shaped segment of ascending aorta is excised in portion of ascending aorta adjacent to implanted coronary button. A roof of either glutaraldehyde-treated pericardium or pulmonary allograft arterial wall is used to create a convex roof over remaining opening in ascending aorta and remainder of free edge of coronary button. **F**, Completed aortic and coronary reconstruction. Pulmonary trunk reconstruction is performed as usual.
between sinus 1 and sinus 2 is attached at a proper level to the patch.

Finally, techniques have been described in which neopulmonary artery reconstruction is performed directly without using prosthetic material.\textsuperscript{22}

Arch obstruction in association with transposition can be managed either as a single-stage procedure, combining arch repair with the arterial switch, or in two stages, with arch repair performed via lateral thoracotomy and arterial switch performed via median sternotomy, usually within a week. In recent years, single-stage repair of both lesions has gained favor at many institutions with extensive neonatal experience.\textsuperscript{12,79}

![Figure 52-31](image)

**Figure 52-31** Arterial switch operation for transposition of great arteries with side-by-side great arteries and aorta to right, with coronary pattern of 1LR-2Cx. This coronary pattern is common with this great artery orientation. \textbf{A}, Dashed lines show proposed transection sites of great arteries. Both arteries are transected high, especially the native aorta, in anticipation of extra length needed for proximal neopulmonary trunk to meet transverse right branch pulmonary artery. \textbf{B}, Several important maneuvers required in this variant are shown. Both great arteries have been transected. Lecompte maneuver is not performed. Coronary buttons have been mobilized and coronary implant sites on proximal neoaoorta developed. Left-sided aspect of opening in distal pulmonary trunk is partially closed with a semilunar-shaped patch of autologous glutaraldehyde-treated pericardium. Right side of this opening is enlarged into right pulmonary artery as shown. This in effect shifts opening in distal pulmonary trunk to right in preparation for proximal neopulmonary trunk to distal pulmonary trunk reconstruction. This in effect reorients proximal pulmonary trunk to right side away from proximal neoaoorta and coronary reimplantation sites. Because proximal neopulmonary trunk is positioned more posterior than usual, access to coronary explantation sites for reconstruction with individual pericardial patches is more difficult. As a result, this part of operation is performed earlier than usual (i.e., before neoaorta reconstruction). Coronary explantation sites can be reconstructed with pericardial patches either before or after coronary reimplantations on proximal neoaoorta; however, this component of procedure should be performed before great artery anastomoses are performed. \textbf{C}, Completed operation. Coronary artery from sinus 2 is particularly vulnerable. Without Lecompte maneuver, proximal neopulmonary trunk is oriented somewhat posteriorly and can compress posterior reimplanted coronary artery (circumflex artery in this case) over its proximal extent. For this reason, it is critical that proximal neopulmonary trunk be implanted as far right along transverse right pulmonary artery as possible.
Atrial Switch Operation

**Senning Technique**

In the Senning type of atrial switch operation, preparations for operation and median sternotomy incision are performed as usual (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2). Operation may be performed during hypothermic circulatory arrest at about 18°C or, preferably, using CPB and direct caval cannulation. When CPB is used, the patient is cooled to at least 25°C; blood flow is then stabilized at 1.6 L · min⁻¹ · m⁻² or lower, and if necessary a period of 10 to 15 minutes of low flow or circulatory arrest may be employed. Myocardial management is the same as in the arterial switch operation (see preceding text).

Before CPB is established, specific measurements are made that are critical in subsequent incisions. First, circumferences of the SVC and IVC are determined (by compressing them momentarily with a clamp, measuring length of clamp occupied by compressed cava, and multiplying by 2). Position and superior and inferior extent of proposed left atriotomy are identified at the point of junction of the left atrial–right pulmonary vein wall with the most rightward aspect of the right atrial wall surface. Incision must not be extended further superiorly or inferiorly, which would necessitate its being carried leftward and behind the cavae (Fig. 52-32, A). The proposed right atriotomy incision is visualized roughly parallel to the left atriotomy incision (see Fig. 52-32, A). The superior extent is 3 or 4 mm anterior to the sulcus terminalis, thus anterior to the sinus node, and is anterior to the superior end of the proposed left atriotomy by a distance that is about two thirds of the SVC circumference. The inferior extent of the proposed right atriotomy is placed anterior to the inferior end of the proposed left atriotomy by a distance equal to two thirds of the IVC circumference. Further right-angled anterior extensions will be needed superiorly and inferiorly so that later a right atrial flap can be created (see Fig. 52-32, A).

CPB is established, preferably with direct caval cannulation or with a simple venous cannula for the hypothermic circulatory arrest technique. Initially the interatrial groove on the right side is dissected (see Fig. 52-32, A). Care is taken to keep the dissection shallow and not enter the atria.

The left atriotomy is made and pump-oxygenator sump sucker inserted if the patient is on CPB. The right atriotomy and anterior extensions are made (Fig. 52-32, B).

The atrial septal flap that will form the anterior wall of the posterior pulmonary venous compartment is fashioned (Fig. 52-32, B and C). When small, the foramen ovale is closed transversely with a few interrupted sutures, and the flap is created. When the foramen ovale is large, the flap consists solely of superior and posterior aspects of the limbus, but this is quite adequate when the maneuvers described next are used.

After making the septal flap, the coronary sinus is cut down precisely so as to leave anterior and posterior lips (Fig. 52-32, C and D). If the septal flap is particularly small, the base of the left atrial appendage can be advanced toward the right to meet the anterior superior aspect of the septal flap, and the posterior lip of the cut coronary sinus is used to connect to the anterior inferior aspect of the septal flap. The septal flap is shown being sewn into place without using the posterior coronary sinus lip in Figs. 52-32, D and E. If not used, the posterior lip may be tacked down (see Fig. 52-32, E).

The caval pathway to the mitral valve is formed posteriorly by the repositioned septal flap. The roof of the caval pathway is now completed by suturing the posterior right atrial flap anteriorly to the limbus. Interrupted sutures are used at each end to begin this (Fig. 52-32, F), placing these with great care so that the extensions of the caval wall will be undistorted. Each suture line is carried toward the midportion of the posterior margin of anterior limbus (see Fig. 52-32, F). The sutures are placed along the cut edge of the limbus anteriorly, visualizing and avoiding the position of the AV node (Fig. 52-32, G).

The pulmonary venous pathway to the tricuspid valve is now constructed. The anterior extensions of each end of the right atriotomy incision allow the right atrial flap to come to the right and posteriorly with ease (Fig. 52-32, H). Suturing is begun superiorly and is completed before beginning the inferior one. This aspect of the reconstruction may be done with 5-0 or 6-0 interrupted or continuous polypropylene sutures. This suture line passes posterior and then superior to the location of the sinus node (Fig. 52-32, I). As the superior suture line is developed, the right atrial flap is sutured to the lateral lip of the left atriotomy over the right superior pulmonary vein. A similar suture line is made inferiorly to complete this last step of the operation (Fig. 52-32, J).

Alternatively, when a near-linear right atriotomy is made and the anterior right atrial flap does not come easily to the lateral lip of left atrium, the lateral lip of the left atriotomy incision is sutured to the adjacent in situ pericardium. The anterior right atrial flap is then sutured to the pericardium at a convenient distance from the left atrial–pericardial suture line to produce a wide opening between posterior and anterior portions of the pulmonary venous compartment. In essence, the pericardium acts as an augmentation patch for the channel between posterior and anterior portions of the pulmonary venous compartments.

When CPB is used, rewarming is begun about 5 minutes before completing suturing of the right atrial flap. When suturing is completed, and with strong suction on the aortic needle vent, controlled aortic root reperfusion is begun, or the aortic clamp is released. The remainder of the procedure, including de-airing, is completed as usual (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2).

When hypothermic circulatory arrest is used with a single venous cannula, the cannula is reinserted through the right atrial appendage into the pulmonary venous atrium, CPB is reestablished, and rewarming is begun after removing the aortic clamp (see “Rewarming” in Section IV of Chapter 2). A small puncture may be considered in the most anterior part of the RV just below the aortic valve to allow escape of any entrapped air as the heart begins to contract. When a single venous cannula is used in this manner, pulmonary venous blood is returned to the pump oxygenator, and the circuit is in reality a systemic (right) ventricular bypass only. Thus, it is necessary to massage the heart and inflate the lungs gently to push blood through the lungs until adequate pulmonary (left) ventricular ejection returns. This is required for only a few minutes as a rule. The single venous cannula tip often partially obstructs the caval tunnels beneath the baffle so that caval pressures of 10 to 20 mmHg are usually during rewarming. They usually fall to that in the pulmonary venous atrium after the cannula has been removed. The remainder of the procedure is completed as usual.
With either technique, it is useful to leave a polyvinyl catheter through the right atrial appendage into the pulmonary venous atrium and one through the left atrial appendage into the systemic venous atrium. These catheters, plus an internal jugular catheter and a radial artery catheter placed at the beginning of the operation, allow complete monitoring of the hemodynamic state in the early postoperative period.

**Mustard Technique**
Preparations for the Mustard type of atrial switch operation and support techniques are the same as when the Senning technique is used.

The most appropriate material, configuration, and size of the atrial baffle to be inserted have been confusing and controversial. *Autologous pericardium* is considered the material of choice because of higher prevalence of baffle complications when polyester is used. If pericardium is not available at a secondary operation, however, allograft or xenograft pericardium, PTFE, or very thin knitted polyester may be used. One concept is to use a relatively small pericardial baffle and sew it snugly in place away from caval orifices in such a manner that as much of the caval pathways as possible is atrial wall rather than baffle. A different concept based on the *Toronto technique* uses a larger baffle that is sewn into place around
the caval orifices, with redundancy around the cavae to minimize the chance of narrowing SVC or IVC pathways.

Sternotomy is made, and before the pericardium is opened, it is cleared laterally to within 4 or 5 mm of each phrenic nerve, generally a distance of 5 or 6 cm in a 5-kg infant. Superiorly, the pericardium is cleared nearly to the level of the brachiocephalic vein after reflecting and partially excising the thymus. A longitudinal incision is made in the pericardium a few millimeters anterior to the right phrenic nerve; in a 5-kg infant this incision is about 6.5 cm. Next, a transverse incision is made in the pericardium along the diaphragm, extending to within 4 or 5 mm of the left phrenic nerve, a distance of about 3.5 cm in a 5-kg infant but proportionally longer in a larger patient. Superiorly, a similar but convex incision is made. A left-sided longitudinal incision is made parallel to the left phrenic nerve, but with a mild concavity in its midportion. After the pericardial patch is removed, a similar concavity is made in the midportion of the other long dimension of the rectangle (see Fig. 52-33, C inset).

After establishing CPB and aortic clamping with cold cardioplegia or establishing hypothermic circulatory arrest, the right atrium is opened through the usual oblique incision (Fig. 52-33, A). Atrial stay sutures may be placed for exposure.

Figure 52-32, cont’d  D, Atrial septal flap is now repositioned into left atrium and connected to left atrial wall, staying clear of ostia of left pulmonary veins. Suture line is brought anterior and superior to left pulmonary vein and anterior and inferior to left inferior pulmonary vein. E, In this illustration, atrial septal flap is well developed and posterior lip of cut coronary sinus is not utilized directly to augment atrial septal flap. After completing atrial septal flap suture line, unused posterior lip of coronary sinus is tacked down to anastomosis. Note position of left superior and left inferior pulmonary veins beneath septal flap (circular dashed lines). F, Posterior edge of right atrial incision is now approximated to remaining edge of atrial septum. Curved arrows show tissue manipulation required to achieve this. Most critical points in suture line are areas over orifices of superior (SVC) and inferior (IVC) venae cavae. These two aspects of suture line must be performed with great care to prevent narrowing of cavae at their transition into surgically created tunnel leading to mitral valve. Various techniques can achieve this. As shown at SVC junction, several interrupted sutures can be used to bring the two edges of tissue together over the cava. As shown at region of IVC, a “hemi–purse string” can be used to gather tissue in this area. Alternatively, interrupted simple sutures can also be used at IVC aspect of suture line. 

Continued
The atrial septum is excised, beginning by dividing the limbus superiorly with scissors, centering the cut just to the left of the midpoint of the superior limbus. The incision is carried nearly into the roof of the atrium and then posteriorly beneath the SVC and then inferiorly, removing the thick tissue from behind the SVC and in front of the right pulmonary veins. Occasionally the incision goes outside the atria, and if so, the opening is closed with fine interrupted sutures. Any remnant of the fossa ovalis is completely excised (Fig. 52-33, B).

The center of the free wall of the coronary sinus is divided downward with scissors for 7 to 10 mm, exactly as described for the Senning procedure (see Fig. 52-33, B). This transfers the coronary sinus opening into the left atrium and widens the area that will be the extension of the IVC toward the mitral valve.

A double-armed 4-0 or 5-0 polypropylene suture is passed through the pericardial baffle, and through the left atrial wall anterior to and between the left superior and inferior pulmonary veins (see Fig. 52-33, C). The superior suture line is

Figure 52-32, cont’d  
G, Remainder of suture line is performed with running monofilament suture to complete systemic venous to mitral valve pathway. Note positions of sinoatrial and atrioventricular nodes. H, Anterior edge of right atrial incision is then advanced posteriorly and attached to lateral free edge of left atrial incision. It is critical to utilize the length of anterior cut edge of right atrial incision appropriately such that underlying venae cavae are not constricted. Stay sutures shown here are positioned to allow appropriate length of right atrial flap overlying the two venae cavae. I, Suture line has been developed along both its superior and inferior aspects, crossing both cavoatrial junctions, and is completed along lateral edge of left atrial incision. Note that sinoatrial node now lies inside heart within wall of superior limb of systemic venous–to–mitral valve tunnel. Superior limb of the external suture line runs superior to sinoatrial node along superior cavoatrial junction.
Chapter 52  Complete Transposition of the Great Arteries

Figure 52-33  Atrial switch operation by Mustard technique (see text). Cardiopulmonary bypass and myocardial protection are similar to those used for Senning technique. A, Dashed line indicates proposed atrial incision. B, Entire atrial septum is excised as shown, and coronary sinus is cut down similar to Senning procedure (dashed line). C, Pericardial patch used to create intra-atrial baffle is shown in inset. Shape of this patch is generally that of an oval, with a gradual waist created in its midportion along long axis. Dimensions of patch will vary depending on size of infant. For a newborn infant weighing less than 5 kg, an initial oval patch measuring approximately 7 cm × 3.5 cm will be adequate, and may need to be tailored substantially. Width of patch at waist should be roughly 2.5 cm. Patch is sewn into place, beginning within left atrium, as shown, anterior to left-sided pulmonary veins.

Continued

made, but as the point just superior to the left superior pulmonary vein is reached, the suture line is carried superiorly to the posterolateral border of the orifice of the SVC and then up around the lateral and anterior margin of the caval orifice (Fig. 52-33, D). A larger distance is left between bites on the patch than between those around the caval orifice so as to avoid “purse-stringing” this orifice and to bring a redundant amount of pericardial patch into the area. The inferior suture line is made using the anterior lip of the incised coronary sinus (Fig. 52-33, D). The baffle is then sutured to the remnant of atrial septum anteriorly (Fig. 52-33, E).

The right atriotomy incision is closed primarily. Alternatively, if there is concern about patency of the pulmonary venous–to–tricuspid valve pathway, the right atrial free wall can be augmented with a patch of pericardium or PTFE.

Repair of Left Ventricular Outflow Tract Obstruction

This discussion refers primarily to the atrial switch operation for TGA with essentially intact ventricular septum, because direct relief of LVOTO is not usually possible in TGA, VSD, and LVOTO.

When obstruction is dynamic and LV systolic pressure is similar to or less than that in the right (systemic) ventricle, nothing is done directly to LVOTO. When LV systolic pressure is considerably higher, surgical relief of LVOTO is
D, Suture lines are developed superiorly and inferiorly around orifices of left pulmonary veins and toward superior and inferior caval orifices on their posterior, lateral, and then anterior aspects as shown. Suture line is then transitioned from caval orifices onto cut edge of atrial septum. Eustachian valve (if well developed) and anterior cut lip of coronary sinus can be used to enlarge pathway from inferior vena cava to mitral valve. 

E, Baffle is shown after suture lines are completed. The four pulmonary veins are visible: right-sided pulmonary veins completely, and left-sided ones partially. All pulmonary veins are unobstructed by baffle. Atrial incision, shown here still open, is closed with a running monofilament suture. If pathway from posteriorly positioned pulmonary veins to anteriorly positioned tricuspid valve appears to be narrowed in its midportion as it passes around baffle, right atrial incision can be augmented with pericardial or polytetrafluoroethylene patch.

**Figure 52-33, cont’d**

- Generally required. This may be in the form of resection of muscle, but in extreme cases a valved extracardiac conduit may be needed (see text that follows).
- When the LVOTO is in the form of localized or diffuse fibromuscular obstruction, the obstructive tissue is resected. One approach is through the mitral valve after creating the septal flap (Senning repair) or excising the atrial septum (Mustard repair). Alternatively, resection is performed through the pulmonary trunk and valve. In the uncommon circumstance of valvar obstruction, valvotomy through the pulmonary trunk is performed.
- When LVOTO is severe and cannot be relieved by resection, placing an LV–pulmonary trunk allograft valved conduit is required. (See “Double Outlet Right Ventricle and Pulmonary Stenosis” under Technique of Operation in Section II of Chapter 55 for additional details about placing left ventricular to pulmonary artery conduits.) After the first part of the atrial switch procedure has been completed, a longitudinal incision is made along the left side of the pulmonary trunk; if necessary, the incision is carried onto the left pulmonary artery. The proposed left ventriculotomy, between or beyond the diagonal branches of the LAD and along the anterolateral aspect of the LV near the apex, is marked with 5-0 sutures. The heart is allowed to fall back against the pericardium, and position on the pericardium of the proposed ventriculotomy is noted. Then, with the heart retracted upward and to the right, the proper length of the conduit can be estimated from the curving course between the pulmonary arteriotomy and the designated points on the pericardium. The conduit is trimmed to a proper length. It is cut short (about 5 mm beyond the aortic valve commissures) distally and beveled proximally. The conduit is sewn into position exactly as is done for other ventriculopulmonary trunk conduits (see “Rastelli Operation” later in text). After completing this, the last stages of the atrial switch operation are carried out.
Intraventricular Repair

In hearts with TGA and large VSD, occasionally a completely intraventricular repair can be done by the intraventricular tunnel technique. Its applicability depends on the relationship of the VSD to the great arteries and tricuspid valve. Techniques for doing this are variable and may require enlarging the VSD, but operation is essentially the same as the intraventricular repair that may occasionally be possible in Taussig-Bing heart (see “Intraventricular Tunnel Repair of Taussig-Bing Heart” under Technique of Operation in Chapter 53). In some cases the tunnel may be made superior to the pathway to the pulmonary trunk rather than inferior to it.

A partially intraventricular repair associated with placing a valved extracardiac conduit between the RV and pulmonary trunk has been described, but in the largest reported series, hospital mortality was high.

Rastelli Operation

Usual preparations for operation are made when performing the Rastelli operation for TGA, VSD, and LVOTO. A conduit is prepared using an estimate of the largest size of extracardiac conduit that can be comfortably placed within the patient’s thorax. A valved conduit is preferred, and options include pulmonary or aortic valved allografts and composite grafts using either woven polyester or PTFE conduits with bioprosthetic valves (see Appendix A in Chapter 12 and Technique of Operation in Section II of Chapter 38). A median sternotomy incision is made, and if stenoses are present at the pulmonary trunk bifurcation or in proximal portions of right or left pulmonary arteries, a piece of pericardium is removed and set aside. Pericardial stay sutures are placed. The pulmonary trunk in most patients with this anomaly is posterior and to the left of the ascending aorta. Therefore, to avoid conduit compression between the right-sided and anterior ascending aorta and sternum, preparations are made for routing the conduit so that it approaches the pulmonary trunk from the patient’s left side. The pulmonary trunk and its bifurcation are dissected completely free of the ascending aorta, and the first portions of left and right pulmonary arteries are also mobilized. Purse-string sutures are placed appropriately (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2). Any previously made systemic–pulmonary arterial anastomotic operations are dissected and closed just after establishing CPB (see “Repair of Tetralogy of Fallot after a Blalock-Taussig or Polytetrafluoroethylene Interposition Shunt” under Technique of Operation in Section I of Chapter 38).

After CPB is established and moderate hypothermia achieved, the aorta is clamped and cold cardioplegia is established (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3). The left side of the heart is decompressed using a vent catheter placed through a purse-string suture in the right superior pulmonary vein and positioned across the mitral valve into the left ventricular cavity.

The infundibular free wall of the RV is opened by a moderate-sized vertical ventriculotomy that avoids major coronary artery branches. The incision may have to extend to the midportion of the RV free wall (Fig. 52-34, A). Appropriate stay sutures are placed on the ventriculotomy edge (Fig. 52-34, B). Origins of the aorta from the RV and pulmonary trunk from the LV are confirmed. It has already been determined by preoperative imaging study that the VSD is a conoventricular perimembranous type in the outflow portion of the ventricular septum, but this is now confirmed visually. The tricuspid valve and its tensor apparatus are usually well away from the pathway between the VSD and aorta, but if not, special measures are required. They may involve detachig tricuspid valve chords, with reattachment onto the intraventricular tunnel material (Hanley FL: personal communication; 2002) or using the conal flap method. Unless the VSD is clearly large and nonrestrictive, it is enlarged by excising the septum anterior to the defect (see dashed line in Fig. 52-34, B). Care is taken that the excision is in the inteventricular septum and not the ventricular free wall. Generally this provides considerable enlargement of the VSD, but care should be taken to not injure the septal coronary artery branches.

Intraventricular tunnel repair is now done similarly to that described for simple double outlet right ventricle (see “Intraventricular Tunnel Repair for Simple Double Outlet Right Ventricle” under Technique of Operation in Chapter 53). The LV ejects into the aorta through this tunnel (Fig. 52-34, C and D).

The pulmonary trunk is divided, and the proximal stump is oversewn at the valve level (see Fig. 52-34, C). The distal portion of the trunk and proximal left and right pulmonary arteries are mobilized, allowing the pulmonary trunk to be reoriented for a straightforward end-to-end anastomosis (see Fig. 52-34, D). Proximal anastomosis of the conduit to the right ventriculotomy is made (Fig. 52-34, E and F).

Remainder of the operation includes controlled reperfusion and de-airing procedures (see Chapters 2 and 3). The foramen ovale may be left open; as with tetralogy of Fallot (see Section I of Chapter 38) the right-to-left shunting across it in the early postoperative period augments cardiac output, although at the expense of systemic arterial desaturation. If a true ASD is present, however, it should be closed. Depending on the patient’shemodynamic status, transesophageal echocardiography findings, and surgeon preference, polyvinyl recording catheters may be placed in the right atrium, left atrium, and pulmonary artery for postoperative monitoring.

Lecompte Operation

The alternative method of managing TGA, VSD, and LVOTO, the Lecompte intraventricular repair, is also applicable to other types of ventriculoarterial discordant connections (see “Lecompte Intraventricular Repair” under Technique of Operation in Chapter 53). Other techniques for reconstructing the RV outflow tract have been described.

Aortic Root Translocation (Nikaidoh)

For patients with TGA and LVOTO with or without VSD, aortic root translocation has been adopted by some surgeons because of concerns about long-term outcomes of the Rastelli procedure. In this procedure, the aortic root is detached from the RV along with the coronary arteries and translocated posteriorly after making a septal incision or enlarging the VSD, then patching it, thereby relieving the LVOTO.
Figure 52-34  Rastelli operation for transposition of great arteries, ventricular septal defect (VSD), and left ventricular outflow tract obstruction. A, After standard median sternotomy incision, pulmonary trunk and left and right pulmonary arteries are completely dissected away from aorta and surrounding structures. Dashed line shows site of proposed right ventricular infundibular incision, which is in line with most anterior aspect of aorta. B, Standard cardiopulmonary bypass and myocardial protection techniques are used. Right ventricular infundibular incision is made and retraction sutures placed. Through this incision, rightward and anterior ascending aorta can be seen immediately, and leftward and posterior pulmonary valve can be visualized through VSD. Dashed line on rim of VSD shows site of incision on ventricular septum where VSD is enlarged in preparation for left ventricular to aortic baffle. This incision is necessary only when VSD is small (less than 60% aortic diameter). Dashed line on pulmonary trunk indicates proposed site of transection at sinutubular junction. C, Pulmonary trunk has been transected and proximal pulmonary trunk oversewn at level of valve. An alternative technique is to close pulmonary valve from within heart, working through infundibular incision and VSD. Using this method, if pulmonary valve anulus is small, it may be closed primarily; otherwise a circular patch is placed around immediately subvalvar tissue. VSD, which has been enlarged by incision, is shown with tunnel from left ventricle to aorta partially constructed. Material for tunnel is fashioned from a tube of polyester with a diameter approximately the size of ascending aorta. After tailoring, this results in a naturally curved baffle that is positioned with convex aspect of baffle facing into right ventricle. Lower aspect of baffle is sewn around rim of VSD, taking standard precautions with respect to inlet valves and conduction system (see “Location in Septum and Relationship to Conduction System” under Morphology in Section I of Chapter 35). Upper aspect of baffle is sewn into place by transitioning suture line away from rim of VSD as patch approaches aortic valve anulus on each side. Baffle is then sewn to immediately subaortic region along lateral aspects, and then finally anterior aspect, of circumference of aorta. A running technique, using nonabsorbable monofilament suture, is used. D, Left ventricular to aortic baffle is shown with suture line completed. A valved allograft conduit (or other composite conduit) is used to reconstruct right ventricular outflow tract. Conduit is tailored to appropriate length and is sewn end to end to pulmonary trunk as shown with a running monofilament technique.
sternotomy, and the usual limited dissection is made (see “Secondary Median Sternotomy” in Section III of Chapter 2) without freeing the front and leftward aspect of the heart. Tapes are passed around the cavae beyond the caval-atrial junctions, and they are cannulated directly. CPB is commenced and conducted as usual. The aorta is clamped and cold cardioplegic solution infused into the aortic root. The right atrium is opened with a centrally placed transverse or oblique incision.

When obstruction involves only the pathway from the SVC, this portion of the baffle may be enlarged. The baffle is incised vertically at its midpoint with a knife and the incision carried upward to open widely the pathway from the SVC. When this is totally occluded, the SVC–right atrial junction, which is always still patent beneath the baffle, is defined by inserting the tip of a curved forceps through a stab wound in the SVC (avoiding the sinus node area) and cutting down onto the tip of the instrument as it tents the baffle toward the right atrial cavity (pulmonary venous compartment). Alternatively, it may be possible to use the tip of a curved forceps to bluntly dissect the area of obstruction from above downward so that the tip appears below it. The baffle is opened at the point at which it joins the right atrial wall in front of the SVC junction, and fibrous thickening is excised to recontour the baffle and floor of the new tunnel. An elliptical PTFE or polyester patch is now sewn into the baffle incision with continuous 4-0 polypropylene suture to create a new roof to the pathway. The patch must not compromise the pulmonary venous channel.

To avoid kinking or stretching of the coronary arteries, modifications of this procedure with transfer of one or two coronary buttons akin to the arterial switch have been reported (Fig. 52-35). The pulmonary outflow tract is then reconstructed with an allograft valved conduit or a valveless patch.

Pulmonary Trunk Banding

Pulmonary trunk banding is discussed in detail in Chapter 35 (see “Pulmonary Trunk Banding” under Technique of Operation in Section I), including the Trusler rules for patients with transposition and large VSDs, and in Chapter 41 (see “Pulmonary Trunk Banding” under Technique of Operation in Section II).

Systemic–Pulmonary Arterial Shunting Procedures

Systemic–pulmonary arterial shunting techniques are described in detail in Chapter 38 (see “Technique of Shunting Operations” in Section I), and in Chapter 41 (see “Systemic–Pulmonary Arterial Shunt” under Technique of Operation in Section II). The same guidelines are followed concerning the size and type of shunt as in tetralogy of Fallot and in univentricular hearts.

Caval Obstruction

With caval obstruction after the Mustard procedure, usual preparations for operation through a median sternotomy are made, although others have preferred a right anterolateral thoracotomy. An oscillating saw is used for the secondary sternotomy, and the usual limited dissection is made (see “Secondary Median Sternotomy” in Section III of Chapter 2) without freeing the front and leftward aspect of the heart.

Tapes are passed around the cavae beyond the caval-atrial junctions, and they are cannulated directly. CPB is commenced and conducted as usual. The aorta is clamped and cold cardioplegic solution infused into the aortic root. The right atrium is opened with a centrally placed transverse or oblique incision.

When obstruction involves only the pathway from the SVC, this portion of the baffle may be enlarged. The baffle is incised vertically at its midpoint with a knife and the incision carried upward to open widely the pathway from the SVC. When this is totally occluded, the SVC–right atrial junction, which is always still patent beneath the baffle, is defined by inserting the tip of a curved forceps through a stab wound in the SVC (avoiding the sinus node area) and cutting down onto the tip of the instrument as it tents the baffle toward the right atrial cavity (pulmonary venous compartment). Alternatively, it may be possible to use the tip of a curved forceps to bluntly dissect the area of obstruction from above downward so that the tip appears below it. The baffle is opened at the point at which it joins the right atrial wall in front of the SVC junction, and fibrous thickening is excised to recontour the baffle and floor of the new tunnel. An elliptical PTFE or polyester patch is now sewn into the baffle incision with continuous 4-0 polypropylene suture to create a new roof to the pathway. An opened, preclotted, knitted or woven double-velour polyester graft of appropriate diameter is used for the patch because it contours toward the pulmonary venous atrium.
Figure 52-35  Aortic root translocation for transposition of great arteries and left ventricular outflow tract obstruction. A, Ventricular and aortic incisions required for aortic autograft excision are shown. Note that infundibular incision is circumferential just below aortic anulus, and as shown in inset depicting cross-section through ventriculoarterial junction, incision is slightly oblique. Coronary ostia are excised as circular buttons from respective sinuses of Valsalva. B, Once aortic autograft is excised and coronaries mobilized, pulmonary trunk is transected and an incision is extended across pulmonary valve anulus and septum connecting to ventricular septal defect (VSD), if present. Enlargement of left ventricular outflow tract is then accomplished by inserting a triangular-shaped VSD patch. C, Aortic autograft is reinserted into left ventricular outflow tract. It is then rotated 180 degrees so that defects from coronary buttons face anteriorly. Coronaries are then reimplanted. Before reestablishing ascending aortic continuity, branch pulmonary arteries are mobilized and brought anterior to aorta (Lecompte maneuver) in preparation for right ventricular outflow reconstruction. D, Right ventricle (RV) to pulmonary trunk continuity is achieved by inserting an interposition allograft connecting RV infundibulum to pulmonary trunk.
Alternatively, the baffle can be removed entirely. When the entire baffle is grossly thickened and distorted, especially if it contains folded polyester and the pathway from the IVC is obstructed, the entire baffle must be excised. A new baffle is inserted using pericardium, if enough is available, or PTFE or polyester. The remainder of the operation is completed as usual.

As a final alternative for isolated SVC obstruction, a bidirectional superior cavopulmonary anastomosis can be created (see Technique of Operation in Section III of Chapter 41).

**Pulmonary Venous Obstruction**

With pulmonary venous obstruction after Mustard repair, initial stages of operation and establishing CPB and cold cardioplegia are as described earlier. A transverse incision is made through the right atrial wall and into the anterior pulmonary venous compartment. Incision is carried posteriorly through the waist between anterior and posterior pulmonary venous compartments and directly between the right superior and right inferior pulmonary veins. Excess fibrous tissue surrounding the open stenosis is excised without breaching the baffle. One technique for repair involves closing the transverse atriotomy with continuous 4-0 polypropylene suture to create a vertical atrial suture line in much the same manner as described by Dillard and colleagues as part of the Mustard baffle technique in 1969. Instead, a V-atrial flap may be created from the lateral right atrial wall anterior to the stenotic site, with the apex of the V advanced posteriorly as a V-Y atrialplasty. Alternatively, a properly sized and shaped precut double-valve woven polyester gusset cut from a tube to create a convex contour is sutured into the atriotomy. This approach has the potential disadvantage that the stenosis may recur as the patch thickens, but this has not yet been reported. The remainder of the operation is completed as usual.

**SPECIAL FEATURES OF POSTOPERATIVE CARE**

Postoperative care is as usual for patients undergoing all types of intracardiac operations (see Chapter 5), with special considerations after some types of procedures.

When an arterial switch operation has been performed, particularly in a neonate, left atrial (or pulmonary artery) diastolic pressure should remain low, less than about 12 mmHg. Because restlessness or agitation increases metabolic demands and cardiac output, neonates and infants are usually kept intubated and sedated for 24 to 48 hours after operation. If cardiac output is less than optimal, particularly when 2D echocardiographic study indicates poor LV function, catecholamine support is used rather than further increasing LV filling pressure. Careful study shows that cardiac output profile occurs independently of the perfusion technique used at operation and occurs with and without associated VSD.

When an atrial switch operation has been done, positive end-expiratory pressure (PEEP) is not used because it tends to obstruct the SVC. Infants are nursed in a slightly head-up position. Atrial pressures are kept as low as is compatible with an adequate cardiac output; low-dose (2.5 to 5 mg·kg⁻¹·min⁻¹) dopamine during the early postoperative hours is helpful.

**RESULTS**

Simple Transposition of the Great Arteries and Transposition of the Great Arteries with Ventricular Septal Defect Using Arterial Switch Operation

**Early (Hospital) Death**

Currently, in institutions properly prepared for the arterial switch operation in neonates, early (hospital) mortality in both simple TGA and TGA with VSD is about 2% to 7%, a considerable improvement compared with about 15% reported in earlier eras.

**Time-Related Survival**

Instantaneous risk of death (hazard function) is extremely low by 6 to 12 months after arterial switch repair, and survival declines minimally after that time (Fig. 52-36). Thus, overall 5-year survival, including hospital mortality, has been 82% among a heterogeneous group of patients operated on in different institutions. In Williams’s group, 15-year survival was 81%. This intermediate-term survival is predicted to
Coronary Arteries

**Figure 52-37** Predicted survival after arterial switch repair in neonate with simple TGA and transposition of great arteries with ventricular septal defect, operated on in an institution of proven competence (“low risk”) in arterial switch repair. Depiction is a specific solution of the multivariable equation described in Appendix 52A, Table 52A-1. Birth weight was entered at 3.4 kg, with usual coronary anatomy (1LCx-2R) and no important coexisting cardiac or noncardiac anomalies. Key: TGA, Transposition of great arteries. (From Kirklin and colleagues.)*

Long-term (20-year) survival after the arterial switch operation is about 90% in patients operated on in the most experienced institutions.

**Modes of Death**

Mode of death is usually acute or subacute cardiac failure secondary to ventricular dysfunction resulting from imperfect transfer of coronary arteries to the neoaorta.\(^{19}\) This applies to deaths after hospital discharge as well as those during postoperative hospitalization. In the Congenital Heart Surgeons Society’s multistitutional study, five of six patients dying 6 or more months after the arterial switch operation died with severe ventricular (usually LV) dysfunction.\(^{41,12,74,76}\)

In one single-institution study, postmortem examination revealed severe proximal coronary artery stenosis caused by fibrocellular intimal thickening in six patients dying after the perioperative period.\(^{14}\)

The only other important mode of death occurs with RV dysfunction secondary to severe pulmonary vascular disease, which was not present at operation in a neonate with simple TGA. This mode has occurred in less than 1% of patients.\(^{42}\)

**Patient-Related Incremental Risk Factors for Death**

**Coronary Arterial Pattern** This has been the most important patient-related risk factor for death, based on multistitutional experience during the first decade after introduction of the arterial switch procedure in neonates, with two specific coronary patterns increasing risk. Risk of death is increased when the LCA or either of its branches arises from sinus 2, and risk is further increased when the LCA or LAD passes anteriorly between the two great arteries, a situation typically accompanied by an intramural course of the artery in the aortic wall (see “Coronary Arteries” under Morphology earlier in this chapter) (Fig. 52-38). As is usually the case, these risk factors are particularly strong in situations in which the overall risks are increased. Other unusual coronary patterns, some introduced more recently, have been identified as risk factors for death.*12,4,74,76*

Coronary arterial pattern is not an immutable risk factor and has been overcome, at least in some institutions, by appropriate techniques of coronary transfer (see “Arterial Switch Operation” under Technique of Operation earlier in this chapter).\(^{42}\) Nevertheless, a recent report of a large single-institution experience cautions that intramural coronary arteries remain associated with increased morbidity and mortality following the neonatal arterial switch operation (Fig. 52-39).\(^{42}\)

**Multiple Ventricular Septal Defects** Multiplicity of VSDs increased the risk of arterial switch repair in the first decade following the procedure’s introduction (Fig. 52-40). This risk factor may be neutralized by technical advances,\(^{4,46}\) but this is less certain than in the case of unusual coronary artery patterns. In some studies, presence of a single VSD increases risk of death compared with TGA and intact ventricular septum.\(^{41}\)

**Older Age at Repair** During the initial decade of the neonatal arterial switch experience, the younger the neonate at arterial switch repair, the safer the operation (Fig. 52-41). This age effect was particularly strong in patients with simple TGA and correlated with the magnitude of age-related differences in wall thickness characteristics of the LV of the normal neonatal heart and those of the heart with TGA. This age effect may be neutralized in current practice.\(^{4,37}\)

Arterial switch has been successfully performed beyond the neonatal period—up to age 9 months—in patients with TGA and intact septum, but such patients are more likely to require postoperative mechanical support.\(^{42}\)
Coexisting Cardiac and Noncardiac Congenital Anomalies
These anomalies may increase the risk of arterial switch repair, but are fortunately infrequent in patients undergoing repair. The most notable coexisting cardiac anomaly is aortic arch obstruction or interruption.

Operative Support and Procedural Incremental Risk Factors for Death
The support technique (CPB vs. hypothermic circulatory arrest) has not been a risk factor for death in the experience of some, but duration of circulatory arrest has been found to increase risk by others. However, longer global myocardial ischemic times have increased probability of death, suggesting that improved methods of myocardial management may improve results of operation. Even in institutions with substantial neonatal experience, CPB time is still a risk factor for early death.

Transection of the aorta or the pulmonary trunk at a site different from that described earlier in this chapter under Technique of Operation has been shown to be a risk factor for death. Inferences from various multivariable analyses support the method of management described there.

Growth of Arteries
All currently available information indicates that aortic, pulmonary, and coronary arterial anastomoses grow at a rate comparable with growth of the child. In one study, the neoaortic root was usually enlarged but with a growth pattern comparable with the normal population. Growth of the neopulmonary anulus was between the fifth and fiftieth percentile of a normal body surface area–matched population. These relationships reflect the normal disparity between pulmonary and aortic roots (see Chapter 1).
Patients with TGA and either intact ventricular septum or VSD treated by the arterial switch operation have been free of supraventricular rhythm disturbances that many patients have after atrial switch procedures. Arensman and colleagues report that this is true whether or not a right ventriculotomy has been made for repair of the VSD.\textsuperscript{113}

Only 3% of patients with simple TGA had arrhythmias after arterial switch repair in one study, compared with 57% after atrial switch repair.\textsuperscript{11,12} This continues to be the case even in more recent reports of longer-term follow-up.\textsuperscript{17} This casts doubt on the supposition that rhythm disturbances are an inherent part of the malformation of TGA.

**Coronary Blood Flow**

Positron emission tomography evaluation of coronary blood flow has revealed significantly lower coronary flow reserve in arterial switch patients compared with control subjects,\textsuperscript{816} although these findings are controversial.\textsuperscript{819} Other studies document exercise-induced perfusion defects and reduced coronary flow reserve at late follow-up;\textsuperscript{610} abnormal autonomic innervation, especially in children undergoing arterial switch at older age;\textsuperscript{814} and small-caliber left coronary systems.\textsuperscript{816,817}

**Coronary Artery Lesions**

Coronary artery obstruction has been documented in a disturbingly high number of asymptomatic TGA patients evaluated prospectively by angiography at 5- to 10-year follow-up. One study showed that 6 of 105 patients (5.7%; 95% CL 1.2%-10.2%) had important coronary lesions.\textsuperscript{813} In patients with perioperative ischemia that subsequently resolved before discharge after arterial switch, coronary obstruction was found in only 1 of 27 patients, whereas in those patients in whom perioperative ischemia persisted, all 10 patients demonstrated coronary obstruction.\textsuperscript{813} In general, coronary patterns involving a major coronary vessel passing behind the pulmonary trunk and operations using unusual techniques of coronary reimplantation demonstrate an increased risk of coronary obstruction.\textsuperscript{813} In other studies, coronary occlusion or stenosis was found in 3.0% to 7.8% of patients at follow-up.\textsuperscript{814,76}

Coronary artery stenosis continues to be higher in complex coronary patterns and in patients with evidence of ischemia.\textsuperscript{826} Also, asymptomatic coronary stenosis remains an ongoing finding with a prevalence similar to earlier reports. Results of both surgical revascularization and percutaneous transluminal angioplasty are acceptable. However, whether or not asymptomatic coronary obstruction with normal ventricular function should be treated remains controversial.\textsuperscript{810,812,11,19,8,13}

Both CTA and magnetic resonance imaging are useful non-invasive modalities to detect coronary abnormalities and myocardial perfusion defects.\textsuperscript{816,818} In a recent study using intracoronary ultrasound in 20 patients at 5 to 22 years after arterial switch, Pedra and colleagues found that a disturbingly high proportion of coronary arteries (89%) displayed a variable degree of proximal eccentric intimal proliferation.\textsuperscript{814} All children had coronary artery lesions, with 50% having moderate to severe intimal thickening (>0.3 mm). No risk factors for such abnormalities were encountered, including age, coronary artery pattern, hemodynamics, and follow-up duration. The authors speculate that this suggests early development of arteriosclerosis in reimplanted coronary arteries, which may play a role in the genesis of late coronary events.

**Functional Status**

Essentially all surviving patients are fully active and without limitations.\textsuperscript{812,811} However, decreased exercise capacity has been documented in patients who have undergone an arterial switch procedure as neonates. Residual RV outflow tract obstruction seems to have an effect on exercise capacity. Impaired chronotropic effect also appears to be an important contributor to reduced exercise capacity.\textsuperscript{811,814,819,820,821}

**Ventricular Function**

LV function is usually normal after an arterial switch operation. In a study of 12 patients, Borow and colleagues found normal contractility and normal dimensions and wall thickness in 10 of 12 patients studied between 2 and 7 years postoperatively (83%; CL 65%-94%).\textsuperscript{836} However, Hausdorf and colleagues identified 1 patient of 14 studied (7%; CL 2%–19%) late after arterial switch operation in whom LV stiffness was severely increased,\textsuperscript{815} and Okuda and colleagues reported three patients with reduced ejection fractions associated with neoaoortic valve regurgitation.\textsuperscript{814} Massin and colleagues found reduced LV function in only 1 of 71 patients at catheterization 1 year after an arterial switch operation, and that patient had had a coronary complication at the time of the arterial switch.\textsuperscript{814} Ventricular function after the arterial switch appears to remain normal at midterm follow-up (mean 3.8 years, maximum 10 years) in a large study,\textsuperscript{819} and with 20-year follow-up, LV dimensions and fractional shortening are within normal limits.\textsuperscript{811}

Interestingly, preoperative dynamic LVOT obstruction, even with a gradient of up to 120 mmHg, disappears after the arterial switch procedure.\textsuperscript{815,811}

In a comparative study between the arterial and atrial switch, Backer and colleagues found late postoperatively that systemic ventricular ejection fraction was within the range of normal in 98% of patients with simple TGA undergoing arterial switch repair,\textsuperscript{811} but in 79% of those who underwent an atrial switch repair.

**Rhythm Disturbances**

Patients with TGA and either intact ventricular septum or VSD treated by the arterial switch operation have been free of supraventricular rhythm disturbances that many patients have after atrial switch procedures. Arensman and colleagues report that this is true whether or not a right ventriculotomy has been made for repair of the VSD.\textsuperscript{113}

Only 3% of patients with simple TGA had arrhythmias after arterial switch repair in one study, compared with 57% after atrial switch repair.\textsuperscript{81,82} This continues to be the case even in more recent reports of longer-term follow-up.\textsuperscript{817} This casts doubt on the supposition that rhythm disturbances are an inherent part of the malformation of TGA.
Neurodevelopmental Status
At 8-year follow-up in one patient cohort, overall physical and psychosocial health status was similar to that of the general population, according to the Mean Physical Health Summary and the Mean Psychosocial Summary scores; however, increased problems with attention, learning, speech, and developmental delay were reported by parents.\textsuperscript{195} Neurologic testing at age 8 years in this cohort revealed that neurodevelopmental status was below expectation in many respects, including academic achievement, fine motor function, visualspatial skills, working memory, hypothesis generating and testing, sustained attention, and higher-order language skills.\textsuperscript{113} Earlier evaluation in this cohort at age 2.5 years suggested increased problems with expressive language and problem behavior if hypothermic circulatory arrest had been used for the repair.\textsuperscript{117} Others have shown reduced neurologic status in 21% of patients evaluated at age 3.0 to 4.6 years after neonatal arterial switch using circulatory arrest.\textsuperscript{119} In a recent study of 193 late survivors who underwent arterial switch more than 15 years previously, 98% were either attending school or working.\textsuperscript{185} It is important to realize that the neurodevelopmental alterations in these studies may have as much or more to do with CPB management as they do with the fact that these children had TGA.

Right Ventricular Outflow Tract Obstruction
Right ventricular outflow tract obstruction (RVOTO) was observed as a postoperative complication of arterial switch soon after this technique was introduced.\textsuperscript{227,4} Whether this is an immutable complication or can be prevented is still not certain.

RVOTO has occurred with sufficient severity to require reintervention in about 10% of patients and in one multi-institutional experience had a peak incidence about 6 months after the arterial switch operation (Fig. 52-43). Others have reported that RVOTO has become evident later after operation.\textsuperscript{4,3} In one analysis, freedom from reintervention was 94% (95% CL 64%-99%) at 1 year, and 79% (95%; CL 64%-94%) at 5 years.\textsuperscript{111} Subsequently, others reported much lower need for reintervention, and it is generally believed that this complication occurs less frequently in current practice.\textsuperscript{112} In one large cohort of patients from a single institution, reoperation for RVOTO was 1.5%.\textsuperscript{111} In general it is agreed that adequate mobilization of the branch pulmonary arteries during the Lecompte procedure is necessary to minimize supravalvar pulmonary stenosis. However, there is no consensus on whether a single vs. double patch technique, or use of a certain type of patch material, increases the risk of RVOTO. Smaller neo-PT or complex coronary patterns requiring larger coronary buttons may predispose patients to later RVOTO. Although reintervention for RVOTO shows a declining trend with experience, there still remains a larger number (up to 24%) of patients with mild RVOT gradients who do not necessarily qualify for reintervention, but may have reduced physical performance because of this.\textsuperscript{842}

Usually, obstruction is in the pulmonary trunk. Less frequently, RVOTO is at the bifurcation of the pulmonary trunk, and some have thought that stenosis at this area is the result of the Lecompte maneuver. In a careful analysis of a two-institution experience, however, the Lecompte maneuver could not be identified as a risk factor (Williams WG, Lincoln CL: personal communication; 1992). Occasionally the obstruction is at the RV–pulmonary trunk junction or in the RV infundibulum.

Neoaortic Valve Regurgitation
The neoaortic valve (pulmonary valve at birth) is competent in about 60% of patients studied several years after the arterial switch operation; mild regurgitation has been found in about 35% of patients and moderate or severe regurgitation in 5% or fewer.\textsuperscript{1,19,8,6,16,111} Risk factors for neoaortic regurgitation include older age at time of arterial switch, prior pulmonary trunk banding, presence of VSD, larger discrepancy between neoaortic root and ascending aorta, LVOTO, Taussig-Bing morphology, use of trap door techniques for coronary reimplantation, and implantation of coronary buttons compromising the integrity of the sinutubular junction of the neoaortic root.\textsuperscript{1,19,59,72,16,1,8,1,2,3,12,23,22,57} Prevalence of neoaortic valve regurgitation in patients at late follow-up is appreciable and progressive over time.\textsuperscript{19,72,1,8,1,2,3,22,57} However, need for
valve reintervention is less than 2% at current follow-up.\textsuperscript{22}\textsuperscript{22,33,57} Neoaoartic root dilatation and abnormalities in its distensibility have been documented.\textsuperscript{22,33,57}

Neopulmonary Valve Regurgitation

Neopulmonary valve regurgitation occurs after an arterial switch operation, but prevalence of important regurgitation has not been well documented. Obstruction at this level is more common, especially in patients with associated aortic coarctation.\textsuperscript{10}\textsuperscript{10}

Reoperation

Reinterventions are mainly for RVOTO and LVOTO\textsuperscript{11} after arterial switch. Freedom from reintervention was 75% at 20 years in one large study, with 58% of reoperations involving RVOTO at various levels and 43% involving LVOTO (Fig. 52-44 and Table 52-6). Over a 10-year period, Serraf and colleagues reported that for supravalvular pulmonary stenosis was necessary in 2.1% of patients, whereas all other indications showed a prevalence of less than 1%.\textsuperscript{22}\textsuperscript{22,24,12} Some reports document an increase in late reinterventions for coronary artery lesions.\textsuperscript{22,24,12} Mortality of reintervention has been low unless reoperation is early following initial operation.

Simple Transposition of the Great Arteries with Atrial Switch Operation

Early (Hospital) Death

Hospital mortality after an atrial switch ranges from 0% to 15%.\textsuperscript{22,33,45,12,20,35,41,73,57} \textsuperscript{1} Variability in prevalence of risk factors and degree of institutional competence with atrial switch repair are the determining factors.

Atrial switch operations are usually delayed for a few weeks to a few months after birth, in contrast to arterial switch operations, which are usually performed within a few days of birth. Thus, in addition to mortality early after the atrial switch operation, deaths that occur before operation must also be considered (Table 52-7). About 10% of uncorrected patients with simple TGA die by age 30 days despite adequate

![Figure 52-44](image-url) Freedom from reoperation among survivors of initial hospitalization after corrective operations for transposition of great arteries, stratified by type of operation.

\textsuperscript{a}Data from study of 188 patients with simple transposition of great arteries admitted to GLH, 1970-1984.

\textsuperscript{b}Three of the 17 patients died before balloon septostomy.

Key: NYHA, New York Heart Association; PDA, patent ductus arteriosus.
Survival after the atrial switch operation is strikingly lower in patients with TGA and VSD than in those with simple TGA (Table 52-9). Currently, there are few risk factors for death after repair of simple TGA by the atrial switch operation (Table 52-9).

**Younger Age at Repair** Younger age has often been found in the past to be a risk factor for death after atrial switch repair. However, some institutions have achieved good results with the Senning atrial switch repair even when performed in the first 2 weeks of life, with hospital mortality in 4 of 26 patients (15%; CL 8%-26%). Several single-institution studies attest to the likelihood that young age can no longer be considered a risk factor for death after atrial switch repair in institutions properly prepared for this type of surgery.

“Older age” at repair (i.e., >3 years) has been shown to be a risk factor for late death, as have RV dysfunction and presence of active dysrhythmias.

**Lower Birth Weight** As with almost all operations for congenital heart disease, very low birth weight is a risk factor for death after atrial switch repair.

**Ventricular Septal Defect or Pulmonary Stenosis** In Senning’s long-term follow-up study, late systemic RV failure was three times more common in patients with VSD than in those with simple TGA, and systemic RV failure was found to be the most common cause of late death.

**Electrophysiologic Disturbances** Although much of the information about electrophysiologic disturbances after atrial switch operations comes from patients undergoing the Mustard technique, no evidence indicates that these disturbances are different with the Senning technique.
The morphologic basis of conduction and rhythm disturbances are understood to some extent. Histologic examination of the sinus node region reveals that the sinus node itself, sinus node artery, and paranodal tissues are frequently abnormal after the Mustard operation. B26,E4,E6 Acute changes include compression of the sinus node artery by sutures or, less often, intimal thickening or thrombus formation and suture compression, necrosis, or infarction of the sinus node itself with interstitial hemorrhage and edema of nodal tissue and adjacent myocardium. Edwards and Edwards found that in nine patients with sinus node artery compression, the sinus node showed acute infarction in seven. E4 Chronic changes include marked fibrosis in the node and paranodal tissue, such that in some cases the sinus node can no longer be identified. Surgical maneuvers responsible for this damage include incorrect techniques for SVC cannulation (e.g., too close to the node such that the purse-string suture damages it, use of crushing clamps in this region), damage to the sinus node

artery by overzealous excision of the limbus and reendothelialization of the bare area so created, and placing suture lines too close to the sinus node.

Although these abnormalities are associated with dysrhythmias and are present in many individuals with late sudden death, it is uncertain whether they explain all late benign arrhythmias after the Mustard and Senning operations. Extensive suture lines within the atria, combined with excision of virtually all the atrial septum, may be related factors. Although it is no longer believed that atrial conduction occurs through discrete, well-defined internodal tracts (see “Internodal Pathways” under Conduction System in Chapter 1), preservation of the anterosuperior portion of the limbus may decrease prevalence of dysrhythmia. In contrast, division of the free wall of the coronary sinus is not detrimental.

Functional rhythm becomes progressively more prevalent as the years pass (Fig. 52-50). Usually sinus rhythm is present on standard ECG tracings at hospital discharge after the atrial switch operation for simple TGA. About 10% of such

patients are in a varying sinus junctional rhythm, and only a few show a pure benign-type junctional rhythm (Table 52-10). Thereafter, there is a gradual decrease in prevalence of sinus rhythm after Mustard-type repair as follow-up continues.\(^{210,219,239}\) Besides the apparent slight increase in risk of sudden death when a benign junctional rhythm is present, this rhythm appears to have no other importance. In some normal subjects in sinus rhythm, heart rate can fall below 40 beats · min\(^{-1}\) during sleep, and rhythm is then usually junctional.\(^{315,58,521}\)

In patients with slow junctional rhythm there is a relatively normal rate response to exercise, often with reversion to sinus rhythm.\(^{109}\) Occasionally rapid (accelerated) junctional rhythm can occur. This rhythm, and occasionally supraventricular tachycardias or atrial flutter, can lead to a malignant arrhythmia that reduces cardiac output and requires active measures for control.\(^{56}\) Sinus node recovery time after atrial switch operations may be abnormal.\(^{357,54,450}\) Also, even when in sinus rhythm, maximal exercise heart rate response and postexercise recovery rate may be abnormal.\(^{109}\)

Twenty-four-hour Holter monitoring after both the Mustard and Senning procedures may reveal dysrhythmias that are infrequent enough to be overlooked on standard ECGs, even when these are repeated on many occasions.\(^{512}\) This technique allows frequency of rhythm disturbances to be assessed, as well as their categorization as a normal or probably abnormal variant. Holter studies that fail to make this latter differentiation overstate dysrhythmia prevalence.\(^{510}\)

Before a postoperative dysrhythmia can be categorized as resulting from the surgical procedure, it is necessary to know that the abnormal rhythm was not present on a preoperative Holter monitor recording.\(^{522}\) Using these criteria, dysrhythmias do not occur often before atrial switch procedures. Thus, 24 patients with TGA aged 1 to 10 months had preoperative monitoring; using the criteria in Table 52-11, only one was abnormal (frequent atrial premature beats), although five patients showed abnormalities within the normal range.\(^{522}\)

Postoperative Holter monitoring reveals additional dysrhythmias (Table 52-12), particularly when the patient is in junctional rhythm. If standard ECG always shows sinus rhythm, however, in about two thirds of patients the Holter study is normal. Rarely is an important abnormality in rhythm disclosed for the first time on Holter monitoring. Dysrhythmias that predispose to sudden death in this context are as yet unknown.

Rhythm monitoring during maximal exercise testing may provide additional information, although at present its prognostic implications are also unknown. Mathews and colleagues noted that of 15 patients in sinus rhythm at rest who underwent exercise testing a mean of 9 years after Mustard repair, nine developed either premature atrial or ventricular contractions or junctional rhythm during exercise.\(^{316}\) This finding contrasted with a control group, none of whom developed a dysrhythmia.\(^{516}\)

Sudden death may well be related to some of these dysrhythmias. This complication was emphasized during early

Development of the atrial switch operation by Aberdeen.3 Sudden death occurs in about 5% of hospital survivors over 10 to 20 years. Sudden death is rare in patients who remain in sinus rhythm postoperatively and when pacemaker recovery times are normal.4,5,6 Risk of sudden death in patients in junctional rhythm is 7%. No other risk factors for sudden death could be identified in a collaborative study of 372 patients. In a prospective 8-year study of 100 Senning and Mustard patients, progressive loss of a stable sinus rhythm was noted in more than 60% of patients at a mean follow-up of 7 years. However, rhythm disturbance identified by ECG or Holter monitoring did not identify patients at risk for sudden death.8

Changes in P-wave amplitude and contour are virtually constant after Mustard repair.4,6 Postoperatively, the P wave is greatly diminished in amplitude and is frequently bifid in shape. The mean frontal plane P-wave axis, however, is unchanged.

At late follow-up (23 years post-Mustard procedure), prevalence of atrial fibrillation or flutter is approximately 20% and seems to be a marker of reduced RV function.4,6,7 Episodes of supraventricular tachycardia occur in 3% to 5% of hospital survivors of the Mustard-type atrial switch procedure. In a 27-year follow-up of survivors of Senning procedures, 78% were in sinus rhythm, and freedom from pacemaker implantation for hospital survivors was 81 ± 5.9% at 25 years.8 In the 20-institution study of the Congenital Heart Surgeons Society, 94% and 91% of patients were free of pacemaker insertion 5 and 9 years after atrial switch repair, with risk factors being TGA and VSD vs. simple TGA and Senning versus Mustard type of repair.8

Growth and Functional Status

Most patients appear to be asymptomatic after an atrial switch procedure, although at 9 to 12 years of follow-up in a large multinstitutional study, only 60% were in New York Heart Association (NYHA) class I, and most of the rest in class II.9 However, graded exercise testing has shown that up to 80% have reduced exercise capacity associated with lower maximal oxygen consumption values compared with normal.3,4 Functional capacity may be better in patients receiving the Senning rather than the Mustard type of atrial switch procedure; Bjornstad and colleagues found atrial function to be superior with the Senning operation.5,6,10 Abnormal lung function has been implicated in reduced exercise capacity.11

Height and weight increase considerably after an atrial switch repair, particularly in those with importantly decreased height and weight preoperatively.11 Return to normal height and weight may be achieved within 2 years of operation.

Coronary Arteries

Abnormalities in the caliber of proximal coronary arteries have been noted in patients after the atrial switch procedure. Diameter of the RCA is larger and that of LCA smaller in
symptomatic patients compared with either asymptomatic or non-TGA patients.\(^\text{47}\)

**Venous Pathway Obstruction**

The complex problem of obstructed venous pathway is discussed in detail under Special Situations and Controversies later in this chapter.

**Right Ventricular Function**

Ventricular function after atrial switch repair of transposition is often discussed by analogy with function of the ventricles in congenitally corrected TGA. Contrary to traditional beliefs, right (systemic) ventricular function is demonstrably abnormal only during stress, and then only mildly (see “Ventricular Function” under Natural History in Chapter 55). This finding suggests that more severe abnormalities in ventricular function found after an atrial switch repair are related primarily to abnormalities in ventricular filling patterns and other post–atrial switch effects.\(^\text{21}\)

RV systolic function, usually studied by measuring ejection fraction at rest or during exercise or another form of stress, is usually reduced after atrial switch repair in patients with simple TGA.\(^\text{B14,B18,D13,G14,H15,M36}\) However, at least some patients have reduced ejection fraction preoperatively, and it is uncertain whether further reduction postoperatively is common.\(^\text{G14}\) When RV systolic function decreases after an atrial switch procedure, it is usually associated with increased RV end-diastolic volume.\(^\text{H13}\)

During exercise, RV ejection fraction may increase, remain unchanged, or decrease; patient age at operation, time of study, and the postoperative interval are not predictive of the change.\(^\text{B37,M36,P8,R4}\) In a group of patients averaging 10 years of follow-up after an atrial switch operation, cardiac output response to submaximal exercise was abnormally reduced compared with non-TGA subjects.\(^\text{P2}\) Other reports support this finding.\(^\text{M17}\) Limitation in cardiac output may have complex etiologies. Dobutamine-induced increases in systemic RV contractility may not be attended by increased stroke volume, possibly because of limited ventricular filling caused by rigid atrial baffle or decreased RV compliance caused by hypertrophy.\(^\text{P2,T15}\) More recent studies examining this stroke volume effect suggest that, in fact, atrial transport is responsible.\(^\text{T14}\)

Further evidence about a possible decrease in RV function after atrial switch repair was obtained by Borow and colleagues.\(^\text{M37}\) The systemic RVs in patients in whom the procedure was performed during the first year of life responded to afterload stress (methoxamine infusion) with a smaller increase in minute work index than did ventricles in normal patients or patients after repair of isolated VSD or tetralogy of Fallot. Parrish and colleagues found a similar impairment of systemic RV response in patients with congenitally corrected transposition.\(^\text{F8}\) The reasons for this finding are not entirely evident. Myocardial fiber arrangement in the RV may differ from that in the LV, which may render it less able to function systemically.\(^\text{S27}\) Possibly the RV cannot benefit from the septal component of ejection because of bellowslike action of the ventricular free wall.\(^\text{B17}\) Benson and colleagues suggest that a mismatch may exist between RV coronary blood supply and demand.\(^\text{B17}\) In a study of 22 patients at a mean of 15 years post–atrial switch, all showed evidence of either fixed or reversible perfusion defects in the RV.\(^\text{M28}\)

In any event, progressive deterioration of RV function is uncommon after the atrial switch procedure in patients with simple TGA, although serial evaluations of RV function suggest worsening of function over time.\(^\text{H19}\) Thus, obvious RV failure with marked hypokinesis and increased end-diastolic volume and signs and symptoms of heart failure\(^\text{F14}\) is rare.\(^\text{C15,P8}\) Frank RV dysfunction is more common in patients with associated large VSD that also requires repair.\(^\text{G14,P8}\) In a 27-year single-institution follow-up of 314 survivors of the Senning operation (82 with VSD), freedom from reoperation for systemic RV failure at 25 years was 96% ± 1.2%.\(^\text{H11}\)

**Left Ventricular Function**

LV function at rest is often normal late after atrial switch operations.\(^\text{H11}\) In some patients, however, LV ejection fraction fails to increase with exercise.\(^\text{M36}\)

**Tricuspid Valve Regurgitation**

Important (moderate or severe) tricuspid regurgitation occurs infrequently after the atrial switch procedure for simple TGA. Exceptional patient groups with a prevalence of up to 15% have been reported,\(^\text{R4}\) but reasons for this variability are not evident. Trivial and mild regurgitation occasionally occur.\(^\text{C15,G9,M3,M34}\)

**Left Ventricular Outflow Tract Obstruction**

When an atrial switch procedure is performed for patients with simple TGA and dynamic LVOTO (see Morphology earlier in this chapter), obstruction rarely progresses thereafter.\(^\text{P4}\) In fact, LVOTO usually regresses to some degree, whether or not a myotomy or myectomy is performed (Fig. 52-51).

Results of direct relief of the other types of LVOTO are also reasonably good (Fig. 52-52). When direct relief has not been possible, bypassing the obstruction with an LV–pulmonary trunk valved conduit provides good relief.\(^\text{C23}\)

![Figure 52-51 Preoperative, intraoperative, and late postoperative (mean 35 months) pressure measurements in patients with simple transposition of great arteries and dynamic type of left ventricular outflow obstruction undergoing an atrial switch procedure (GLH, 1964-1984). Follow-up time is 23 to 134 months (mean 56 months). When myotomy or myectomy was performed, approach was through pulmonary trunk. Key: Intraop, Intraoperative; LV/RV, left ventricular/right ventricular; Postop, postoperative; Preop, preoperative.](image-url)
Residual Atrial Shunting

Trivial leaking at the baffle suture line occurs in about a fourth of patients (26%; CL 24%-29% in 390 collected cases).\textsuperscript{A12,C9,G13,H2,M3,M34,P4,S29,T1,T13}

Severe leaks requiring reoperation are uncommon, occurring in 12 (3%; CL 2%-4%) of the 390 collected cases. Leaks are most common in the trabeculated upper portion of the atrium.

Pulmonary Vascular Disease

When an atrial switch operation is performed in the first 3 months for patients with TGA and essentially intact ventricular septum, new and progressive pulmonary vascular disease is uncommon; Mahoney and colleagues found no instances (0%; CL 0%-7%) in 28 patients undergoing operation during the first 100 days of life.\textsuperscript{M3} However, when repair is done after age 3 months, some patients (5%-10%) with normal Rp preoperatively develop pulmonary vascular disease postoperatively (Table 52-13).\textsuperscript{N8,R16} The disease often progresses and causes death.\textsuperscript{B20} More recent studies confirm that pulmonary hypertension can develop and progress in patients documented as having normal pulmonary artery pressure postoperatively.\textsuperscript{R11}

Infants with simple TGA with evidence of elevated Rp preoperatively to levels less than about 12 U \cdot m\(^2\) may experience a satisfactory fall in resistance late postoperatively.\textsuperscript{C16} Some of this fall is related to reduction in hematocrit that occurs postoperatively.\textsuperscript{C16,D12,H5} In some patients, however, preexisting pulmonary vascular disease may progress postoperatively and be a cause of late mortality (Table 52-14).\textsuperscript{M5} The occasional neonate with TGA who manifests evidence of pulmonary vascular disease may have antenatal constriction of the ductus arteriosus.\textsuperscript{K17}

Transposition of the Great Arteries, Ventricular Septal Defect, and Left Ventricular Outflow Tract Obstruction

Early (Hospital) Death

In the early years of their use, early mortality after both the Rastelli and Lecompte operations (see “Lecompte Intravenous Repair” under Technique of Operation in Chapter 53) was high: 20% to 30%.\textsuperscript{H38,L6} In more recent times, however, mortality after both types of repairs has been reduced to less than 5%.\textsuperscript{K15,V13} Contemporary early mortality after Rastelli, Lecompte, or Nikaidoh operations are comparable.\textsuperscript{H15}

Time-Related Survival

Including early in-hospital mortality, 10-year predicted survival of patients undergoing surgery during the 1980 to 1991

*aData are from patients with simple transposition of great arteries operated on at age 3 or more months; GLH, 1964-1984. Patients for whom no data are available preoperatively are presumed to have then had normal resistance.

*bMild fibrous left ventricular outflow tract obstruction.

*cMild dynamic left ventricular outflow tract obstruction.

Key: PDA, Patent ductus arteriosus; PVD, pulmonary vascular disease; Rp, pulmonary vascular resistance.
period was 80% to 85%, with no difference attributed to whether the Rastelli or Lecompte operation was done. Predicted 10-year survival for patients operated on in the latter part of that period was even higher—about 95% (Fig. 52-54). Recently, 15- and 20-year follow-ups have been reported after the Rastelli operation. In this experience, 10-year follow-up was comparable with that just described, but 15- and 20-year survival dropped to 68% and 52%, respectively. Based on very small numbers, late survival appears to be similar for the Nikaidoh operation.

**Incremental Risk Factors for Death**

Few if any patient-related risk factors for death have been identified for TGA, VSD, and LVOTO repair, but advanced disability has been (Table 52-15), probably in part because it is usually associated with severe cyanosis, polycythemia, advanced ventricular hypertrophy, and heart failure. Young age at operation has not been found to be a risk factor with the Lecompte operation; Vouhe and colleagues reported no deaths (0%; CL 0%-21%) among infants undergoing this operation, although the youngest patient was 4 months old. Straddling tricuspid valve has been identified as a risk factor for early death in at least one series.

*Earlier date of operation* has been a risk factor for death after repair, but results have been better in recent years (see Table 52-15).

**Procedural risk factors** for premature death have not yet been identified. Survival is similar after the Rastelli and Lecompte procedures. Reports on the Nikaidoh procedure or modifications thereof have yielded comparable early results, although numbers are small.

**Functional Status**

Functional status of most patients undergoing repair of TGA, VSD, and LVOTO by either the Rastelli or Lecompte method is good. Vouhe and colleagues report that 98% of patients undergoing these operations were in NYHA class I or II.

*Analysis is of 57 patients (22 deaths, including hospital and later deaths) operated on at UAB, 1967-1984. See Appendix 52C for variables entered into analyses.*

Key: NYHA, New York Heart Association; SD, standard deviation.
**Complete Heart Block**

Complete heart block may occur with slightly greater frequency than after repair of simple primary VSD. Vouhe and colleagues report one such patient (2%; CL 2%-5%) among 62.\(^{11,13}\)

**Reoperation**

Reoperation is in general ultimately inevitable when an extracardiac conduit is used. When the Rastelli operation is properly performed, however, placing the conduit to the left of the ascending aorta rather than to the right as originally described by Rastelli,\(^{88}\) reoperation occurs with the same prevalence as when it is used in other operations (see “Reoperation and Other Reinterventions for Right Ventricular Outflow Problems” in Section I of Chapter 38).

Patients have not been entirely free of reoperation for RVOTO after the Lecompte operation for TGA, VSD, and LVOTO; 7% (CL 2%-15%) of 30 surviving patients had reoperation over a 5-year period.\(^{11,13}\) However, the proportion of patients having either reoperation for this problem, or the problem itself but as yet without reoperation, was lower in those undergoing the Lecompte operation (26%) than in those undergoing the Rastelli operation (67%; \(P = .005)\).\(^{11,13}\)

Reoperation for obstruction in the subaortic region within the surgically created tunnel between the LV and aorta may occur in as many as 35% to 40% of patients undergoing the Rastelli operation or one of its variants.\(^{110}\) Risk factors are not clearly defined but may include small VSD size and early age at operation. Other factors such as surgical technique and ventricular geometric changes may also be important. At medium term, the need for intervention for LVOTO may be higher after the Rastelli operation compared with the Lecompte and Nikaidoh operations; however, again the numbers are very small.\(^{11,18}\) Resection of the infundibular septum and adequate enlargement of the VSD may be the reason for this. Nevertheless, mortality with reintervention is currently far better than previously reported. Although the Nikaidoh operation has theoretical advantages, concern about developing translocated aortic valve regurgitation is very high.

**INDICATIONS FOR OPERATION**

**Simple Transposition of the Great Arteries in Neonates**

Presence of the malformation is an indication for operation. If cyanosis and symptoms are severe, BAS is performed as soon as possible. A less attractive alternative is immediate arterial switch.

When indicated, an arterial switch operation should be performed within the first week of life, and at least within the first 30 days of life. Increased Rp at this stage is not a contraindication to repair.\(^{57}\) LVOTO, which is typically dynamic in this setting, is also not a contraindication regardless of its imaged appearance.\(^{11,95}\) Risk of operation is probably lowest when it is performed in the first week of life (see Fig. 52-41), and there is the additional advantage of minimizing exposure time of the brain to the hypoxia of uncorrected TGA.\(^{11,66}\)

Excellence of results to date favors the arterial switch over the atrial switch operation (see Fig. 52-37).

**Simple Transposition of the Great Arteries Presenting after Age 30 Days**

Primary arterial switch operation may carry a higher risk for infants with simple TGA who are beyond age 1 month, because by then the LV has usually become morphologically adapted to supporting the low-pressure pulmonary circulation. Davis and colleagues have taken exception to this and, based on their favorable experience, recommend a primary arterial switch operation unless the infant is older than age 8 weeks.\(^{118}\) Arterial switch has been successfully performed beyond the neonatal period and up to 9 months of age in patients with intact septum, but such patients are more likely to require postoperative mechanical support.\(^{11,2}\) Based on these experiences and similar observations by others, there is a willingness in most cases to perform primary arterial switch in infants younger than 8 weeks of age, and in some cases even in older infants with persisting large PDA, as long as mechanical assistance can be provided (see “Temporary Ventricular Assistance” in Section I of Chapter 5). If mechanical assistance is not available, or if primary arterial switch is not undertaken for some other reason, the options are:

- Pulmonary trunk banding with concomitant systemic–pulmonary artery shunting, followed within 1 or 2 weeks by arterial switch operation\(^{11,2,17,3}\)
- Atrial switch operation

Because the first approach appears to carry only slightly more risk than a primary atrial switch operation in a neonate in institutions properly prepared for this surgery, it is the more desirable of the two procedures.\(^{17}\)

When arterial switch operation is delayed for a month or more after banding, risk of postoperative death may be considerably increased,\(^{11,12}\) although others have shown no increased risk in waiting up to 4 months after banding.\(^{11,3}\) In institutions not well prepared for this type of surgery, an atrial switch operation may be more appropriate.

**Transposition of the Great Arteries with Ventricular Septal Defect**

TGA with VSD is an indication for arterial switch operation and repair of the VSD. It is indicated at the time the patient is first seen, with the procedure performed within the first few weeks of life.

**Transposition of the Great Arteries with Ventricular Septal Defect and Left Ventricular Outflow Tract Obstruction**

Diagnosis of TGA with VSD and LVOTO is an indication for operation, but type and timing of the definitive procedure remain controversial.

Many babies born with TGA, VSD, and LVOTO are not sufficiently cyanotic in early life to require urgent surgical intervention. Although the youngest age at which the Lecompte operation can be performed is not certain, it can be performed in infants older than age 6 months with a reasonably low mortality. The Lecompte procedure is probably the indicated operation in patients with this anomaly who appear for surgical repair between age 6 months and 4 to 5 years. When cyanosis and symptoms are important before age 6 months, either a systemic–pulmonary artery shunt, followed by a Lecompte operation within 6 to 18 months, or a primary
Lecompte operation, is indicated. The choice is best made in individual institutions according to their capabilities and experience.

In children age 3 to 5 years, either the Lecompte or Rastelli operation provides good results. In special situations, the Nikaidoh procedure may be considered as an alternative to the Rastelli or Lecompte operation.

**SPECIAL SITUATIONS AND CONTROVERSIES**

**Arterial Switch Repair**

*Transposition of the Great Arteries with Posterior Aorta*

The unusual posterior aorta variant of TGA, described in 1971 by Van Praagh and colleagues, had been considered a contraindication to the arterial switch operation until a successful case was reported by Tan, Murphy, and Norwood. They repaired the conoventricular VSD through the aorta after transecting the great arteries, and transplanted the coronary ostia just as in the routine approach. Switch of the great arteries was accomplished without the Lecompte maneuver. Benatar and colleagues had previously reported treating a patient with this morphology by an arterial switch repair, but the patient died on the fifth postoperative day.

*Straddling Atrioventricular Valves*

Serraf and colleagues have shown that straddling AV valves, either tricuspid or mitral, do not represent a contraindication to two-ventricle repair in TGA. When appropriate, the arterial switch operation can be combined with AV valve repair in most patients, with good outcome.

*Other Techniques*

Current surgical techniques for the arterial switch operation (see Technique of Operation earlier in this chapter) have evolved from original descriptions of Jatene and of Yacoub, in which a synthetic tube was used to aid in reconstruction of the neopulmonary artery. This approach is now rarely necessary.

The Damus-Kaye-Stansel type of arterial switch procedure has also been used in patients with TGA and large VSD. The pulmonary trunk is transected near its bifurcation and the proximal end anastomosed end-to-side to the ascending aorta. A valved extracardiac conduit is placed between the RV and distal pulmonary trunk and the VSD closed. RV systolic pressure falls to about 30 mmHg, and aortic pressure, which is above 100 mmHg, keeps the aortic valve closed. Mortality in this relatively simple and theoretically attractive operation has been considerable; Ceithaml and colleagues from the Mayo Clinic report 10 deaths (53%; CL 38%-66%) among 19 patients. However, if patients younger than 1 year of age or those with severe pulmonary vascular disease or LV systolic pressure less than two-thirds systemic are excluded, hospital mortality was 1 in 7 patients (14%; CL 2%-41%). Patients have been clinically well after repair. Over time, an increasing prevalence of regurgitation of the original aortic valve has been observed. The Damus-Kaye-Stansel repair is now rarely used for patients with TGA and VSD.

**Atrial Switch Complications**

*Superior Vena Caval Obstruction*

SVC pathway obstruction appears late postoperatively in 5% to 10% of survivors of the Mustard type of atrial switch procedure (Table 52-16). Prevalence appears to be unrelated to age at repair, although Cobanoglu and colleagues reported that freedom from reoperation was 59% in patients younger than 7 months of age at operation, compared with 95% in those older than 1 year. A Congenital Heart Surgeons Society multiinstitutional study found that the highest hazard for reintervention (operative or percutaneous intervention) for pathway obstruction was in the first 6 months after repair, followed by a constant low risk of 0.018% per year thereafter. At 1 and 9 years, freedom from such reinterventions was 97% and 95%, respectively.

SVC obstruction is maximal at the site of excision of the superior remnant (limbus) of the atrial septum beneath the

*Data from analysis based on 166 hospital survivors of Mustard operation for transposition of great arteries of all types at GLH, 1964 to July 1981.

*Pressure gradients ranged between 9 and 22 mmHg.

*One patient had associated significant lower venous compartment obstruction.

*Two of these three deaths occurred without reoperation (one from associated severe pulmonary venous compartment obstruction, the other from noncardiac causes).

Key: SVCO, Superior vena caval obstruction.
upper baffle compartment, and thus lies within the right atrium rather than at the SVC–right atrial junction. This location was first described by Mazzei and Mulder in 1971. The venous pathway may be totally occluded for over 1 cm or more in this area, or there may be only a localized zone of narrowing. Baffle shape, size, and composition are each important in its production, as is the position of suture lines within the atrium. Because it has proven impossible to eliminate this problem after the Mustard procedure, despite intense study, the exact mechanism is not understood.

Prevalence of late SVC obstruction after a Senning operation is probably lower than after a Mustard operation, although some have found no difference. Geometry of the pathway is, on average, better with the Senning-type repair, and the entire compartment is composed of viable atrial wall. Chin and colleagues, however, found SVC obstruction present in 2 of 28 (7%; CI 2.4%-16%) recatheterized patients after Senning repair.

Clinical Features The patient may be asymptomatic. Venables and colleagues found that although symptoms could be present with an SVC mean pressure as low as 10 mmHg, they were not constant until it rose above 16 mmHg.

The least conspicuous clinical feature, but one that suggests diagnosis, is ruddiness of the cheeks. Puffiness of the eyelids, face, and neck can mask fixed distention of the jugular veins. Tortuous subcutaneous venous collaterals can occur but are uncommon. A bilateral or right-sided pleural effusion may be present, sometimes chylous. On chest radiograph, there may be bilateral cervical and axillary lymphadenopathy and paramediastinal densities caused by tortuous collaterals. Less common features are increasing head circumference and hydrocephalus associated with widening of the cranial sutures in children younger than age 18 months (the upper age limit for normal closure of the cranial sutures), which is a response to increased intracranial venous pressure. Children older than age 3 may develop pseudotumor cerebri. There may also be protein-losing enteropathy, presumably caused by interference with the normal return of intestinal lymph to the venous system secondary to a high venous pressure (this is more common with IVC obstruction).

Time of Onset SVC obstruction is usually apparent within 12 months of operation, although asymptomatic patients may not be discovered until they are investigated later. The appearance between 12 and 18 months after operation of a new stenosis has not been convincingly documented, although slow progression of a mild to severe stenosis has been. Prevalence is 9% at 4 years, with no further events up to 17 years postoperatively (Fig. 52-55). Late postoperatively (Fig. 52-57), nor is there necessarily a gradient, but they are common. When SVC obstruction is mild, the striking feature is the damped waveform in the SVC tracing.

Obstruction severe enough to become apparent clinically is associated with an SVC mean pressure above about 15 mmHg and an SVC–systemic venous atrium gradient of at least 10 mmHg. In 19 patients with severe obstruction, Silove and Taylor recorded a mean gradient of 17 ± 9.0 mmHg. SVC pressure tends to be higher when there is also IVC obstruction. Occasionally the SVC tracing may show tall a waves caused by contraction of the right atrial appendage (when it lies above the site of stenosis); in this situation the blood refluxes up the SVC (see Fig. 52-56).

Angiography shows either complete obstruction or severe stenosis.

Treatment When symptoms are present, reoperation is indicated (see Technique of Operation earlier in this chapter). Reoperation is also indicated in any child who shows progressive increase in head size beyond the normal range. Balloon expandable stents delivered using interventional cardiologic techniques have been successful in relieving some obstructions. Alternatively, if Rp is acceptably low, a bidirectional superior cavopulmonary anastomosis can be performed.

Inferior Vena Caval Obstruction Although an important occurrence of IVC pathway obstruction was reported in the early series of Stark and associates and Venables and colleagues using polyester baffles, current prevalence is low (1%-2%). This complication

Figure 52-55 Freedom from superior vena caval obstruction in hospital survivors of Mustard-type atrial switch operation (GLH, 1964-1981). Time of appearance of obstruction is taken as time of postoperative catheterization (n = 10) or recognition of an increase in head circumference (>2 SD of expected mean for age) at 6 and 9 months postoperatively. Obstructions documented as appearing after 1 year postoperatively were either without symptoms or at an earlier stage or, in one patient, had serial cardiac catheterization showing progression of a mild stenosis. Of 166 patients, 94 had late postoperative cardiac catheterization. Each closed circle up to 4 years is an event, vertical bars represent 68% confidence limits, and numbers are traced patients.
Figure 52-56 Data from postoperative cardiac catheterization in patient who had undergone Mustard repair and developed severe obstruction to superior vena caval (SVC) flow into systemic venous atrium (SVA). A, Phasic withdrawal pressures from SVA to SVC. Mean pressures were 5 and 20 mmHg, respectively. Note dominant a wave in SVC tracing, caused by contraction of portion of right atrial appendage that lies above site of obstruction. B, Cineangiogram after injection into SVC, in 20-degree left anterior oblique projection. Heavy arrow marks site of obstruction. Fine dotted lines (small arrows) outline that portion of original right atrial appendage that lies in upper venous compartment beneath baffle and above site of obstruction. There is retrograde flow into azygos vein. Key: A, Azygos vein; LAA, left atrial appendage; LV, left ventricle. (From Clarkson and colleagues.\textsuperscript{15})

can be minimized when at the atrial switch procedure, the coronary sinus is opened down into the left atrium (see Technique of Operation earlier in this chapter).

Postoperative IVC obstruction, as with SVC obstruction, occurs within the heart at about the midpoint of the lower portion of the systemic venous compartment adjacent to the coronary sinus ostium. Patients with important IVC obstruction usually are symptomatic, with liver enlargement, ascites, and leg edema. A protein-losing enteropathy may occur more frequently than with SVC obstruction,\textsuperscript{315} and particularly when combined with some degree of SVC obstruction, there may be low cardiac output and premature late death.

Diagnostic techniques used in obstructed IVC are similar to those for SVC obstruction. Pressure gradients are also similar, averaging $18 \pm 8.8$ mmHg in the series reported by Silove and Taylor.\textsuperscript{318}

Reoperation with insertion of a new baffle is always indicated for IVC obstruction (see Technique of Operation earlier in this chapter). Balloon expandable stents have been used for IVC as for SVC obstruction.\textsuperscript{48,50}

Pulmonary Venous Obstruction
Pulmonary venous obstruction is a less common but more lethal type of venous pathway obstruction. It is more common
hypertension and usually an elevation of the calculated Rp are present. Normal pulmonary artery and LV systolic pressures argue against important stenosis. On cineangiography, narrowing of the pulmonary venous atrium waist can be seen best in lateral projection. Diagnosis is also possible using 2D echocardiography.

Treatment Urgent reoperation is indicated.

Palliative Operations for Patients with Severe Pulmonary Vascular Disease

Palliative operations may be indicated when Rp is elevated beyond about 10 U · m². However, more recent experience suggests that full repair can be achieved with good long-term outcome, including regression of pulmonary hypertension, even when initial Rp calculations show levels of 10 to 20 U · m².2 Thus, in the current era, with general improvements in preoperative and postoperative care and the availability of pulmonary vasoactive agents such as nitrous oxide, palliative procedures are rarely indicated. Palliation consists of an atrial (or preferably an arterial) switch procedure without closing an existing VSD or creating a VSD when one is not present.

Technique of Operation

When the ventricular septum is essentially intact, a large VSD is created in the apex of the ventricular septum through a limited apical left ventriculotomy. After the ventriculotomy is made, a finger is inserted through the tricuspid valve through the previously made right atriotomy to tent the ventricular septum toward the left, and a limited opening is made with a knife onto the finger. The opening is then progressively enlarged (up to 20 mm) using the knife, avoiding damage to the inferior papillary muscle. (Hegar dilators are used to measure the size of the created defect.) The ventriculotomy is closed, and the switch procedure completed.
Special Features of Postoperative Care

SaO₂ in TGA depends on the relative proportions of systemic venous and pulmonary venous blood reaching the aorta, and on SvO₂. After palliative switch repair, the effective systemic flow is greatly increased, with the ratio usually changing from 1:3 to approximately 2:1. Decrease in the proportion of systemic venous blood entering the aorta is also influenced by the rise in systemic arteriolar resistance that follows the rise in SaO₂, because the increase in systemic vascular resistance decreases the right-to-left shunting of systemic venous blood through the open VSD. Finally, doubling of effective systemic flow results in an important increase in SvO₂ despite concomitant reduction in hemoglobin concentration. As a result of these complex interactions, there is an absolute increase in SaO₂ of approximately 20% in most patients after a palliative switch operation; the increase ranged from 6% to 48% (mean = 24%) in the report by Byrne and colleagues. The only preoperative variable that correlates with postoperative SaO₂ is pulmonary arteriovenous oxygen difference: A higher arteriovenous oxygen difference is associated with a higher postoperative SaO₂.

Results

Hospital mortality after a palliative switch operation has been surprisingly low. Lindsey and colleagues report no deaths in 10 patients with VSD. Byrne and colleagues report no deaths in 23 patients (20 with VSD, 3 with created VSD), and Benhard and colleagues report one death in 8 patients.

Staged Conversion of Atrial Switch to Arterial Switch for Systemic Right Ventricular Failure

Late failure of the systemic RV occurs in up to 10% of patients after the atrial switch procedure. Because ample evidence suggests lesser degrees of RV dysfunction in a much greater percentage of patients with the atrial switch procedure, it seems likely that late RV failure will become an increasingly common problem as longer follow-up is obtained.

When the systemic RV fails, treatment options include lesion-specific surgical intervention (e.g., tricuspid valve repair or replacement), medical management, transplantation, and conversion from atrial to arterial switch. Escalation of medical management may be effective in the short term, but this form of therapy should be seen as limited in a young individual with progressive systemic RV failure. Nevertheless, this form of therapy, followed by cardiac transplantation when end-stage ventricular failure develops, represents an effective therapeutic plan. Tricuspid valve repair is difficult when the valve is in the systemic position and is generally not indicated. Valve replacement is indicated in highly selected patients who have good systemic RV function. An alternative plan is to intervene earlier in the course of systemic RV failure by performing a staged conversion to the arterial switch. Indications for embarking on the staged conversion are not clearly defined; however, it is generally accepted that the process should begin well before end-stage heart failure is present. Relative indications include worsening functional status, progressive loss of RV function, and progressive tricuspid valve regurgitation. Besides end-stage heart failure, biventricular dysfunction and severe rhythm disturbances are contraindications.

There are two general controversies related to this topic. First, the choice of management between (1) medical management followed by transplantation and (2) staged conversion; and second, if staged conversion is considered, the timing of the intervention in the gradual course of progressive RV dysfunction. The conversion process carries substantial risk. Initiation of the process too late in the course of progressive failure results in unacceptable outcome, whereas initiation of the process at the first signs of RV dysfunction or tricuspid regurgitation, although effective in minimizing the risk of the conversion process, may be premature. Adding to the uncertainty, only limited experience and data are available to define the ideal interval between pulmonary trunk banding and the arterial switch, or the preferred methodology for determining when the LV is adequately prepared. The subject of LV training and conversion to arterial switch in atrial switch patients with failing RV is discussed in more detail under “Transposition of the Great Arteries” in Chapter 29. Pulmonary trunk banding alone as a treatment for isolated progressive tricuspid valve regurgitation has resulted in a decrease in regurgitation in some cases, but the evidence is only anecdotal. In one study, banding did not improve the severity of regurgitation at follow-up, but did improve symptoms in a cohort of patients.

Occasionally, LV-to-pulmonary trunk obstruction is already present. If LV peak pressure is greater than 75% of systemic pressure, it is possible to proceed with conversion immediately. It should be emphasized that the biomechanics of the unconditioned LV are poorly appreciated.

Technical details of the staged conversion have been described and outcomes reviewed. Operative mortality was 12.5% (CL 4%-27%) and 1-year survival 80% (CL 62%-92%) in one series. In that series, age younger than 16 years was thought to increase the chance of successful conversion. In another study, early mortality was 33% (2 of 6 patients). In the experience of Winlaw and colleagues, of 31 patients entering a banding protocol, 52% met criteria to proceed to conversion. Survival after conversion was 75% at mean follow-up of 5 years. Age at banding did not influence outcome. The experience of Winlaw and colleagues was similar. Nine of 20 banded patients (45%) underwent conversion, with 6 successful midterm outcomes (67%). Another study suggests that conversion may be more appropriate for Mustard than for Senning patients; however, most studies show no difference based on the type of former atrial procedure. Important differences in outcome among these studies is not surprising, considering the small number of patients, lack of consensus regarding patient selection, and lack of a universal protocol for LV training.

**Multivariable Analysis of Risk Factors for Death after Atrial Switch Operation**

Variables entered into the multivariable logistic regression analysis of hospital deaths in patients with TGA at Green Lane Hospital between 1970 and 1984 after atrial switch repair were as follows:

- Age at operation
- Date of operation
- Atrial septal defect creation (none, septostomy, repeat septostomy, septectomy)
- Other palliation (Blalock-Taussig, Waterston, banding, ductus ligation, coarctation repair)
- Atrial septal defect size at repair (none, small, moderate, large)
- Ventricular septal defect size (small, moderate, large)
- Additional ventricular septal defects (yes/no)
- Left ventricular outflow tract obstruction (yes/no) and type (valvar, fibrous, muscular)
- Coarctation (yes/no)
- Right ventricular size (moderate or severe hypoplasia: yes/no)
- Urgency of operation (elective, New York Heart Association class IV, semi-urgent, urgent)
- Type of operation (standard Mustard, V-Y Mustard, Senning)
- Technique of cardiopulmonary bypass (standard/profound hypothermia; circulatory arrest)
- Preoperative pulmonary vascular resistance (or lung histology) in patients aged 3 months or older
Early reoperation (for bleeding, baffle obstruction, baffle leak, infection)

Discharge electrocardiogram (sinus, junctional, complete heart block)

Patent ductus arteriosus (absent/small, moderate, large in various combinations)

Operation (baffle repair) at age 30 days or younger (yes/no)

Early operation (repair or palliation) at age 30 days or younger (yes/no)

Preoperative growth patterns (normal, third percentile, well below third percentile, always below third percentile but steady, always below third percentile but declining, and various combinations)

Addition variables considered in Cox’s proportional hazard model for late mortality in the same data set are as follows:

- Upper systemic venous compartment obstruction (none/mild, moderate, severe)
- Lower systemic venous compartment obstruction (same criteria)
- Pulmonary venous compartment obstruction (same criteria)
- Baffle leak (same criteria)
- Residual left ventricular outflow tract obstruction
- Residual ventricular septal defect (yes/no)

Risk factors entered into the multivariable analysis of death, in the hazard function domain, after Rastelli operation (UAB experience) are as follows:

- Demographic: gender, age at operation, body surface area
- Clinical: New York Heart Association functional class, hematocrit
- Morphology: juxtaposition of atrial appendages
- Surgical: cardioplegia; aortic clamp time in cardioplegic group; type of valved conduit; enlargement of ventricular septal defect

**Complications of Intraventricular Tunnel Repair 1956**

**Complications after Taussig-Bing Repair 1957**
Double outlet right ventricle (DORV) is a congenital cardiac anomaly in which both great arteries arise wholly or in large part from the right ventricle. It is a type of ventriculoarterial connection (see “Cardiac Connections” under Terminology and Classification of Heart Disease in Chapter 1).

In this chapter, DORV with atriovenous (AV) concordant connection is discussed in detail. DORV also occurs in other settings (Fig. 53-1), but when the AV connection is discordant, that becomes the surgically more important feature, and patients with this combination (commonly called congenitally corrected transposition of the great arteries) are better considered along with others with AV discordant connection (see Chapter 55). DORV may also occur in patients with univentricular AV connections (see “Ventriculoarterial Connections” under Morphology in Chapter 56). It is a frequent occurrence in patients with atrial isomerism (see “Ventriculoarterial Connections” under Morphology in Chapter 58).

One or both great arteries may directly overlie the ventricular septal defect (VSD) and thus arise biventricularly. For purposes of categorization, the great artery so arising is assigned to the ventricle it overlies by more than 50% on morphologic examination. Thus, when one great artery arises wholly or nearly so from the right ventricle (RV) and the other more than 50% from it, the condition is termed DORV. Uncommonly, both great arteries arise biventricularly in association with a doubly committed juxta-arterial VSD (see Chapter 35, Figs. 35-8 and 35-9). One option is to arbitrarily assign each great artery to the ventricle above from which more than 50% arises and categorize the anomaly accordingly; the alternative is to term the malformation double outlet both ventricles.

Tetralogy of Fallot is an entity characterized by a variable amount of dextroposition of the aorta. When the aorta arises more than 50% from the RV, the anomaly may be categorized as tetralogy of Fallot with DORV or as DORV with pulmonary stenosis. Edwards uses different criteria for distinguishing between these two conditions. Taurig-Bing heart (see description under Morphology later in this chapter) is an entity with variability in the origin of the pulmonary artery. This diagnosis may be made when the pulmonary artery arises wholly or nearly so from the RV (in which case, it is a type of DORV), equally from right and left ventricles, or more than 50% but not entirely from the left ventricle (LV; in which case, it is not a type of DORV). When it arises entirely or essentially so from the LV, the assignment is to transposition of the great arteries with VSD.

Because of this differing terminology, surgical reports must clearly describe the entities under discussion.

HISTORICAL NOTE

When Kirklin performed the first repair of DORV (which was of the simple type with a subaortic VSD) in May 1957 at the Mayo Clinic, the anomaly was virtually unknown, and the preoperative diagnosis was large VSD with high pulmonary blood flow. Diagnosis was correctly made at operation, the term double outlet right ventricle or origin of both great vessels from the right ventricle coined in the operating room, position of the His bundle deduced, and intraventricular tunnel repair performed in much the same manner as is done today. An identical sequence occurred at GLH in September 1958. Earlier, in 1952, Braun and colleagues reported what was clearly a case of DORV with pulmonary stenosis and used the phrase double outlet ventricle, but the title of their paper was confusing, and it escaped notice. About the time of the first repair, the first morphologic paper with the title “Double Outlet Right Ventricle” was published by Witham; subsequently, other early descriptions of the morphology appeared. In 1963, Redo and colleagues also reported repair of this entity.

Taurig-Bing heart was described in 1949, but its place in the spectrum of DORV was not recognized until later. Many early papers understandably referred to it under the heading Transposition. Levy and colleagues recognized it as a form of DORV with subpulmonary VSD. They and earlier workers did not clearly state, however, that Taussig-Bing heart is different from the heart with classic DORV with...
subaortic VSD, not only with respect to relationships of the VSD but also with respect to position and interrelations of great arteries and infundibular (outlet) septum.\textsuperscript{A4,A7,W2}

Early reports of successful surgical treatment were published in 1967 and 1969.\textsuperscript{D1,H2} Other early reports were by Patrick and McGoon in 1968 and by Kawashima and colleagues in 1971.\textsuperscript{K3,P3}

The other types of DORV with AV concordant connection began to be clarified in the classic paper by Lev and colleagues in 1972.\textsuperscript{L4} Successful correction of unusual forms was reported in the 1970s and early 1980s.\textsuperscript{K6,P6,S13}

**MORPHOLOGY AND MORPHOGENESIS**

Although controversies developed concerning categorization of hearts with DORV and their basic morphologic features, these are now straightforward because of numerous detailed morphologic and clinical studies. The basic categorization of Lev and colleagues forms the basis of most surgical thought about this anomaly, but the terms they used, such as “sub-aortic” and “subpulmonary,” are relational ones.\textsuperscript{L4} Confusion arises when their terms are used as morphologic ones for actual location of the VSD (see “Location in Septum and Relationship to Conduction System” under Morphology in Section I of Chapter 35).

Actual categorization of DORV and related conditions (specifically, Taussig-Bing heart, transposition of the great arteries with VSD, and double outlet left ventricle) is less important than a generalized surgical plan for their management.\textsuperscript{S1} Even so, development of a valid body of knowledge concerning surgical methods and outcomes requires accurate categorization of morphologic details and other patient characteristics. Even with the goal of accurate morphologic categorization and description, problems remain. Although a conus (or infundibulum) is easy to define as the presence of a muscle strip between a semilunar and AV valve, the muscle strip may vary from a few millimeters to a few centimeters wide. An aorta that is to the right and side by side with the pulmonary trunk may seem essentially normal in position to one observer or in D-malposition to another. These matters complicate categorization accuracy and precision.

**Morphogenesis**

Complex categorization points to a unifying hypothesis of morphogenesis put forth in a series of papers by the Van Praaghs, summarized recently by Richard Van Praagh.\textsuperscript{V2} He hypothesizes that “the distal or subsemilunar part of the infundibulum or conus arteriosus performs an arterial switch during cardiogenesis,” with the development stage similar to the Taussig-Bing heart. The developmental steps that avoid double outlet right ventricle relate to asymmetric conal free wall enlargement. Van Praagh proposes that failure of this morphologic step leads to such entities as double outlet right ventricle with subaortic ventricular septal defect (VSD). There is a prominent subaortic conus and a well-developed infundibular septum separating pulmonary valve (PV) from aorta, tricuspid valve (TV), and VSD. Key: AR, Aortic root (conus); RT, right. (From Kirklin and colleagues.\textsuperscript{L5,4})

In most DORV hearts, the VSD is conoventricular, lying between the limbs of the trabecula septomarginalis (TSM; septal band).\textsuperscript{C1,71} However, such defects vary in their relationships with the great arteries. Therefore, the VSD is discussed in relational categories.\textsuperscript{S5,14}

**Subaortic Ventricular Septal Defect**

The subaortic VSD and TSM lie more posteriorly in the ventricular septum than subpulmonary and doubly committed VSDs, and are tucked beneath the infundibular (conal) septum (Fig. 53-2). Distance between the VSD and aortic valve varies, depending on presence and length of the subaortic conus (infundibulum); this determines whether the aorta overrides the VSD and hence whether the VSD is juxtaaortic.

When there is aortic-mitral fibrous continuity, absence of a subaortic conus, and a typical juxtaaortic VSD, the posteroseptal margin of the VSD is formed by the left aortic cusp or base of the anterior mitral leaflet, depending on degree of overriding. The ventriculoinfundibular fold and rightward posterior division of the TSM may form the posterior margin of the VSD. Alternatively, the VSD may reach the tricuspid anulus (opposite the anteroseptal leaflet commissure), resulting in mitral-tricuspid continuity, and the VSD is perimembranous\textsuperscript{H4,W2} (see “Perimembranous Ventricular Septal Defect” under Morphology in Section I of Chapter 35). In this event, the rightward posterior division of the trabecula septomarginalis is deficient, and the bundle of His lies along the posteroinferior border of the VSD and is at risk during surgical repair\textsuperscript{A4,A5} (Fig. 53-3). Occasionally

![Figure 53-2 Autopsy specimen of simple double outlet right ventricle with subaortic ventricular septal defect (VSD). There is a prominent subaortic conus and a well-developed infundibular septum separating pulmonary valve (PV) from aorta, tricuspid valve (TV), and VSD. Key: AR, Aortic root (conus); RT, right. (From Kirklin and colleagues.\textsuperscript{L5,4})](image-url)
The VSD and TSM lie more superiorly and anteriorly in the ventricular septum, directly beneath the pulmonary conus and valve, than they do in subaortic VSD with right-sided aorta, but in a position similar to that of subaortic VSD with aortic L-malposition. If there is a subpulmonary conus, infundibular (conal) muscle forms the superior margin of the defect. If there is no subpulmonary conus, there is pulmonary-mitral and occasionally pulmonary-tricuspid continuity, and the VSD is juxtapulmonary with the pulmonary valve over-riding it (Fig. 53-5). The infundibular septum inserts behind left anterior division of TSM, and its leftward end contributes to the interventricular septum in front of the VSD. The posterosuperior margin of the VSD is formed by the zone of fibrous continuity or by the pulmonary cusps, depending on degree of pulmonary valve over-riding, or by the subpulmonary conus if present. As with subaortic VSD, the defect may extend to the tricuspid anulus posteroinferiorly and be perimembranous (see Fig. 53-5), but often it does not. The infundibular septum is usually sagittally oriented and is then not a part of the interventricular septum.

The VSD and TSM lie more superiorly and anteriorly in the ventricular septum, directly beneath the pulmonary conus and valve, than they do in subaortic VSD with right-sided aorta, but in a position similar to that of subaortic VSD with aortic L-malposition. If there is a subpulmonary conus, infundibular (conal) muscle forms the superior margin of the defect. If there is no subpulmonary conus, there is pulmonary-mitral and occasionally pulmonary-tricuspid continuity, and the VSD is juxtapulmonary with the pulmonary valve over-riding it (Fig. 53-5). The infundibular septum inserts behind left anterior division of TSM, and its leftward end contributes to the interventricular septum in front of the VSD. The posterosuperior margin of the VSD is formed by the zone of fibrous continuity or by the pulmonary cusps, depending on degree of pulmonary valve over-riding, or by the subpulmonary conus if present. As with subaortic VSD, the defect may extend to the tricuspid anulus posteroinferiorly and be perimembranous (see Fig. 53-5), but often it does not. The infundibular septum is usually sagittally oriented and is then not a part of the interventricular septum.

The VSD and TSM lie more superiorly and anteriorly in the ventricular septum, directly beneath the pulmonary conus and valve, than they do in subaortic VSD with right-sided aorta, but in a position similar to that of subaortic VSD with aortic L-malposition. If there is a subpulmonary conus, infundibular (conal) muscle forms the superior margin of the defect. If there is no subpulmonary conus, there is pulmonary-mitral and occasionally pulmonary-tricuspid continuity, and the VSD is juxtapulmonary with the pulmonary valve over-riding it (Fig. 53-5). The infundibular septum inserts behind left anterior division of TSM, and its leftward end contributes to the interventricular septum in front of the VSD. The posterosuperior margin of the VSD is formed by the zone of fibrous continuity or by the pulmonary cusps, depending on degree of pulmonary valve over-riding, or by the subpulmonary conus if present. As with subaortic VSD, the defect may extend to the tricuspid anulus posteroinferiorly and be perimembranous (see Fig. 53-5), but often it does not. The infundibular septum is usually sagittally oriented and is then not a part of the interventricular septum.

Subpulmonary Septal Defect
Taussig-Bing heart is the typical example of DORV and subpulmonary VSD. It may be considered a form of DORV in which the VSD is subpulmonary and associated with malalignment of the infundibular septum.

Doubly Committed Ventricular Septal Defect
In doubly committed VSD, an uncommon variant, the VSD and TSM lie more superiorly in the septum than subaortic or
subpulmonary VSDs. This, plus absence (or severe hypoplasia) of the infundibular septum and consequent confluence of the aortic and pulmonary valves, place the defect in a juxtaarterial position. The semilunar valves are related to posterior and superior boundaries of the defect. Anterior and inferior boundaries are formed by the TSM and its left anterior division; posteroinferior boundaries are formed by the posterior division. This muscle band usually separates the VSD from the tricuspid valve anulus. There is usually no conus, but if present it is very narrow, and there may be aortic-tricuspid and pulmonary-mitral continuity (Fig. 53-6).

The VSD and its relationships resemble those of isolated juxtaarterial VSD (see Chapter 35), tetralogy of Fallot with juxtaarterial VSD (see Chapter 38), and some types of double outlet left ventricle (see Chapter 54). Both semilunar valves usually lie over the RV, but it can be difficult to decide whether this is the case or whether they lie mostly over the LV. At times, they may arise equally over both ventricles, a condition that can be called double outlet both ventricles.

Noncommitted or Remote Ventricular Septal Defect

Trabecular VSDs are not related to the TSM and its divisions, as are VSDs of most hearts with DORV, and they are clearly away from the semilunar valves. However, an inlet septal VSD (see Morphology in Section I of Chapter 35) may be sufficiently remote from the great arteries as to be considered noncommitted (Fig. 53-7).

Infundibulum

In general, hearts with DORV may have bilateral conuses, one beneath the aortic valve and one beneath the pulmonary valve, or a single conus beneath either semilunar valve, or no conus. About three fourths of hearts with subaortic VSD have bilateral conuses, and about one fourth have only a subpulmonary conus (Table 53-1). An operative experience, however, may reflect a nonrepresentative prevalence of morphologic features. For example, in 350 patients operated on at Madras Medical Mission, the distribution of conal morphology was weighted far more toward absent conus (86%); prevalence of subaortic VSD was 57% (KM Cherian; personal communication, 2000) (Table 53-2). Hearts with subpulmonary VSD (Taussig-Bing hearts) have either bilateral conus or a single conus beneath the aortic valve, in about equal proportions. Hearts with doubly committed VSDs may have a single common conus beneath the two semilunar valves (“doubly committed”), or there may be fibrous continuity between one of the semilunar valves and one of the AV valves, associated with absence of a conus.

There is a pattern of relations between conus and position of the great arteries (Table 53-3). As a general rule, presence of conus beneath a semilunar valve tends to result in an anterior position of the valve and great artery. Absence of conus links semilunar valve and artery to the mitral valve with fibrous continuity, resulting in a posterior position of valve and artery. As a result, degree of conal development beneath the aortic and pulmonary valves fairly well predicts position and relationship of the great arteries. This can be inferred from the Madras experience (see Table 53-2), in which there is a high prevalence of normally related great arteries and subaortic or absent conus. Anterior position (D-malposition) of the aorta is uncommon (26%) when there are bilateral conuses, but common (67%) when there is only a subaortic conus. An anterior position has not been observed to occur with only subpulmonary conus or with no conus. An aorta side by side with or posterior to the pulmonary trunk occurs in all conal patterns.

Great Arteries

Both great arteries may lie over the RV in their entirety in the rare instances of DORV with intact ventricular septum and noncommitted VSD. This is often the situation as well when the VSD is subaortic. When the VSD is doubly

Figure 53-4  Specimen of double outlet right ventricle (RV) with bilateral conus and subaortic ventricular septal defect (VSD) in a patient with a pulmonary trunk band. A, Right ventricular outflow tract has been opened as has aortic valve (AoV) and aorta (Ao). VSD (arrow) is only just visible, because it is partly overlaid by anomalously attached chordae from the tricuspid valve (TV), which may interfere with placing an intraventricular tunnel patch. B, Infundibular (conal) septum (CS) displaced to right to reveal pulmonary valve (PV) and extensive subpulmonary conus. Infundibular septum inserts posteriorly and is unrelated to interventricular septum. In some respects, this VSD is intermediate between a subaortic and a subpulmonary defect and illustrates the difficulties of accurate and precise categorization. (From Barratt-Boyes and Calder.)
Figure 53-5 Specimen of double outlet right ventricle (RV) with subpulmonary ventricular septal defect (VSD) (Taussig-Bing heart). A, Right ventricular outflow tract, aortic valve (AoV), and aorta (Ao) have been opened. The subaortic conus separates aortic from tricuspid valve (TV). Rightward aspect of infundibular (conal) septum is visible. B, Infundibular septum and adjacent portion of free wall are displaced toward aorta to reveal opened RV outflow tract, pulmonary valve (PV), and pulmonary trunk (PT). Infundibular septum lies in a sagittal plane and has no attachment to the ventricular septum; moreover, it separates VSD from aortic valve. VSD lies directly above trabecula septomarginalis (TSM), but because the rightward posterior division of the TSM is deficient, it reaches the tricuspid anulus and is perimembranous. PV overrides VSD onto left ventricle (LV). There is no subpulmonary conus. Aorta is to the right and slightly anterior to pulmonary trunk. C, View from opened LV. Overriding PV is in direct fibrous continuity with anterior leaflet of mitral valve (MV). (From Barratt-Boyes and Calder.22)
committed or subpulmonary, there is usually a variable degree of overriding of one or both great arteries over the VSD.

Positional interrelationships of the great arteries are variable in hearts with DORV. Interrelationships are normal or near-normal in most patients with DORV, with the aorta located rightward and posterior relative to the pulmonary trunk. Less often, the great arteries are side by side, with the aorta to the right. D-malposition may be present in hearts with DORV, with the aorta anterior and to the right of the pulmonary trunk or at times directly anterior. Rarely, it is anterior and to the left. Occasionally there is L-malposition, with the aorta to the left but side by side with the pulmonary trunk.

Although in 77% of hearts with subaortic VSD the aorta is to the right and either side by side or posterior to the pulmonary trunk (more or less normally related), it is anterior (D-malposition) in 23% of cases (see Table 53-4). Furthermore, more or less normally related great arteries are not unique to hearts with subaortic VSD; those with subpulmonary VSD have normally related great arteries in similar frequency (P for difference = .8).

Only in hearts with noncommitted VSD is the frequency of more or less normally related great arteries less (33%) (P for difference = .06; see Table 53-4). Although D-malposition of the aorta may be considered characteristic of ordinary transposition (see “Great Arteries” under Morphology in Chapter 52) and by implication Taussig-Bing heart, hearts with DORV and subpulmonary VSD are associated with typical D-malposition in a minority of cases (see Table 53-4).

*Data and presentation are as described for Table 53-1.

*Side by side or posterior refers to aorta being to the right and beside or slightly posterior to pulmonary trunk, with the great arteries more or less normally interrelated.

*Anterior refers to D-malposition, with aorta anterior and more or less to the right.

*P*-value column refers to difference in occurrence of the given VSD position in the two great artery positions.

Key: CL, 70% confidence limits.
Hearts with doubly committed VSD tend to have more or less normally related great arteries. Observing great artery position at cineangiography or operation does not permit a reasonably accurate inference as to the position and category of the VSD (see Table 53-4). There is no greater certainty that the VSD is subaortic when the great arteries are more or less normally interrelated than when in D-malposition (\( P = .2 \)). When the aorta is in D-malposition, there is no greater certainty that the VSD will be subpulmonary than subaortic (\( P = .8 \)).

### Pulmonary Stenosis

Pulmonary stenosis is common in hearts with a subaortic VSD. It is most often infundibular (Fig. 53-8), but it may be valvar, with or without a small pulmonary valve ring. Thus, all types of pulmonary stenosis observed in hearts with tetralogy of Fallot may be seen in DORV. Rarely, infundibular stenosis may be of the isolated low-lying variety, producing a two-chambered RV.\(^{15,334}\)

Pulmonary stenosis is also common in hearts with doubly committed VSD (five of five in the GLH experience). It is uncommon in association with Taussig-Bing heart and in hearts with a noncommitted VSD.\(^{14,19}\)

### Conduction System

The AV node is in its normal position in the AV septum, and the bundle of His penetrates the right fibrous trigone in the usual way. Thus, the course of the bundle of His relative to the VSD is the same as in primary VSD and in tetralogy of Fallot (see Chapters 35 and 38). The bundle is at risk of damage during repair when the defect reaches the tricuspid anulus (and becomes perimembranous). This is true whether the defect is subaortic or subpulmonary and whether the ascending aorta is right or left sided.\(^{45,69,18}\) However, as in other conditions with clockwise rotation and dextroposition of the aorta, the bundle is more on the LV side of the septum than usual.\(^{88}\) Furthermore, the trigone is often attenuated in DORV when there is a subaortic conus, which removes the aortic anulus from the central fibrous skeleton of the heart.

When a complete AV septal defect coexists, the node and bundle course are altered accordingly (see “Conduction System” under Morphology in Chapter 34).

### Coronary Arteries

Coronary artery pattern depends on position of the great arteries. In most varieties of DORV, it is similar to normal except that the aortic sinuses are rotated in a clockwise direction (viewed from below), such that the right coronary arises anteriorly and the left coronary posteriorly.\(^{12,13,17}\) When the aorta is anterior and rightward, the pattern is usually similar to that in transposition of the great arteries (see “Coronary Arteries” under Morphology in Chapter 52), with the right coronary artery arising from sinus 2 (right posterior facing sinus).\(^{1,2,12}\) In 15% of cases, a single coronary ostium may arise either anteriorly or posteriorly that supplies left and right sides of the heart.\(^{1,2,12}\) The branching pattern is also usually normal, except for occasional origin of the left anterior descending from the right coronary artery, with this vessel crossing the RV outflow from right to left as in tetralogy of Fallot (see Chapter 38). This anomaly was found in 25% of the DORV hearts reported in the early Mayo Clinic series, but it was not encountered in 42 GLH autopsy cases.\(^{62}\)

When the aorta is to the left in L-malposition, the right coronary artery passes to the right from the anterior sinus of the leftward anterior aorta to reach the AV groove in front of the pulmonary trunk. Its position prohibits extensive anterior patching across the pulmonary “anulus.”

### Associated Anomalies

Major associated cardiac anomalies, in addition to pulmonary stenosis of the tetralogy of Fallot type, may coexist. Coarctation of the aorta may be present, particularly in Taussig-Bing...
variant, and may require repair in the neonatal period; rarely, discrete subvalvar aortic stenosis may coexist. Various other cardiac anomalies coexist in about 30% of patients coming to intracardiac repair of DORV with a subaortic or doubly committed VSD (Tables 53-5 and 53-6).

Morphologic Syndromes of Double Outlet Right Ventricle

**Simple Double Outlet Right Ventricle**

The phrase *simple DORV* connotes the commonly occurring and easily repaired type of DORV in which the VSD is subaortic and the aorta is to the right, usually by the side of the pulmonary trunk or slightly posterior to it, or which in about 20% of cases is somewhat anterior to the pulmonary trunk (see Table 53-4). The aorta may spiral around the pulmonary trunk as it leaves the heart, or the great arteries may course parallel to each other. Usually there is a conus (infundibulum) beneath both the aorta and pulmonary valve, but in some cases there may be no subaortic conus (see Table 53-1). Coronary arterial anatomy is normal.

![Figure 53-8 Specimen of double outlet right ventricle (RV) with subaortic ventricular septal defect (VSD) and infundibular pulmonary stenosis. A, Right ventricular outflow tract is opened to aortic valve (AoV) and aorta (Ao). A subaortic conus separates aortic and tricuspid valves (TV). Poorly expanded subpulmonary conus narrows outflow tract. B, Infundibular (conal) septum is displaced to reveal opened pulmonary outflow tract. Pulmonary valve (PV) is bicuspid, and it and the pulmonary trunk (PT) are smaller than normal. Aorta is slightly anterior to pulmonary trunk. A probe passes through VSD and into aorta. Key: PT out, Pulmonary outflow. (From Barratt-Boyes and Calder.)](image)

*Data combine the experience at UAB (1967-1982; n = 42) and GLH (1958-1984; n = 28). Because some patients had multiple anomalies, total is not cumulative, nor is list mutually exclusive. Key: IVC, Inferior vena cava; LV, left ventricular; MV, mitral valve; VSD, ventricular septal defect.*

In borderline cases, this type of DORV merges with the type in which a perimembranous VSD demonstrates inlet extension and appears to be noncommitted and, on the other hand, the type in which the VSD demonstrates outlet extension and appears to be doubly committed.

**Taussig-Bing Heart**

In the most representative cases, the Taussig-Bing heart is similar from heart to heart. The VSD is anterior and superior and subpulmonary. The left main coronary artery is anterior to the pulmonary trunk. The pulmonary trunk arises biventricularly over the VSD, and the aorta is to the right and slightly anterior to or alongside it (see Table 53-4). The first portions of aorta and pulmonary trunk are parallel rather than tending to spiral as do normally positioned great arteries. The infundibular septum is in the sagittal plane and is not part of the interventricular septum. Lev and colleagues were able to use specific morphologic features within the RV as the hallmark of Taussig-Bing heart, but this is rarely possible clinically or surgically.

Subaortic stenosis, from narrowing of the subaortic infundibulum, may develop in Taussig-Bing heart. Pulmonary stenosis is uncommon. The mitral valve may straddle across the subpulmonary VSD, and in such cases the LV may be hypoplastic. Associated coarctation of the aorta is
common (about 50% of cases). This contrasts with the 6% prevalence in transposition with VSD.

In borderline cases, this type of DORV merges with transposition of the great arteries and large VSD and, on the other hand, may merge with DORV and noncommitted VSD of the trabecular type.

### Double Outlet Right Ventricle with Doubly Committed Ventricular Septal Defect

In DORV with doubly committed VSD, an uncommon syndrome, the VSD is immediately beneath both aorta and pulmonary trunk and is juxta-arterial.

### Double Outlet Right Ventricle with Noncommitted Ventricular Septal Defect

When the VSD is in the trabecular septum and clearly far removed from the great arteries, the anomaly is easily categorized into this subset. When the VSD is in the inlet septum and up against the tricuspid valve, categorization as DORV with noncommitted VSD can be questioned, but at least the defect is further removed from the aorta than in most hearts with DORV and subaortic VSD.

### Double Outlet Right Ventricle with L-Malposition

DORV with L-malposition usually has a subaortic VSD (rarely extending back to the tricuspid anulus) and pulmonary stenosis and presents a rare but distinctive clinical and surgical syndrome. Rarely the VSD may be perimembranous and extend up toward the pulmonary valve, or it may be truly subpulmonary. The VSD may, contrariwise, extend into the inlet septum and be noncommitted. Mehrizi has reported DORV with L-malposition and doubly committed VSD.

### Double Outlet Right Ventricle with Complete Atrioventricular Septal Defect

In cases of DORV with complete AV septal defect, the interventricular communication is large and usually extends deeply beneath a bridging left superior leaflet (see “Atrioventricular Valves” under Morphology in Chapter 34) to be subaortic in position. Occasionally, however, the interventricular communication does not extend in this manner and is noncommitted.

### Double Outlet Right Ventricle with Superior-Inferior Ventricles

In most hearts with this ventricular position, there is a ventricular L-loop, atrial situs solitus, and AV discordant connection (see Chapter 55). Uncommonly, in DORV with atrial situs solitus, AV concordant connection, and D-ventricular loop, there is a positional anomaly termed superior-inferior ventricles (over-and-under ventricles, upstairs-downstairs ventricles) (see “Cardiac and Arterial Positions” under Terminology and Classification of Heart Disease in Chapter 1). The RV is superior (and sometimes a little posterior) and the LV inferior. There may be D- or L-malposition of the aorta. The VSD is usually perimembranous and in the inlet portion of the septum. The right AV valve is usually more superiorly placed than usual relative to the left AV valve, and either AV valve may straddle the VSD (see “Ventricular Septal Defect with Straddling or Overriding Tricuspid Valve” under Morphology in Chapter 35). Severe LV hypoplasia may be present, and pulmonary stenosis is common.

### CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

#### Pathophysiology

Clinical features of patients with this morphologically highly variable anomaly are necessarily also highly variable. In general, patients with a large VSD and no pulmonary stenosis or severe pulmonary vascular disease are not clinically cyanotic. This is because pulmonary blood flow (Qp) is high and the resultant mixture of blood in the RV has a high enough oxygen saturation to prevent clinically evident cyanosis; however, there is some arterial desaturation.

#### Streaming of Blood Flow

SaO₂ is also affected by streaming of blood within the RV, which is determined by the relationship of the semilunar valves to the VSD and the position and presence of the infundibular septum. Thus, in simple DORV, flow of highly oxygen-saturated LV blood through the VSD is directed preferentially beneath the infundibular septum into the adjacent aorta (particularly when the subaortic conus is short or absent), whereas systemic venous blood passes largely out of the pulmonary trunk. As a result, patients with this arrangement present in infancy with high Qp in heart failure without cyanosis and cannot be clinically distinguished from infants with a large VSD (see Clinical Features and Diagnostic Criteria in Section I of Chapter 35).

When the VSD is subpulmonary, as in Taussig-Bing heart, flow through it of highly saturated LV blood is directed into

---

aData from experience with surgical correction at GLH (1964-1984; n = 15). Because most patients had multiple anomalies, total is not cumulative, nor is list mutually exclusive.

Key: ASD, Atrial septal defect; AV, atrioventricular; CS, coronary sinus; LSVC, left superior vena cava; LV, left ventricle; MV, mitral valve; P5, pulmonary stenosis; RV, right ventricle; TV, tricuspid valve; VSD, ventricular septal defect.
the adjacent pulmonary trunk by the vertically positioned infundibular septum. SpaO₂ is then higher than Sao₂, with systemic venous blood from the RV tending to flow more into the aorta. This situation is aggravated when there is overriding of the pulmonary trunk onto the LV. Thus, these infants present in a fashion similar to patients with transposition of the great arteries with large VSD in heart failure with mild cyanosis (see “Large Ventricular Septal Defect, Large Patent Ductus Arteriosus, or Both [Good Mixing]” under Morphology in Chapter 52).

**Pulmonary Vascular Disease**

Pulmonary vascular disease may be more rapid in onset in patients with DORV without pulmonary stenosis than in patients with simple large VSD, particularly in Taussig-Bing heart (see “Pulmonary Vascular Disease” under Natural History in Section I of Chapter 35). The resultant reduction in Qp has a more marked influence on Sao₂ than in simple VSD, because it reduces the amount of highly saturated blood in a common mixing chamber.

**Pulmonary Stenosis**

When important pulmonary stenosis is present, cyanosis becomes severe, and the clinical features and presentation are similar to those of patients with tetralogy of Fallot (see Chapter 38).

**Examination**

On physical examination, no clinical signs distinguish patients with DORV with and without pulmonary stenosis from the conditions that they mimic. The electrocardiogram (ECG) is not diagnostic, nor is the chest radiograph. However, in those uncommon instances in which there is L-malposition of the aorta, the aorta may be evident on the posteroanterior chest radiograph as it ascends vertically from the cardiac silhouette in the left upper mediastinum; this finding is not specific, however (see Clinical Features and Diagnostic Criteria in Chapter 57).

**Echocardiography**

Two-dimensional echocardiography provides a considerable amount of information regarding size of the VSD, relationship of the VSD to the semilunar valves, presence of subvalvar conus, and AV valve abnormalities. Position of the great arteries and conus are usually apparent (Fig. 53-9). The coronary arterial anatomy can also generally be defined accurately in neonates and infants by echocardiography alone.

**Cardiac Catheterization and Cineangiography**

Because echocardiographic assessment of morphology is reliable, cardiac catheterization before surgical intervention is not routinely required in neonates and young infants. In older infants and children, it may be needed to assess hemodynamics such as pulmonary vascular resistance and ventricular end-diastolic pressure, and to define extracardiac morphology such as the peripheral pulmonary vasculature and presence of aortopulmonary collateral vessels. Cineangiography can be used when necessary to define intracardiac morphology (Fig. 53-10). The whole of the ventricular septum must be profiled so that its upper part can be projected cranially. In this way, great vessel positions can be assessed relative to the two ventricles, and location of the VSDs determined. VSD size can be judged and subsets such as Taussig-Bing heart identified (Fig. 53-12). Cineangiography is of particular value in assessing the complex interrelationships present in DORV with superior-inferior ventricles and criss-cross hearts.

**NATURAL HISTORY**

The natural history of patients with DORV and AV concordant connection is highly variable, but some general trends can be identified.

The natural history of simple DORV is similar to that of simple large VSD (see Natural History in Section I of Chapter 35); this is probably also true for patients with DORV whose VSD is doubly committed or noncommitted. The exception is that spontaneous VSD closure, which is fatal rather than curative, is rare in DORV.

When the VSD is subpulmonary, as in Taussig-Bing heart, the natural history is similar to that for transposition and large VSD, but it is even more unfavorable (see “Ventricular Septal Defects” under Natural History in Chapter 52). This is in part because severe pulmonary vascular disease occurs early in life. Poor prognosis for these patients may also be related to frequent occurrence of left-sided cardiac and extracardiac malformations such as coarctation of the aorta and LV and mitral valve hypoplasia (see “Coarctation as Part of Hypoplastic Left Heart Physiology” under Morphology in Section I of Chapter 48).

When pulmonary stenosis or atresia is present in DORV with subaortic VSD, and probably in those with doubly committed or noncommitted VSD as well, the natural history is indistinguishable from that of patients with tetralogy of Fallot and pulmonary stenosis or atresia (see Chapter 38).
Figure 53-10  Cineangiograms of simple double outlet right ventricle (DORV) with conoventricular ventricular septal defect (VSD). A, Left ventriculogram in elongated right anterior oblique view. Infundibular septum is well shown. B, Four-chambered view. VSD is also perimembranous and abuts tricuspid valve (TV). C, Left ventriculogram in four-chamber view of another patient in whom VSD is separated from the tricuspid valve (arrowheads) by a bar of muscle. D, This is from the same cineangiogram a few frames later.

Continued
PART VII  Congenital Heart Disease

Blood flow in doubly committed VSDs is usually baffled using a more complex patch from LV to aorta. Noncommitted VSD may be treated by baffling of blood through the VSD to the aorta, accompanied by myocardial flap reinsertion of the straddling tricuspid valve or by a Fontan type of procedure.

The natural history in some patients is dominated by an associated cardiac anomaly, such as a complete AV septal defect (see Natural History in Chapter 34).

TECHNIQUE OF OPERATION

The type of operation selected depends in part on position of the VSD, relationship of the great arteries, size of the patient, and adequacy of the resulting ventricles and their respective outflows after closing or baffling the VSD. In general:

- Subaortic VSD with an adequate tricuspid to pulmonary valve distance is treated by simple intraventricular baffling that directs LV blood through the VSD to the aorta (intraventricular tunnel repair).
- Subpulmonary VSD, as in Taussig-Bing heart, without pulmonary stenosis is treated with an arterial switch procedure with simple VSD closure that directs blood from the LV to the neo-aortic valve.
- Blood flow in doubly committed VSDs is usually baffled using a more complex patch from LV to aorta.
- Noncommitted VSD may be treated by baffling of blood through the VSD to the aorta, accompanied by myocardial flap reinsertion of the straddling tricuspid valve or by a Fontan type of procedure.

Various surgical procedures are described, but description does not imply recommendations. Indications are described later in this chapter under Indications for Operation. Only the general methods are described here, and each patient may be sufficiently unique to require an individual approach.

Intraventricular Tunnel Repair of Simple Double Outlet Right Ventricle

Preparation for operation, draping, arrangement for cardiopulmonary bypass (CPB), median sternotomy, and placing stay sutures and sutures for cannulation are as usual (see Section III in Chapter 2). The pericardium is cleared in case...
**Figure 53-11** Cineangiogram of simple double outlet right ventricle with restrictive subaortic ventricular septal defect (VSD). Early phase (A) and late phase (B) of cineangiogram made in long axial projection after injection of contrast into left ventricle. Key: Ao, Aorta; LA, left atrium; LV, left ventricle; MV, mitral valve; PT, pulmonary trunk; RV, right ventricle.

**Figure 53-12** Cineangiogram made in an elongated right anterior oblique view (A) and in a long axial view (B) of a Taussig-Bing heart. The prominent infundibular septum is seen between aorta (Ao) and pulmonary trunk (PT), but it is clearly (B) not interventricular in position. The ventricular septal defect is between the arrows, and the pulmonary trunk somewhat overrides it. Key: IS, Infundibular (conal) septum; LV, left ventricle; MV, mitral valve; RV, right ventricle; TV, tricuspid valve.
it is needed, and a double velour woven polyester tube (see “Decision and Technique for Transanular Patching” under Technique of Operation in Section I of Chapter 38) whose diameter is about 20% larger than that of the aorta is precotted, or a collagen-impregnated polyester tube is selected (see “Grafts for Use in Aortic Surgery” in Chapter 24). The intrapericardial anatomy is carefully evaluated.

Support technique and myocardial management are chosen from the usually available alternatives (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3). If two venous cannulae are used, after placing the aortic clamp, the right atrium is opened through a small incision, and a pump-oxygenator sump sucker is placed across the natural or surgically created foramen ovale. A single venous cannula can be used if the operation is to be performed through the RV. Operation is performed at 25°C with continuous CPB at a flow of 1.6 L·min⁻¹·m⁻², or at 18°C with low CPB flow rate and circulatory arrest when needed for improved exposure. If the desire is to perform the operation entirely during hypothermic circulatory arrest, that technique may be chosen (see Section IV of Chapter 2).

A thorough examination of the intraventricular anatomy can usually be made through the tricuspid valve, and based on this examination, the repair is planned. Repair of simple DORV can be accomplished through the right atrium, although the most superior part of the repair must sometimes be made through a radial incision along the base of the tricuspid anterior and septal leaflets (see Fig. 35-26 in Chapter 35). Through the atrial approach, it is more difficult to be certain that the geometry of the intraventricular tunnel is exactly correct; lacking firm evidence for increased safety of the atrial approach to repair of isolated VSD (see Chapter 35) or tetralogy of Fallot (see Chapter 38), the RV approach may be equally satisfactory.

An intraventricular tunnel is created within the RV that conducts LV blood through the VSD to the aorta. For the transatrial approach, the right atrium is opened in a cephalad-caudal direction near the AV groove. Stay sutures are placed as for the approach for closure of an isolated VSD or as for transatrial repair of tetralogy of Fallot (see Technique of Operation in Section I of Chapters 35 and 38). The anterior tricuspid valve leaflet is elevated by fine stay sutures. For the RV approach, a transverse ventriculotomy is made low in the RV outflow tract, unless the distance between the left anterior descending coronary artery (LAD) on the left and the right coronary artery (RCA) on the right is inadequate, in which case a vertical infundibular incision is used. Special care is required if there is an anomalous origin of the LAD from the RCA. For exposure, stay sutures are placed on the ventriculotomy. The anatomy is carefully assessed, verifying anatomic details of the diagnosis. Location and size of the VSD are noted, and particularly whether it abuts the tricuspid valve or has a rim of muscle along its posterior border (Fig. 53-13). This latter determines the relationship of the bundle of His to the posterior margin of the VSD.

Small size of the VSD does not alone negate the possibility of an adequate intraventricular tunnel between LV and aorta. The possibility of enlarging it and creating a tunnel of adequate size and configuration depends primarily on the distance between the tricuspid and pulmonary valves. Sakata, Lecompte, and colleagues estimate that when this distance is less than the diameter of the aorta, a tunnel placed posterior to the pulmonary trunk will be stenotic; they recommend that in such a case, the tunnel be placed anterior to the orifice of the pulmonary trunk. However, in simple DORV, this distance is usually long (see Figs. 53-2 and 53-4), making this malformation suited for intraventricular tunnel repair, with the tunnel posterior to the orifice of the pulmonary trunk.

As a first step, the VSD is enlarged anteriorly if it is clearly restrictive to flow into a tunnel from the LV. Before this is done, the area of the proposed enlargement is carefully examined to be certain that it is interventricular septum and not hypertrophied and trabeculated anterior ventricular wall. Cutting into the latter imposes the risks of damaging the LAD and developing an LV false aneurysm. Generally, a simple incision into the interventricular septum from the VSD gapes open widely and suffices, but occasionally some muscle must be excised. In doing this, the mitral valve must be kept out of harm’s way.

The VSD patch is then cut from a polyester tube (see Fig. 53-13). Geometry of the patch is crucial in preventing subaortic stenosis after the repair. The patch will form the anterior half of the tunnel connecting the VSD to the aortic orifice; the posterior half of the tunnel will be heart tissue, and experience indicates that this provides adequately for growth of the tunnel. Thus, initial trimming is made to retain about half to two thirds of the circumference of the tube graft that was selected, so as to have a diameter about 20% greater than that of the ascending aorta. The patch is trimmed so that its length is the distance from the anterior angle of the VSD to the anterior edge of the subaortic conus or, if this is hypoplastic, LV-aortic junction (aortic valve “anulus”).

The technique for inserting the patch is analogous to that for inserting the patch in isolated VSD (see Fig. 35-24 in Chapter 35) or tetralogy of Fallot (see Chapter 38). Because correct orientation of the patch is essential to creating a geometrically correct tunnel, a marking stitch is placed at the most anterior part of the repair, and another is placed through the patch at a corresponding point. A similar marking stitch is placed over the midportion of the aorta anteriorly and in the patch. The first pledged mattress stitch is passed from the atrial to ventricular side through the base of the tricuspid commissural tissue between the anterior and septal leaflets (see Fig. 53-13). If the approach is through the right atrium and tricuspid valve, the suture is usually begun anteriorly at the most caudal aspect of the VSD. (If a bar of muscle separates the VSD from the tricuspid valve “anulus,” the sutures may be placed just on the right side of the subaortic infundibulum and then trimmed so that its length is the distance from the anterior angle of the VSD to the anterior edge of the subaortic conus.) Suturing is carried leftward for a short distance between the patch and tricuspid leaflet tissue and after a few stitches between the patch and ventriculoinfundibular fold and up along the right side of the subaortic infundibulum. When the marking stitch is reached, the suture is held. With the other arm of the suture, the patch is sewn to the RV side of the septum, 5 to 7 mm back from the edge of the VSD, proceeding rightward, anteriorly, and then superiorly (see Fig. 53-13). When the repair is completed, the contoured polyester patch forms the anterior portion of an unobstructed intraventricular tunnel between the VSD and aorta.

Rewarming the patient by the perfusate is commenced, and the interatrial communication is closed with a few sutures, but not tied until there is effective ventricular contraction (to
Figure 53-13  Intraventricular tunnel repair for simple double outlet right ventricle with subaortic ventricular septal defect (VSD). A, Pulmonary and aortic valves are at nearly the same level. The perimembranous VSD has been exposed through a right ventriculotomy. There is moderate hypertrophy of the parietal band, which is mobilized and partially resected. B, A polyester tube of diameter about 20% larger than that of the aortic root has been cut to a length that is the same as the distance from the anterior border of the VSD to the aortic valve. About three-fifths circumference of the tube is used and is contoured as shown. Corrugations in the polyester patch assist the surgeon in maintaining proper orientation of the patch as it is being sewn in place. A pledgeted mattress suture is placed through the base of the commissure between septal and anterior tricuspid leaflets to begin the tunnel repair. C, Suturing has been carried to the left along the ventriculoinfundibular fold and up over the subaortic conus. With the other arm of the suture, inferior and superior portions of the repair are completed. The contoured tunnel offers no obstruction to flow from left ventricle to aorta. Key: RBB, Right bundle branch; TV, tricuspid valve.
Repair of Double Outlet Right Ventricle with Subaortic Ventricular Septal Defect and Pulmonary Stenosis

Repair is essentially that for tetralogy of Fallot, as described in “Technique of Operation” in Section I of Chapter 38. The only difference is the intraventricular tunnel repair, as just described, rather than simple VSD closure.

Repair of Taussig-Bing Heart by Arterial Switch Repair

The usual Taussig-Bing type of DORV with subpulmonary VSD is best treated by closure of the VSD in such a manner that the LV ejects into the neo-aorta, and by an arterial switch (see “Arterial Switch Operation” under Technique of Operation in Chapter 52).

Approach to repair of the VSD is varied, and the decision is best made before operation, based on the following considerations (Quaegebeur JM; personal communication, 1991):

- When the VSD is perimembranous or juxta-tricuspid, and particularly when it extends toward the inlet septum, repair is probably most effectively accomplished from the right atrium.
- When the VSD extends toward the RV outlet and the pulmonary trunk does not override the VSD, repair is most easily accomplished through the proximal aortic (neopulmonary) segment after removing the aortic buttons containing coronary ostia. The landmarks and techniques are identical to those used when a VSD is repaired through a right ventriculotomy.
- When the pulmonary trunk is large and overrides the VSD, as is usually the case, an approach to the VSD through the proximal pulmonary (neoaortic) segment is convenient. However, the posteroinferior portion of the insertion of the patch to close the VSD (performed so that the LV ejects into the pulmonary trunk [neoaorta]) is approached from the RV aspect as a protection against damaging the conducting tissue.

The arterial switch is then performed (see “Arterial Switch Operation” under Technique of Operation in Chapter 52). Because the great arteries are often side by side, suitable adjustments are made in the operation (see Chapter 52, Fig. 52-28). If arch hypoplasia is present, it is addressed surgically with one of several possible approaches. Either a standard interrupted arch repair technique is used (see Technique of Operation in Section II of Chapter 48) or the relatively hypoplastic ascending aorta can be reoriented from its vertical position to a horizontal position and anastomosed end to end to the descending aorta, followed by anastomosis of the proximal pulmonary trunk (neoaorta) to the transversely positioned ascending aorta. When arch hypoplasia is present, there is a high likelihood of hypoplasia of the RV outflow tract, and clinically important postoperative infundibular obstruction is common. Therefore, the RV outflow tract should be addressed surgically when arch obstruction is present. In this setting, the VSD is best repaired through a vertical infundibular incision, with infundibular resection and patching.

Intraventricular Tunnel Repair of Taussig-Bing Heart

Although the place of the intraventricular tunnel repair of Taussig-Bing heart is not securely established, small series of successful operations have been reported.

Initial stages of operation are the same as in other operations for Taussig-Bing heart. After CPB and cold cardioplegia have been established and the right atrium opened, morphology within the RV is studied through the tricuspid valve. Distance from tricuspid to pulmonary valves is estimated; if this distance is too short, the LV-to–pulmonary trunk tunnel will probably need to pass anterior to the pulmonary valve (see “Intraventricular Tunnel Repair of Simple Double Outlet Right Ventricle” earlier in this chapter); alternatively, an arterial switch operation is used. Any attachment of tricuspid chordae to septal edges of the malaligned infundibular septum is noted because special measures are needed for these. Straddling or overriding of the mitral valve is of considerable importance because this may make the planned operation impossible. Usually, after completing the examination from the right atrium, a transverse right ventriculotomy is made for the repair, although sometimes repair may be accomplished from the right atrial approach.

Ideally, the surgically created intraventricular tunnel is fashioned to lie posterior to the pulmonary trunk (Kawashima method), but this depends on availability of space between the tricuspid and pulmonary valves, as noted earlier (Fig. 53-14). Adequate space is more likely to be available when the great arteries are side by side rather than in an anteroposterior position. Generally the VSD is enlarged anteriorly, and at least a portion of infundibular septum is excised. It may be helpful to open the pulmonary trunk and pass a Hegar dilator through the pulmonary valve to expose the infundibular septum and protect the mitral apparatus (see “Lecompte Intraventricular Repair” in text that follows). As this is being done, care is taken to avoid damaging the aortic valve cusps and chordae from the tricuspid valve. If these chordae attach alongside an area that requires enlargement, that portion is not excised but instead is turned up as a flap. After creation of the intraventricular tunnel, the flap of infundibular septum is sutured in place over the tunnel. The polyester patch is trimmed to an appropriate size and configuration (see Fig. 53-13) and sewn into place with the usual care to avoid damaging the conduction system (see Fig. 53-14).

When the aorta is directly anterior, there is usually insufficient space between the tricuspid and pulmonary valves for a posterior position of the intraventricular tunnel. If an intraventricular tunnel repair is performed, the VSD is enlarged appropriately and the tunnel created anterior to the
pulmonary orifice (Patrick-McGoon method)\textsuperscript{98,99,100} (Fig. 53-15). In some cases, if this technique is used, a prosthetic tube (rather than a patch) is needed for part of the pathway, and part of the tube is incorporated into the closure of the right ventriculotomy.\textsuperscript{101}

**Lecompte Intraventricular Repair**

Although the role of this operation, which Lecompte calls \textit{REV} (réparation à l’étage ventriculaire), is not yet certain, its concepts and results mandate consideration. In this operation, the LV is connected to the aorta and the RV to the pulmonary trunk by a technique that does not require an extracardiac conduit.\textsuperscript{98,99,100,101,102} It is designed for patients in whom a simple intraventricular tunnel repair is not possible, nor is an arterial switch operation combined with repair of the VSD in such a manner that the LV is connected to the proximal pulmonary trunk (neoaortic) segment. The reason for the latter is usually coexisting important pulmonary (LV outflow) stenosis. The diagnosis may be some form of DORV or transposition with VSD and LV outflow obstruction. The Lecompte operation has also been demonstrated to be applicable to double outlet LV in infancy, thus avoiding need for a valved extracardiac conduit (Bailey LL; personal communication, 1991).

Initial stages of operation are the same as for intraventricular repair. After CPB and cold cardioplegia have been established, and after the preliminary examination from the right atrium is accomplished, a vertical right ventriculotomy is made and extended as far cephalad as possible. After thorough assessment of intraventricular anatomy and great arteries, the aorta and pulmonary trunk are transected (Fig. 53-16, A). All interventricular and infundibular septal tissue between the VSD and great arteries is resected. A Hegar dilator introduced through the pulmonary trunk helps with exposure during resection (Fig. 53-16, B). Cusps of the aortic valve
must be visualized to protect them from damage in the course of resection. The excision is kept away from regions occupied by the bundle of His and its primary branches. When tricuspid chordae are attached to a portion of the infundibular or ventricular septum, this portion is raised as a flap with chordae attached. After completing the intraventricular repair, the flap is sutured to the roof of the tunnel, more or less in its original position.

The intraventricular tunnel repair is performed by suturing a polyester or polytetrafluoroethylene (PTFE) patch into place to form the roof of the LV-aortic pathway (Fig. 53-16, C).

The proximal segment of the pulmonary trunk is closed (for details, see “Bidirectional Superior Cavopulmonary Shunt” under Technique of Operation in Chapter 41). Because this repair is generally performed in patients in whom the aorta is anterior to the pulmonary trunk, the pulmonary trunk and its bifurcation are usually translocated anterior to the aorta. For this, the aortic clamp is repositioned, and the distal aortic segment is brought behind the bifurcation of the
Figure 53-16  Lecompte operation for double outlet right ventricle with pulmonary stenosis and for other abnormalities of ventriculoarterial connection and ventricular septal defect (VSD), including transposition of the great arteries with VSD and left ventricular outflow tract obstruction. A, Dashed lines indicate sites for transecting aorta and pulmonary trunk and for the right ventriculotomy. B, Right ventriculotomy has been made, great arteries have been transected, a Hegar dilator has been passed down through the proximal segment of the pulmonary trunk and into the left ventricle to improve exposure (and protect the mitral valve), VSD has been enlarged, and infundibular (conal) septum has been resected. C, Polyester patch has been sewn into place to form anterior portion of newly created left ventriculoaortic pathway, using the same general technique shown in Fig. 53-13. Proximal pulmonary trunk stump is oversewn. D, Aorta has been repositioned behind pulmonary trunk bifurcation and reconstructed. Pulmonary trunk has been enlarged by an incision anteriorly and its posterior wall anastomosed to the right ventriculotomy. E, Repair is completed with a polyester (or polytetrafluoroethylene or pericardial) patch placed as a roof over the right ventriculopulmonary trunk pathway, using the same principles as in placing a transanular patch in repair of tetralogy of Fallot (see Fig. 38-29 in Chapter 38).
pulmonary trunk (Fig. 53-16, D), as in the Lecompte maneuver for the arterial switch operation (see “Arterial Switch Operation” under Technique of Operation in Chapter 52). The aorta is reconstructed behind and to the right of the distal pulmonary trunk segment.

The posterior lip of the distal segment of the pulmonary trunk is anastomosed to the cephalad margin of the right ventriculotomy. The right ventricular–pulmonary trunk pathway is completed by suturing a roof of pericardium, polyester, or PTFE into place (Fig. 53-16, E). Lecompte incorporates a monocusp valve beneath the patch.

Nikaidoh Aortic Translocation and Right Ventricular Outflow Reconstruction

The first step in this procedure is to core out the intact aortic root from the RV, including aortic valve and coronary arteries, as described earlier by Bex and colleagues (Fig. 53-17). The pulmonary trunk is transected, and an incision in the interventricular septum between the VSD and lumen of the proximal stump of the pulmonary trunk opens this area widely. This allows the VSD (and through it the LV) to be joined to the aorta by a roofing patch, which is similar to that

Figure 53-17  Nikaidoh aortic translocation and right ventricular outflow tract reconstruction. A1, Anteriorly located aortic root is fully mobilized beneath the valve and both coronaries skeletonized. A2, Division of pulmonary trunk and infundibular (conal) septum (when present). Pulmonary-mitral continuity is demonstrated. B1, Anastomosis of aorta to open pulmonary “anulus” after posterior translocation. Ventricular septal defect (VSD) patch will be anastomosed to apical rim of VSD. B2, Anastomosis of superior portion of VSD patch to anterior rim of mobilized aortic root. C, Right ventricular outflow tract (RVOT) is reconstructed by anchoring right lateral wall of pulmonary trunk to aortic root and overlaying a patch of pericardium to cover aortic root, right ventriculotomy, and pulmonary trunk. D, Large pericardial patch is used to reconstruct RVOT. Care must be taken to avoid RVOT obstruction. A flat patch is required to curve longitudinally (along axis of aorta) and from anterior to posterior (to reach distal pulmonary trunk). (From Yeh 2006.)
placed in the other intraventricular tunnel repairs. The pulmonary trunk is then joined to the RV outflow tract as described for the Lecompte intraventricular repair.

**Repair of Taussig-Bing Heart by Atrial Switch Procedure**

Operation is begun through the atrial incision mandated by the venous switch procedure to be used (see “Atrial Switch Operation” under Technique of Operation in Chapter 52). Working through the tricuspid valve, the VSD is repaired so that the LV ejects into the pulmonary trunk. An atrial switch procedure is done. When important LV outflow obstruction is present, an allograft valved extracardiac conduit is also placed between the LV and pulmonary trunk.

**Intraventricular Tunnel Repair of Double Outlet Right Ventricle with Doubly Committed Ventricular Septal Defect**

After CPB and cold cardioplegia are established, a transverse right ventriculotomy is made. A slightly modified tunnel repair is done, very much as described under “Intraventricular Tunnel Repair of Simple Double Outlet Right Ventricle” earlier in this chapter. However, when the two semilunar valves lie side by side and the pulmonary “anulus” is the larger, contouring the patch to achieve this may be difficult without obstructing flow into the pulmonary trunk. This problem can be minimized by enlarging the VSD anteriorly as much as possible before placing the patch.

**Intraventricular Tunnel Repair of Double Outlet Right Ventricle with Noncommitted Ventricular Septal Defect**

When the noncommitted VSD is of the inlet septal type (see Morphology in Section I of Chapter 35), it extends beneath the tricuspid septal leaflet rather than anteriorly or superiorly. It may be possible to enlarge this defect anteriorly and superiorly so that a tunnel repair can be performed that connects the LV to the aorta (Fig. 53-18). The precautions used against damaging the conduction system are those used for repair of inlet septal VSD (see Fig. 34-20 in Chapter 34). If the tunnel obstructs access to the pulmonary valve, an allograft (or other biological) valved conduit is placed from the RV to the pulmonary trunk.

**Other Operations for Double Outlet Right Ventricle with Noncommitted Ventricular Septal Defect**

In some patients with an inlet septal type of noncommitted VSD, tricuspid valve chordae may overhang the defect; in these cases, its enlargement as described is not possible, and a tunnel repair cannot be carried out. The same situation may exist when there is a large single or multiple muscular VSDs in the trabecular septum.

When pulmonary stenosis coexists, a Fontan operation is performed. The technique of total cavopulmonary connection (see discussion under Technique of Operation in Chapter 41) is particularly suited to this situation because nothing has to be done to the AV valves or within the ventricle except to enlarge the VSD if it is restrictive.

When the tunnel repair cannot be made and pulmonary stenosis is not present, the situation should be identified very early in life, and a pulmonary trunk band should be placed (see “Pulmonary Trunk Banding” under Technique of Operation in Chapter 35). Subsequently a Fontan operation should be performed.

**Repair of Double Outlet Right Ventricle with Complete Atrioventricular Septal Defect**

Technique of repair is similar to that for repair of complete AV septal defect and tetralogy of Fallot as described under Technique of Operation in Chapter 34. However, the situation becomes considerably more complex in the setting of heterotaxy syndromes, in which anomalous pulmonary venous connection is common and the VSD of the AV septal defect may be remote from the aortic valve in the presence of a muscular subaortic infundibulum (conus) (see Chapter 58).

**Repair of Double Outlet Right Ventricle with L-Malposition of the Aorta**

In nearly all surgical patients in this subset, the VSD is subaortic and pulmonary stenosis coexists. The heart is opened by a vertical incision in the RV. Usually, the VSD is easily visualized anterosuperiorly in the ventricular septum and well away from the tricuspid anulus. An intraventricular tunnel repair with a contoured patch may not be necessary, and a simple polyester or PTFE patch may be used to close the VSD in such a way that the LV ejects into the aorta. Stitches may be placed along the edge of the VSD posteriorly unless the defect abuts the tricuspid valve. An allograft valved extracardiac conduit is usually placed between the RV and pulmonary trunk, because of associated severe valvar and subvalvar pulmonary stenosis (see Figs. 38-68 and 38-70 in Chapter 38).

**Repair of Double Outlet Right Ventricle with Discordant Atrioventricular Connections**

A complete discussion of discordant AV connections is found in Chapter 55. In DORV with discordant AV connections, three major options are available:

- Traditional or physiologic repair in which the morphologic RV is retained as the systemic ventricle
- Anatomically corrective operations that leave the morphologic LV as the systemic ventricle
- Single-ventricle strategies ending in the Fontan operation

**Traditional repairs** that use the RV as the systemic ventricle include VSD closure and the Rastelli procedure, or VSD closure with baffling of LV to pulmonary trunk, with or without relief of LV outflow tract obstruction to the pulmonary trunk. **Anatomic repairs** include the “double switch” procedure (atrial switch procedure and arterial switch combined with VSD closure to direct blood from LV to neoaortic valve) and atrial switch procedure with rerouting of blood from LV through VSD to aortic valve, with or without a Rastelli procedure.
Palliative Operations

Shunting operations are described in Chapter 38 (see “Technique of Shunting Operations” under Technique of Operation in Section I) and pulmonary trunk banding in Chapter 35 (see “Pulmonary Trunk Banding” under Technique of Operation in Section I).

SPECIAL FEATURES OF POSTOPERATIVE CARE

Care after corrective or palliative operations for DORV is described in Chapter 5.

RESULTS

Survival

Early (Hospital) Death

Even intraventricular tunnel repair of simple DORV in heterogeneous patient populations has had a hospital mortality through the years of about 20%.

Currently, patients undergoing repair of simple DORV during the first 6 months of life have about a 99% chance of 1-month survival and a 95% chance of long-term survival and surgical cure.

Among patients with Taussig-Bing heart, age greater than about 6 months is a risk factor for mortality, likely related to pulmonary vascular disease. However, Feng and colleagues found similar survival among a small group of patients with transposition and VSD and those with Taussig-Bing heart who underwent an arterial switch operation and VSD closure before or after age 6 months.

Type of Double Outlet Right Ventricle

Simple DORV and DORV with doubly committed VSD and no pulmonary stenosis are particularly favorable types of DORV with regard to survival after repair and are not risk factors for death.

In the past, DORV with subpulmonary VSD was a strong risk factor for death early or late after repair, largely related to combining repair of the VSD with an atrial switch procedure. Early and long-term survival after repair of the VSD combined with an arterial switch procedure are similar to those after the arterial switch repair of transposition of the great arteries and VSD (see Chapter 52, Fig. 52-37).

In the past, survival after repair of DORV with noncommitted VSD has been less than that of any other group, but assignment of patients to this group is almost by exclusion.

This makes it the least homogeneous group morphologically; also, a number of different kinds of repairs are used. The anatomic subset is sufficiently uncommon, the categorization of patients into it sufficiently arguable, and operations for difficulty is true of DORV with noncommitted VSD, exacerbated by the variety of operations used and the uncertainty of categorization of many patients in this group. Early mortality has probably been about 50%. The Fontan operation should be expected to yield the same mortality as in patients with univentricular AV connection, which is less than 5% in appropriately selected patients (see Chapter 41).

Time-Related Survival

Long-term survival after repair of simple DORV exceeds 95% at 15 years (see Fig. 53-19).

Incremental Risk Factors for Premature Death

An analysis based on the UAB experience between 1967 and July 1984 probably still serves reasonably well for simple DORV and DORV with doubly committed VSD, but not for varieties of DORV in which the arterial switch operation is now performed.

Age at Repair

Currently, and in contrast to an era before about 1980, young age at operation is not a risk factor for death early or late after repair of simple DORV and probably of DORV with doubly committed VSD. In fact, older age at operation is now the risk factor, and it is a particularly strong risk factor in the constant hazard phase (see Fig. 53-19). These relationships, and indeed survival in general, are similar to those obtained after repair of primary isolated VSD, and they probably are explained largely by absence or presence and severity of pulmonary vascular disease. Currently, patients undergoing repair of simple DORV during the first 6 months of life have about a 99% chance of 1-month survival and a 95% chance of long-term survival and surgical cure.

Factors for Premature Death

Factors for premature death include age at operation (< 6 months), male sex, the presence of additional cardiac anomalies (other than VSD), and the presence of pulmonary stenosis (PS). Long-term survival is now best for patients with simple DORV and DORV with doubly committed VSD, but not for other varieties of DORV in which the arterial switch operation is now performed.

Given the frequency of concomitant coarctation and the possible application of preliminary pulmonary trunk banding for Taussig-Bing hearts, controversy exists regarding the advisability of initial repair of coarctation only vs. one-stage correction using the arterial switch operation. In the current era, low mortality (< 5%) has been reported both with initial repair of coarctation through a left thoracotomy followed by subsequent arterial switch and with single-stage repair via sternotomy.

Kawashima and colleagues used an interventricular rerouting repair with extensive resection of the infundibular septum in 10 of 41 patients with Taussig-Bing heart (average age 2 years), with no deaths (0%; CL 0%-17%).

Estimating overall early mortality after repair of DORV with doubly committed VSD is difficult because of the small number of reported cases, but in general it has been about the same as after repair of simple DORV. The same mortality has probably been about 50%. The Fontan operation should be expected to yield the same mortality as in patients with univentricular AV connection, which is less than 5% in appropriately selected patients (see Chapter 41).
correcting it sufficiently variable that some time may elapse before early and intermediate-term survival are known with a reasonable degree of certainty. When known, it may indicate more frequent use of the Fontan group of operations in this subset of patients.

**Major Associated Cardiac Anomalies**

*Pulmonary stenosis* coexists with DORV in many patients, and its presence often requires creating a nonvalved or valved connection to the pulmonary trunk. Related to this, the presence of pulmonary stenosis is probably an incremental risk factor for death, because both procedures increase mortality.\(^{513}\)

*Complete AV septal defects, straddling AV valves, hypoplasia of a ventricular chamber, mitral valve abnormalities, and other coexisting anomalies increase risk.*\(^{84}\) This has usually been related to persisting in an attempt to perform an optimal operation rather than accepting the need for a more appropriate and often simpler procedure such as the Fontan group of operations.

---

**Figure 53-18** Repair of double outlet right ventricle with noncommitted inlet septal ventricular septal defect (VSD). A, VSD is noncommitted, but typically is not far from being either subaortic or subpulmonary. It is enlarged anteriorly (dashed line) after visualizing the mitral apparatus, being certain not to damage the anterior free wall or anterior descending coronary artery with the enlargement. B, An intraventricular tunnel repair is made. In the case illustration, the pulmonary trunk is left on the right ventricular side, but the tunnel partially obstructs approach to it. In some patients, an appropriate tunnel cannot be made except by leaving the pulmonary trunk on the left ventricular side of the tunnel; entry into the pulmonary trunk is closed off before making the tunnel repair, or the pulmonary trunk is divided when the conduit is placed. Right ventriculopulmonary artery continuity is established with a xenograft (C) or allograft valved extracardiac conduit (D).
Relationship between age at operation and early and long-term survival after repair of simple double outlet right ventricle. Depiction is a nomogram of a specific solution of a multivariable risk factor equation. Solid lines represent continuous point estimates, and dashed lines enclose 70% confidence intervals. A, Percent survival. B, Hazard function for death. Key: VSD, Ventricular septal defect. (From Kirklin and colleagues.)

Surgical Era

Earlier date of operation has been clearly identified as a risk factor for death by several studies. This indicates that outcomes after repair of all types of DORV are currently better than at any time in the past, and this difference is quantifiable.

Type of Operation

Atrial Switch Operation Use of an atrial switch operation in conjunction with an intraventricular tunnel repair has given poor results in general, including hospital mortalities of 30% to 40%. In this setting, the atrial switch repair is at least as strong a risk factor as it is in transposition of the great arteries and VSD (see Chapter 52). For this reason, it is no longer used.

Complex Intraventricular Tunnel Repair A simple intraventricular tunnel repair, such as that performed for DORV with subaortic VSD, has no more demonstrable risk than repair of a large primary isolated VSD with a patch (see Chapter 35). This is the reason for excellent outcome after repair of simple DORV in early life.

A somewhat more complex intraventricular tunnel repair, such as that used to redirect LV outflow in the Rastelli operation (see “Rastelli Operation” under Technique of Operation in Chapter 52) but with minimal excision of septal tissue and a resultant straight and relatively short pathway leading to the aorta, has little demonstrable incremental risk. This is supported by the current low early mortality after the Rastelli operation and by the low prevalence of complications from the tunnel itself late postoperatively. When used under proper circumstances for Taussig-Bing malformation, early and intermediate-term survival has been good and comparable to that obtained with the arterial switch repair.

More complex intraventricular tunnel repairs appear to be incremental risk factors, although this idea has not been properly tested by analysis. Hospital mortality has been 10% to 15% after such procedures but may currently be less than 5%. However, late mortality may be affected by baffle obstruction and patch dehiscence with complex tunnels.

Transanular Patches and Extracardiac Conduits Use of transanular patches and extracardiac conduits has increased the risk of operations for DORV, but at times their use is inescapable. As in other situations, controversy exists as to whether absence of a valve in the RV–pulmonary trunk connection adds to risk. Whether the risk of these procedures is any different from that imposed by the type of RV–pulmonary artery connection used in the Lecompte operation (REV) remains to be determined.

Operations for Double Outlet Right Ventricle with Atroventricular Discordant Connections A variety of operations have been successfully applied to this subset of DORV. No single strategy has proved superior in terms of long-term survival and freedom from reoperation. Shin’oka and colleagues found no significant difference in late survival 15 to 20 years after operation according to procedure performed, whether traditional repair, anatomic repair, or Fontan procedure was employed.

Complications of Intraventricular Tunnel Repair

Need for reoperation for complications of the tunnel repair (leakage or obstruction primarily) is directly related to complexity of the tunnel. Thus, in simple intraventricular tunnel repair for DORV and subaortic VSD, only 1% of patients have had catheterization evidence of tunnel leakage or obstruction, or reoperation for it. By contrast, 18% or more of patients with complex intraventricular tunnel repairs have required reoperation for important obstruction or leakage, or have had evidence of these problems (P = .005). An analysis by Fujii and colleagues indicated that length of the intraventricular tunnel is predictive of mortality. Among patients in whom the length between the top of the interventricular septum and aortic valve was less than 80% of normal LV end-diameter, event-free survival at 7 years was 89%, vs. 26% when it was greater than 80%. Late tunnel obstruction of complex intraventricular tunnel repairs may be more likely to develop when performed in young infants.

The likelihood of reoperation for LV outflow tract (LVOT) obstruction also relates to presence of potentially obstructing infundibular muscle in the new LVOT under the patch. Dearani and colleagues have emphasized the importance of VSD enlargement and infundibular septal resection when performing the Rastelli operation. Similarly, Rubay and colleagues emphasized the importance of conal resection in the REV procedure. Yeh and colleagues have reported the advantages of the Nikaidoh procedure in preventing late LVOT obstruction. In the setting of Taussig-Bing heart with valvar or subvalvar pulmonary stenosis of sufficient severity to
Complications after Taussig-Bing Repair

Complications of complex intraventricular tunnel repair have been detailed in the preceding discussion. Reoperations following the arterial switch operation have also been common, most notably RV outflow tract (RVOT) obstruction, both supravalvar—likely related to insufficient mobilization of the pulmonary arteries in preparation for the Lecompte maneuver, pericardial patch shrinkage, or inadequate patch size (see Chapter 52)—and subvalvar. Alsoufi and colleagues reported a 10-year freedom from RVOT obstruction of 55%.\(^1\) They indicate that alterations in constructing the patch for pulmonary trunk reconstruction have reduced supravalvar obstruction. More complete resection of the subaortic RV outlet has reduced occurrence of RVOT obstruction requiring reoperation.\(^2,3,4\) Further studies are needed to clarify the importance of these problems with current techniques.

INDICATIONS FOR OPERATION

Much of the previous information on outcomes after surgical repair of DORV is not applicable to patient care decisions in the current era, except that it permits developing equations that take into account the change in outcomes related to more recent dates of operation. Greater safety of intracardiac operations done early in life and good results of the arterial switch operation are two important factors in the improvement of current results. Improvements in myocardial management, support techniques, and intensive care unit management of neonates and infants undoubtedly play a role as well.

Recommendations for specific operations can only be general, and some cases may require special consideration. Representative strategies based on location of the VSD are presented in Table 53-7.

Simple Double Outlet Right Ventricle with Subaortic Ventricular Septal Defect

Simple DORV can be diagnosed very early in life, often by echocardiography alone. Repair should be electively planned by age 3 to 6 months, or sooner if signs of heart failure or failure to thrive persist. The operation should be intraventricular tunnel repair performed via a right atrial or, more frequently, RV approach.

When important pulmonary stenosis coexists, indications for operation and the operation are the same as for tetralogy of Fallot (see Indications for Operation in Section I of Chapter 38). Essentially, repair is advisable whenever important symptoms develop or electively, according to the same principles that apply to tetralogy of Fallot.

Double Outlet Right Ventricle with Subpulmonary Ventricular Septal Defect (Taussig-Bing Heart)

Taussig-Bing heart should be repaired by closure of the VSD so that the LV ejects into the pulmonary trunk (neoaorta), combined with an arterial switch repair. Operation should be performed during the first month of life or as soon as possible thereafter. Some surgeons continue to prefer the Kawashima procedure when the great arteries are side by side.\(^2,3,4\) but many currently apply the arterial switch operation irrespective of great artery position.\(^2,3,4\)

There is possibly no longer an indication for one of the intraventricular repairs for this anomaly unless there is coexisting subpulmonary obstruction of such a type and severity as to contraindicate arterial switch repair. Under these circumstances, an intraventricular tunnel repair (Kawashima) is indicated, supplemented by RV–pulmonary trunk valved conduit or a reconstruction of the type described under “Lecompte Intraventricular Repair.” Nikaidoh aortic translocation and RV outflow reconstruction can also be considered in this setting. The atrial switch type of operation no longer has a place in managing this group of patients.

Operations other than those including the arterial switch repair but including an extracardiac conduit should ideally be deferred until about 3 to 6 years of age. However, if more than a single systemic-pulmonary shunt appears to be necessary in the interim, it is preferable to proceed prematurely with complete repair (see Indications for Operation in Section II of Chapter 38).

Double Outlet Right Ventricle with Doubly Committed Ventricular Septal Defect

Generally this malformation is uncomplicated by coexisting cardiac anomalies, and the rationale and timing of repair are the same as for simple DORV.

Double Outlet Right Ventricle with Noncommitted Ventricular Septal Defect

Placing a patient in the subset of DORV with noncommitted VSD is often controversial, complicating the discussion of indications. When the malformation truly seems to be of this type, repair should consist of appropriately enlarging the VSD if possible so that an intraventricular tunnel can be created to direct LV blood to the aorta. When the pulmonary trunk is obstructed by the tunnel, a RV–pulmonary trunk valved extracardiac conduit or the Lecompte procedure is added. Hu and colleagues have reported using the translocation technique for this anomaly, with a double root translocation procedure.\(^5\) When the anatomy dictates that the tunnel be directed to the pulmonary trunk, and if pulmonary stenosis

is not present, the tunnel is made and an arterial switch operation added. Alternatively, pulmonary trunk banding early in life and a subsequent Fontan operation may be considered.

**SPECIAL SITUATIONS AND CONTROVERSIES**

**Single-Ventilcle Strategy versus Biventricular Repair for Complex Double Outlet Right Ventricle**

There is controversy regarding the optimal treatment strategy for certain forms of complex DORV related to the most reliable approach to achieve long-term survival, maintain good functional outcome, and minimize reoperation. Evidence-based recommendations are confounded by the large variety of anatomic variants within specific morphologic subsets (and potential importance of such variants for the conduct of and outcome after specific operations), the small number of specific operations for these anatomic variants at any given institution, the duration of follow-up needed to fully evaluate newer surgical procedures, and “philosophical” differences among institutions regarding single versus biventricular approaches. The controversial aspects relate primarily to two areas: hypoplasia of mitral valve or LV and nonsubaortic VSDs that are not reparable with the arterial switch operation and simple baffling of the LV to the neoaoaric valve. Bradley and colleagues have drawn attention to this controversy with an elegant analysis of nearly 400 patients in which they conclude that extending biventricular repair in “borderline anatomic candidates” may be of questionable long-term benefit compared with the Fontan pathway. Similar observations have been made by others. In favor of the Fontan approach is its current low operative risk, low risk of reoperation, and excellent functional outcomes in most patients. This may be especially relevant given the improved results with the Fontan approach in the presence of two functioning ventricles. The major limitations of the Fontan operation relate to the increasing hazard of ventricular dysfunction and heart failure after 15 to 18 years. Whether this risk will be decreased or neutralized by more current energy-efficient methods of Fontan construction remains to be determined. It is also important to consider the reality that certain components of these “borderline anatomic variants” (eg, modest elevation of pulmonary vascular resistance, ventricular hypertrophy, AV valve regurgitation) may represent risk factors for the Fontan operation.

The increasing late risk for reoperation and mortality after Rastelli-type operations for DORV have been well documented. Late morbidity and mortality relate not only to RVOT and extracardiac conduit obstruction but also to progressive LVOT obstruction in the setting of complex intraventricular baffles (see preceding text under Results). However, encouraging early and midterm results are emerging from newer procedures such as the REV procedure, and single and double root translocation operations (see also previous discussions under Technique of Operation and Results), as well as modifications of baffling techniques that provide some optimism for improved late survival and freedom from reoperation. For example, Devaney and colleagues reported biventricular repairs in 12 patients with AV septal defect with an interventricular communication remote from the aortic valve in the presence of a muscular subaortic infundibulum. There were 11 early and 10 late survivors. Infundibular resection and a complex extended intraventricular baffle contributed to absence of late LV outflow obstruction.

Until appropriate short- and longer-term outcome analyses are available, coupled with experiential insights, selection of one- or two-ventricle strategies for many of these complex variants will remain a function of institutional bias and surgeon preference.

### Double Outlet Left Ventricle

---

**DEFINITION**

Double outlet left ventricle (DOLV) is a cardiac anomaly in which both great arteries arise from the left ventricle (LV). The great arteries are assigned to one or the other ventricle by the rules described under Definition in Chapter 53. DOLV may occur with atrioventricular (AV) concordant or discordant connection, as does double outlet right ventricle (DORV; see Chapter 53). DOLV with AV discordant connection is discussed in Chapter 55. DOLV, like DORV, may also occur in patients with univentricular AV connections (see Chapter 56) and in those with atrial isomerism (see Chapter 58).

**HISTORICAL NOTE**

Marechal is credited with describing the first case of DOLV in 1819, but this was in a heart with double inlet LV with an infundibular outlet chamber. The first reported case in a heart with two ventricles and without pulmonary stenosis was that of Sakakibara and colleagues in 1967, for which they performed a successful intraventricular repair. Marechal is therefore another congenital cardiac anomaly that remained, for all practical purposes, undescribed until the advent of intracardiac surgery. It is also of interest that the first case reported by Potts and colleagues as tetralogy of Fallot and receiving a side-to-side aortopulmonary artery anastomosis underwent subsequent repair for well-documented DOLV with pulmonary stenosis (John Kirklin: personal communication; 1983). A unique case of DOLV with an intact ventricular septum was reported by Paul and colleagues in 1970, establishing with certainty the existence of the entity. Subsequent reports expanded the surgical possibilities by reporting reconstruction of the pulmonary pathway in cases in which a completely intraventricular repair was not possible, usually by a valved extracardiac conduit from the right ventricle to pulmonary trunk. Anderson and colleagues reported the sixth case of DOLV in 1974. Sharratt and colleagues in 1976 reported use of a Fontan-type procedure in hearts with DOLV and severe right ventricular hypoplasia. Five cases were added to the literature in 1976. Additional cases have been reported by Urban and colleagues and Stegmann and colleagues.

---

**MORPHOLOGY AND MORPHOGENESIS**

As with DORV, there is great variability among hearts with DOLV and AV concordant connection. Because of its rarity, generalizations are even more difficult than for DORV.

---

1. The adjectives left and right used to modify atrium or ventricle mean morphologically left and morphologically right. Position of the chamber is referred to as right-sided or left-sided.
Diagnosis can be ambiguous, because some override of one of the great arteries is commonly present. Defining a DOLV based on 50% or more of great arterial override may result in a substantially higher number of cases being reported. Many patients with complete transposition of the great arteries with subaortic ventricular septal defect (VSD), pulmonary stenosis, and a variable degree of aortic override have been misclassified as having DOLV. An exclusive or near-exclusive origin of both great arteries from the left ventricle (<20% override) will identify the classic form of DOLV and prevent misdiagnosis. Although it was initially thought bilateral absent conus was a prerequisite for the diagnosis of DOLV, all possible conal configurations have been described: subpulmonary, subaortic, bilaterally present, and bilaterally absent. When present, the length of conus under either great artery is typically relatively short and is an important factor in causing the great artery to embryologically align with the left ventricle.

A segmental approach is necessary for complete understanding of this malformation (see “Terminology and Classification of Heart Disease” in Chapter 1). DOLV occurs in each of the four basic hearts (Fig. 54-1) but is most common in hearts with atrial situs solitus and ventricular right-handedness or D-loop (S,D,D). Morphologic characteristics of the VSD and its relationship to the great arteries at the level of the semilunar valves are similar to those in DORV and described by terms defined in “Ventricular Septal Defect” under Morphology in Chapter 53. Subaortic VSD is the most common, followed by subpulmonic, and then by doubly committed. VSD remote from the great arteries is rare (Table 54-1). Absence of a VSD (intact ventricular septum) is also rare but has been described.

Atrial Situs Solitus and Ventricular Right-Handedness (D-Loop) (Atrioventricular Concordant Connection)

In this subset, the aorta is usually in D-malposition (S,D,D), but examples occur with it in L-malposition (S,D,L) (see “Symbolic Convention of Van Praagh” in Chapter 1). In the former, the great arteries may appear in relatively normal position (aorta to the right and somewhat posterior to pulmonary trunk), side to side, or with aorta somewhat anterior to the pulmonary trunk.

Data from Menon and Hagler. Key: VSD, Ventricular septal defect.

**Ventricular Septal Defect**

The ventricular septum is rarely intact. Usually, a large VSD is present and lies between the limbs of the trabecula septomarginalis (septal band).

Most commonly, the VSD is *subaortic* in position (Fig. 54-2; see Table 54-1). It may extend back to the tricuspid anulus, or it may be separated from the anulus by a muscular bridge. When the aorta overrides the VSD and arises in part from the right ventricle, the VSD is *juxtaaortic*, and this entity begins to merge with transposition of the great arteries.

When the VSD is subpulmonary, it is usually more anterior and well separated from the tricuspid valve by a rather wide band of muscle. In some cases, the pulmonary trunk origin overrides the VSD and lies in part over the right ventricle. Malalignment of conal septum may be present and can cause aortic outflow obstruction and be associated with aortic arch hypoplasia.

Occasionally the VSD is juxtaarterial and lies immediately below both great arteries (*doubly committed*; see Chapter 53, Fig. 53-6). The VSD is typically very large, and there is absence or near absence of conus bilaterally, resulting in aortic-mitrall and pulmonary-mitrall fibrous continuity and side-by-side great arteries. It is frequently difficult to decide whether DOLV or DORV is present, in which case the term *double outlet both ventricles* is appropriate.

**Conal Pattern**

Most often there is absence of a subaortic conus and presence of aortic-mitrall fibrous continuity and a subpulmonary conus displaced into the LV (Fig. 54-3). Rarely, bilaterally absent conus permits aortic-mitrall-tricuspid and pulmonary-tricuspid fibrous continuity (see Fig. 54-2). In this event, both semilunar valves arise at the same level. Very rarely, only a subaortic conus is present. There may be a conus bilaterally.

**Pulmonary Stenosis**

Pulmonary stenosis is present in most cases and is either valvar (sometimes with anular stenosis) or subvalvar when it is due to a restrictive subpulmonary conus with secondary fibrosis of the ostium. When the VSD is subaortic and there is infundibular pulmonary stenosis, the great arteries are usually relatively normally interrelated.

**Right Ventricular and Tricuspid Valve Hypoplasia**

There is a tendency for the right ventricular sinus and tricuspid valve to be at least somewhat hypoplastic. The
PART VII  Congenital Heart Disease

Figure 54-2  Specimen of double outlet left ventricle and atrioventricular concordant connection. A, Viewed from opened left ventricle (LV) and aorta (Ao). Aortic valve (AoV) is bicuspid but otherwise normal. Ventricular septal defect (VSD) is subaortic, with its upper margin separated from AoV by 4 mm. Tricuspid valve (TV) is visible through VSD (Ebstein anomaly of tricuspid valve is present). B, Close-up of LV outflow tract before aorta was opened. Pulmonary valve (PV) is not stenotic, and AoV and PV are in continuity, separated only by a thin fibrous ridge called the truncal septum (TS). There is both PV and aortic–mitral valve (MV) fibrous continuity (i.e., conus is absent bilaterally). (From Brandt and colleagues.13)

extreme example is coexistence of tricuspid atresia, with the two reported cases having ventricular right-handedness (S,D,D).22,23 Rarely, the tricuspid valve may show an Ebstein anomaly.23

Left Ventricle
The LV is usually well formed. One case of mitral atresia with large LV and infundibular outlet chamber (S,D,D segmental arrangement) has been reported.22

Conduction System
Position of AV node and bundle of His is normal. Thus, the bundle penetrates from a normally positioned posterior AV node through the right trigone in the region of the commissure between tricuspid septal and anterior leaflets and at the base of the noncoronary aortic cusp, and its two branches distribute in normal fashion. Whether it is at risk during repair depends on the relationship of the lower VSD margin to the tricuspid anulus (see “Location in Septum and Relationship to Conduction System” under Morphology in Section 1 of Chapter 35).

Atrial Situs Inversus and Ventricular Left-Handedness (L-Loop) (Atrioventricular Concordant Connection)
Both I,L,L and I,L,D arrangements have been reported (i.e., aorta to the left or right), although both are rare. Usually the VSD is subaortic, and pulmonary stenosis coexists.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Pathophysiology
In hearts with DOLV and AV concordant connection, the LV is a common mixing chamber, receiving pulmonary venous blood through the mitral valve and caval blood through the right ventricle and VSD. Clinical presentation, however, is dominated by varying degrees of cyanosis due to a combination of the frequent occurrence of pulmonary stenosis and streaming caused by the variable malposition of the great arteries and their relationship to the VSD. Thus, streaming of desaturated right ventricular blood into the aorta may occur when the VSD is subaortic, leading to unexpectedly severe cyanosis. In the absence of pulmonary stenosis, heart failure often develops early in life because of large pulmonary blood flow.

In hearts with DOLV and AV discordant connection, the LV receives caval blood through the mitral valve, and pulmonary venous blood through the right ventricle and VSD. The tendency to develop severe cyanosis is more likely than in AV concordant connection.

Examination
Physical findings, chest radiograph, and electrocardiogram are not diagnostic, but reflect cardiopulmonary physiology in each case.

Echocardiography
Echocardiography with color flow imaging may be diagnostic, and associated morphologic lesions are readily detected.22,23 The main challenge is to distinguish DOLV from other, more common conotruncal anomalies such as transposition of the great arteries and DORV (Fig. 54-4). The focus is on defining the VSD and the relationship of the VSD to the two great arteries, presence or absence of conus under each great artery, presence or absence of pulmonary stenosis, and positioning of the two great arteries in relation to each other. Coronary artery pattern is also important because some surgical repair techniques used for DOLV require specific knowledge of coronary artery course. Other imaging studies are not usually performed unless clinical presentation indicates that specific and quantitative knowledge of physiologic of the pulmonary vasculature is important in formulating the management plan. Even with increased recognition of DOLV by echocardiography, diagnosis may be elusive. In a recent experience with six patients with both echocardiography and cardiac catheterization available, diagnosis was made preoperatively in four patients and intraoperatively in two.23
Cardiac Catheterization and Cineangiography

Biplane cineangiography, selecting injection sites and projections suited to the individual problem, is diagnostic but provides little additional morphologic information beyond that obtained by echocardiography. Because DOLV is rare, cineangiography was once performed to support a diagnosis made by echocardiography, but this role has now been overtaken by magnetic resonance imaging (MRI). Cardiac catheterization, however, remains the only way to obtain specific hemodynamic and oxymetric data if it is necessary to define the physiology of the pulmonary vasculature.

When catheterization is performed, both left and right ventricular injections are desirable. With appropriate projections, angiography can confirm the diagnosis of DOLV and rule out other conotruncal anomalies, but it is rarely necessary in current practice. Angiography can also define the position and number of VSDs, presence and site of pulmonary and aortic stenosis, and size of the right ventricle and tricuspid valve relative to the LV and mitral valve (see Fig. 54-3).

Magnetic Resonance and Computed Tomography Imaging

Computed tomography provides no specific advantages over MRI in diagnosing DOLV and thus is not routinely used. MRI may be used to supplement the intracardiac
entities the degree of hypoxia and clinical course are directly related to severity of pulmonary stenosis.

**TECHNIQUE OF OPERATION**

**Identification of Morphology**

There are no clues to the specific diagnosis of DOLV from external examination of the heart when it is exposed at operation. Generally, only AV connection—concordant or discordant—can be confirmed by external observation. For this reason, detailed and complete preoperative imaging must be performed to identify all aspects of the anomaly. Even when this has been done, relation of the great arteries to VSD, and VSD to AV valves, may be different from that anticipated from preoperative imaging. Thus, when the heart is opened, accurate evaluation must be made of all aspects of morphology.

When the AV connection is **concordant**, finding a large VSD located far downstream (distally) and anterosuperiorly in the ventricular septum mandates thorough consideration of all diagnostic possibilities associated with a VSD in this position, including not only DOLV but also ordinary subpulmonary VSD with ventriculocardiac discordant connection, tetralogy of Fallot with subpulmonary VSD (if pulmonary stenosis coexists), anterosuperior VSD with complete transposition of the great arteries, DORV with doubly committed VSD, and Taussig-Bing-type DORV (which has its VSD in this same position, but an aorta far removed from the VSD and clearly originating from the right ventricle alone).

When the AV connection is **discordant**, the same detailed observations must be made. These generally reveal findings similar to those of congenitally corrected transposition of the great arteries (see Chapter 55), but in DOLV, the aorta as well as the pulmonary trunk arise entirely or in large part from the right-sided (in atrial situs solitus) LV.

**Repair of Double Outlet Left Ventricle and Atrioventricular Concordant Connection**

Preparations for operation, sternotomy, and placement of purse-string sutures are those generally used (see “Preparation for Cardiopulmonary Bypass” in Section 3 of Chapter 2). Cardiopulmonary bypass (CPB) is established, perfusate temperature lowered to 25°C, the aorta clamped, and usual techniques of myocardial management instituted (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3). The usual oblique right atriotomy is made (see Chapter 30, Fig. 30-14, A), and the interior of the right ventricle is inspected through the tricuspid valve. It can usually be confirmed from the right atrium that neither great artery arises wholly or in large part from the right ventricle, and that the VSD is in the outlet portion of the ventricular septum.

Usually, repair is made through a vertical incision in the distal portion of the right ventricle. After placing stay sutures, position of VSD, origin of aorta and pulmonary trunk from LV and their relationships to the VSD, and the nature of any pulmonary stenosis are verified.

**With Pulmonary Stenosis**

When pulmonary stenosis is present in a DOLV, it is usually not possible to relieve it directly and do a completely

---

**NATURAL HISTORY**

Natural history of patients with DOLV without pulmonary stenosis appears to be similar to that of patients with isolated large VSD (see Natural History in Section 1 of Chapter 35), except that progressive VSD narrowing and closure has not been documented in DOLV. Cyanosis may be present because of the common mixing chamber beneath the great arteries, but considerable streaming of flow is often present and accounts for significant variability in arterial oxygen levels.

Natural history of patients with DOLV and pulmonary stenosis is similar to that of patients with tetralogy of Fallot (see Natural History in Section 1 of Chapter 38), and in both morphologic information obtained by echocardiography (Fig. 54-5).
patch, because the left anterior descending coronary artery is immediately in front of the pulmonary anulus, and a valved extracardiac conduit or a variant of the Lecompte operation (réparation à l’étage ventriculaire [REV]) is necessary. In the former, the pulmonary trunk is transected at the sinutubular junction, and the proximal pulmonary trunk stump is oversewn by placing two rows of continuous polypropylene sutures at the level of the valve. Then the VSD is closed by suturing into place a patch, taking the usual precautions to avoid damaging the bundle of His (Fig. 54-6, A). An intraventricular repair, as is described for patients with no coexisting pulmonary stenosis. However, if examination of the pulmonary valve through a vertical anterior incision in the pulmonary trunk or through the ventricle shows it to be widely patent and the subvalvar fibromuscular obstructing ring localized, the ring may be excised satisfactorily, permitting a completely intraventricular repair.

Usually the pulmonary anulus is small and the subvalvar stenosis too long and narrow for a simple intraventricular repair to be effective. It is not possible to place a transanular patch.
allograft-valved extracardiac conduit is prepared (see Figs. 38-77 and 38-78 in Chapter 38) and sutured distally to the pulmonary trunk and proximally to the right ventriculotomy (Fig. 54-6, B). Returning to the right atrium, the foramen ovale is closed, and the remainder of the operation is completed in the usual manner.

Alternatively, a Lecompte operation (REV) can be performed (see “Lecompte Intraventricular Repair” under Technique of Operation in Chapter 53). This has the great advantage of not requiring an extracardiac conduit. Transfer of the pulmonary trunk to the right ventricle can be accomplished without the need to transect and reconstruct the aorta.\(^{3,1,31}\)

Patch augmentation of the right ventricular outflow tract may be possible in selected cases of DOLV with pulmonary stenosis. For this to be possible, the pulmonary trunk must be either anterior or side by side relative to the aorta, and the coronary arteries must course behind the pulmonary root\(^{13}\) (Fig. 54-7).

**Without Pulmonary Stenosis**

When pulmonary stenosis is not present, the morphologic arrangements may allow intraventricular tunnel repair. A contoured patch is placed into the VSD so that the right ventricle ejects into the pulmonary trunk while the LV continues to ejet into the aorta. The VSD may have to be enlarged anteriorly and superiorly before this is done. When an intraventricular tunnel repair is not possible, the pulmonary orifice is closed off from within the ventricle or from within the pulmonary trunk, or the pulmonary trunk is divided; the VSD is closed, leaving the aorta coming off the LV; and an allograft-valved extracardiac conduit is placed between the right ventricle and pulmonary trunk. Alternatively, the pulmonary trunk can be connected to the right ventricle by the Lecompte operation (REV). If the pulmonary valve is relatively normal in size (with or without subpulmonic stenosis), the pulmonary root, including the valve, can be translocated to the right ventricle in the same fashion. This has been described in patients with DOLV who have a subpulmonic conus.\(^{1,3,31}\) Additionally, the intact pulmonary valve and root can be translocated to the right ventricle even when a subpulmonic conus is absent, as described by Hanley and colleagues\(^{33}\) (Fig. 54-8). Pulmonary root translocation in the presence of severe pulmonary stenosis, using a monocusp valve and patch augmentation of the small pulmonary anulus, has also been described.\(^{11}\)

Rarely, in the absence of pulmonary stenosis, are these types of repair not possible. It may then be possible to close the VSD with a contoured patch so the right ventricle ejects into the aorta and the LV into the pulmonary trunk, and to

---

**Figure 54-7**  Patch augmentation of right ventricular (RV) outflow tract in double outlet left ventricle with pulmonary stenosis. **A**, Great arteries are side by side, with aorta (Ao) to right of pulmonary trunk (PT). Right coronary artery arises anteriorly from aorta, and left anterior descending coronary artery (LAD) is shown, with left main coronary artery arising posteriorly and passing behind PT. Right ventriculotomy is performed overlying subaortic ventricular septal defect (VSD). Pulmonary arteriotomy is also performed to expose stenotic pulmonary valve orifice (PO). **B**, Bridge of muscle between right ventriculotomy and pulmonary arteriotomy has been incised to create continuity between these two openings. VSD has been closed with a Dacron patch (DP). Various options for RV outflow reconstruction can be used, but stenotic native pulmonary valve opening is always closed from within pulmonary artery. In this illustration, a monocusp valve is used. Triangular-shaped patch is sutured to edges of ventriculotomy, serving as a monocusp valve. Woven Dacron vascular graft patch (VG) is placed to construct a roof for RV outflow tract. Alternatively (not shown), vascular graft roof can be used without monocusp prosthesis, or a full prosthetic valve can be positioned within RV outflow tract underneath the roof. Key: AV, aortic valve; MP, monocusp patch. (Redrawn from Sohn and colleagues.\(^{31}\))
**Figure 54-8** Repair of double outlet left ventricle (DOLV) without pulmonary stenosis: pulmonary root translocation. A, Pulmonary root (including intact pulmonary valve) (PT), positioned to left and slightly posterior to aorta (Ao), being excised. Care is taken to separate pulmonary valve from any attachments to central fibrous body or mitral valve anulus. Through a right ventriculotomy and ventricular septal defect (VSD), aortic (AV) and mitral (MV) valves can be visualized in LV. B, Two separate polytetrafluoroethylene patches (PP) have been used to close VSD and defect in LV created from excision of pulmonary root. If pulmonary-mitral fibrous continuity is present, patch on LV will be partially sewn to anterior mitral leaflet hinge point. Posterior rim of mobilized pulmonary root (PT) is sutured to superior aspect of right ventriculotomy. C, Procedure is completed by creating a hood (PH) across anterior aspect of anastomosis. (Redrawn from Menon and Hagler.546)

**Complete the operation by performing an arterial switch procedure** (see “Arterial Switch Operation” under Technique of Operation in Chapter 52).

**Double Outlet Left Ventricle with Atroventricular Concordant Connection and Important Hypoplasia of Right Ventricle and Tricuspid Valve**

An important degree of hypoplasia of the right ventricle and tricuspid valve (see later text on Indications for Operation) makes the types of repair described in the preceding text inadvisable. A Fontan operation may be performed (see Technique of Operation and Indications for Operation in Chapter 41), or one combining an intracardiac septation with a bidirectional cavopulmonary anastomosis (“one-and-a-half” ventricle repair; see Chapter 40).

**SPECIAL FEATURES OF POSTOPERATIVE CARE**

Postoperative care follows the usual protocols (see Chapter 5).

**RESULTS**

Survival

**Early (Hospital) Death**

In the current era, hospital mortality is expected to be about 5%, based on recent reports of patients doing well after surgical correction.51,104 Total number of surgically managed cases reported, however, is only several dozen. The experience of McElhinney and colleagues has been updated to include six patients undergoing intracardiac repair, with no early or midterm deaths (FL Hanley: personal communication; 2002).513

**Time-Related Survival**

The number of cases is so small, and variability of the anomaly and repairs so great, little useful information is available about time-related survival and risk factors for death. However, these are probably similar to those for DORV (see Fig. 53-19 in Chapter 53) and transposition, VSD, and LV outflow obstruction (see Figs. 52-53 and Figs. 52-54 in Chapter 52).

**Other Outcome Events**

The small number of patients and variability in the morphology and surgical procedures mitigate against obtaining sufficient information in this area to draw reasonable inferences.

When an allograft-valved extracardiac conduit is used, reoperation will probably be necessary at some time (see “Reoperation” under Results in Section II of Chapter 38).

**INDICATIONS FOR OPERATION**

Diagnosis of DOLV is an indication for operation. When pulmonary stenosis coexists, Lecompte intraventricular repair (REV; see Chapter 53) may be considered optimal, and in this case, young age is not a contraindication. Conduit repair may be performed in infancy, accepting the need for early reoperation and conduit replacement. Classic shunting operations (see Chapter 38) remain an alternative. Arguments for and against this approach are similar to those outlined for tetralogy of Fallot (see Chapter 38).

In the absence of pulmonary stenosis, corrective operation should usually be performed in the first 6 months of life if preoperative imaging studies support the likely success of a completely intraventricular repair. Alternatively, but less desirably, pulmonary trunk banding may be performed if the patient has heart failure or if pulmonary vascular resistance is
ranging, and repair delayed until later in life. Ideal timing of the subsequent repair may be influenced by morphology. If preoperative imaging studies suggest that a completely intraventricular repair will be straightforward, repair can be pursued at age 1 to 2 years. If morphology is more challenging for a completely intraventricular repair, some believe it may be of benefit to delay repair beyond age 2 years to maximize the likelihood of success. The logic underlying this approach is not proven, but the argument is that a complex intracardiac baffle is more likely to remain unobstructed over time if operation is performed in a more fully grown patient.

When there is right ventricular and tricuspid valvar hypoplasia, with z value for diameter of the tricuspid valve less than −2, a Fontan operation (see Chapter 41) or, alternatively, the “one-and-a-half” ventricle repair (see Chapter 40) should be considered. Usual indications, timing, and techniques of the Fontan operation are used (see Chapter 41).

Section I  Congenitally Corrected Transposition of the Great Arteries

DEFINITION

Congenitally corrected transposition of the great arteries is a congenital cardiac anomaly with ventriculoarterial discordant connection (transposition of the great arteries) and atrioventricular (AV) discordant connection, the right atrium connecting to left ventricle and left atrium connecting to right ventricle. Circulatory pathways are therefore in series. The condition occurs in atrial situs solitus and atrial situs inversus. Ventricles may lie in any position.

HISTORICAL NOTE

Rokitansky probably was first to describe a case of congenitally corrected transposition of the great arteries (CCTGA) in 1875. After that, pathologists recognized the condition easily but considered it rare. With advent of cardiac surgery, interest and knowledge expanded rapidly, and papers by Anderson and colleagues from the University of Minnesota in 1957 and by Schiebler and colleagues from the Mayo Clinic in 1961 established the clinical syndromes associated with it.

Monckenberg (1913) and later Uher (1936) described the anterior position of the AV node, its usual location in CCTGA. In 1931, Walmsley recognized fundamental differences in cardiac structure in such hearts, including a different coronary arterial pattern and altered morphology in the central fibrous body and conduction system. In 1963, Lev and colleagues again described the anomalous position of the AV node and His bundle. Clinicians, however, remained unaware of these observations until Anderson and colleagues confirmed the unusual position of the AV node and extended knowledge of the pathway of the bundle of His.

First repairs of a cardiac malformation associated with CCTGA were reported in 1957 by Anderson, Lillehei, and Lester from the University of Minnesota. This repair and others reported from the Mayo Clinic resulted in the morphologic right ventricle serving the systemic circulation. In 1990, Ilbawi and colleagues introduced the double switch concept in which the morphologic left ventricle serves the systemic circulation.

MORPHOLOGY

In atrial situs solitus, the most common arrangement of CCTGA is ventricular L-loop and L-malposition of the aorta (S,L,L; see “Symbolic Convention of Van Praagh” under Terminology and Classification of Heart Disease in Chapter 1) (Fig. 55-1). The left ventricle (LV) usually lies to the right side and right ventricle (RV) to the left side. The mitral valve then lies to the right side and tricuspid valve to the left side. The LV is usually slightly posterior and inferior to the RV.

Fig. 55-1  Diagrammatic models of the four basic hearts (see Appendix 1H in Chapter 1) as they occur in transposition of the great arteries (ventriculoarterial discordant connection), with most common great arterial positions indicated. Degree of elevation of great arteries above their respective ventricles corresponds to usual type of conal development. Models 1 and 4 are complete transposition of the great arteries, and models 2 and 3 are congenitally corrected transposition of the great arteries. Key: LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.
along its long axis occurs, resulting in atypical topology (criss-cross heart). For example, in atrial situs solitus, there may be a discordant AV connection, but the ventricles are D-loop; similarly, discordant AV connection in atrial situs inversus will have L-loop ventricles.\textsuperscript{12}

Ventricles

Usually there is fibrous continuity in the right-sided LV between the right-sided mitral and pulmonary valves and a well-developed left-sided RV infundibulum separating left-sided tricuspid and aortic valves. However, rare cases have been described with bilateral conus or bilaterally deficient conus.\textsuperscript{3}

The LV outflow tract beneath the pulmonary valve lies between the septal (pulmonary) leaflet of the mitral valve on the right and muscular ventricular septum on the left (Fig. 55-2). In its anterior part, there is often a prominent recess.\textsuperscript{13} Ventricular outflow tracts do not cross, and ascending aorta and pulmonary trunk are parallel.

In atrial situs solitus, the apex of the heart is usually to the left and is formed by the RV. Dextrocardia exists in about 25% of cases, and occasionally mesocardia.\textsuperscript{2} In atrial situs inversus, there is nearly always dextrocardia.

Other bizarre rotational anomalies occasionally occur in this and other hearts with AV discordant connections (see Morphology in Section II later in this chapter).

Pulmonary Outflow Tract

The pulmonary valve lies in a transverse plane and arises from the right-sided LV in a wedged position between the mitral and tricuspid valves. Wedging of the pulmonary valve is said to be more marked in corrected than in complete transposition (see Morphology in Chapter 52) and more marked than that of the aorta in the normal heart\textsuperscript{7} (see Chapter 1). The pulmonary valve lies to the right and posterior to the aortic valve. Axis of the AV valves is partway between transverse and sagittal planes as in the normal heart.

The long axis of pulmonary outflow from the right-sided LV is obliquely oriented\textsuperscript{5,14} and potentially restrictive, particularly when there is LV hypertrophy. Obstruction is organic in about half the hearts,\textsuperscript{5,14} and in at least 25% it is hemodynamically important.\textsuperscript{17}

Pulmonary valve cusps may be thickened and fused or occasionally bicuspid or unicuspid. When valve stenosis is present, the pulmonary trunk may be narrowed by valve tethering, as in tetralogy of Fallot (see “Pulmonary Valve” under Morphology in Section I of Chapter 38). There may be pulmonary atresia with or without confluence between right and left pulmonary arteries. There may be subvalvar narrowing due either to a membrane that is adherent on its right (laterally) with the right-sided anterior mitral leaflet (see Fig. 55-2) or to an aneurysmal bulging of the membranous septum into the posterior part of the outflow tract with or without a ventricular septal defect (VSD)\textsuperscript{5,12} (Fig. 55-3). Less severe obstruction is usually due to fibrous tags (valvar...
excrences) attached to the LV–pulmonary trunk junction, membranous septum, or right-sided mitral valve or due to valvar excrescences projecting through a VSD from the left-sided tricuspid valve leaflet. In about 1% of cases, pulmonary atresia is associated with arborization abnormalities of the branch pulmonary arteries and presence of major aortopulmonary collateral arteries.

### Atrial Septum

Atrial and ventricular septa are malaligned except where pulmonary, mitral, and tricuspid valves lie in close proximity and are joined by the right fibrous trigone. Elsewhere, atrial septal attachment to the fibrous skeleton of the heart is moved to the right of ventricular septal attachment. These alignment differences are usually severe enough in hearts with atrial situs solitus to prevent the normally positioned (regular) AV node (known as posterior, inferior, or lateral node) from reaching the underlying ventricular septum.

### Mitral Valve

The right-sided mitral valve lies at the entrance to the right-sided LV. Because of the wedged position of the pulmonary valve, the mitral anulus extends anterior to the pulmonary anulus so that the pulmonary valve is tucked beneath (to the left of) the septal mitral valve leaflet (see Fig. 55-2). The mitral valve is rotated so that its usual septal leaflet, which is in fibrous continuity with the pulmonary valve and can therefore be called the pulmonary leaflet, is posterior and its mural leaflet anterior (see Fig. 55-3). The smaller papillary muscle arises from the anterolateral free wall of the ventricle, where it can be damaged by left ventriculotomy. Its position is frequently marked by direct coronary artery branches crossing the front of the LV from the anterior descending coronary artery. The larger papillary muscle arises from the posterolateral free wall of the ventricle, having been found in 55% of an autopsy series (Fig. 55-4). Mitral valve abnormalities are common, having been found in 55% of an autopsy series (Fig. 55-4).

### Aortic Valve

The aortic valve, usually normal, is over the RV infundibulum, and it and the aorta are usually in a leftward and anterior position (S,L,L). Occasionally the aorta lies to the right and anterior to the pulmonary artery (S,L,D), associated with infundibular rotation in this direction. In atrial situs inversus, the aorta is virtually always to the right (I,D,D).

Subaortic obstruction rarely occurs in the left-sided RV outflow tract.

### Tricuspid Valve

The left-sided tricuspid valve lies at the entrance to the left-sided RV, which has usual coarse trabeculations, a trabecula septomarginalis (septal band), and an infundibular septum. The valve is positioned almost in a sagittal plane and has the usual three leaflets but with the septal leaflet more medial and anterior than normal. According to some, it is nearly always structurally abnormal (90% of cases according to Allwork et al.). Others report fewer structural abnormalities, ranging from 23% to 43%. In most instances, there is leaflet dysplasia with abnormal thickened chordal attachments of the septal and posterior leaflets, and in a minority there is a true Ebstein anomaly with downward displacement of origins of septal and posterior leaflets. Ebstein anomaly often differs from that in a heart with normal connections in three respects:

- The anterior leaflet is normal in size rather than large and sail-like.
- The anulus is not dilated.
- The RV sinus is not enlarged.

In about 30% of hearts, morphologic changes make the tricuspid valve regurgitant or, rarely, stenotic. There may be a thinned, dilated atrialized portion of the RV with a variable degree of hypoplasia.

### Atrioventricular Node and Bundle of His

The AV node and bundle of His in CCTGA (and in most, if not all, hearts with atrial situs solitus and AV discordant connection) differ from normal. Although a regular (posterior) AV node is present in front of the coronary sinus ostium in the apex of the triangle of Koch, the penetrating bundle of His usually does not extend from it because of septal malalignment. In exceptions in which the regular (posterior) AV node gives rise to the penetrating bundle, septal malalignment is mild. Degree of septal malalignment is influenced by size of the pulmonary trunk. Thus, presence of either pulmonary atresia or severe pulmonary stenosis results in less septal malalignment and an increased chance that the posterior AV node will align with the penetrating bundle.

In contrast, in atrial situs inversus, the penetrating bundle of His most commonly extends from the regular (posterior)
Ventricular Septal Defect

VSD is the most common coexisting anomaly and is present in about 80% of hearts. Usually it is large, subpulmonary, and associated with virtual absence of the membranous septum (infundibulum). The pulmonary valve commonly overrides the VSD to arise from the left-sided RV. As viewed from the right (LV) side (Fig. 55-5), the VSD is bounded superiorly by the pulmonary anulus or pulmonary valve itself, depending on degree of overriding. There may be membranous septal remnants along this margin (see Fig. 55-3). Posteriorly, it is bounded by that part of the right-sided mitral anulus from which the septal leaflet arises, and anteriorly and inferiorly by infundibular and muscular interventricular septa, respectively. Its postero-inferior margin may extend to the mitral anulus with a zone of mitral-pulmonary-tricuspid fibrous continuity. It is frequently narrowed or nearly closed by an aneurysm of the membranous septum (see Fig. 55-3) or valvar excrescences from the left-sided tricuspid valve (see Section IV in Chapter 38).

Viewed from the RV (left) side, this perimembranous VSD lies, as usual, within the Y of the trabeculae septomarginalis and beneath the infundibular septum; the VSD, in other words, is infundibular in type and is often accompanied by some malalignment of the infundibular septum that

Figure 55-5  Specimen of a heart with congenitally corrected transposition of the great arteries in which a large conoventricular ventricular septal defect had been closed with a polyester patch 4 years before death. Right-sided left ventricle and pulmonary trunk have been opened. Limits of patch are easily discerned. Defect is bounded superiorly by the pulmonary anulus, posteriorly by the mitral ring, anteriorly by the infundibular (conal) septum, and inferiorly by the muscular ventricular septum. Key: Cs, Infundibular (conal) septum; D, ventricular septal defect closed by a patch; LV, left ventricle; MV, septal mitral valve leaflet; PT, pulmonary trunk; PV, normal pulmonary valve; VS, ventricular septum.
Coronary Arteries

Coronary arteries demonstrate anatomy appropriate to their ventricles. Thus, the right-sided left coronary artery (coronary artery to right-sided LV) with its left anterior descending and circumflex branches supplies the LV, and the right coronary artery and its conal and posterior descending branches supplies the RV. Aortic origins are, however, peculiar to the malformation. The anterior sinus is the noncoronary one; the right-sided left coronary artery arises from the right posterior sinus and passes directly in front of the pulmonary valve to divide into left anterior descending and circumflex branches, the latter passing in front of the right atrial appendage in the AV groove; the left-sided right coronary artery arises from the left posterior sinus and runs in the AV groove and in front of the left atrial appendage, terminating posteriorly as the posterior descending artery. Lev and Rowlatt used the terms “right sided” and “left sided” to describe these vessels.\(^1,3\) The most common major variation from this arrangement is for a single coronary artery to arise from the right sinus and divide into right and left main branches; this occurs in less than 10% of cases. Other minor variations occur.\(^1,3,4\)

Other Associated Anomalies

Only 1% to 2% of hearts with CCTGA have no coexisting anomalies.\(^4,6,16,17\) Coexisting anomalies other than those described in the preceding text include a supravalvar left atrial ring, which may be a cause of left-sided (tricuspid) valve stenosis,\(^16\) and coarctation of the aorta in association with a VSD.\(^18,54\) Coarctation may be particularly common when severe forms of Ebstein anomaly are present.\(^4\) A patent ductus arteriosus is sometimes present, as is a true atrial septal defect in about 20% of cases.

Overriding or straddling of AV valves is more common when there are positional anomalies, as is hypoplasia of one or other ventricle.\(^31\) The left-sided tricuspid valve may over-ride or straddle a VSD,\(^35\) which is at times associated with hypoplasia of the left-sided RV and at times with superior-inferior ventricles (see “Positional Anomalies” under Ventricular Position and Rotation in Section II of this chapter and “Cardiac and Arterial Positions” under Terminology and Classification of Heart Disease in Chapter 1). The left-sided tricuspid valve straddles the posterior part of the ventricular septum, which is then prevented from reaching the crux, and the conduction tissue passes anterior to the pulmonary anulus.\(^51,11\) More rarely, the right-sided mitral valve may behave similarly (as it does at times in AV discordant connection with double outlet right ventricle [see Section II]); invariably this is associated with LV hypoplasia and superior-inferior ventricles.\(^8,69\) The mitral valve straddles the anterior part of the septum so that it does not extend to the crux, and a regular posterior node only may be present, with the bundle passing posterior to the pulmonary anulus.\(^86\)

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

Clinical features depend solely on the presence and combination of associated cardiovascular lesions. The rare patient with no associated lesions will be asymptomatic for years or decades and may present with left-sided RV failure after several decades or more. More commonly, clinical features are dominated by a large VSD associated with some restriction of features:

**Contribution to Subpulmonary Stenosis**

The bundle of His courses along its anterior margin on the LV (right) side in a subendocardial position and bifurcates at its anteroinferior angle with the right bundle branch crossing this angle of the defect to reach the RV.

In about 10% of cases (more often in Japanese patients),\(^12\) the VSD lies within the infundibular septum; when it completely replaces it, it is immediately below both great arteries (doubly committed, juxta-arterial) (Fig. 55-6). Uncommonly, it is muscular, lying in the sinus (trabecular) septum. A large, typical inlet septal VSD may uncommonly occur. Also, there may be multiple VSDs.

---

**Figure 55-6** Specimen of a heart with congenitally corrected transposition of the great arteries and doubly committed subarterial ventricular septal defect (VSD). A. Viewed from right-sided left ventricle (LV). There is a partially obstructing subpulmonary fibrous membrane present (arrows). B. Viewed from left-sided right ventricle (RV). Infundibular septum is absent, but there is a relatively short subaortic conus and tricuspid-mitral-pulmonary fibrous continuity through VSD. Key: C, Subaortic conus; LC, left coronary (right-sided) aortic cusp; MV, mitral valve; NC, non-coronary (anterior) aortic cusp; PVC, pulmonary valve; RC, right coronary (left-sided) aortic cusp; TV, tricuspid valve.
pulmonary blood flow attributable to morphology of the subpulmonary LV outflow tract. Therefore, symptoms from sequelae of large pulmonary blood flow occur in only about 30% of cases, but finding a loud second heart sound at the second left intercostal space is suggestive because it may represent closure of the leftward and anterior aortic valve.

Although chest radiography may suggest that a congenital cardiac malformation has AV discordant connection by an ascending aortic shadow appearing along the left upper cardiac silhouette, this is not diagnostic because there are many other anomalies with the aorta in L-malposition (see Clinical Features and Diagnostic Criteria in Chapter 57). Echocardiography (ECG) may suggest a correct diagnosis when there is reversal of precordial Q-wave pattern with deep Q waves in leads V_2 and aVR, and QS complexes in leads V_3 and aVF in right precordial leads. Congenital or developing complete heart block is also suggestive of CCTGA. Additional findings of transposed great arteries with aorta anterior and to the left, and a left-sided ventricle containing a coarsely trabeculated endocardial surface and moderator band, help confirm the diagnosis (Fig. 55-8). Presence of VSDs, valve function, and venous connections can all be defined.

Computed tomography (CT) and magnetic resonance imaging (MRI) provide excellent delineation of the morphology of CCTGA, but in neonates and infants, these imaging modalities add little to echocardiography with respect to making the diagnosis and identifying associated cardiac anomalies. These additional studies can be extremely helpful, however, in providing additional information that may be important in complex management decisions that eventually must be made for many of these patients. MRI can be particularly helpful in quantitating ventricular volumes and valve regurgitant fraction (Fig. 55-10). It can also be helpful in quantitating LV mass and determining the ventricular septal position in cases being evaluated for a double switch procedure (Fig. 55-11). Volume-rendered CT imaging is capable of showing excellent spatial resolution of the coronary arteries and is particularly helpful in demonstrating the interrelationships between the coronary arteries and adjacent structures (Fig. 55-12).

Cardiac catheterization and biplane cineangiography provide confirmatory diagnostic data (Fig. 55-13). Pressure and flows are measured to quantify severity of pulmonary stenosis and any intracardiac shunt. Angiographic views must profile the ventricular septum and establish morphology of various chambers and sites of systemic and pulmonary venous connection and, thus, cardiac connections present. They can define location and number of VSDs, nature of the pulmonary stenosis and of tricuspid valve function, and other associated anomalies. Catheterization is rarely used in modern practice to define morphology, because echocardiography, CT, and MRI adequately provide these details in essentially all cases. Catheterization is indispensable if pulmonary vascular resistance, shunt fractions, or ventricular end-diastolic pressure is required for decision making.
potentials are not recordable, and morphologic evidence of a connection between an AV node and more distal parts of the His bundle cannot be found. At least 40% to 50% of patients with AV discordant connection are born with first- or second-degree AV block. As time passes, prolongation of the PR interval often develops, even in those with originally normal intervals. Thus, Gillette and colleagues found normal AV conduction at age 6 to 7 years in only 38% (CL 29%-47%) of 40 patients with CCTGA. Progressive prolonging of the PR interval may eventuate in

NATURAL HISTORY

Heart Block

About 5% to 10% of infants with CCTGA or other types of AV discordant connection (see Section II) have complete heart block at birth. This proportion slowly increases at about 2% per year to reach a prevalence of about 10% to 15% by adolescence and 30% by adulthood. Block may be in the AV node or in single or multiple sites more distally. In some infants born with complete heart block, bundle of His potentials are not recordable, and morphologic evidence of a connection between an AV node and more distal parts of the His bundle cannot be found.

At least 40% to 50% of patients with AV discordant connection are born with first- or second-degree AV block. As time passes, prolongation of the PR interval often develops, even in those with originally normal intervals. Thus, Gillette and colleagues found normal AV conduction at age 6 to 7 years in only 38% (CL 29%-47%) of 40 patients with CCTGA. Progressive prolonging of the PR interval may eventuate in
**Figure 55-9** Computed tomography (CT) image of corrected transposition of the great arteries. Axial maximum intensity projection CT image shows the right atrium (RA) connects to the morphologic left ventricle (MLV), and the left-sided ventricle shows prominent trabeculation (stars) with a thickened moderator band (arrow), which are characteristic of a morphologic right ventricle (MRV). Key: Ao, Aorta; LA, left atrium. (From Kantarci and colleagues [Fig. 1].)

**Figure 55-10** Four-chamber view from magnetic resonance imaging (MRI) cine sequence of a 33-year-old man with congenitally corrected transposition of the great arteries. The patient has symptoms of heart failure. The right ventricle (RV) is enlarged, with reduced ejection fraction. Tricuspid anulus enlargement caused multiple tricuspid regurgitant jets (arrow), which worsen the volume loading of the right ventricle.

**Figure 55-11** Mid-short-axis view from a cardiac gated computed tomography angiogram (CTA) of a 4-year-old girl with congenitally corrected transposition of the great arteries without ventricular septal defect or pulmonary stenosis. Note the thin left ventricular (LV) wall and bulging of the septum (arrowhead) from right ventricle (RV) to the LV because the RV is pumping at systemic pressure. RV is hypertrophied and dilated. LV wall and septum are thin. Patient underwent this study as a baseline evaluation in preparation for placing a pulmonary artery band for LV retraining in anticipation of performing a double switch procedure.

**Figure 55-12** Three-dimensional volume-rendered computed tomography image shows spatial relationship of great arteries, with ascending aorta anterior and to left of pulmonary trunk. Anterior descending artery (short arrow) and circumflex artery (arrowhead) arise from common left anterior descending coronary artery off anterior aortic sinus. Right coronary artery (long arrow) arises from posterior aortic sinus. (From Chang and colleagues [Fig. 1F].)
Figure 55-13  Cineangiograms in congenitally corrected transposition of the great arteries. A, Left ventricular injection in four-chamber position, anteroposterior (AP) projection. Pulmonary trunk arises from right-sided left ventricle (RV). Note concavity into low-pressure left ventricle (LV) produced by the nonopacified high-pressure left-sided RV. B, RV injection in four-chamber position, AP projection. Aorta arises from left-sided RV. C, In another patient, RV injection in four-chamber position, AP projection. In this patient, in contrast to the first one, a ventricular septal defect allows dye to pass into right-sided LV and out pulmonary trunk. Pulmonary trunk and ascending aorta are superimposed. D, In a patient with coexisting subvalvar pulmonary stenosis, LV injection in four-chamber position, AP projection. Severe subvalvar narrowing is evident as well as poststenotic dilatation of the pulmonary trunk. E, LV injection, lateral projection. The long severe subvalvar narrowing is evident.

episodic or permanent complete heart block. However, about 40% of patients with AV discordant connection retain normal PR intervals and QRS durations throughout their lives.

Ventricular Function

General outlines of the truth about systemic (morphologic right) and pulmonary (morphologic left) ventricular function are gradually becoming apparent, although many of the details are missing (see Special Situations and Controversies later in this section). Ventricular function is not normal but is sufficiently good that a large proportion of patients maintain essentially normal functional status well into adult life. In 12 adults with CCTGA, many with associated anomalies, followed longitudinally for 10 years, ventricular ejection fraction did not change. However, systemic ventricular function (function of the RV) tends to gradually deteriorate during and after the second decade of life; isolated reports of survival into the seventh, eighth, and ninth decades do exist.

In the unusual circumstance of CCTGA without other cardiac anomalies, an adequate cardiac index is usually sustained during exercise, but increase in heart rate accounts for this, and stroke volume is not increased. Response of the systemic (right) ventricular ejection fraction to exercise is variable, the ejection fraction increasing in some patients but not in others. Systemic (right) ventricular end-systolic and end-diastolic volumes also behave variably during exercise, but on the average do not change, whereas in normal individuals, systemic (left) ventricular end-systolic volume decreases with exercise.

Pulmonary (left) ventricular ejection fraction usually increases with exercise in patients with CCTGA without other cardiac anomalies. Other indices do not change systematically with exercise, as is also the case in normal individuals.
Etiology of ventricular dysfunction is poorly understood. Myocardial perfusion plays a role. Perfusion defects at rest are common in the morphologic RV in CCTGA, and their extent correlates inversely with ejection fraction.\textsuperscript{134,164,147}

Women of childbearing age seem to tolerate pregnancy and delivery moderately well, with some increased risk of maternal complications and fetal loss.\textsuperscript{137,144}

**Effect of Coexisting Cardiac Anomalies**

Because of the high prevalence of coexisting cardiac anomalies, survival free from cardiac intervention is less than 30% at 36 months after birth.\textsuperscript{132} Even without coexisting anomalies, the likelihood of developing heart block and reduced systemic (right) ventricular function probably adversely affects natural history; coexisting cardiac anomalies further affect it. A multicenter study involving 182 patients confirms these points: By age 45 years, 25% of patients without coexisting anomalies developed heart failure, and 67% of those with associated anomalies did.\textsuperscript{139} Other studies link heart failure in this setting to increased risk of death.\textsuperscript{144}

The natural history of CCTGA patients whose only coexisting lesion is a large VSD tends to be slightly better than that of patients with isolated large VSDs (see Fig. 55-7); this may be because their VSDs are smaller than in patients presenting with isolated VSDs. (This difference was not apparent in the report of Friedberg and Nadas,\textsuperscript{135} possibly related to their inclusion of patients with univentricular AV connection [single ventricle] in their study.) Chronic symptoms of effort intolerance and growth failure are common in patients with CCTGA in the first 2 decades of life, but death is infrequent. Although estimates of survival are unavailable, presumably death from chronic heart failure occurs with increasing frequency during the third, fourth, and fifth decades of life.

When important pulmonary stenosis coexists with VSD, cyanosis appears in early life, and the natural history may be similar to that of tetralogy of Fallot (see Natural History under Section I of Chapter 38). However, compared with tetralogy of Fallot, lack of a subpulmonic infundibulum in CCTGA may substantially alter the likelihood of a dynamic muscular component of pulmonary obstruction.

The natural history of the left AV valve in patients with CCTGA and other types of AV discordant connection is unclear. Occasionally the valve may be importantly regurgitant from early in life, but more commonly there is little or no regurgitation initially, and then its prevalence and magnitude increase progressively during the second through fifth decades. The exception is Ebstein anomaly of the left-sided tricuspid valve, when regurgitation is commonly present from birth.

In atrial situs inversus, VSD and pulmonary stenosis are more likely to be present than in atrial situs solitus. However, there is less likelihood of developing spontaneous complete heart block, because of the considerably higher prevalence of the penetrating bundle connecting to a normally positioned AV node.\textsuperscript{138}

**TECHNIQUE OF OPERATION**

**Repair of Coexisting Ventricular Septal Defect**

Preparations for operation, median sternotomy, and placing pericardial stay sutures are as usual (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2). Placing purse-string sutures for aortic cannulation and cannulation itself are more difficult than usual because of aortic L-malposition. These procedures are facilitated by grasping aortic adventitia with one or two small curved hemostats and retracting them inferiorly and rightward. Usual purse-string sutures are placed for aortic cannulation and the cardioplegic catheter; caval tapes and purse-string sutures are also placed. In atrial situs solitus and dextrocardia, right atrium and vein cavae are hidden behind the ventricle, making cannulation difficult, although difficulty of direct caval cannulation is not increased.

**Through Right-Sided Mitral Valve**

Cardiopulmonary bypass (CPB) is established in the usual manner, as are cardioplegia and controlled reperfusion (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3). The right atrium is opened through an oblique incision (Fig. 55-14). A pump-oxygenator sump sucker is introduced through the right superior pulmonary vein across the left-sided AV valve into the left-sided ventricular chamber.

The VSD is examined through the right-sided mitral valve (Fig. 55-15, A). Although it does not permit quite as free access to the interior of the ventricle as the normal right-sided tricuspid valve, in most cases the VSD can be repaired through the intact mitral valve. When exposure is suboptimal, an incision is made in the base of the mitral valve septal leaflet near the superior commissure and through the base of the
Figure 55-15  Repair of ventricular septal defect (VSD) in patient with situs solitus, congenitally corrected transposition of the great arteries, and VSD. A, Close-up view of VSD through intact mitral valve. Intracardiac exposure is gained through a right atrial incision as shown in Fig. 55-14. Exposure of a typical conoventricular VSD is more difficult working through the mitral valve orifice compared with a similar defect in a patient with atrioventricular concordant connection working through tricuspid valve. However, VSD can be exposed and closed in most circumstances without incising the posterior leaflet. The retractor is used to move aside anterior aspect of mitral valve anulus and anterior valve leaflet. In this case, the VSD patch is sewn into place with a running monofilament nonabsorbable suture, beginning at the most anterior aspect of the rim of the VSD. To avoid injury to the conduction system, sutures must be placed on morphologic right ventricular side of VSD rim along its anterior and superior aspects. Here, a single felt pledget is positioned on morphologic right ventricular side of septum to initiate the suture line. Two dashed lines to left and right of pledget represent partial thickness suture placement on morphologic right ventricular side of defect along its anterior aspect. Branching bundle of His is shown coursing along anterior aspect of VSD. B, If VSD cannot be adequately exposed through the mitral valve orifice, it may be beneficial to incise the posterior mitral valve leaflet 1 to 2 mm from its anular attachment as shown by dashed lines. C, Incised posterior leaflet of mitral valve has been retracted anteriorly, allowing direct exposure of conoventricular VSD. VSD patch is then sewn into place exactly as described in A.

The technique is similar to that used occasionally for inlet septal VSD. Working through the aperture created, VSD repair can be accomplished nicely (Fig. 55-15, D-E). However, the alternative of repairing the VSD through the aorta should be considered when approach through the right atrium is not optimal (see text that follows).

Margins of the VSD are studied (see Fig. 55-15, A and C). Location of the anterior AV node and bundle of His arching over the subpulmonary outflow tract and passing anterior to the VSD are conceptualized (in fact, the bundle often can be seen as a thin, pale line as shown in Fig. 55-14). Electrophysiologic mapping is unnecessary. The left-sided tricuspid valve can usually be seen through the
VSD, and some of its chordae often attach to the inferior VSD border.

VSD repair is made by sewing into place a properly sized patch of either glutaraldehyde-treated autologous pericardium or double-velour knitted polyester, keeping sutures on the left (RV) side of the defect anterosuperiorly, anteriorly, and as much as possible inferiorly (see Fig. 55-15, A and D). Chordae from the left-sided tricuspid valve, often attached to the inferior edge of the VSD, limit this possibility inferiorly. Continuous polypropylene suture, ranging from 6-0 to 4-0 depending on the size of the patient, is used, or interrupted pledgeted mattress sutures when exposure is difficult because of overlying chordal structures. After VSD repair is complete, if a circumferential incision has been made in the mitral leaflets, this incision is closed with continuous polypropylene suture using previously placed fine stay sutures to keep the closure properly oriented so valve distortion is avoided (Fig. 55-15, E). If a patent foramen ovale or atrial septal defect is present, it is closed.

The subpulmonary (LV outflow) tract is examined. Unless the pulmonary valve itself is stenotic or valvar excrescences obstruct the subvalvar area, little can be done to improve the variable degree of narrowing usually present (see Results). Only placing an LV–pulmonary trunk valved extracardiac conduit provides good relief. However, if pulmonary blood flow has been large (>2.0 preoperatively), even a 50-mmHg gradient does not necessarily indicate need for a conduit. With elimination of left-to-right shunt by closing the large VSD, right-sided LV pressure usually decreases appreciably.

The usual de-airing procedures are accomplished (see “De-airing the Heart” in Section III of Chapter 2). The aortic clamp is removed, and the right atrial incision is closed with a continuous polypropylene suture. The remainder of the procedure, including placing temporary atrial and ventricular pacing wires, is carried out in the usual manner (see “Placing Epicardial Pacemaker Leads” later in this section and “Completing Cardiopulmonary Bypass” in Section III of Chapter 2).

Through Aorta
An attractive alternative approach is closing the VSD through the aorta, which allows the patch to be sutured into place from the RV (left-sided) aspect of the septum. Experience of Russo and colleagues suggests this may reduce the prevalence of perioperative complete heart block. This approach is more attractive than that through the pulmonary trunk, which some advocate.

Through Left-Sided Tricuspid Valve
When isolated dextrocardia complicates CCTGA and VSD, the VSD can be repaired through a left-sided incision in the usually large left-sided left atrium. Exposure through the left-sided tricuspid valve usually allows good exposure, and surgically induced heart block should be avoidable because suturing is all on the RV (left) side of the septum.

Repair of Coexisting Ventricular Septal Defect and Pulmonary Stenosis
The main decision-making challenge is determining whether satisfactory repair can be accomplished without a valved extracardiac conduit. When the pulmonary valve is stenotic, it is approached through a pulmonary arteriotomy during moderately hypothermic CPB and cold cardioplegia,
and valvotomy is performed as for isolated pulmonary valve stenosis (see Fig. 39-10 in Chapter 39). The pulmonary arteriotomy is best closed with a patch and continuous suture. Obstructing fibrous subvalvar tags are excised, bearing in mind the His bundle position (see Fig. 55-14). A subvalvar fibrous membrane can be excised with utmost care if it is at the anteroinferior angle. Aneurysm of the membranous ventricular septum is excised and the deficiency closed as part of VSD repair. If other excrescences are present, they are first examined to ensure they are not functioning parts of the AV valves or subvalvar mechanisms; then they are sharply resected.

Muscle must never be removed from the rightward (medial) aspect of the right-sided LV outflow tract or from the anterior part adjacent to the pulmonary anulus, because the His bundle lies there. Then Hegar dilators are used to measure the resulting orifice and the z value estimated (see “General Plan and Details of Repair Common to All Approaches” under Technique of Operation in Section I of Chapter 38). Valvotomy may be inadequate because of a bicuspid valve, supravalvar pulmonary trunk narrowing (tethering) at the level of commissural attachment, or (most commonly) a narrow subpulmonary LV outflow tract. However, if the z value is greater than ~1, the pulmonary trunk is repaired, usual de-airing and other procedures carried out, and CPB discontinued.

Pressures are measured before removing the cannulae. Relationship between the postvalvotomy left-to-right ventricular pressure (P_{LV/RV}) in the operating room and that the next morning and late postoperatively is not known. However, it has seemed reasonable not to revert to CPB and place a valved extracardiac conduit if P_{LV/RV} in the operating room is less than about 0.85, considering that the right-sided ventricle and valve are a morphologic LV and mitral valve. On the other hand, pulmonary stenosis usually represents a fixed resistance, and the LV-to-pulmonary trunk gradient will increase with exercise.

A polyvinyl catheter is placed in the right-sided LV and, if possible, threaded into the pulmonary trunk. LV pressure is remeasured the next morning in the intensive care unit with this catheter, and if calculated P_{LV/RV} is less than about 0.7, the patient is not returned to the operating room for placing a valved extracardiac conduit.

**Placing Valved Extracardiac Conduit**

When pulmonary stenosis is so severe that the patient is cyanotic preoperatively, or when simple procedures to relieve the stenosis are unsatisfactory (see earlier) or postrepair P_{LV/RV} is too high, a valved extracardiac conduit is used. After VSD repair, working through the right atrium, a site is chosen for attaching the conduit to the right-sided LV by examining the LV interior through the mitral valve. A site is chosen on the anterior wall, but rather inferior and away from any papillary muscles and major coronary artery branches. Left ventriculotomy is then made. If there is reasonable flow across the native LV–pulmonary trunk outflow tract, it can be left intact, creating an end-to-side anastomosis of conduit to pulmonary trunk. This results in LV ejection via two routes: native tract and conduit. More commonly when a conduit is required, obstruction is severe; therefore the pulmonary trunk is transected at the valve level, the proximal stump oversewn, and the conduit connected end to end to the distal pulmonary trunk (Fig. 55-16).

Reconstruction can be accomplished in a number of ways. An allograft-valved conduit has previously been prepared by extending it proximally with a woven polyester tube (see Fig. 55-16). Alternatively, proximal extension may be with an aortic allograft, or the allograft aortic valve and ascending aorta may be left long distally, and proximal anastomosis augmented with a pericardial hood (see “Placement of Valved Conduit” in Section II of Chapter 38). These extensions are particularly necessary in this situation because the conduit must be of sufficient length to prevent kinking, and the valve must lie away from the LV so that it is not distorted. Estimating length and lie of the conduit is important to avoid its compression by the sternum.

The conduit is trimmed to size, cutting the distal end square but leaving more of the ascending aorta beyond the aortic valve than in the case of tetralogy, because this facilitates a smooth conduit contour and limits length of the polyester extension. The proximal polyester end of the conduit is trimmed to make a cobra head, the distal allograft end anastomosed end to end to the distal pulmonary trunk, and the proximal polyester end anastomosed to the
ventriculotomy. The conduit most commonly is placed to the right around the right atrium and atrial appendage (see Fig. 55-16), although extreme deviations in cardiac position may influence conduit position, occasionally making a left-sided placement appropriate. Aeba and colleagues describe placing the conduit from the apex of the LV to the pulmonary trunk to avoid the well-known problem of sternal compression.\textsuperscript{A2}

**Transanular Patch**

Doty and colleagues\textsuperscript{D10} proposed using a posteriorly placed transanular patch across the pulmonary valve anulus in this situation. However, average gradient across the repair was 40 mmHg.

**Correction for Regurgitant Left-Sided Tricuspid Valve**

When important left-sided tricuspid valve regurgitation coexists, repair and anuloplasty are only occasionally successful but should be attempted if it seems feasible.\textsuperscript{D9} If replacement is required, the same considerations apply to the replacement device as in ordinary left-sided mitral valve replacement (see “Choice of Device for Valve Replacement” in Section I of Chapter 11). Valve replacement is the same as for a left-sided mitral valve, including choice of venous cannulae and approach through the right side of the left atrium (see “Mitral Valve Replacement” in Section I of Chapter 11 and Fig. 11-19). The replacement device is either sewn in with interrupted pledgeted mattress sutures or simple interrupted sutures. A continuous suture technique is not desirable when there is absence of a well-defined anulus in some areas, as may occur when there is downward displacement into the ventricle of some of the left-sided tricuspid valve leaflets, as in Ebstein anomaly.

**Double Switch Procedures**

Because of concern over long-term fate of the morphologic LV and mitral valve in the systemic circulation, some suggest placing the morphologic LV and mitral valve into the systemic circulation. This requires switching both venous return and arterial outflow (double switch) by one of several procedures, all of which are technically substantially more complex than those already described. The double switch concept was originally suggested by Ilbawi and colleagues for patients with CCTGA, VSD, and pulmonary stenosis.\textsuperscript{D11} In this setting, the morphologic LV is connected to the aorta by creating an intraventricular baffle (which also closes the VSD); an extracardiac conduit is placed from morphologic RV to pulmonary trunk, and a Mustard or Senning intraatrial transposition of venous return is performed. The concept was subsequently applied to CCTGA without pulmonary stenosis, with or without VSD. In this setting, an arterial switch is performed to correct the ventriculoarterial discordant connection. (All of these reconstructive procedures used in combination in the double switch procedures are individually described in detail in Chapter 52.) Aortic translocation has also been used for selected cases of CCTGA with VSD and pulmonary stenosis.\textsuperscript{D9,D10,K14}

If these procedures are being considered for patients without VSD in whom the morphologic LV is working at low pressure, the same considerations must be addressed as in simple transposition of the great arteries (TGA) with unprepared LV (see “Simple Transposition of the Great Arteries Presenting after Age 30 Days” under Indications for Operation in Chapter 52).

Both major double switch procedures are performed using a standard median sternotomy incision, CPB with moderate hypothermia using bicaval venous cannulation through purse-string sutures placed directly on the vena cavae, aortic cannulation at the base of the brachiocephalic artery, and venting of the systemic ventricle by way of a cannula introduced through the right upper pulmonary vein. Multiple doses of cold cardioplegic solution are used for these extensive procedures (see “Methods of Myocardial Management” under Neonates and Infants in Chapter 3). Individual components of the two major double switch procedures are as follows:

1. The *atrial baffle procedure*, which is performed exactly as for simple TGA (see “Mustard Technique” and “Senning Technique” under Technique of Operation in Chapter 52). It is not uncommon in CCTGA of both the S,L,L and the I,D,D types for cardiac positioning abnormalities such as mesocardia or apicocaval juxtaposition to be present. In these cases, the free wall of the systemic venous atrium is likely to be deficient, making the Mustard technique preferable to the Senning. Atrial baffle placement may be more difficult than in simple TGA, because the left-sided tricuspid valve is positioned much more posteriorly across the atrial septum in relation to the vena cavae.

2. For patients with VSD and pulmonary stenosis, the *morphologic LV-to-aortic intracardiac baffle procedure*, which is accomplished through a subaortic incision in the infundibulum of the morphologic RV as described under “Intraventricular Repair” in Chapter 52, for S,D,D transposition with VSD and pulmonary stenosis or atresia. The morphologic RV-to-pulmonary trunk conduit is placed as described under “Rastelli Operation” in Chapter 52. This procedure is shown in Fig. 55-17, A to E.

3. For patients without pulmonary stenosis, the *arterial switch procedure* is performed using the same techniques described under “Arterial Switch Operation” in Chapter 52 for simple TGA. If a VSD is present, it is closed as described earlier under “Repair of Coexisting Ventricular Septal Defect.” This procedure is shown in Fig. 55-18, A to D.

**Double Switch Procedures Combined with Bidirectional Superior Cavopulmonary Anastomosis**

Bidirectional superior cavopulmonary anastomosis may provide substantial advantages in the setting of both double switch procedures. It reduces complexity of the intratrial procedure, because only the inferior vena cava is baffled to the tricuspid valve. This reduces myocardial ischemia time because (1) the cavopulmonary anastomosis can be performed during rewarming after the aortic clamp is removed and myocardial reperfusion is established, and (2) the simplified inferior vena cava baffling can be accomplished much more quickly than a full Mustard or Senning procedure. An additional advantage is that recognized complications of the full Mustard or Senning procedure (e.g., superior caval obstruction, pulmonary venous obstruction, sinus node dysfunction) are eliminated.
Figure 55-17 Double switch concept using a Rastelli morphologic left ventricle-aortic intraventricular tunnel and an intraatrial Mustard baffle. A, Dashed lines on inset show the two incisions used for this procedure; one is along right atrial free wall, the other along subaortic infundibulum of left-sided morphologic right ventricle (MRV). Routine cardiopulmonary bypass techniques and myocardial protection are used. After cardiac arrest, right atrium is opened and Mustard intraatrial baffle constructed. As illustrated, baffle suture line is almost completed. Details of Mustard procedure are provided in Chapter 52. The only important difference when the Mustard procedure is performed in congenially corrected transposition is that the surgeon must be aware of superior displacement of the atrioventricular node. B, After completing Mustard intraatrial baffle, the right atriotomy is closed with a running monofilament suture. The left-sided MRV infundibular incision is made, and exposure to intraventricular morphology is aided by a combination of stay sutures and retractors. In this case, the stenotic pulmonary valve and subpulmonic morphologic left ventricular (MLV) outflow tract are identified and closed internally with doubly pledgeted interrupted mattress sutures. Pulmonary anulus and subpulmonic region are exposed by gently retracting superior anterior aspect of rim of the ventricular septal defect (VSD) with a vein retractor, as illustrated.
Vein retractor on rim of VSD has been removed. Dotted line shows suture line used to create intraventricular baffle that will establish a pathway from the right-sided posterior MLV through VSD to left-sided anterior aorta. Note that exposure through this incision in MRV allows the surgeon to directly view MRV aspect of the ventricular septum, making it easy to place all sutures on right ventricular aspect of the rim of VSD, thereby avoiding direct injury to conduction system. It is important to realize that from this perspective on the MRV side, the vulnerable area for conduction injury is now at posterior and inferior aspect of VSD. A polyester tube graft of diameter approximately equal to that of the aorta is used to create MLV-to-aortic baffle. Natural curvature of resulting baffle patch is placed such that it is seen as convex when viewed through infundibular incision in MRV. Typically a running monofilament suture technique is used to place baffle. Routine care must be taken with respect to the conduction system along posterior inferior rim of VSD (see Chapter 35). Aortic end of baffle is sewn into place along the immediate subaortic musculature (see text for further details). As can be seen from C, there is potential for an hourglass deformity in the pathway from MLV to aorta at its midportion as the baffle passes the tricuspid valve anulus. Obstruction at this level can be avoided by attending to several factors. The baffle itself should be made particularly wide at its midportion. Additionally, the suture line should be placed into anulus of tricuspid valve at this level in order to maximize width of the pathway. Finally, judicious resection of muscle along floor of pathway in subpulmonic region at the upper rim of VSD may be helpful. It is critical to perform this resection with absolute knowledge of the position of conduction system.
**Figure 55-17, cont’d** E, Procedure is completed by placing an external valved conduit from left-sided anterior MRV to pulmonary trunk. In this instance, the subpulmonic area was closed previously during the intracardiac portion of the operation (B). Conduit is placed from infundibular incision in the MRV, coursing either to left or right side of aortic valve and ascending aorta. Positioning of conduit in this operation is somewhat more problematic than placing conduit from right-sided MLV to pulmonary trunk, as described in the “standard repair” in Fig. 55-16. Ventricular incision in MRV is more anterior and much more likely to be immediately substernal, increasing risk of compression. Whether to place the conduit to left or right of aortic valve and ascending aorta is an individual decision based on particular details of cardiac position within chest cavity. The principle is to place conduit in such a way that minimizes sternal compression. In this case, a composite graft of polyester and a bioprosthetic valve is used. Again, length of conduit is typically much longer than in cases of tetralogy of Fallot with pulmonary atresia. Similar to the situation described in Fig. 55-16, the valve is placed distally within the conduit, close to conduit to pulmonary trunk anastomosis.

**Figure 55-18** Double switch concept for situs solitus congenitally corrected transposition of the great arteries (CCTGA), with or without ventricular septal defect, and without pulmonary stenosis. A, Dashed line on right atrium shows proposed incision for performing Mustard intraatrial baffle. Dashed lines on aorta and pulmonary trunk show proposed incisions for transecting the great arteries and mobilizing coronary arteries. Cardiopulmonary bypass and myocardial protection are standard. B, Mustard intraatrial baffle is performed as described in Fig. 55-17 and as detailed in Chapter 52.
Other advantages exist specifically in CCTGA with VSD and pulmonary stenosis. If an extracardiac conduit is necessary owing to severe pulmonary stenosis, its longevity will be extended because of reduced volume of flow it carries. This may be particularly pertinent in a small growing child. Additionally, if the morphologic RV size is reduced, either because of intrinsic reasons or as a result of a large morphologic LV–aortic baffle occupying part of its cavity, the bidirectional superior cavopulmonary anastomosis may provide superior hemodynamics. Finally, in patients with positional abnormalities such as situs solitus with mesocardia or dextrocardia, or with situs inversus, simplicity of the “hemi-Mustard” procedure makes it preferable to the full Mustard or Senning procedure.

For these reasons, bidirectional superior cavopulmonary anastomosis with hemi-Mustard procedure has become the preferred technique for performing the atrial component of the operation in both forms of the double switch for at least one of the authors. The procedure is performed as described in Chapter 41 under “Bidirectional Superior Cavopulmonary Shunt.” The double switch procedure, inferior vena cava–to–tricuspid valve atrial baffle (hemi-Mustard), and bidirectional superior cavopulmonary anastomosis are shown in Fig. 55-19.

Placing Epicardial Pacemaker Leads
When complete heart block has been present intermittently or permanently preoperatively, or when it has developed intraoperatively, permanent epicardial atrial and ventricular pacemaking leads are placed, and a permanent pacemaker pulse generator is placed subcutaneously (see “Technique of Intervention” in Section I of Chapter 16).

SPECIAL FEATURES OF POSTOPERATIVE CARE
Patients are managed with protocols generally used after cardiac surgery (see Chapter 5). In patients with AV discordant connection such as these, particular attention is paid to the cardiac rhythm. When complete heart block is present, AV sequential pacing augments cardiac output and is therefore used routinely.
PART VII  Congenital Heart Disease

Figure 55-19  Bidirectional superior cavopulmonary anastomosis and “hemi-Mustard” modification for double switch procedure for congenitally corrected transposition of the great arteries. As in all double switch variations, atrial and arterial components can be performed in any order desired. In certain circumstances (see text), modifying the atrial component by performing a hemi-Mustard connection of the inferior vena cava to the tricuspid valve in combination with a bidirectional superior cavopulmonary anastomosis, rather than the full Mustard procedure, is beneficial. When this procedure is elected, the simplified intraatrial baffle can be performed either before or after the great artery component, whether that be a formal arterial switch or a Rastelli morphologic left ventricle–aortic intraventricular baffle. It is advantageous, however, to perform the bidirectional superior cavopulmonary anastomosis as the last component of the operation after removing the aortic clamp and establishing myocardial reperfusion. The intraatrial component of this procedure proceeds by performing a formal atrial septectomy (see “Mustard Technique” under Technique of Operation in Chapter 52). It may be advantageous in some cases to further enlarge the intraatrial opening by incising superiorly into the limbus of the atrial septum. The intraatrial baffle is much simplified, in essence constructing only inferior vena caval limb of Mustard baffle. Shape of baffle patch used is circular. Diameter of patch is equal to the straight-line distance measured from most superior limit of tricuspid valve anulus to orifice of inferior vena cava. Suture line follows exact details of the standard Mustard patch around inferior vena cava orifice. Superior aspect of baffle is sewn around tricuspid valve orifice. Bidirectional superior cavopulmonary anastomosis is performed exactly as described in Chapter 41.

RESULTS

Survival

Morphologic Right Ventricle Supporting Systemic Circulation

Early (Hospital) Death  When operation is performed for CCTGA and VSD, hospital mortality has been 5% to 10%. When performed for CCTGA with coexisting VSD and important pulmonary stenosis, it has been 10% to 20%. When performed for coexisting left-sided tricuspid valvar regurgitation requiring valve replacement, it has been 15% to 25%.11,B13,D3,I8,M6,M8,S1,T3,W4,W6,Y4 Reducing hospital mortality is surely possible and has been documented in studies showing a reduction from 21% (17/82; CL 16%–26%) for operations performed prior to 1987 to 3.4% (1/29; CL 0.6%–11%) for those performed between 1987 and 1996.11

Time-Related Survival  The 1-month and 1-, 5-, 10-, and 20-year survivors after repair of important coexisting cardiac anomalies in heterogeneous groups of patients with CCTGA repaired over the past 35 years have been about 88%, 80%, 76%, and 46%, respectively, including hospital deaths.11,12,Y8 In more recent experience, close to 90% 10-year survival has been demonstrated in a risk-unadjusted population of patients undergoing surgery for CCTGA.58,Y8 When a later-rising phase of hazard will become evident in patients operated on in the current era is not yet known.

Hrasko and colleagues suggest that time-related survival is best when a Fontan procedure is performed (100% at 5 years), with lower survival in septated patients undergoing VSD closure (75% at 5 years) and even lower survival in septated patients undergoing tricuspid valve surgery (55% at 5 years).311 It should be emphasized that their patients underwent surgery between 1963 and 1996. Hörer and colleagues found similar long-term outcomes in patients undergoing septation and those undergoing a Fontan procedure.315

Morphologic Left Ventricle Supporting Systemic Circulation

Early (Hospital) Death  Early outcomes appear to be as good or better with more complicated double switch procedures (“anatomic repair”) that assign the morphologic LV to the systemic circulation than with the “physiologic” procedures just described. Jahangiri and colleagues reported no mortality in the anatomic repair group (0 of 19 patients; 0%; CL 0%–10%), and 7% mortality in the physiologic repair group (5 of 70 patients; CL 4%–12%), P = .31

In a group of patients with structurally abnormal tricuspid valves, mortality was 11% (1 of 9 patients; CL 1%–33%) following anatomic repair and 33% (5 of 15 patients; CL 19%–50%) following physiologic repair (P for difference = .2).11
Results reported from 10 single institutional experiences between 1993 and 2002 reveal that early mortality for procedures placing the morphologic LV in the systemic circulation compares favorably with that of simpler, more classic repairs. In these 10 studies, early mortality ranged from 0% to 14%. Each experience was small, with a combined total of 150 patients with 11 early deaths (7.3%; CL 5.1%-10%).12,13,15,K2,R2,S5,S11,S12

Reports between 2002 and 2010 have larger numbers of patients and confirm that early mortality can be low. In three recent large single-institution studies, early mortality was 0% (46 patients; CL 0%-4.0%),14,15 2.1% (1 of 48 patients; CL 0.3%-6.8%),14 and 6.8% (3 of 44 patients; CL 3.0%-13%).15 These studies included both the arterial switch type and the Rastelli type of double switch. In another study focusing on 20 patients with the arterial switch type of double switch only, there was no early mortality.19 Other large series report early mortality of about 15%.57 Most studies show similar early mortality of the two major double switch operations, but Gaies et al. found a difference, with 94% early survival (33 of 35 patients; CL 87%-98%) in the arterial switch type and 77% survival (23 of 30 patients; CL 66%-85%) in the Rastelli type.41

**Time-Related Survival** Recent data suggest midterm survival is excellent. Two studies with follow-up extending to 15 years (mean 5 years) show no intermediate mortality.13,41 Another shows 15-year survival of 75% in patients with the arterial switch type of double switch and 80% in patients with the Rastelli type.58 Still another study of 45 patients (38 underwent the Rastelli type and 7 the arterial switch type) showed survival of 84% at 5 years and 78% at 10 years.60 As with early mortality, most studies show similar time-related survival of the two major double switch operations, but the Gaies group reported a substantial difference, with 10-year survival of 91% in the arterial switch type and 55% in the Rastelli type.41

**Modes of Death**

Some patients die suddenly.58,60 This has even been noted when operation places the morphologic LV as the systemic ventricle,51; however, one large study suggests that it is more common following anatomic repair than physiologic repair.58 Whether this is due to sudden appearance of complete heart block with ventricular asystole or fibrillation or to pacemaker failure or change in conductance of leads is unknown. Well-documented progression of morphologic RV dysfunction and tricuspid valve regurgitation when these structures are in the systemic circulation no doubt play a role, particularly in those dying from low-output state and heart failure.51 Table 55-1 shows cause of death in one series of 151 patients.58

### Incremental Risk Factors for Death

Systemic tricuspid valve regurgitation is a risk factor for death.12,38,58 Studies identifying Ebstein anomaly and tricuspid valve replacement as risk factors are probably identifying the same underlying problem of systemic tricuspid valve regurgitation.12,51 Risk factors for death following anatomic repair have been identified and include left ventricular training using a pulmonary artery band and severe preoperative RV failure.52,58 Inclusion of a bidirectional cavopulmonary anastomosis as part of the repair has a survival benefit.58 Reasons for lower survival in patients with CCTGA than that observed after repair of VSD, AV septal defect, tetralogy of Fallot, or transposition with AV concordant connection are not evident, even after risk adjustment. Speculatively, the major reasons may be abnormalities of the conduction system, imperfection of methods used to prevent and manage heart block, and abnormalities of systemic (right) ventricular function. It follows that patients receiving anatomic repair, although subject to the same conduction risks, would not have the additional risk of the systemic RV. In an analysis of 40 patients with a mean follow-up of 20 years, important regurgitation of the systemic tricuspid valve was found to be the major risk factor for death.50 In another study,31 presence of an abnormal systemic tricuspid valve resulted in early mortality of 33% (5 of 15 patients; CL 19%-50%) when the morphologic RV was assigned to the systemic circulation. Another study examining both anatomic and physiologic repair identified tricuspid regurgitation as a risk factor for physiologic but not anatomic repair patients.58 Subsequent studies show both early and late survival after anatomic repair to be similar to survival following repair of the other index lesions mentioned.15,41,19,51 This improvement is probably due to multiple factors including presence of a systemic LV,

Adapted from Shin’oka and colleagues (Table E1).58
Multivariable analysis indicates that chordal straddling or insertion on the septal crest (usually from the left-sided tricuspid valve) increases the probability of producing complete heart block at the time of VSD repair (Table 55-3). This arrangement may prevent surgeons from placing sutures precisely where they prefer them. Presumably, placing the LV in the systemic circulation should have little effect on these rhythm complications. Malhotra and colleagues noted that 21% of patients developed complete heart block following surgery in a series of 48 double switches. In patients with complete heart block and systemic RV failure, improved ventricular function has been demonstrated in selected individuals by upgrading the pacing system to a biventricular system to achieve cardiac resynchronization.

Development of Tricuspid Valve Regurgitation

Immediately after simple classic repair of CCTGA with VSD, left-sided tricuspid valve regurgitation sometimes appears. Fox and colleagues reported this to have occurred immediately after repair in 6 of 14 patients (43%; CL 27%-60%) in whom it was not present before operation. Westerman and colleagues observed the same phenomenon. Its mechanism is not completely understood, but as best as can be determined, regurgitation does not result from direct damage to valvar tissue or chordae. Rather, its mechanism when the tricuspid valve is abnormal is primarily related to decreased morphologic LV pressure after VSD closure, resulting in shifting of the ventricular septum toward the morphologic LV side. It seems likely a similar mechanism is involved when the tricuspid valve is normal.

Operations assigning the morphologic LV to the systemic circulation result in improved tricuspid valve function, increased experience with the complex procedures involved in anatomic repair, and improved management of conduction problems. In the meta-analysis performed by Alghamdi and colleagues, anatomic repair—in particular anatomic repair of the Rastelli type—had a beneficial effect on early survival compared with physiologic repair.

Reoperation

Reoperation is common after all types of surgery for CCTGA except for the Fontan operation. The morphology of associated cardiac defects and the type of operation both influence the prevalence of reoperation (Fig. 55-20). Common causes for reoperation are those to be expected: heart block, ventricular-to-pulmonary trunk conduit obstruction or regurgitation, and systemic tricuspid valve regurgitation.

Postrepair Complete Heart Block

It was anticipated that a repair (see Technique of Operation earlier) based on secure knowledge of location of the cardiac conduction system would eliminate complete heart block as a complication of VSD repair in patients with CCTGA. Such has not been the case. In all reported series, prevalence has been 15% to 30% (Table 55-2). This is very different from the near-zero prevalence after repair of VSD in hearts with AV concordant connection. Westerman and colleagues observed the same phenomenon. Its mechanism is not completely understood, but as best as can be determined, regurgitation does not result from direct damage to valvar tissue or chordae. Rather, its mechanism when the tricuspid valve is abnormal is primarily related to decreased morphologic LV pressure after VSD closure, resulting in shifting of the ventricular septum toward the morphologic LV side. It seems likely a similar mechanism is involved when the tricuspid valve is normal.

Operations assigning the morphologic LV to the systemic circulation result in improved tricuspid valve function,

Data from McGrath and colleagues.\textsuperscript{1,6}

\textsuperscript{1}Patients with complete heart block before repair were excluded. Excluded also were patients \((n = 9)\) in whom repair did not include either closure of the VSD or an intraventricular tunnel repair, because developed heart block was limited to these two groups.

Key: CCTGA, Congenitally corrected transposition of the great arteries; VSD, ventricular septal defect.

probably for two reasons: the pressure in the morphologic RV is markedly reduced, and the ventricular septum is shifted toward the morphologic RV.\textsuperscript{1,3,12,41} This hypothesis is further supported by the work of Kollars and colleagues, who showed not only that systemic tricuspid valve regurgitation improved by increasing LV pressure with pulmonary artery banding but also that tricuspid regurgitation became worse in patients in whom LV pressure was reduced to less than half of systemic levels with an LV-to–pulmonary trunk conduit.\textsuperscript{110} It also may be associated with development of complete heart block.\textsuperscript{64}

Tricuspid regurgitation may be sufficiently severe to require later valve replacement. Attempts at valve repair when the valve is in the systemic circulation are usually futile.\textsuperscript{1,63} In one series of 52 patients with up to 10 years of follow-up, tricuspid valve regurgitation was severe enough to require reoperation in 12 (24%).\textsuperscript{13} When the RV is placed in the pulmonary circulation, tricuspid valve function typically improves, often without specifically surgically addressing the valve.\textsuperscript{13,15,21,41}

Functional Status

In the study by Malhotra and colleagues in which all patients underwent anatomic repair, 91% were in New York Heart Association (NYHA) class I postoperatively.\textsuperscript{41} Similar functional outcome has been reported by others following anatomic repair.\textsuperscript{\textsuperscript{11}} In the multicenter study of Graham and colleagues of patients with physiologic or no repair, 60% of those with associated defects were in NYHA class I, and 70% of patients without associated defects were in NYHA class I.\textsuperscript{65} Despite these functional class findings, the same study showed that by age 45 years, clinical heart failure was present in 67% of those with associated lesions and 25% of those without associated lesions; moderate or severe systemic RV dysfunction was present in 56% and 32%, respectively.\textsuperscript{65} Hraska and colleagues showed that only 40% of physiologically repaired patients were free of RV failure at 15 years.\textsuperscript{41}

Ventricular Function

The preponderance of evidence suggests that the systemic RV functions abnormally in unoperated patients at rest, even if they are asymptomatic.\textsuperscript{65} If some form of physiologic repair has been performed, these preoperative abnormalities are more severe. Ischemia appears to play an underlying role in deterioration in most cases, along with other hemodynamic stresses such as volume overload from tricuspid regurgitation. Systemic RVs commonly show evidence of deterioration over time. Giardini and colleagues studied 34 patients at a mean age of 25 years with either CCTGA not undergoing anatomic repair or simple TGA following atrial baffles surgery.\textsuperscript{43} The groups were similar. Abnormal myocardial fibrosis, determined by late gadolinium enhancement at MRI, was found...
in 41%. These findings were associated with RV dysfunction, poor exercise tolerance, arrhythmias, and progressive clinical deterioration. However, normal systemic RV systolic function late postoperatively has been found in some patients. The rule is that after physiologic repair, even asymptomatic adult patients demonstrate abnormalities of the systemic RV, including reduced resting and stress ejection fraction, large ventricular volumes, and regional wall motion abnormalities. Asymptomatic patients also demonstrate a neurohormonal profile typical of heart failure. Additionally, systemic RV coronary flow reserve is reduced, even in unoperated patients and those with isolated CCTGA, with both ischemic and persistent perfusion defects.

When surgery involves placing the morphologic LV in the systemic circulation, early and midterm follow-up studies demonstrate both well-maintained LV and RV function. However, late systemic LV dysfunction has been observed, mostly in association with prior LV training and in patients with complete heart block requiring pacemakers.

**INDICATIONS FOR OPERATION**

CCTGA per se is not a definitive indication for a reparative operation. On the other hand, the natural history of the morphologic RV in the systemic circulation presents enough concern that the question of performing a double switch procedure should be left open. When VSD coexists, indications for operation are those for repair of VSD in otherwise normal hearts (see Indications for Operation in Section I of Chapter 35).

When VSD and important pulmonary stenosis coexist, repair may require an allograft-valved extracardiac conduit; surgical indications and staging are therefore the same as described for tetralogy of Fallot with pulmonary atresia (see Indications for Operation in Section II of Chapter 38). When important left-sided tricuspid regurgitation coexists, indications for operation are the same as those described for acquired mitral regurgitation (see Indications for Operation in Section I of Chapter 11). When complete heart block develops, indications and techniques for pacemaker intervention are those described in Technique of Intervention in Section I of Chapter 16.

Certain morphologic characteristics may increase difficulty of the various septation procedures described in this chapter: (1) presence of straddling tricuspid chordae—increasing complexity of the surgery and risk of postoperative complete heart block, (2) AV septal defect, and (3) non-committed VSD with pulmonary stenosis. These, among others, may be considered by some to be indications for a Fontan rather than a biventricular repair. Whatever the initial interventions, patients may ultimately develop a situation in which only cardiac transplantation can be effective.

**SPECIAL SITUATIONS AND CONTROVERSIES**

**Anatomic versus Physiologic Repair**

Definitive data are unavailable to determine whether long-term outcome is better in CCTGA with the morphologic RV or LV in the systemic circulation. A multicenter retrospective study of 167 patients undergoing repair did, however, show that long-term systemic AV valve function and systemic ventricular function were better in patients undergoing a double switch type operation compared with those undergoing physiologic repair (Fig. 55-21). Surgical procedures are simpler technically when the morphologic RV is assigned to the systemic circulation, in theory reducing both short- and long-term complications related to reconstruction. However, available data from the same study indicate that surgically induced arrhythmias and reoperation are not higher in the more complex anatomic repair group (Fig. 55-22). Operative, midterm, and late mortalities following procedures placing the LV in the systemic circulation have been well documented over the past decade and are excellent.

Even prior to 1998, superiority of the anatomic repair was evident. The meta-analysis of 11 different studies (in which all dates of operation were 1998 or earlier) performed by Alghamdi and colleagues showed that anatomic repair of the Rastelli type had superior outcomes to physiologic repair. In a limited study of nine patients who underwent a procedure assigning the morphologic LV to the systemic circulation and six who underwent a procedure assigning the morphologic RV to the systemic circulation, exercise capacity was equivalent, but this does not mean exercise capacity was normal. Other studies testing patients after both anatomic and physiologic repair reveal that oxygen uptake, exercise duration, heart rate responses, and other variables measured are subnormal.

**Left Ventricular Training**

An important variable that must be considered when assessing long-term outcome following the double switch is whether it is necessary to train the morphologic LV with a pulmonary artery band. This situation arises only when the double switch is being considered in patients in whom the LV myocardial mass has involuted because it has been functioning at low pressure—that is, when CCTGA is present without VSD or pulmonary stenosis.

Although definitive evidence is lacking that trained LVs are functionally different from normal, there is concern and some suggestion that when placed in the systemic circulation, involuted LVs trained with a band may not perform as well as those that never involuted. Comparing trained LVs and those not requiring training, Quinn and colleagues showed that the early outcome after the double switch was similar for mortality and LV function, but there was increased risk of LV deterioration and death or transplantation over time in the trained LV group. Lim and colleagues suggest that LV training is a risk factor for death after anatomic repair. However, Bautista-Hernandez and colleagues showed that after anatomic repair, there was no reduction in LV function and no deaths at midterm follow-up in the cohort of patients who had received LV training with a band.

An important factor that limits drawing definitive conclusions about the adequacy of the trained LV is that there are currently no standardized criteria for defining when an LV is trained. Thus, any reduction in function of trained LVs following anatomic repair may represent an intrinsic limitation of the trained LV itself, or the fact that an adequate training protocol was not in place. It is clear that some LVs do not respond to training, and these patients never become candidates for a double switch procedure.
Use of Bidirectional Superior Cavopulmonary Anastomosis

Use of the bidirectional superior cavopulmonary anastomosis with hemi-Mustard atrial baffle, either selectively or exclusively, as part of operations for CCTGA when the morphologic LV is placed in the systemic circulation has a number of specific advantages:

- It may benefit the small or poorly functioning RV.
- It importantly reduces complexity of the atrial baffle procedure.
- It eliminates complications related to the superior limb of the atrial baffle.
- It reduces flow across an RV–pulmonary trunk conduit.
- It likely increases conduit longevity.
The study by Malhotra and colleagues documents that RV–pulmonary artery conduits have increased longevity when a bidirectional superior cavopulmonary anastomosis is used. Lim and colleagues have described improved survival when it is used. In some cases with VSD and moderate pulmonary stenosis, a bidirectional superior cavopulmonary anastomosis may allow use of the small native pulmonary valve as an adequate structure for RV outflow, avoiding a prosthetic conduit. In this operation, the native pulmonary valve and anulus, in continuity with the pulmonary trunk, are removed from the LV outflow tract intact and transposed onto the RV infundibulum. The resulting opening in the LV outflow tract is closed with a patch, and the LV is baffled to the aorta with an intraventricular tunnel. The bidirectional cavopulmonary anastomosis and hemi-Mustard can also be helpful when constructing a full atrial baffle is difficult, such as in patients with juxtaposition of the ventricular apex and inferior vena cava, as found in mesocardia or dextrocardia with situs solitus. The bidirectional superior cavopulmonary anastomosis can also be used in specific cases when physiologic repair is performed.

Fontan versus Intracardiac Repair

After weighing the benefits and risks of performing the complex procedures described in this chapter versus those of a Fontan operation, one study concludes that the Fontan operation is advisable. Many surgeons disagree, and recent outcomes after any of the various procedures that use the double switch concept or physiologic repair concept support their position. Reoperation is almost certainly higher after operations (both anatomic and physiologic) that separte the heart in CCTGA than for the Fontan, at least up to midterm follow-up (see Fig. 55-20).

Neonatal Congenitally Corrected Transposition of the Great Arteries without Associated Cardiac Anomalies

The era of anatomic repair presents an interesting possibility for patients with CCTGA without associated lesions. Compared with normal control subjects, these patients are considered to have a reasonable prognosis without intervention, but a number of studies document that abnormal systemic RV function and even RV failure with systemic AV valve regurgitation are much more likely to occur over time, usually over decades. The question arises whether anatomic repair would benefit them. Although there is no evidence available to answer this question, it has been posed by many in the field.

If it is hypothesized that anatomic repair is beneficial, it can be argued that the neonatal period would be the optimal time for surgery to take advantage of the prepared LV. Allowing the LV to involute, followed by retraining with a pulmonary artery band, before anatomic repair is much less attractive because of concerns about the function of a retrained LV. To date, there are no reports of elective neonatal anatomic repair in asymptomatic patients with this anatomic profile. Bautista-Hernandez and colleagues report successful neonatal anatomic repair in two patients with Ebstein-like changes of the systemic AV valve and severe regurgitation with severe heart failure.

An alternative to neonatal anatomic repair in asymptomatic patients without associated cardiac anomalies is neonatal placement of a band, thereby preventing LV involution. Metton and colleagues have placed bands in 11 asymptomatic neonates and infants with isolated CCTGA. Some degree of systemic AV valve regurgitation was present preoperatively in eight patients and depressed systemic RV function in two. The band procedure was performed without mortality, but five patients required inotropic support. There was one late death. In the remainder, there was no progression of systemic AV valve regurgitation in seven and improvement in three. Only one patient has undergone anatomic repair, successfully. The others are candidates, having preserved LV mass and function.

Section II Other Forms of Atrioventricular Discordant Connection

DEFINITION

Atrioventricular discordant connection is a congenital cardiac anomaly in which the right atrium connects to the LV and the left atrium connects to the RV (see “Cardiac Chambers and Major Vessels” in Chapter 1). When AV discordant connection occurs in atrial situs solitus, there is ventricular L-loop (left handedness of the ventricular internal architecture), when it occurs in atrial situs inversus, there is ventricular D-loop (right handedness).

Conditions with AV discordant connection (other than CCTGA, covered earlier) are discussed together in this section. Were accumulated experience large enough, each of the other subsets would deserve separate chapters, just as in the setting of AV concordant connection.

HISTORICAL NOTE

History of development of knowledge and surgical treatment of CCTGA is discussed in Section I. The time of first recognition of AV discordant connection associated with double outlet right ventricle (DORV) is not clear, but as late as 1960 the entity was not distinguished from DORV with concordant AV connection. Ruttenberg and colleagues described DORV coexisting with AV discordant connection in 1964. In 1965, this type of DORV (with VSD and pulmonary stenosis) was recognized and repaired using an extracardiac conduit for rerouting pulmonary blood flow, perhaps for the first time. Double outlet left ventricle (DOLV) associated with AV discordant connection is rare; the first surgical case was reported in 1976 by Brandt and colleagues. Isolated ventricular inversion was named by Van Praagh in 1966 when he described one such case, but a similar malformation had been reported by Ratner, Abbott, and Beattle in 1921 and by Lev and Rowlett in 1961. In 1975, Quero-Jimenez and colleagues reviewed six reported cases, as noted in Section 1 of this chapter, the adjectives left and right used to modify atrium or ventricle always mean morphologically right or left. Position of the chamber is referred to as right-sided or left-sided.
including two of their own.\textsuperscript{Q1} Isolated atrial inversion was named when the first such case was reported in 1972.\textsuperscript{C6}

**MORPHOLOGY**

Among hearts with AV discordant connection, there is great variability in ventriculoarterial connections and in many other morphologic details.\textsuperscript{A4}

**Ventricular Architecture**

The ventricles are said to be inverted, but because many ventricular positional anomalies occur, the term ventricular inversion is not very useful; it is necessary to describe the internal architecture of each ventricle more specifically. A convenient way of doing this is with Van Praagh's terms ventricular D-loop and ventricular L-loop, defined in Chapter 1 (see “Situs of the Ventricles” under Terminology and Classification of Heart Disease in Chapter 1), or right handedness and left handedness,\textsuperscript{C9,Q1,V1,V6} also defined in Chapter 1.

**Ventricular Position and Rotation**

In patients with atrial situs solitus, the RV is generally left sided and the LV lies side by side and to the right of it. The entire length of the ventricular septum is usually visualized in profile in an anteroposterior view during diagnostic imaging. However, there are variations in anterosuperior orientation of the ventricles and variations in their rotation (see “Cardiac and Arterial Positions” under Terminology and Classification of Heart Disease in Chapter 1).

**Positional Anomalies**

An extreme variation of anterosuperior position occurs in so-called superior-inferior ventricles (“over-and-under” or “upstairs-downstairs” ventricles). The septum is not vertically oriented, as is usual in AV discordant connection, but horizontal, and the LV lies inferiorly and RV superiorly. This may have been described first by Kinsley and colleagues.\textsuperscript{E3} When ventricles are positioned in this manner, there is usually AV discordant connection, an inlet VSD, and DORV.\textsuperscript{L3,E4} One chamber may be hypoplastic, and there may be AV valve straddling. Rarely, superior-inferior ventricle position is associated with AV discordant connection and DORV (see “Double Outlet Right Ventricle with Superior-Inferior Ventricles” under Morphology in Chapter 53).

**Rotational Anomalies**

When rotational anomalies are present, even more bizarre situations occur. Although the LV inlet portion generally remains on the right side in patients with atrial situs solitus, trabecular and outlet portions may be left sided and present a confusing picture.\textsuperscript{A9,V3} Generally, however, the ventricular septum is in the coronal plane, the LV is posterior, and the RV anterior. In the domain of these extreme rotational anomalies, criss-cross pathways occur in which inflow pathways of the ventricles appear to cross rather than being parallel.\textsuperscript{A15,F3,F4,S14,T6} Then the question arises as to whether an AV discordant connection necessarily implies ventricular L-loop (or left handedness) in atrial situs solitus, and D-loop or (right handedness) in atrial situs inversus. In this text, the assumption is made that it does, although this may not always be the case.\textsuperscript{D12}

**Ventricular Size**

Varying degrees of hypoplasia of the left-sided RV may be present.\textsuperscript{E3} When the ventricles are in a superior-inferior position, the LV may be hypoplastic. Ventricular hypoplasia is frequently associated with straddling and overriding of the AV valve of the hypoplastic ventricle.

**Cardiac Position**

Dextrocardia occurs in about 25% of cases with atrial situs solitus, and rarely levocardia exists when the atrial situs is inverted.\textsuperscript{C2}

**Ventriculoarterial Connection**

**Discordant Connection**

The morphology of congenitally corrected transposition of the great arteries (AV discordant connection and ventriculoarterial discordant connection) is described in Section I.

**Double Outlet Right Ventricle**

Double outlet left-sided RV may coexist with situs solitus and AV discordant connection (L-loop), and in nearly all cases VSD and pulmonary stenosis coexist. Because the left-sided RV is the systemic ventricle, cyanosis is not a necessary result of the ventriculoarterial connection, but of associated pulmonary stenosis. The apex of the heart may point to the right (dextrocardia with atrial situs solitus and ventricular L-loop).\textsuperscript{E4} The aorta is usually in L-malposition but may be in any position. The VSD is usually very distal in the septum and beneath the adjacent great arteries (usually pulmonary) but can be anywhere.

The pulmonary trunk is not in a wedged position. Probably related to this, location of the conduction system tends to be different from that in corrected transposition (see “Atrioventricular Node and Bundle of His” later).\textsuperscript{L7} This entity is closely related to corrected transposition with VSD in which the pulmonary trunk partially overrides the VSD and partly arises over the left-sided RV. Corrected transposition is the appropriate diagnosis when there is fibrous continuity between the pulmonary and mitral valves. When there is lack of continuity between these valves, there is subpulmonic conus muscle, and the case is assigned the diagnosis of AV discordant connection with DORV. In most cases of DORV and AV discordant connection, the pulmonary trunk is nearly completely over the left-sided RV.

**Double Outlet Left Ventricle**

DOLV may coexist with AV discordant connection.\textsuperscript{B17,S12,V5} Because the right-sided LV is the pulmonary ventricle, cyanosis is the necessary result. The VSD is in a position similar to that in DORV with AV discordant connection, but the aorta overrides the VSD to such an extent that it emerges wholly or in large part from the right-sided LV. This may occur in patients with atrial situs inversus.\textsuperscript{A3}

**Concordant Connection**

Ventriculoarterial concordant connection is unusual in AV discordant connection and is of two types: isolated ventricular inversion\textsuperscript{Q1,V2} and isolated atrial inversion.\textsuperscript{C6} The systemic and pulmonary circulations are parallel, and the physiology is that of ordinary transposition of the great arteries (see “Essentially
Intact Ventricular Septum [Poor Mixing] under Clinical Features and Diagnostic Criteria in Chapter 52), and cyanosis results.

In isolated ventricular inversion with atrial situs solitus, as originally defined,\(^{22}\) the aortic origin lies to the right and posterior to the pulmonary trunk origin, and there is aortic-mitral fibrous continuity and a muscular subpulmonary infundibulum (conus), as in the normal heart. However, there is AV discordant connection, and the aorta arises from a right-sided LV; for this reason, both great arteries are parallel. Other variations exist and are due to positioning of the great arteries and presence or absence of a subaortic and subpulmonary conus.\(^{23}\) A VSD may be present; pulmonary stenosis is generally absent.\(^{24}\) When there is situs inversus, a mirror-image pattern occurs.\(^{21,23}\)

As in CCTGA, the inverted ventricles in patients with isolated atrial or ventricular inversion usually lie side by side with the ventricular septum in a sagittal plane and have a coronary artery distribution pattern similar to that in CCTGA (see Morphology in Section I). It is important surgically to note that in isolated ventricular inversion, the right-sided left coronary artery does not cross in front of the pulmonary outflow, so its enlargement anteriorly is feasible. Although Losekoot and colleagues have suggested that the conduction tissue will be as for CCTGA,\(^{25}\) position of cardiac conduction tissue in this condition is at present uncertain.

In isolated atrial inversion, there is atrial situs inversus with ventricular D-loop and dextrocardia with fibrous aortic-mitral continuity and a subpulmonary conus (Fig. 55-23, A, model 3). However, in a case reported by Clarkson\(^{16}\) (Fig. 55-24), the great arteries crossed in a virtually normal fashion, with the morphologic RV lying to the right and posterior to the morphologic LV. The unusual feature of this heart was viscerocorial discordance, with abdominal organs in situs solitus position and the atria (and their venous connections) inverted. This rare additional feature did not alter the circulatory pathways from those present in isolated ventricular inversion.

In addition to the heart just described, there are others with identical connections but conal development that is the reverse of that described in isolated ventricular inversion (see Fig. 55-23, B, models 2 and 3). That is, the aorta arises from the morphologic LV and lies, in a situs solitus heart, to the right of the pulmonary trunk, but it is separated from the mitral valve by a muscular subaortic conus. Under these circumstances, there is usually pulmonary-tricuspid fibrous continuity, but a subpulmonary conus may also (rarely) be present. These hearts can be considered to have anatomically corrected malposition of the great arteries,\(^{22}\) or contrariwise (as in this text) a variant within the general category of AV discordant connection and ventriculocardiacal concordant connection.

Atrioventricular Node and Bundle of His

The AV conduction tissue is abnormal in most patients with AV discordant connection and typically so in the subset of CCTGA with atrial situs solitus, where an anterior AV node gives rise to the bundle of His (see “Atrioventricular Node and Bundle of His” under Morphology in Section I).

When DORV coexists and left-sided RV wedging of the pulmonary trunk is not present, both anterior and posterior AV nodes usually persist, connected by a sling of conduction tissue around the VSD, which continues on as the branching bundle.\(^{17}\) However, only the anterior AV node or the regular
posterior one gives rise to the penetrating bundle. This variability may predispose patients to surgically induced complete heart block.

When there is DOLV, the AV node connecting to the penetrating bundle is usually the anterior one. Duplicated, or twin, AV nodes may exist, especially in the presence of malaligned AV septal defect. Reciprocating tachycardia may then be present. Position of conduction tissue is uncertain in patients with isolated ventricular or atrial inversion.

Accessory Conduction Pathways

Kent bundles may occur, particularly in those with CCTGA, and may give rise to preexcitation and the Wolf-Parkinson-White syndrome (see “Wolf-Parkinson-White Syndrome” in Section III of Chapter 16). Kent bundles may be in the posterior wall of the left-sided RV or posterolateral wall of the right-sided LV. It is presumed by Harrati and colleagues that the relative frequency of these findings is associated with the high prevalence of Ebstein anomaly of the left-sided tricuspid valve in these cases.

Coronary Arteries

Coronary arteries are abnormal, but appropriate terminology for describing them is controversial. The simple terms right-sided and left-sided seem best. The right-sided coronary artery, arising from the right posterior coronary sinus and analogous to the normal left coronary artery, gives rise to the anterior descending coronary artery, coursing from right to left, and circumflex artery. The left-sided coronary artery arises from the left posterior aortic sinus and passes around the left-sided tricuspid orifice, usually to become the posterior descending artery on the back of the heart.

Atroventricular Valves

The right-sided mitral valve typically has two leaflets and usually is in fibrous continuity with the pulmonary valve. As in the normal heart, it has no septal attachments but rather has typically paired papillary muscles.

The left-sided tricuspid valve consists of three leaflets. The septal leaflet, and often the posterior (inferior) leaflet, is displaced more than normally into the ventricle, but the deformity is not typically an Ebstein anomaly of the left-sided tricuspid valve in these cases.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

The clinical features of patients with AV discordant connection vary widely, depending on ventriculoarterial connection and associated cardiac anomalies, most commonly VSD or pulmonary stenosis. Thus, there is no typical clinical picture.

Double Outlet Right Ventricle and Double Outlet Left Ventricle

There is no characteristic presentation of either DORV or DOLV coexisting with AV discordant connection. However, because with DORV there is usually coexisting pulmonary stenosis, cyanosis is usually evident; and because in this setting with DOLV the aorta arises from the ventricle receiving systemic venous blood (see Morphology earlier in this section), cyanosis is evident. Diagnosis is made by the same methods as described for CCTGA (see Section I). Echocardiography can usually define the morphology definitively, even in very complex cases.

Isolated Ventricular or Atrial Inversion

Patients present similarly to those with complete transposition of the great arteries (see Clinical Features and Diagnostic Criteria in Chapter 41). When the ventricular septum is intact, there is severe cyanosis in infancy; when there is a large VSD, moderate cyanosis is accompanied by heart failure and cardiomegaly. Pulmonary stenosis adds to degree of cyanosis. Diagnosis is made by the same methods as described for corrected transposition (see Section I). Cineangiography has been important in the past for definitive diagnosis (Fig. 55-25), but now two-dimensional echocardiography is extremely reliable, even in this complex setting.

NATURAL HISTORY

Most of the information concerning natural history drawn from patients with CCTGA is discussed in Section I. Other morphologic findings may affect natural history. For example, patients with situs inversus are more likely to have DORV and tetralogy of Fallot physiology, but less likely to have systemic AV valve regurgitation and heart block than patients with situs solitus.

TECHNIQUE OF OPERATION

Except for CCTGA, most malformations associated with AV discordant connection require complex and often unique operations, and only their general nature can be described.
is less complete. Further, there is controversy as to whether a completely intraventricular repair is adequate or whether a valved extracardiac conduit between LV and the pulmonary trunk is usually necessary.\textsuperscript{34,47} In part because of the data presented by Tabry and colleagues\textsuperscript{71,75} and in part because important subpulmonary stenosis is usually present, use of a valved extracardiac conduit has been preferred. However, the concepts underlying the Lecompte, or REV (réparation à l’étage ventriculaire), operation (see “Lecompte Intraventricular Repair” under Technique of Operation in Chapter 53) may well be applicable in this and other subsets of AV discordant connection and would avoid use of an extracardiac conduit. Also, various double switch operations may be applicable (see Technique of Operation in Section I).

**Double Outlet Left Ventricle**

The preferred surgical option consists of leaving the aorta with the right-sided LV, connecting pulmonary trunk to RV with a conduit, and performing an atrial switch operation\textsuperscript{812} utilizing the double switch concept described under Technique of Operation in Section I.

The alternative physiologic repair, an intraventricular tunnel repair, may be used (see “Intraventricular Tunnel Repair of Simple Double Outlet Right Ventricle” in Chapter 53) and constructed so as to conduct blood from the left-sided RV (in atrial situs solitus) through the VSD and then to the aorta. Sutures between the polyester patch for the tunnel and the ventricular septum are placed with due regard for location of the conducting tissue (see “Double Outlet Right Ventricle and Pulmonary Stenosis” earlier in this section). On occasion, it may be possible to do this repair without obstructing LV access to the pulmonary trunk. However, if access is compromised or if pulmonary stenosis is present, an allograft-valved extracardiac conduit is placed between the LV and the pulmonary trunk (see Technique of Operation in Section I) or a Lecompte procedure (REV) performed (see “Lecompte Intraventricular Repair” under Technique of Operation in Chapter 53).

**Isolated Ventricular or Atrial Inversion**

When the ventricular septum is intact, balloon septotomy is required in infancy, followed by an atrial switch operation (see Technique of Operation in Chapter 52). This returns the circulation functionally and anatomically to normal, because the LV is the systemic ventricle.\textsuperscript{59}

When there is a large VSD, it is closed through the left-sided RV in a fashion similar to that for primary VSD (presuming the bundle lies on the LV side) or from the right atrium.\textsuperscript{82} An atrial switch operation is then performed.\textsuperscript{117}

**Placing Epicardial Pacemaker Leads**

When complete heart block is present preoperatively or develops intraoperatively, and when in sinus rhythm the PR interval is long, permanent epicardial atrial and ventricular pacemaking leads are placed and connected to a permanent pacemaker pulse generator placed subcutaneously (see Technique of Intervention in Section I of Chapter 16 for the details of the technique).
**SPECIAL FEATURES OF POSTOPERATIVE CARE**

Patients are managed with protocols generally used after cardiac surgery (see Chapter 5). Particular attention is paid to cardiac rhythm. When complete heart block is present, AV sequential pacing is advantageous to cardiac output and therefore is used routinely.

**RESULTS**

**Survival**

**Early (Hospital) Death**

Hospital mortality after intracardiac repair of coexisting cardiac anomalies in patients with CCTGA was discussed in detail in Section I. In series reported prior to 1985, mortality was generally higher in patients with AV discordant connection and other types of ventriculoarterial connections such as DORV, DOLV, and isolated ventricular inversion.\textsuperscript{13,31} This is probably related to complexity of the operations required for these conditions, often involving intraventricular rerouting and extracardiac conduits. However, increased knowledge about congenital heart disease, improved surgical techniques, and improved techniques for cardiopulmonary bypass and myocardial management currently allow lower mortalities.\textsuperscript{13,14,39,56,58,59,12,14} This has been verified by recent studies indicating that when either classical repair techniques or the double switch concept are used, outcomes are comparable whether the associated morphology is transposition (CCTGA) or one of the other ventriculoarterial connections.\textsuperscript{81,13,38}

**Time-Related Survival**

Among all patients with AV discordant connection undergoing intraventricular repair prior to 1985, long-term survival has been compromised by a slowly rising late phase of hazard.\textsuperscript{36} The long-term outcome concerns are supported by data from Yeh and colleagues, who show survival of 48% at 20 years.\textsuperscript{34} It is not yet certain that deaths occurring late postoperatively can be prevented as effectively as those occurring early after operation, nor has it yet been demonstrated that the double switch concept benefits long-term outcome.

**Modes of Death**

In the past, most patients dying after early operation had acute or subacute cardiac failure.\textsuperscript{36} Although abnormal ventricular architecture probably contributed to this, current methods, including improved methods of myocardial management, should considerably reduce the prevalence of this mode of death.

Some deaths late postoperatively have been sudden.\textsuperscript{36,48,56} Whether this is due to sudden appearance of unidentified complete heart block with ventricular asystole, ventricular fibrillation related to myocardial dysfunction, or pacemaker failure is unknown.

**Incremental Risk Factors for Death**

Probably AV discordant connection itself is a risk factor for death after intracardiac repair (see “Incremental Risk Factors of Death” in Section I). This is the result of abnormal ventricular architecture (see “Ventricular Function” under Natural History in Section I), abnormalities in the conduction system, problems associated with the tricuspid valve being a part of the systemic circulation, and relative unfamiliarity of even experienced congenital heart surgeons with approach and exposure to the surgical procedures required for this type of congenital heart disease.

Although early-era experience suggested that ventriculoarterial connections other than discordant ones (CCTGA) were risk factors for premature death,\textsuperscript{36} more recent experience does not support the position that ventriculoarterial connections other than discordant ones are risk factors.\textsuperscript{13,14,39,52}

**Postrepair Complete Heart Block**

It is disappointing that reasonably secure knowledge of the location of the bundle of His has not allowed complete heart block to disappear as a postoperative complication of repairing a VSD or constructing an intraventricular tunnel. There is about a 20% risk of developing complete heart block after repair of a VSD (Table 55-4; see also “Postrepair Complete Heart Block” under Results in Section I).

\(\textsuperscript{a}\)Congenitally corrected transposition of the great arteries.

\(\textsuperscript{b}\)Isolated ventricular inversion.

\(\textsuperscript{c}\)Heart transplant patient not considered at risk.

Key: CL, 70% confidence limits; DOLV, double outlet left ventricle; DORV, double outlet right ventricle; SORV, single outlet right ventricle.
Abandoning ECG monitoring of each stitch\textsuperscript{52} in favor of a repair\textsuperscript{29} based on knowledge of morphology during cold cardioplegic cardiac arrest has not increased the risk of heart block.\textsuperscript{36} Prevalence of surgically induced heart block was not demonstrated to have been reduced by electrophysiologic mapping at surgery.\textsuperscript{28,29}

Risk factors for developing complete heart block are discussed in Section I of this chapter.

Other Outcome Events

The discussions of developing left-sided tricuspid valve regurgitation, functional status, and ventricular function after repair of CCTGA (see Results in Section I) apply to all subsets of patients with AV discordant connection undergoing repair. When indications for cardiac transplantation are present, the procedure should be carried out.\textsuperscript{19,23}

Outcome of valved extracardiac conduits frequently used in repairs for this group of anomalies appears to be the same as for their use in general (see “Reoperations” under Results in Section II of Chapter 38).

INDICATIONS FOR OPERATION

The diagnoses of DORV, DOLV, and isolated ventricular or atrial inversion in patients with AV discordant connection are indications for operation, but each has special considerations.

Isolated ventricular and atrial inversion have un repaired pathophysiology and prognosis similar to that of patients with complete transposition of the great arteries (see “Essentially Intact Ventricular Septum [Poor Mixing]” in Chapter 52). Therefore, repair is indicated, and it should be performed as early in life as possible.

DORV and DOLV in the setting of AV discordant connection usually require a valved extracardiac conduit (or the Lecompte operation [REV]) for repair. Thus, there are advantages to deferring repair until age 3 to 4 years when an adult-sized conduit can be inserted, even though a palliative shunt or pulmonary trunk banding may be required in the interim. Alternatively, primary repair may be done in early life, accepting the likelihood of early conduit replacement.

Knowledge of the concepts and techniques of Lecompte and others (see “Lecompte Intraventricular Repair” under Technique of Operation in Chapter 53) may, in some cases, allow repair without an extracardiac conduit, and this permits repair earlier in life.

When one ventricle is importantly hypoplastic, a Fontan operation can provide the same result as in other single-ventricle patients (see Chapter 41).\textsuperscript{55}

When myocardial function has deteriorated severely, cardiac transplantation can provide the same result as in patients with AV concordant connection. Abnormal positions of the great arteries are not contraindications.

SPECIAL SITUATIONS AND CONTROVERSIES

Many of the controversies surrounding management of CCTGA apply to all subsets of AV discordant connection (see Special Situations and Controversies in Section I).

Intraoperative Electrophysiologic Mapping

The bundle of His can often be identified during cardiac operations by electrophysiologic mapping techniques\textsuperscript{1,13,22} that usually (but not always) allow localization of the bundle and, by implication, locus of the AV node. However, the procedure is cumbersome surgically because the heart must be open but perfused and beating during mapping, which means the patient must be on CPB at a normal or near-normal temperature with the aorta not clamped for more than a few minutes (unless controlled aortic root perfusion is used during mapping). Risk of air embolization exists, and the CPB time is prolonged by 5 to 20 minutes. In the Mayo Clinic\textsuperscript{25} and UAB experiences,\textsuperscript{28} mapping did not reduce prevalence of complete heart block during VSD repair in patients with CCTGA, so intraoperative mapping is not routinely used at present.

Routine Placement of Permanent Epicardial Pacemaker Leads

A selective approach to placing permanent epicardial pacemaker leads is followed, but some prefer to routinely place such leads. Should heart block develop, the transvenous route of placement (usually through the subclavian vein\textsuperscript{113}) is simple. Difficulty with stability of the intraventricular endocardial pacemaker lead has not been encountered, despite the relatively smooth interior of the right-sided morphologic LV.\textsuperscript{22} Placing prophylactic epicardial myocardial leads at operation without connecting them to a pacemaker pulse generator would seem irrational, so unless a clear indication of need exists, this appears to be unwise. One important indication for placing prophylactic epicardial leads is if the cardiac repair involves use of a bidirectional cavopulmonary anastomosis, because transvenous access is not possible.

Double Inlet Ventricle and Atretic Atrioventricular Valve

**Definition**
Double inlet ventricle is a congenital cardiac malformation in which both atria connect to only one ventricular chamber by either two separate atrioventricular (AV) valves or a common AV valve. Closely related to double inlet ventricle are cardiac malformations in which both atria connect to only one ventricular chamber because of atresia of one AV valve that is imperforate or absent. As a group, double inlet ventricles and those with an atretic AV valve are appropriately considered as having a single ventricle or univentricular AV connection, although these phrases are not appropriate for describing morphology of an individual heart.\(^4\)

The ventricular mass in these settings rarely consists only of a solitary ventricle. When, as is usual, there are two ventricles, one is usually incomplete (rudimentary) and hypoplastic. Often the incomplete ventricle is connected to an atrium by overriding of an AV valve. Such arrangements are termed double inlet ventricle only if more than 50% of the overriding valve lies over the main (dominant) ventricle.

Classic tricuspid atresia (univentricular AV connection with atrial situs solitus, ventricular D-loop, single inlet left ventricular main chamber, right-sided AV valve [tricuspid] atresia, and ventriculoarterial [VA] concordant or discordant connection)^7,8,4^ is separately discussed in Chapter 41.\(^1\) Most

---

^1^The adjectives left and right used to modify atrium or ventricle mean morphologically left or right. Position of a chamber or valve is referred to as right sided or left sided.
morphologic variants of left-sided AV valve (mitral) atresia with patent aortic outlet are included in this chapter. Mitral atresia in association with either aortic atresia or aortic stenosis, intact ventricular septum, and concordant AV and VA connections represent two of the four classic morphologic forms of hypoplastic left heart physiology and are discussed in Chapter 49.

HISTORICAL NOTE

One of the earliest descriptions of a variety of this congenital anomaly was by Holmes, who in 1824 noted that it was intermediate between a normal heart and one with a solitary ventricular chamber.1 He is believed that Peacock described a heart with “both auricles opening into the left ventricle” in 1854. Rokitansky described and illustrated a case of double inlet left ventricle in 1875, as did Mann in 1907, describing the heart as cor triloculare biaatriatum.2,3 Taussig described “single ventricle with a diminutive outlet chamber” in 1939.4 Lev and colleagues have listed a number of other descriptions of “single (primitive) ventricle” that were published more than 100 years ago.5,6

An important contribution by Van Praagh and colleagues in 1964 at the Mayo Clinic was clear definition of the entity as one in which both AV valves empty into the same ventricle.7 About the same time, Elliott and colleagues expressed the view, now accepted, that hearts with atresia of one AV valve (and thus a single AV valve) have much in common with hearts with double inlet ventricle.8,9 Anderson and colleagues introduced the phrase univentricular AV connection to collate this group of malformations.10,11,12

Lev clearly established as a different entity hearts with a huge ventricular septal defect (VSD) or common ventricle, in which one side of the common chamber was morphologically right ventricle and the other left ventricle; he thereby excluded them from the single-ventricle category.13,14

Surgical palliation of double inlet ventricle without pulmonary stenosis began with the original description of pulmonary trunk banding by Muller and Damman in 1952.15,16 Palliation of double inlet ventricle with pulmonary stenosis has as its basis the original Blalock-Taussig shunt; its application to patients with double inlet ventricle and pulmonary stenosis was only a matter of time.17,18 Redo and colleagues may have been the first to show the favorable effect of a Blalock-Hanlon atrial septectomy in patients with left-sided (mitral) valve atresia.19

Septating the main chamber to establish two circulations in series emerged from the Mayo Clinic experience of unexpectedly encountering a patient with double inlet ventricle in 1956.20 Preoperative diagnosis was corrected transposition with VSD, but correct diagnosis was made after opening the ventricle. Septation was accomplished, but the patient died about 6 months after operation, probably during a Stokes-Adams episode. This concept lay dormant for some years, but in 1972 it was further developed by Sakakibara and colleagues and in 1973 by Edie, Malm, and colleagues, who reported four successful septation repairs.21,22 Three long-term survivors of septation were reported in 1973 by Arai, Sakakibara, and colleagues, and one was reported by Ionescu and colleagues.23,24 McGoone, Danielson, and colleagues began to report successful results from the Mayo Clinic about this same time.25 The right atrial approach to septation was suggested and applied by Doty and colleagues in 1979.26

A different surgical concept—using the main (dominant) ventricular chamber for generating systemic blood flow and allowing the via a to the systemic venous system to generate pulmonary blood flow—was stimulated by the work of Fontan and Baudet (published in 1971 and known as the Fontan operation, Table 1)27 and by the work of Kreutzer and colleagues.28 Application of this concept to surgical treatment of double inlet ventricle was reported by Yacoub and Radley-Smith in 1976.29

Subaortic stenosis became apparent as a major problem when experience with the Fontan operation increased during the early 1970s.30,31 In 1973, Neches and colleagues applied the concept of placing the main chamber in direct communication with the aorta by performing an anastomosis of pulmonary trunk to aorta.32 Others have accomplished this by an anastomosis of the proximal segment of the divided pulmonary trunk to the side of the ascending aorta, a part of a Damus-Kaye-Stansel (DKS) operation.33,34,35 This concept has been revitalized more recently by extensive augmentation of the usually hypoplastic aortic arch in conjunction with the DKS operation in the Norwood I operation and by using the arterial switch operation for this purpose, first by Freedom, Williams, Trusler, and colleagues in 1980 and in neonates by Karl and colleagues in 1991.36,37,38 Penkoske and colleagues approached the problem directly by enlarging the VSD in 1984.39

Application of cardiac transplantation to this group of patients was a natural evolution in managing patients with univentricular AV connections and myocardial failure.

MORPHOLOGY

Generalizations

Ventricular Mass

The main (dominant) chamber making up the ventricular mass in double inlet ventricle with two ventricles may have a left ventricular internal architecture, a right ventricular internal architecture, or an indeterminate architecture. Main chamber volume is largest when there is no pulmonary stenosis but considerably smaller when pulmonary stenosis is present.41 This is related to the fact that main chamber volume is positively correlated with pulmonary-to-systemic flow ratio (Qp/Qs).42 The nondominant, incomplete (rudimentary) hypoplastic chamber, when present, is always opposite architecture to the main chamber. Ventricular topology in double inlet ventricles may be either right-handed (D-loop), left-handed (L-loop), or indeterminate (Tables 56-1 and 56-2). (See “Symbolic Convention of Van Praagh” under Terminology and Classification of Heart Disease in Chapter 1.)43

The nondominant chamber is called incomplete (or rudimentary) because it lacks one or more of its component parts, usually the inlet portion but occasionally also the outlet, leaving only the apical trabeculated part. The incomplete chamber is always smaller than the dominant chamber and is connected to the dominant chamber by a VSD. The VSD is sometimes called a bulboventricular foramen, but this term applies only when the incomplete chamber is of right ventricular morphology. Rarely, such as when there is double inlet to one chamber and double outlet from the other, both chambers are incomplete. The ventricular septum is malaligned

Modified from Kitamura and colleagues.55 Key: CILV, common inlet left ventricle; CIRV, common inlet right ventricle; DIRV, double inlet right ventricle; DILV, double inlet left ventricle; DOLV, double outlet left ventricle; DORV, double outlet right ventricle; PA, pulmonary arteries; SORV, aorta arising from right ventricle with pulmonary atresia.

and incomplete in nearly all hearts with double inlet ventricle, or is completely absent.

Some consider a solitary ventricle with double inlet to be an indeterminate ventricle, and some consider it to be a right ventricle.53,54

Atria

Any type of atrial situs can be present. However, with double inlet left ventricle, there is usually atrial situs solitus, and with double inlet right and indeterminate ventricles, about half have situs solitus and half have a heterotaxy pattern, right atrial isomerism predominating (see Chapter 58).58 Situs inversus (mirror image) is unusual (see Tables 56-1 and 56-2).

Atrioventricular Connection

There are usually two perforate AV valves positioned entirely in the dominant ventricle. Their morphologic characteristics are frequently indeterminate, neither tricuspid nor mitral, and it is therefore best to call them left-sided (draining the
Coronary Arteries
Terminology of the coronary artery branches is arguable. Left and right coronary arteries usually arise from the two aortic sinuses facing the pulmonary trunk. There are usually prominent descending branches (encircling coronary arteries) that indicate points of attachment of septum to free ventricular wall, and therefore the boundaries of the incomplete ventricle.

Ventriculoarterial Connections
VA connections can be of any type, except in the case of a solitary ventricle, where there can only be a single or double outlet. In double inlet left ventricle, the most frequent connection is discordant, with aorta and subaortic incomplete right ventricle (outlet chamber) to the left, but sometimes to the right, of the pulmonary trunk; concordant, double outlet, and single outlet connections occur (Table 56-3).

Conduction Tissue
Morphology of the AV node and conduction system is abnormal. Position of the AV node is determined primarily by whether the ventricular septal remnant reaches the crux (see “Atrophicventricular Node” under Conduction System in Chapter 1). From the surgeon’s standpoint, it is important to know that the AV node can be anywhere around the perimeter of the right-sided AV valve.

Types
Double Inlet Left Ventricle
In double inlet left ventricle, the most common double inlet connection, the dominant ventricle is of left ventricular morphology. Apical trabeculations beyond insertions of the papillary muscles display a delicate criss-cross pattern. The septal surface is typically smooth in its superior half, and the crescentic margin bounding the VSD is smooth (Fig. 56-3). VSD morphology, however, can be variable. Of 46 patients with double inlet left ventricle carefully evaluated by Bevilacqua and colleagues, 24 had VSDs separated from the semilunar valves and completely surrounded by muscle (muscular defects), 19 had VSDs adjacent to the anterior semilunar valve (subaortic defect) in association with malalignment or...

Modified from Uemura and colleagues.\(^{U1}\)
\(^a\)For overriding of the aortic or pulmonary valve, the so-called 50% rule was applied.
Key: LV, Left ventricle; RV, right ventricle.

Figure 56-3  Interior view of specimen of double inlet left ventricle. Right-sided atrioventricular valve (RAV) is larger than the left-sided one (not completely visualized). The large ventricle has left ventricular morphology, with fine trabeculations near the apex and a smooth surface to the superior half of the ventricular septum (VS). There is a smooth crescentic lower margin bounding the ventricular septal defect. The incomplete right ventricle (RV) lies superiorly and leftward (L-loop). Key: LAV, Left-sided atrioventricular valve; LV, left ventricle.

Figure 56-4  Specimen of double inlet left ventricle with L-loop. Incomplete right ventricle (RV) has been opened, showing coarse trabeculations present in its inferior part and a restrictive ventricular septal defect (VSD). The aorta (Ao) arises from this chamber. Key: LAA, Left atrial appendage; LV, left ventricle.

hypoplasia of the infundibular septum, and 3 had multiple muscular defects.\(^{B3}\)

The small incomplete (rudimentary) ventricle is of right ventricular morphology, with coarse apical trabeculations and frequently a recognizable trabeacula septomarginalis (septal band) bounding the VSD anteriorly. A smooth-walled infundibulum is present when one or both great arteries arise from this chamber (Fig. 56-4). Otherwise, and rarely, the chamber exists as a blind pouch. It is always positioned on the anterosuperior shoulder of the dominant left ventricle (Fig. 56-5), usually to the left but sometimes to the right. The septum thus lies obliquely and never extends to the crux.

The typical morphology of double inlet left ventricle, with ventricular L-looping, left-sided incomplete right ventricle, and VA discordant connections, occurs in about half of all cases, with a wide variety of VA connections in the remainder\(^{U1}\) (see Table 56-3). The relatively uniform internal cardiac architecture of the AV valves and myocardium in typical double inlet left ventricle may be more variable when double outlet right ventricle occurs with it.\(^{A3}\) Atrial situs is usually solitus, occasionally ambiguous, but rarely situs inversus.

Two variants of double inlet left ventricle warrant further description: (1) double inlet left ventricle with ventricular L-loop, left-sided incomplete right ventricle, and VA discordant connection and (2) double inlet left ventricle with ventricular D-loop, right-sided incomplete right ventricle, and VA concordant connection.

With Ventricular L-Loop, Left-Sided Incomplete Right Ventricle, and Ventriculoarterial Discordant Connection This is the largest subset of hearts with double inlet ventricle, comprising half the cases (see Figs. 56-3 through 56-5). The large left ventricular main chamber lies to the right and receives left-sided and right-sided AV valves, which usually are of tricuspid and mitral morphology, respectively, although both may be bicuspid. There may be some straddling and overriding (but <50%) of the AV valves. The majority of AV valves function normally, but the most common abnormality is stenosis of the left-sided “tricuspid” valve.\(^{B3}\) A heavy trabecula often separates insertion of the papillary muscles into the diaphragmatic free wall of the left
ventricle. The left-sided tricuspid valve commonly has attachments of the subvalvar tension apparatus to the ventricular septum.\textsuperscript{D1}

The aorta arises above the short infundibulum of the incomplete left-sided right ventricle (see Fig. 56-4). The pulmonary trunk arises from the base of the left ventricle, anterior and superior to the right-sided AV (“mitral”) valve, usually with pulmonary-mitral fibrous continuity. Subvalvar and valvar pulmonary stenoses occur but are not common, and pulmonary atresia occurs only occasionally.

The VSD is usually large and lies beneath the infundibular septum, but it may be restrictive, producing subaortic stenosis (see “Subaortic Stenosis” later under Natural History). As noted, the VSD may be in an atypical position within the apical septal trabeculations, and occasionally it is multiple. Muscular defects are more likely than subarterial defects to be restrictive.\textsuperscript{B5}

The AV node is anterior and away from the atrial septum, lying in the right atrial wall adjacent to the superior comissural tissue between anterior and posterior leaflets of the right-sided AV valve.\textsuperscript{A3,B4,B5} This arrangement also pertains to ventricular D-loop when the left ventricle is the main chamber, because again there is no ventricular septum extending to the crux. The bundle of His passes anterior to the pulmonary valve to reach the ventricular septum (see later Figs. 56-19 and 56-21).\textsuperscript{A3,B2,B4}

Configuration of coronary arteries is similar to that in congenitally corrected transposition of the great arteries (see “Atrioventricular Node and Bundle of His” and “Coronary Arteries” under Morphology in Section I of Chapter 55).

With Ventricular D-Loop, Right-Sided Incomplete Right Ventricle, and Ventriculoarterial Concordant Connection

This occurs in about 10% of cases and most resembles the normal heart. The large left ventricle lies to the left and posteriorly, and the small right ventricle lies to the right, anteriorly and superiorly. It was first described by Holmes and is often called the Holmes heart.\textsuperscript{A6,H1}

There are usually two AV valves (often with the right-sided one straddling but with less than 50% override) or a common valve. The incomplete right ventricle is similar to that present in classic tricuspid atresia, with an extensive infundibulum leading to a pulmonary valve that is normally related to the aortic valve. Pulmonary stenosis is common, and the VSD may be restrictive.

The AV node is again anterior at about the 11-o’clock position relative to the right AV valve, as seen by the surgeon from the right atrium. The bundle of His descends from the anteriorly positioned AV node directly onto the ventricular septum without coming into relation with the ventricular outflow tract.\textsuperscript{B8,W3} Rarely the AV node and bundle encircles the anterior aspect of the right AV orifice.\textsuperscript{A6}

Double Inlet Right Ventricle

In double inlet right ventricle, both atria connect to a morphologically right ventricle. Apical trabeculations are coarse, and the trabecula septomarginalis is recognizable on the septal surface, with the VSD contained between its anterior and posterior limbs. The incomplete left ventricle is always positioned posteriorly and inferiorly (“in the hip pocket”) in relation to the main chamber and usually lies to the left (D-loop; Fig. 56-6) or rarely to the right (L-loop). More often than not, it is very small and slitlike, communicating with the main chamber by a tiny VSD, with no connection to a great artery.\textsuperscript{A2,S11} In other cases, the left ventricle is of reasonable size and the obliquely placed septum is well
formed; in contrast to that in double inlet left ventricle, it extends superiorly to the crux. In these cases, fine apical trabeculations are recognizable, and the superior septal surface beneath the VSD is smooth.

The VA connection is usually double outlet or single outlet (pulmonary atresia) from the right ventricle (Fig. 56-7; see also Fig. 56-1). A concordant connection sometimes occurs, with the aorta arising from the incomplete left ventricle. Pulmonary stenosis can be present.\(^9\)

Two AV valves may enter the large right ventricle, with the left one straddling, or frequently a common AV valve. Atrial situs inversus, and particularly right atrial isomerism, is more common in double inlet right ventricle than in double inlet left ventricle. Double inlet right ventricle associated with right atrial isomerism seems to be particularly prevalent in the Chinese.\(^14\)

In the presence of a D-loop and a ventricular septum reaching the crux, the AV node has its usual posterior position in the atrial septum with its normal relation to the ostium of the coronary sinus.\(^7\) The perforating bundle of His passes through the AV anulus and on to ventricular myocardium, either on the ventricular septum or on a trabecula on the posterior ventricular wall. In rare L-loop, the conduction system is variable, but a conventionally located AV node may be present, as well as a more rudimentary node located more anteriorly and superiorly along the right-sided AV anulus.\(^5\)

The nonbranching bundle then descends onto a free-running trabecula in the main chamber.

**Double Inlet Indeterminate Ventricle**

Double inlet indeterminate ventricle includes hearts in which both atria connect to a solitary ventricle.\(^24\) Prevalence of this subset depends on the care with which a search is made for the possibility that the malformation is actually double inlet right ventricle, because a tiny isolated accessory ventricular chamber may be missed by cardiac imaging and may be found only on careful autopsy examination. Even when the ventricle is truly solitary, it may represent a morphologically right ventricle without a rudimentary left ventricle, because apical trabeculations are always coarse, and there may be a free-standing column posteriorly reminiscent of the trabecula septomarginalis (see Fig. 56-7).\(^3\)

There is a higher prevalence of heterotaxy in double inlet indeterminate ventricle than in the other types of double inlet ventricle. With it, as well as with atrial situs solitus and inversus, two perforate AV valves are usually present. The only VA connection possible is double or single (pulmonary atresia) outlet ventricle. Pulmonary stenosis is common. The great arteries are often more or less normally related.

The AV node is usually posterior when there is a rudimentary ridge in the ventricle and distinct papillary muscles to both AV valves. In this case, the AV node passes down a free-running trabecula.\(^24\) When a ridge is absent, the AV node is usually situated laterally (away from the atrial septum) and anteriorly, and the nonbranching bundle descends into the right parietal wall of the indeterminate ventricle.\(^24\)

**Common Ventricle**

Rarely an apparently common (solitary) ventricle has no ventricular septum or a diminutive apical ridge, but importantly, one side of the ventricular mass is morphologically right ventricle and the other morphologically left. Lev and colleagues consider this to be a heart with a huge VSD rather than double inlet common ventricle.\(^14\)

**Left Atrioventricular (Mitral) Valve Atresia and Patent Aortic Outlet**

Left-sided AV (mitral) valve atresia with patent aortic outlet has a widely varying morphology.\(^5\) All variants are discussed here, with one exception: mitral atresia with patent aortic outlet (aortic stenosis) with intact ventricular septum, atrial situs solitus, levocardia, single inlet right ventricle with D-loop, and hypoplasia of all left cardiac segments, together with VA concordant connection. This variant is considered one of the four classic morphologic variants of hypoplastic left heart physiology, along with mitral atresia–aortic atresia, mitral stenosis–aortic atresia, and mitral stenosis–aortic stenosis (see “Left Ventricle and Mitral Valve” under Morphogenesis and Morphology in Chapter 49).

The atretic valve may be imperforate, in which case there is a hypoplastic membrane, sometimes with a miniature chordal apparatus beneath it; or the AV connection may be absent, with the floor of the atrium being separated from the ventricle by fibrofatty tissue.\(^5\) In a study of 23 patients with patent aortic outlet and atresia of the left AV valve, 15 had absence of the left AV connection, 5 had an imperforate left AV valve, and 3 had atrial isomerism. Those with imperforate left AV valve demonstrated concordant AV connections.\(^1\)

The patent right-sided AV valve may occasionally override the remnant of ventricular septum, but with more than 50% of the anulus committed to the larger right ventricular chamber. The tension apparatus may straddle the septum, which reaches the crux.\(^2\)

In this most common arrangement (“mitral” atresia), there is atrial situs solitus, ventricular D-loop, and a dominant

---

**Figure 56-7** Specimen of double inlet right ventricle and double outlet right ventricle. Arguably, the main chamber can be considered of indeterminate type rather than right ventricular. Key: Ao, Aorta; LAV, left-sided atrioventricular valve; PT, pulmonary trunk; RAV, right-sided atrioventricular valve; RV, right ventricle.
right ventricle connected to the right atrium by a patent right-sided (usually tricuspid) AV valve and a small and incomplete left ventricle lying posteriorly and to the left (Figs. 56-8 and 56-9). The left ventricle may be a blind chamber connecting to the right ventricle by a small VSD (in which case the VA connection is either double or single outlet right ventricle), but more commonly it functions as an outlet chamber giving origin to the aorta (concordant VA connection) and rarely to the pulmonary artery. The left ventricle is often smaller than suggested by the position of the left anterior descending coronary artery (see Fig. 56-9). Characteristically, when the aorta arises from the small left ventricle, the VSD is restrictive and the aorta small in association with coarctation or aortic arch hypoplasia. Interatrial obstruction is also common.

Alternatively, and less commonly, the arrangement is atrial situs solitus and ventricular L-loop with single inlet and more or less right-sided left ventricle, in which case the right atrium

Figure 56-8 Specimens of hearts with left-sided mitral atresia but no aortic atresia in hearts with ventricular D-loop. A, Posterior view of the atria, with atrial walls and septum displaced anteriorly and superiorly, except for septum primum. Arrow indicates site of atretic mitral valve. B, External frontal view of another heart. Enlarged right ventricle (RV) is demarcated by anterior descending coronary artery (arrow), although large branches extend over RV. Left ventricle (LV) is underdeveloped. C, View of opened LV in same specimen as in B. Midmuscular ventricular septal defects (VSD) and normally connected aorta (Ao) are seen.
is connected to the dominant left ventricle by a patent AV valve with either mitral or indeterminate morphology. There is an incomplete left-sided right ventricle situated anteriorly and to the left, above which is the atretic left-sided AV valve, and the VSD may be restrictive. The septum does not reach the crux. The usual VA connection is discordant with the right ventricle giving origin to the aorta, but double outlet left ventricle also occurs.

Right Atrioventricular (Tricuspid) Valve Atresia
Excluding cases of classic right-sided (tricuspid) valve atresia (see Chapter 41), right-sided AV valve atresia can occur with single inlet and more or less left-sided right ventricle (ventricular L-loop). Right AV valve atresia has also been reported in association with an indeterminate solitary ventricle. The patent left-sided AV valve may occasionally override the septum and may have multiple leaflets.
Associated Cardiac Anomalies

Associated cardiac anomalies occur in at least one third of patients with double inlet ventricle. AV valve malformations are common and include leaflet dysplasia, leaflet cleft and tags, and anular hypoplasia, in addition to straddling.\(^{31,32}\) These can produce either valvar regurgitation or stenosis. The pulmonary valve may be stenotic from anular hypoplasia and leaflet thickening, or it may be atretic. Subvalvar pulmonary stenosis is common and results from either infundibular narrowing (muscle hypertrophy, hypoplasia, or occasionally a deviated septum) (see Fig. 56-1) or, more commonly, a restrictive VSD leading to an outflow chamber from which the pulmonary trunk arises (see Fig. 56-4). Aortic arch anomalies (coarctation, aortic arch interruption, or arch hypoplasia) also sometimes coexist with single ventricle (see Table 56-2). Multiple VSDs are not rare.

Subaortic stenosis is one of the most important coexisting cardiac anomalies. Because of the variable time of its appearance, it is discussed later under Natural History.

| Figure 56-9 | Relation of left anterior descending coronary artery (LAD) to ventricular septum in hearts with mitral atresia and patent aortic root. Note that in this heart, the clearly visible artery is the LAD, which does not closely relate to the left ventricular (LV) cavity. Key: LA, Left atrial cavity; PT, pulmonary trunk; RV, right ventricle. (From Gittenberger-de Groot and colleagues.\(^\text{30}\)) |

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Clinical manifestations vary with morphology. Patients without pulmonary stenosis or atresia, about one third of the total, present in a manner similar to those with tricuspid atresia and normally related great vessels without pulmonary stenosis or atresia (see Clinical Features and Diagnostic Criteria in Chapter 41).

When mild or moderate pulmonary stenosis coexists, early years of life may be without important symptoms. A \(Q_p/Q_s\) of approximately 2 or less results in only moderate cardiomegaly and mild pulmonary overcirculation on the chest radiograph and good functional status, albeit with mild cyanosis. Presentation in early or middle childhood rather than in infancy is common and is usually precipitated by cyanosis, a cardiac murmur, or typical findings on a chest radiograph. Clinical presentation is similar to that of tricuspid atresia and normally related great arteries with mild to moderate pulmonary stenosis (see Chapter 41).

When pulmonary stenosis is severe or pulmonary atresia is present, important cyanosis usually results in presentation in the early days or weeks of life, similar to that of tricuspid atresia and normally related great vessels with severe pulmonary stenosis or pulmonary atresia.

Atresia of the left-sided AV valve, when combined with a restrictive foramen ovale, results in severe pulmonary venous hypertension with its typical chest radiographic appearance and severe respiratory distress in early life. The presentation can mimic that of classic hypoplastic left heart physiology with restrictive or intact atrial septum (see Chapter 49). This situation may be masked initially by pulmonary stenosis and small pulmonary blood flow, only to become apparent after a systemic-pulmonary artery shunt is created. Severe AV valve regurgitation results in elevated atrial pressure and early appearance of heart failure.

Double inlet single left ventricle with AV and VA discordant connections, restrictive VSD (bulboventricular foramen), and aortic arch hypoplasia typically mimics hypoplastic left heart physiology in its presentation (see Chapter 49).

The electrocardiogram and chest radiograph may raise suspicion of the presence of double inlet ventricle, but echocardiography usually is the first definitive diagnostic procedure. Absence of the posterior (inlet) septum between the AV valves, one of the hallmarks of double inlet ventricle, can usually be diagnosed from the echocardiogram, particularly when associated with apposition of the unsupported septal leaflets of the two AV valves.\(^{31,32,33,34}\) Echocardiography with Doppler color flow imaging can provide all the necessary diagnostic information (Figs. 56-10 and 56-11).\(^{34,35}\)

Cineangiography may be performed (Figs. 56-12 and 56-13) but currently is not necessary for planning therapy in the neonate or infant, and may be disadvantageous to the condition of the patient. It should be recalled that the Holmes heart is easily misdiagnosed as tetralogy of Fallot.\(^35\) Cardiac catheterization and cineangiography can provide important information about the patient presenting in older infancy or later, or about the patient who has previously undergone surgery, primarily by defining pulmonary vascular resistance and morphology of the branch pulmonary arteries.

Magnetic resonance imaging and computed tomography have little diagnostic role in the neonate.
PART VII  Congenital Heart Disease

Figure 56-10  Four-chamber echocardiographic view demonstrating S,L,L double inlet left ventricle (see “Symbolic Convention of Van Praagh” in Chapter 1). Atrial septum is intact, and right-sided atrioventricular valve (RAVV) is smaller than left-sided one (LAVV). The dominant ventricle shows features of a morphologic left ventricle and is positioned to right side and posteriorly. The small outlet ventricular chamber is positioned to the left side and anteriorly. This image views the posterior aspect of the heart, so the great arteries, which are L-transposed with the aorta arising from the incomplete ventricle, are not seen. There is a communication between main and incomplete ventricular chambers (ventricular septal defect, or bulboventricular foramen). Key: AS, Atrial septum; BVF, bulboventricular foramen or ventricular septal defect; LA, left atrium; LV, left ventricle; OC, outlet ventricular chamber, or incomplete right ventricle; RA, right atrium.

Figure 56-11  Echocardiogram from heart with S,L,L double inlet left ventricle. A, Subcostal coronal image demonstrating a somewhat more anterior region (compared with that shown in Fig. 56-10). This image shows pulmonary trunk and aortic connections to heart. Aorta is left sided and anterior in relation to pulmonary trunk and arises from incomplete outlet ventricular chamber. Bulboventricular foramen is visible. Inlets to dominant left ventricle and atrioventricular valves are not visualized because of the anterior image. B, Lateral projection. Note anterior position of aorta arising from the anterior incomplete ventricle, and posterior position of pulmonary trunk arising without obstruction from dominant left ventricle. Bulboventricular foramen is very small, causing severe subaortic obstruction. Key: A, Aorta; BVF, bulboventricular foramen, or ventricular septal defect; LV, left ventricle; OC, outlet ventricular chamber, or incomplete right ventricle; PT, pulmonary trunk.

NATURAL HISTORY

Double Inlet Ventricle

Estimated overall survival without treatment is about 57% at 1 year and 45% at 5 years. The monumental study by Franklin and colleagues documented the relatively favorable prognosis of certain subsets. Specifically, patients with atrial situs solitus and double inlet left ventricle, ventricular L-loop, discordant VA connection without systemic outflow obstruction, Qp/Qs of about 1 to 2 (due to mild to moderate pulmonary stenosis), and presentation between 14 and 60 days of age have about a 90% chance of surviving for at least 10 years without intervention. Although the natural history impact of differing AV connections has not been clearly defined, evidence exists that differences in left ventricular function are present depending on whether the inlet connection has two patent valves or one. Presentation with severe acidosis and low cardiac output has been a particularly severe risk factor for early death without intervention. Systemic outflow obstruction at any level, particularly aortic atresia, is also a strong risk factor for early death.

Mitral Atresia

When atresia of the left AV valve coexists with a restrictive opening in the atrial septum, such as in mitral atresia (atrial situs solitus, ventricular D-loop, right ventricular main...
chamber, and absent or imperforate left AV valve), the situation is rapidly fatal; death usually occurs within the first few months of life. Prognosis is the same in patients with ventricular L-loop and ventriculoarterial discordant connection. Atria are in situs solitus, and small left-sided right ventricle (outlet chamber) gives origin to aorta. The ventricular septal defect is large. (Frontal projection.)

**Figure 56-12** Ventriculograms in double inlet ventricle. **A,** Double inlet left ventricle with ventricular L-loop and ventriculoarterial discordant connection. Atria are in situs solitus, and small left-sided right ventricle (outlet chamber) gives origin to aorta. The ventricular septal defect is large. (Frontal projection.) **B,** Double inlet left ventricle (LV) with ventricular L-loop and ventriculoarterial concordant connection. Atria are in situs solitus, and small left-sided right ventricle (RV) gives origin to pulmonary trunk (PT). (Frontal projection.) **C,** Double inlet LV with ventricular D-loop and ventriculoarterial discordant connection. Atria are in situs solitus, and small right-sided RV gives origin to aorta (Ao). (Long axial view.)

Continued

**Subaortic Stenosis**

The tendency to develop subaortic stenosis when the aorta arises from the incomplete ventricle (outlet chamber) poses a serious threat. This category includes patients with (1) double inlet left ventricle and VA discordant connection, (2) tricuspid atresia and VA discordant connection, and (3) mitral atresia and VA concordant connection. The

E, Double inlet indeterminate ventricle, with double outlet and severe subpulmonary stenosis. There is an azygos extension of inferior vena cava, which accounts for catheter course. (From Soto and colleagues.)

**Figure 56-13**  
Cineangiogram in mitral (left atrioventricular valve) atresia with ventricular D-loop and double outlet right ventricle.

**Figure 56-14**  
Survival without treatment of patients born with double inlet ventricle. Kaplan-Meier estimates are based on 191 patients, with vertical bars representing 70% confidence limits. Numbers represent patients still being followed. Solid line depicts overall survival, including any definitive repair (septation or Fontan operation). Dashed line represents survival before definitive repair (patients censored at time of definitive surgery; see “Competing Risks” in Section IV of Chapter 6). (From Franklin and colleagues.)
Figure 56-15 Estimated survival without definitive repair (septation or Fontan operation) of patients born with double inlet left ventricle, left-sided subaortic outlet chamber (ventricular L-loop with discordant ventriculoarterial connection) with sufficient pulmonary stenosis that pulmonary-to-systemic flow ratio Qp/Qs was 1 to 2, presenting at 14 to 60 days of age (line A), or with Qp/Qs less than 1 (line B). Line C depicts the same morphology, but with pulmonary atresia. Line D depicts patients with right atrial isomerism, double inlet and double outlet right ventricle, a common atrioventricular orifice, anomalous pulmonary venous connection, and low pulmonary blood flow, presenting at less than 14 days of age. Numbers in parentheses are calculated relative risks with respect to fictitious baseline patient (dotted curve) (see Fig. 56-14). (From Franklin and colleagues.)

Figure 56-16 Estimated survival without definitive repair of patients with double inlet ventricle (format same as Fig. 56-15). Line E represents patients with usual atrial situs solitus, double inlet left ventricle, discordant ventriculoarterial connection, and high pulmonary blood flow, presenting between age 14 and 60 days. Line F represents same form of double inlet left ventricle but with a common atrioventricular valve. Line G represents same form of double inlet left ventricle but with systemic arterial obstruction (a form of hypoplastic left heart physiology; see under Morphology in Section I of Chapter 49) and high pulmonary blood flow. (From Franklin and colleagues.)

Figure 56-17 Left ventricular ejection fraction in tricuspid atresia compared with that in double inlet left ventricle. Ejection fraction is lower in tricuspid atresia. Key: DILV, Double inlet left ventricle; TA, tricuspid atresia. (From Redington and colleagues.)

Technique of Operation

Fontan Operation

Patients are commonly managed clinically as “single ventricle” physiology. This approach usually results in a definitive Fontan operation, but one or more staging operations done before the Fontan procedure are usually required. These include various forms of pulmonary trunk banding (see “Pulmonary Trunk Banding” in Section I of Chapter 35 and in Section II of Chapter 41), systemic-to-pulmonary artery shunting (see “Techniques of Shunting Operations” in Section I of Chapter 38 and in Section II of Chapter 41), and superior cavopulmonary anastomosis (see Chapter 41). Timing, number, and appropriate application of these staging operations, and details of the Fontan operation itself, are described under Technique of Operation in Section IV of Chapter 41. Table 56-4 lists the palliative procedures performed in 225 patients with double inlet left ventricle prior to the Fontan operation.

Closure of Right Atrioventricular Valve

When one AV valve is regurgitant and the other is more or less normal in size and function, the regurgitant valve is closed, either before or as part of the Fontan operation. When both valves are competent and of adequate size, there has been concern that leaving both open will permit flow through each to be only half normal, and that this may encourage thrombosis in and around the valve. There is no strong support for this concern, however, and it appears reasonable at present to leave both open.

If one AV valve is closed surgically, it is usually the right-sided AV valve. Technique of closure must be secure and not produce heart block. Both criteria are met by polyester patch closure of the area occupied by the valve, sewing the patch in place with a continuous whipstitch of 4-0 polypropylene suture in a way that avoids heart block (Fig. 56-18). This can

subaortic obstruction is usually caused by a restrictive VSD; however, sometimes muscle within the incomplete subaortic ventricle is the cause, not a small VSD per se. The three morphologic variants have a similar natural history, which is discussed in detail for tricuspid atresia and VA discordant connection in Chapter 41.
be achieved by sewing the patch as shown in the figure, or by sewing it precisely to the valve anulus itself. Because the underlying AV valve can open and close beneath the patch, and because thrombi might form between patch and valve, a stitch is placed through the midpoint of the free edge of each leaflet and then through the center of the patch and tied on the atrial side. This is most conveniently done after placing the posterior half of the patch suture line. Simpler techniques of suturing together the free edges of the leaflets, or suturing the patch to the leaflets themselves inside the hinge line, have been associated with more dehiscences than the technique described.

Septation

The septation operation can be performed in either one or two stages. Both procedures are performed exactly the same way as described in text that follows, with the exception that in the two-stage procedure, after the main septation patch is placed, a large hole is made in the center of the patch to create a nonrestrictive VSD. A pulmonary artery band is also placed if there is absence of pulmonary stenosis. At the second stage, performed 6 to 12 months later, the created VSD is closed with a second patch sewn to the first one, and the pulmonary artery band is removed and pulmonary artery reconstructed. The two-stage procedure tends to be performed in smaller patients, particularly those with relatively small ventricular chamber size.334

Although septation occasionally can be applied under appropriate circumstances to several types of double inlet left ventricular main chamber and anterior outlet chamber (and possibly a few with double inlet right ventricle), it is most commonly applied to double inlet left ventricle, ventricular L-loop, and small left-sided subaortic right ventricle. Thus, it is described for this situation. In the series of 11 patients reported by Margossian and colleagues, nine had double inlet left ventricle, one double inlet right ventricle, and one double inlet indeterminate ventricle. Of the nine patients, five had L-transposition of the great arteries, three had related great arteries, and one had D-transposition of the great arteries.334

Preparation, draping, incision, and preliminaries to cardiopulmonary bypass (CPB) are the same as for most operations (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2). The aortic purse-string suture may be awkward to place and is most easily done as described for corrected transposition (see Technique of Operation in Section I of Chapter 55).

Cardiac morphology is examined, particularly to identify anomalies of pulmonary or systemic venous return or of AV valve regurgitation. The ventricular mass is frequently enlarged. Interestingly, the right atrium does not usually appear to be as large as it is in patients with isolated VSD, atrial septal defect, or tetralogy of Fallot, but this should not discourage use of the atrial approach.

The approximate size of the septation patch is determined before CPB. This is done by noting the external dimensions of the ventricular mass and subtracting estimated wall thickness.335 An appropriate-sized patch is cut from a polyester tube (see “Grafts for Use in Aortic Surgery” under Special Situations and Controversies in Chapter 24) or alternatively, polytetrafluoroethylene.334 Although the patch usually seems too small, this size is appropriate because if it is made too large, it bulges into the right ventricle with each systole and impairs cardiac function.334 If it is made too small, there is an increased tendency toward dehiscence.

CPB is established by the usual techniques (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2), using direct caval cannulation. Myocardial management is by cold cardioplegia and controlled reperfusion (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” under Methods of Myocardial Management during Cardiac Surgery in Chapter 3) or by simple single-dose cold crystalloid cardioplegia (see “Single-Dose Cold Cardioplegia in Neonates and Infants” in Chapter 3). The patient is usually cooled to

**Figure 56-18** Right atrioventricular (AV) valve may be closed as part of Fontan-type repair in double inlet left ventricle. Several possible locations of AV node and proximal bundle of His are shown. Because the location in a given patient is not known precisely, suture line for patch closure of right-sided AV valve is 5 mm outside anulus all the way around.
18°C to 20°C so that periods of circulatory arrest can be used when needed to improve exposure. A small right atriotomy is made and a pump-oxygenator sump sucker passed across a natural or surgically created foramen ovale. The atriotomy is extended into the usual long oblique atriotomy, and stay sutures are applied (Fig. 56-19).

The interior of the left ventricular main chamber is examined through the right-sided AV valve. The subpulmonary area is visualized, as are the VSD, left-sided AV valve, and the relation between these structures. A determination is made whether the repair can be made through the intact right AV valve or whether a radial incision needs to be made in its base. Such an incision (see Fig. 55-15, B in Chapter 55) gives a direct approach to the area between the tension apparatus of the left-sided and right-sided AV valves where the sutures for septation must be placed.

A few marking sutures are placed to outline the proposed septation suture line (see Fig. 56-19, A-B). Goals are to (1) partition the two ventricles about equally; (2) provide unobstructed pathways from right atrium through the right-sided AV valve to pulmonary trunk, and from left atrium through the left-sided AV valve to VSD, outlet chamber (right ventricle), and aorta; and (3) avoid damage to coronary arteries by placing all sutures from within the ventricle. As McGoon and colleagues emphasized, position of the suture line is predeterined by anatomy of the tension apparatuses of the AV valves posteriorly and inferiorly and by location of semilunar valves and VSD superiorly. Therefore, only anteriorly can the surgeon select the suture siting in an attempt to partition the ventricle equally.

Pledged 2-0 polyester mattress sutures are placed and held individually by small hemostatic forceps. The most difficult area is the heavily trabeculated diaphragmatic surface. Suturing is begun here, if necessary invaginating the ventricular wall with a finger outside the heart as the stitches are placed. Suture placement is then carried posteriorly and superiority between the tension apparatuses of right-sided and left-sided AV valves. Starting again at the diaphragmatic surface, suture placement is carried to the left and anteriorly and then superiorly along the anterior left ventricular wall along the previously determined line. The suture line passes over the VSD and then swings posteriorly and to the right beneath the subpulmonary area (see Fig. 56-19, A-B). Sutures must be placed close together; 20 to 30 sutures are usually required. As they are individually clamped and set aside, care is taken to maintain their proper order. Alternatively, a running suture can be used.

Size and shape of the previously trimmed patch are inspected and altered if needed. Sutures are passed through the patch, the patch slid into position, and the sutures tied. If a two-stage approach is used, the hole in the patch is made at this time (Fig. 56-20). If the right-sided AV valve has been incised, it is repaired with continuous 6-0 polypropylene sutures (see Fig. 55-15 in Chapter 55).

Cardiac reperfusion is begun, and remainder of procedure is completed as described previously (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2). A groove or indentation can usually now be seen in the ventricular wall along part of the suture line. Two temporary right atrial and two temporary ventricular epicardial wires are placed, and AV sequential pacing is begun. Usual de-airing procedures are carried out (see “De-airing the Heart” in Section III of Chapter 2).

After hemostasis has been secured, two permanent pacing electrodes are placed on the right atrium and two on the ventricle. Their ends are brought subcutaneously into the right upper quadrant, and in most patients an appropriate pacemaker is inserted a day or two later (see “Permanent Pacing after Intracardiac Surgery” under Technique of Intervention in Section I of Chapter 16).

Cardiac Transplantation

Cardiac transplantation can usually be accomplished, no matter how complex the coexisting venous and arterial anomalies (see Technique of Operation in Chapter 21). Procedures for Subaortic Obstruction

Operations designed to address subaortic stenosis are detailed in Chapter 41. Arguments have been developed both in favor of routinely addressing real or potential subaortic stenosis using the DKS anastomosis, Norwood procedure, or rarely the arterial switch in the neonatal period, and in favor of selective use of neonatal pulmonary artery banding with early follow-up and surgical management of subaortic stenosis, if and when it develops. If subaortic stenosis is to be surgically approached by direct VSD enlargement, an incision is made in the free wall of the incomplete ventricular chamber. This exposes the VSD, aortic valve, and internal dimensions of the incomplete ventricle. From this perspective, the conduction pathway is always posterior and inferior in relation to the VSD (Fig. 56-21), regardless of whether the heart is L-looped or D-looped. Based on this relationship, the VSD is enlarged as depicted in Figs. 56-22 to 56-24. The ventriculotomy is always closed with a patch (see Fig. 56-24).

SPECIAL FEATURES OF POSTOPERATIVE CARE

Fontan Operation

Care after a Fontan-type procedure is discussed under Special Features of Postoperative Care in Section IV of Chapter 41.

Septation Operation

Usual protocols are followed postoperatively (see Chapter 5). Following septation, right atrial pressure is usually a few mmHg higher than left and should be maintained around 12 to 14 mmHg in the early hours after operation.

Other Operations

Special features of postoperative care after pulmonary trunk banding, atrial septectomy, shunting operations, and operations for subaortic stenosis are described in Chapter 41.

RESULTS

Fontan Operation

Results of the Fontan operation are discussed in detail under Results in Section IV of Chapter 41. However, the several studies have examined the effect of ventricular hypertrophy on outcome following the Fontan operation. In those
Figure 56-19  Septation operation for double inlet left ventricle and left-sided, small subaortic right ventricle in a patient with atrial situs solitus. A, Septation operation is performed through a right atrial approach, but it is best illustrated through the alternative fishmouth incision in the ventricular main chamber. Positions of atrioventricular (AV) node and bundle of His are shown by dashed lines. Note that AV node is anterior, in the right atrial wall at the junction of right atrial roof and atrial septum. The bundle of His penetrates the junction of right AV valve and pulmonary valve to pass over subpulmonary area along anterior left ventricular free wall. B, As viewed through right atrium, as it passes along the interventricular septum, it courses anterior to ventricular septal defect (VSD) (or outlet foramen), as seen from this perspective, and divides into left and right bundle branches (see Figs. 56-20 to 56-23 to appreciate the posterior relationship of conduction system to the VSD when viewed from the perspective of an incision in the free wall of the incomplete ventricle). Septation operation usually results in heart block when performed in one stage. Dots indicate suture placement for inserting septation patch. Key: Ao, Aorta; AV, atrioventricular; LA, left atrium; LV, right-sided morphologic left ventricle; PT, pulmonary trunk; RA, right atrium; RV, left-sided morphologic right ventricle; SVC, superior vena cava.
Chapter 56  Double Inlet Ventricle and Atretic Atrioventricular Valve

Figure 56-20  Illustration of septation patch fenestration in two-stage repair of double inlet left ventricle with left-sided small subaortic right ventricle in situs solitus. Hole in septation patch (created “VSD,” fenestration) is placed in a convenient spot in middle of patch for easy access at second-stage procedure. It must be made large enough to create a nonrestrictive communication. (Modified from Margossian and colleagues.\textsuperscript{144})

Figure 56-21  Relationship of course of conduction system to ventricular septal defect in hearts with double inlet left ventricle, as viewed from the incomplete (rudimentary) ventricle, which is the same whether the incomplete subaortic ventricle is left sided (left depiction) or right sided (right depiction). Line of tiny circles illustrates course of conduction system. (Modified from Cheung and colleagues.\textsuperscript{142})

Figure 56-22  Direct relief of subaortic stenosis in double inlet left ventricle with left-sided subaortic incomplete right ventricle. A portion of apical ventricular septum is removed by wedge resection, as illustrated in upper panel. Lower panel shows resection to be clear of conduction tissue (pathway depicted by line of small circles). (From Cheung and colleagues.\textsuperscript{142})
studies, the populations were either predominantly or exclusively patients with double inlet left ventricle with subaortic obstruction. Ventricular hypertrophy was shown to be a risk factor for death and poor outcome at and following the Fontan operation, and attempted relief of subaortic stenosis at the time of, or anytime following, the Fontan operation was attended by an increased risk of death at the time of the procedure.\textsuperscript{1,4,8}

**Fig. 56-23** Autopsy specimen, viewed after opening incomplete right ventricle and aorta, from a patient who died after enlarging ventricular septal defect as described in Fig. 56-22. Sinus rhythm had been present throughout the postoperative period. A large opening has been created that is clear of conduction tissue, the path of which is demonstrated by black dots. (From Cheung and colleagues.\textsuperscript{2})

### Septation Operation

#### Early (Hospital) Death

In a 1984 report, overall hospital mortality after septation operation was high, about 30% to 40%\textsuperscript{14} (Table 56-5). However, among patients with moderate enlargement of the left ventricular main chamber without concomitant AV valve replacement or an extracardiac conduit, hospital mortality has been about 5%, but confidence limits are wide (Table 56-6 and Fig. 56-25). In a more recent report (1997), overall hospital mortality was less than 10%.\textsuperscript{1} In the series by Margossian and colleagues, 2 of 11 (18%; CL 6.3%-38%) patients died. One death occurred in a two-stage repair that included an arterial switch, and the other in a one-stage repair. This improvement may reflect general progress in the field but may also be influenced by patient selection.

#### Time-Related Survival

So few patients have survived the early postoperative period after septation operation that estimates of long-term survival have wide CLs, but intermediate survival is reported to be about 60% when all deaths, including those in hospital, are accounted for (see Fig. 56-25).\textsuperscript{M7} Remarkably, the single slowly declining hazard function is low after about 5 years. In a more recent study of a 23-patient experience, midterm follow-up (3-11 years) showed an overall survival of 78%.\textsuperscript{N1} In the 11-patient series of Margossian and colleagues, there was one late death with median follow-up of 2.3 years, with survival documented up to 8 years.\textsuperscript{M4} There are two single-patient case reports of survival of 9 and 12.5 years.\textsuperscript{N2, O3}

#### Modes of Death

Hospital deaths have usually been in acute heart failure, and late deaths sudden or after reoperation (usually for AV valve replacement).\textsuperscript{M7}

Data from Stefanelli and colleagues.114

aNo patients with atrial situs inversus had septation; cases are with or without pulmonary stenoses.

bOne patient, who lived after operation in 1983, had ventricular L-loop, essentially AV and VA discordant connections with essentially two ventricles, an absent septum, right-sided LV morphology, and left-sided RV morphology; another patient, who also lived after operation in 1983, had ventricular D-loop, essentially AV and VA concordant connections with essentially two ventricles, an absent septum, right-sided RV morphology, and left-sided LV morphology (common ventricle); the other three patients had an indeterminate, primitive ventricle.

cSeverely overriding right-sided ventricular AV valve.

dData from patients with main chamber enlarged grade 3 or more without concomitant atrioventricular valve replacement or use of a valved extracardiac conduit.

Data from McKay and colleagues.407

Incremental Risk Factors for Death

Within the group that currently is considered for septation (double inlet left ventricle, ventricular L-loop, left-sided incomplete right ventricle with VA discordant connection, atrial situs solitus), no risk factors have been identified. However, unusual forms of double inlet ventricle, a small ventricular main chamber, concomitant AV valve replacement, and placement of a valved extracardiac conduit have been risk factors.417 Aside from morphologic factors, increasing age and ventricular hypertrophy have been identified as risk factors.431

Functional Status

Functional status is generally good after septation. This might be expected from the experimental study by Seki, Tsakiris, and McGoon, which showed no demonstrable detrimental hemodynamic effect of replacing the dog’s ventricular septum (and tricuspid valve) with a prosthesis.435 It is also supported

Figure 56-25 Survival after septation operation for double inlet ventricle without atrioventricular valve replacement and without valved extracardiac conduit, in patients with main chamber enlargement greater than grade II (patients are described in Table 56-6). Open circles represent deaths and vertical bars 70% confidence limits (CLs). Solid line represents parametrically estimated survival, and dashed lines enclose 70% CLs. Values in the table are from parametrically determined survival. Numbers in parentheses indicate number of patients available for further follow-up at the interval shown. A, Survival. B, Hazard function. There is only a single slowly declining hazard phase, which reaches a low level 5 years after septation. (Data, except for subsequently updated follow-up, from McKay and colleagues.435)
by detailed hemodynamic study of two patients late after septation by Shimazaki and colleagues. In one patient 8 years post-septation, both right and left ventricular ejection fractions were normal, as was hemodynamic response to exercise. Kurosawa and colleagues found cardiac indices to be higher after septation than after a Fontan operation. However, late after a septation or Fontan operation, cardiorespiratory function by objective measurements at rest and during exercise is depressed compared with normal. Evidence is contradictory as to whether septation provides better cardiorespiratory function than the Fontan operation. In one study, objectively measured postoperative exercise tolerance, compared with that preoperatively, was more improved after the Fontan operation than after septation, but in a later study, superior cardiorespiratory function was found after septation. In a more recent study of double inlet left ventricle patients comparing Fontan or septation, septation patients with native AV valves demonstrated superior cardiopulmonary response to exercise compared with either Fontan patients or septation patients with prosthetic AV valves.

Heart Block
Complete heart block is not inevitable after septation. It occurred after most septation operations in one series from 1982. However, in a series from 2002, only 1 of 11 patients (9.1%; CL 1.5%-28%) developed it. The difference may be that a running suture technique was used in the series with a low occurrence of heart block, rather than interrupted pledgeted mattress sutures that penetrate deeper into the myocardium.

Cardiac Transplantation
Results of cardiac transplantation are discussed in detail under Results in Section II of Chapter 21.

Other Operations
Results for systemic–pulmonary artery shunts, pulmonary trunk banding, operations to relieve systemic outflow obstruction, coarctation repair, atrial septectomy, bidirectional superior cavopulmonary anastomosis, and hemi-Fontan are reported in Chapter 41.

Outcome Related to Specific Morphology
In a multicenter analysis of 150 patients with double inlet left ventricle who were younger than 3 months of age at diagnosis, overall survival was 88% at 1 month and 76% at 10 years. By multivariable analysis, the only risk factor for premature death was a neonatal operation of any kind.

Outcome for the Fontan in double inlet left ventricle patients is excellent, with a 3% early mortality in patients operated on after 1989, and 20-year actuarial survival of about 70% in one large series. Pass and colleagues reported a series of bulboventricular foramen (VSD) enlargement for systemic outflow obstruction in eight patients, five with S,L,L double inlet left ventricle and three with left AV valve atresia. Patients ranged in age from 2 months to 27 years. There was one early and one late death. Gradient relief was complete initially in seven, with one persistent gradient. Two patients developed recurrent obstruction following initial complete relief. All three patients with recurrent or persistent gradients underwent reoperation with relief of the gradient. At mean follow-up of 22 months, all patients were unobstructed. One patient in the series developed new-onset heart block; there was no new-onset aortic regurgitation.

Clarke and colleagues reported a 4% early mortality for interval DKS operation in a series of 15 S,L,L double inlet left ventricle patients initially managed as neonates with pulmonary artery banding and arch reconstruction. These excellent results are more expected in a favorable population of patients that did not have severe neonatal obstruction of the bulboventricular foramen. In contrast, Lan and colleagues noted a higher mortality when the DKS operation was performed in neonates, as did Lotto and colleagues for the Norwood operation in neonates.

Kawahira and colleagues reported on a series of 31 double inlet right ventricle patients. Compared with patients having double inlet left ventricle and common inlet ventricle, the prevalence of pulmonary atresia and discontinuous pulmonary arteries was higher in double inlet right ventricle, resulting in more frequent systemic-to-pulmonary artery shunt procedures in this subgroup. Overall outcomes for double inlet right ventricle were similar to those for double inlet left ventricle, however, and were superior to outcomes for common inlet ventricle (Fig. 56-26).

INDICATIONS FOR OPERATION
Primary considerations in managing patients with double inlet ventricle of any type are first and foremost assessment of, and correction of, important neonatal and infant hemodynamic abnormalities, using the palliative operations described in this chapter. Thereafter, considerations become (1) patients’ suitability for septation, Fontan operation, or cardiac transplantation and (2) preventing additional mortality.
complicating conditions such as subaortic stenosis or pulmonary arterial stenoses.

Fontan Operation

All patients suitable for septation are suitable for a Fontan operation (except those with elevated pulmonary vascular resistance). Some 70% to 80% of patients with various types of double inlet ventricle or atretic AV valve appear at birth to be suitable at a later date,^{14} but nearly 50% of those become unsuitable by about age 2 years (Fig. 56-27). Thus, when in early life a Fontan operation is considered feasible and advisable, an appropriate staged surgical management approach as outlined in Chapter 41 is planned.

Septation Operation

In the past, a septation operation was considered the most desirable of the three if intracardiac morphology was suitable. However, outcomes following the Fontan operation have improved markedly; currently, Fontan operation is generally considered the procedure of choice, possibly even in many cases with suitable morphology for septation.

Apparently, 20% to 25% of patients born with double inlet ventricle are suitable at birth for septation.^{14} By 2 years of age, 30% of those with the malformation are either dead or no longer suitable for septation, and this proportion increases as time passes (Fig. 56-28). A common reason for developed lack of suitability is subaortic stenosis.^{14}

To be suitable for septation, the patient must have a somewhat, but not severely, enlarged dominant ventricle (Fig. 56-29) into which enter two reasonably competent and nonstenotic AV valves with little or no overriding or straddling.^{14,7,1,14} Success with a single common AV valve has been reported.^{8} The VA connection must be concordant with the AV valve connections projected for the septated ventricle. There should be little or no pulmonary or systemic outflow obstruction.

Because of the age-related declining proportion of patients suitable for septation, resulting from the adverse effect of increasing hypertrophy of the dominant (main) chamber, and the strong tendency for development of pulmonary vascular disease unless there is natural or produced (by banding) pulmonary stenosis, septation should be performed during the first year or two of life. Consideration should be given to a two-stage approach to minimize the probability of producing complete heart block (see “Staged Septation” under Special Situations and Controversies).

Cardiac Transplantation

At birth, 25% to 30% of patients are already unsuitable for either septation or a Fontan operation.^{15} Only about 30% survive the first year of life (Fig. 56-30). The place of cardiac transplantation is arguable for this group of patients, but if
anything is to be done for them, transplantation would appear to be appropriate. It should be performed in the first month if possible (see “Indications for Cardiac Transplantation” in Section II of Chapter 21).

Therapeutic Plan in Older Patients

Some patients come for decision making and therapy after infancy, frequently after various palliative procedures. Each case represents a special situation, but some guidelines can be followed.

Unless pulmonary trunk banding has been performed, septation is often contraindicated because of pulmonary vascular disease, severe ventricular hypertrophy, or AV valve regurgitation. Fontan operation is possible when AV valve regurgitation has developed in one of two valves, but at Fontan operation, or as a separate preliminary operation, the valve needs to be perfectly repaired or closed (see “Closure of the Right Atrioventricular Valve” under Technique of Operation earlier in this chapter).

If pulmonary trunk banding was performed in early life, probability of subaortic stenosis is considerable. It should be suspected, even if no gradient is demonstrable, if the VSD is small or only moderate sized. If subaortic stenosis is severe, consideration should be given to treating this before undertaking the Fontan operation. In this setting, direct enlargement of the VSD is a better option than in neonates, but the DKS anastomosis or arterial switch operation can still be considered.

SPECIAL SITUATIONS AND CONTROVERSIES

Staged Septation

Ebert reported a two-stage approach to septation in a subset of patients. At the first stage, performed in infancy, a partially septating patch was placed at the apex of the ventricle and a second superiorly between the AV valves, using widely spaced interrupted sutures. A pulmonary trunk band was placed. Septation was completed with a third patch 6 to 18 months later. The other patches were then completely sealed into position. The band was removed. All patients survived, and all were in sinus rhythm. Margossian and colleagues have also reported success with this approach, as have McKay and colleagues.

Anatomically Corrected Malposition of the Great Arteries

**Definition**
Anatomically corrected malposition is an anomaly in the position of the great arteries but not in cardiac connections. Thus, there is atroventricular (AV) and ventriculoarterial (VA) concordant connection as in the normal heart, but the aortic origin lies to the left and usually anterior to the pulmonary trunk origin when there is situs solitus (Van Praagh’s S,D,L; see “Symbolic Convention of Van Praagh” in Chapter 1) and to the right of the pulmonary trunk origin when there is situs inversus (I,L,D). The circulatory pathways remain in series.

**Historical Note**
Anatomically corrected malposition of the great arteries was first reported by Theveanin in 1895 (cited by Van Praagh and Van Praagh\textsuperscript{2}) and was first termed *anatomically corrected transposition of the great arteries* by Harris and Farber in 1939.\textsuperscript{1} It is possible similar cases were described earlier under a variety of names. This confusion is exemplified by the case of Raghib and colleagues, described in 1966 with the phrase *isolated bulbar inversion in corrected transposition.*\textsuperscript{8,1} The Van Praaghs, who had doubted its existence, described three cases in 1967 using the term *anatomically corrected transposition of the great arteries.*\textsuperscript{2} At that time, Abbott’s influential 1927 definition of transposition, according to which any abnormality in the relationship of the great arteries or between the great arteries and the ventricles was called *transposition,* was still accepted.\textsuperscript{1} This confusion was clarified when Van Praagh and colleagues redefined *transposition* in 1971 as the origin of the aorta from the morphologically right ventricle and the pulmonary trunk from the morphologically left ventricle (i.e., VA discordant connection) and proposed that other positional and connection abnormalities be included in the definition of *malposition.*\textsuperscript{2} The present condition was thus renamed *anatomically corrected malposition of the great arteries.*\textsuperscript{1,3}

**Morphology and Morphogenesis**

**Morphology**
When there is situs solitus of the atria, usually the right atrium is connected to the right ventricle\textsuperscript{1} (D-loop), which lies to the right, and the left atrium is connected to the left ventricle, which lies to the left (S,D,L arrangement). Structure of the sinus portions of both ventricles is normal. However, although the aorta arises from the left ventricle and the pulmonary trunk from the right ventricle, there are abnormalities of the outlet, or infundibulum, in both ventricles. The left ventricle probably always exhibits a subaortic conus (infundibulum) with a well-formed conal septum, and muscle exists between aortic and mitral valve anuli.\textsuperscript{1} Aortic origin is accordingly displaced superiorly and anteriorly. The right ventricle may also have an infundibulum, but it may be less well developed than normal and in some cases is absent.\textsuperscript{2} In the latter case, there is pulmonary-tricuspid fibrous continuity. The aorta lies to the left and usually anterior to the pulmonary trunk, and both arteries are parallel. Rarely, there may be situs inversus with an I,L,D arrangement.\textsuperscript{2}

Hearts with similar types of infundibular development but AV discordant connection, although originally included in this category by both the Van Praaghs and Anderson and colleagues, are not called *anatomically corrected malposition* in this text but are included as variants of isolated ventricular inversion (see Section II of Chapter 55).\textsuperscript{2,2}

**Morphogenesis**
Van Praagh argues that all forms of abnormally related great arteries relate to maldevelopment of the subsemilunar conal free walls—an abnormality of what he terms the *embryonic*...
aortic switch procedure. In anatomically corrected malposition of the great arteries, the ventricles have looped in one direction, which the great arteries have twisted in the opposite direction, carrying with them the subsemilunar conal free wall. Although the great arteries are normally related (aligned), Van Praagh notes that the VA connection is very abnormal because of the abnormality in subsemilunar conal resorption.

Associated Anomalies

All reported cases of anatomically corrected malposition have been associated with other congenital cardiac anomalies. A large ventricular septal defect (VSD) is commonly present, usually conoventricular but occasionally elsewhere, as would be anticipated with abnormal subarterial conal connections to the ventricles; VSDs may be multiple. When the VSD is subpulmonary, the pulmonary trunk may override onto the left ventricle such that the condition merges with double outlet left ventricle (see Morphology in Chapter 54). When the VSD is subaortic, the aorta may override onto the right ventricle such that the condition merges with double outlet right ventricle (see Morphology in Chapter 53). In a recent report of six cases from one institution, VSD was absent in three, although a literature review of 53 cases reported absence of VSD in only three.

Pulmonary stenosis is usual, often infundibular in association with the subpulmonary conus, but occasionally valvar. Subaortic stenosis may occur from narrowing of the muscular subaortic conus. Tricuspid atresia or tricuspid valve hypoplasia has been noted in half the reported cases, accompanied by right ventricular hypoplasia. A right aortic arch is common, as is leftward juxtaposition of the atrial appendages and dextrocardia.

Aortic coarctation and arch hypoplasia has been reported in five cases. Two of these have had severe subaortic stenosis and left ventricular hypoplasia, and three had no physiologic left ventricular outflow tract obstruction and a normally developed left ventricle.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Clinical features depend on associated anomalies such as VSD or pulmonary stenosis. Correct diagnosis may first be suspected from the characteristic appearance of L-malposition in the chest radiograph (Fig. 57-1). Two-dimensional echocardiography usually establishes the diagnosis, confirming abnormalities of ventricular outflow tracts, concordant AV and VA connections, situs, positions of cardiac chambers and great vessels, and associated intracardiac defects. Additional studies such as cineangiography (Fig. 57-2), magnetic resonance imaging (Fig. 57-3), or computed tomography (Fig. 57-4) are confirmatory or diagnostic if echocardiography fails to fully characterize the lesion. Occasionally, correct diagnosis is made only at operation. The diagnosis may remain ambiguous when there is a conoventricular VSD and one of the great arteries is overriding.

Possible diagnoses other than anatomically corrected malposition in patients with atrial situs solitus and L-malposition of the aorta include complete transposition with L-malposition (see Chapter 52), AV discordant connection with double outlet right ventricle and L-malposition (see Chapter 53), AV discordant connection with double outlet left ventricle (see Chapter 54), congenitally corrected transposition of the great arteries (see Chapter 55), AV discordant connection with double outlet right or left ventricle (see Chapter 55), and several forms of univentricular AV connection, most commonly those associated with double inlet left ventricle, rudimentary left-sided right ventricle, and VA discordant connection (see Chapter 56).

NATURAL HISTORY

The simple positional anomaly of anatomically corrected malposition per se has no impact on the natural history of patients. Rather, natural history is affected as typical for the associated cardiac anomalies.

TECHNIQUE OF OPERATION

Surgical treatment of anatomically corrected malposition is determined by associated cardiac anomalies. The few special problems imposed on aortic cannulation by L-malposition are discussed under surgical treatment of congenitally corrected transposition of the great arteries (see Technique of Operation in Section I of Chapter 55).

When there is tricuspid atresia or important right ventricular hypoplasia, a Fontan-type procedure is performed (see Technique of Operation in Section IV of Chapter 41). When both ventricles are of adequate size, the VSD (if present) is closed, and pulmonary stenosis is treated. This may be accomplished as simply as possible, preferably by valvotomy, infundibular resection, or both. When necessary, a more complex solution is required, such as a transanular patch, an allograft-valved extracardiac conduit, a Lecompte intraventricular repair (réparation à l’étage ventriculaire [REV]) (see
undergoing biventricular repair can reasonably be expected to have outcomes similar to those of patients with double-outlet right or left ventricle. Those treated as having single-ventricle physiology can reasonably be expected to have outcomes similar to those of patients undergoing various staged procedures leading to and including the Fontan operation (see Chapter 41). In one series, three of four patients survived biventricular repair at midterm follow-up, with one patient dying at reoperation for an obstructed conduit. In another

"Lecompte Intraventricular Repair" under Technique of Operation in Chapter 53), or translocation in continuity of the pulmonary trunk and valve to the right ventricle.

RESULTS

Because the anomaly is rare and the associated anomalies that determine indication for operation are variable, no meaningful statements can be made regarding outcomes. Patients undergoing biventricular repair can reasonably be expected to have outcomes similar to those of patients with double-outlet right or left ventricle. Those treated as having single-ventricle physiology can reasonably be expected to have outcomes similar to those of patients undergoing various staged procedures leading to and including the Fontan operation (see Chapter 41). In one series, three of four patients survived biventricular repair at midterm follow-up, with one patient dying at reoperation for an obstructed conduit. In another

Figure 57-2  Left ventriculograms of anatomically corrected malposition of the great arteries and ventricular septal defect. There is an infundibulum beneath both aorta and pulmonary trunk. report, two patients undergoing VSD closure and right ventricular outflow tract conduit placement survived operation. Kirklin and colleagues reported two patients, both of whom survived following VSD closure and procedures to relieve right ventricular outflow obstruction. In the largest single institution report to date (six cases), two patients underwent surgical correction, both successfully. Beyond these reports, only isolated case reports exist. Two separate cases of associated aortic coarctation with VSD report repair with staged operations. The first had arch repair with pulmonary artery banding followed by VSD closure and debanding. Both patients survived.

INDICATIONS FOR OPERATION
Anatomically corrected malposition of the great arteries is not an indication for operation. Coexisting cardiac anomalies may present an indication for operation. Most frequently these are VSD and obstruction to right ventricular outflow.

SPECIAL SITUATIONS AND CONTROVERSIES
Several special morphologic concerns warrant emphasis. A transanular patch may be difficult or impossible to place in some cases of right ventricular outflow obstruction, because the right coronary artery passes across the free wall of the
right ventricular infundibulum. Not unexpectedly, coronary artery abnormalities are common, including abnormalities of the origins and surface course along the ventricles. These variations make the coronary arteries unreliable guides when planning ventriculotomy.

DEFINITION

Atrial isomerism is a condition in which the right-sided and left-sided atria, normally morphologically different, are morphologically similar.\(^1\) Thus, left atrial isomerism and right atrial isomerism can occur. Atrial isomerism is a specific phenotypic feature highly associated with generalized somatic laterality disorders characterized by abnormal arrangement of thoracic and abdominal viscera, including important structural cardiovascular anomalies. The terms *situs ambiguous* and *heterotaxy* are used to describe these laterality disorders.

Attempts to classify specific constellations of the many clinical and phenotypic features that can occur with heterotaxy have resulted in descriptive terms such as *asplenia syndrome* and *polysplenia syndrome*.\(^2\) Experience shows that although there is some tendency for certain constellations to occur, exceptions are frequent or even the rule. About 3% of all congenital heart anomalies occur in the context of heterotaxy.\(^3\) The various cardiac anomalies found in heterotaxy are shown in Table 58-1.\(^4\)

In this chapter, individual cardiovascular anomalies and commonly recognized constellations of cardiovascular anomalies that occur with heterotaxy are discussed. These complex associations are analyzed from a perspective that uses left atrial isomerism and right atrial isomerism as reference points or starting points for analysis.

HISTORICAL NOTE

Anomalies of right and left sidedness related to asymmetry of the body were recognized at least by the 15th century with Leonardo da Vinci’s drawing of situs inversus. In the early 17th century, Marco Aurelio Severino described this anatomic variant, but it was Matthew Baille, a student of John Hunter, who is credited with scientifically describing anomalies of sidedness and their associated lesions in the latter part of the 18th century.\(^5\) In 1933 Kartagener drew attention to the association of situs inversus with sinusitis (Kartagener syndrome), providing an important clue to the possible morphogenesis of all anomalies of sidedness, although this had been suggested by Siewert in 1904.\(^6\) Biorn Ivemark in 1955 identified the syndrome of right atrial isomerism, asplenia, symmetry of thoracic organs, and conotruncal anomalies during his studies at Children’s Hospital Boston.\(^7\)

Subsequently, general interest in the asymmetry of many bilateral animals, from snails to humans (the science related to chiral [asymmetric] bodies), has led to the hypothesis that left-right patterning is related to genetic factor processes that become reflected in midline left-right ciliary structure and function during embryogenesis.\(^8,9\) In the 1986 first edition of this book, Kirklin presented the UAB surgical experience with heterotaxy patients, consisting of 28 complete repairs and 28 palliative operations (including two Fontan operations).
MORPHOLOGY AND MORPHOGENESIS

Morphology

Atrial Isomerism

In atrial isomerism, both atria have similar internal, external, and appendage configuration. They are considered either morphologically bilaterally right atria or bilaterally left atria.\(^\text{M6,R4,V2}\) Validity of the concept of atrial isomerism, at least from the perspective of the purist, has been questioned.\(^\text{C4,V3}\)

Atrial situs is most usefully determined by morphology of the atrial appendages,\(^\text{Cl,M1,S4}\) because all other studies provide indirect information. Right atrial appendage morphology is present when the appendage is blunt and has a broad junction with a smooth-walled atrium. This type of junction is accompanied by protrusion of the crista terminalis into the atrial cavity.\(^\text{M5}\) Left atrial appendage morphology is present when the appendage is long and thin with constrictions along its length. Such appendages have a rather constricted junction with a smooth atrium, within which a crista terminalis is not identifiable.\(^\text{M1}\) Rarely, atria and their appendages have mixed right and left atrial morphology.

Atrial isomerism (right or left) commonly corresponds to thoracic isomerism; however, disharmony between atrial and thoracic morphology and pulmonary and bronchial morphology occurs.\(^\text{C1,P5,S4,U1}\) Atrial and thoracic isomerism (i.e., bilateral atrial and thoracic right- or left-sidedness) usually corresponds to bilateral right-sidedness (asplenia) or left-sidedness (polysplenia) of the abdominal viscera, but there are exceptions to this correspondence.\(^\text{1,2,U1}\) Abdominal asplenia or polysplenia may occasionally exist without atrial isomerism, so splenic state does not always predict atrial morphology.\(^\text{55}\)

Because of this variability, Anderson prefers the term heterotaxy to denote presence of any of the numerous possible lateralization abnormalities, and then recommends describing the morphologic details for each patient.\(^\text{A2}\)

Among 58 consecutive newborn cases of heterotaxy within a single institution, 25 had asplenia and 20 had polysplenia.\(^\text{1,6}\)

In surgical series, left atrial isomerism is more common than right, in one surgical experience with 41 patients, 23 had left and 18 had right atrial isomerism.\(^\text{57}\) Several heterotaxy studies performed in Asian populations show a strong predilection (80% of cases) for right atrial isomerism, suggesting there may be racial differences in the expression of left and right atrial isomerism.\(^\text{15,31}\)

Conduction System

Right atrial isomerism is usually accompanied by bilateral sinus nodes, one in each atrium.\(^\text{53,D3,V2}\) Two atrioventricular (AV) nodes may be present, with a sling of conduction tissue between them. In left atrial isomerism, the sinus node is absent in the majority of cases, but when present is unusually positioned and often hypoplastic.\(^\text{H8}\)

The AV node may be normally situated when ventricular architecture is right-handed (D-loop); when it is left-handed (L-loop), two AV nodes and a sling may be present.\(^\text{D3}\) Other more severe conduction system abnormalities may also be present, because complete heart block occurs in some neonates with left atrial isomerism.\(^\text{G1,H4,M5}\)

Supraventricular atrial tachycardias occur in right atrial isomerism in up to 25% of patients, whereas abnormal axis P waves with slow atrial or junctional rates are the rule in left atrial isomerism.\(^\text{W3}\)

Anomalies of Systemic Venous Connection

Anomalies of systemic venous connection are common. The inferior vena cava often does not connect directly to the atrium from below, but instead passes superiorly along the right-sided paravertebral gutter (azygos extension of inferior vena cava) or left-sided gutter (hemiazygos extension of inferior vena cava), emptying into a right-sided or left-sided superior vena cava\(^\text{12}\) (Table 58-2). Azygos extension of the inferior vena cava occurs exclusively in patients with left atrial isomerism, in whom it occurs in about 75% of cases (see Table 58-2).

Data from Uemura and colleagues.\(^\text{12}\)
Bilateral superior venae cavae occur frequently: in half of patients with right atrial isomerism and in two thirds of patients with left atrial isomerism.\textsuperscript{12} (Table 58-3). When present, each typically connects to the top corner of the corresponding atrium; however, in left atrial isomerism, one may connect to the coronary sinus.\textsuperscript{M1}

When the inferior vena cava connects directly to the atria from below, it may connect to either the left- or right-sided atrium (see Table 58-2). Hepatic veins connect directly to the atria from below, usually to one atrium but sometimes to both or to both sides of a common atrium.\textsuperscript{M1} Such a direct hepatic vein connection is present in all patients with an azygos extension of the inferior vena cava, but it also occurs in patients whose inferior vena cava connects to the atria from below (Table 58-4).

Uemura and colleagues report that the coronary sinus orifice is absent in about 40% of patients with left and in 100% of patients with right atrial isomerism.\textsuperscript{U1} Other series, however, show substantial variation from these percentages.\textsuperscript{P2,P4,V3} Anomalies of systemic venous connection do not occur exclusively in patients with atrial isomerism.\textsuperscript{M4}

### Anomalies of Pulmonary Venous Connection

Extracardiac total anomalous pulmonary venous connection (TAPVC) is usually seen in patients with right atrial isomerism (Table 58-5). When pulmonary veins connect to an atrium, pattern of connection is variable. Importantly, there is usually the normal wide area of posterior atrial wall between the pulmonary veins when the heart is viewed from behind.\textsuperscript{M1} Pulmonary venous obstruction may be present in up to 40% of patients with right atrial isomerism, especially when the connection is extracardiac.\textsuperscript{C3,H2,R3} Pulmonary venous obstruction in left atrial isomerism is much less common.\textsuperscript{P2} Atresia of the common pulmonary vein has been reported in right atrial isomerism.\textsuperscript{M1}

### Atrioventricular Connections

About 75% of patients with left atrial isomerism have biventricular AV connections that are ambiguous.\textsuperscript{C3,D2} However, there is a univentricular AV connection in about 50% to 75% of patients with right atrial isomerism, a considerably higher percentage than in any other type of atrial situs, and most of these patients have a solitary ventricular chamber.\textsuperscript{C3,H3,S7,U1} (Table 58-6).

### Atrioventricular Septal and Other Atrial Septal Defects

The complexities of pulmonary and systemic venous connections, variability in the position and nature of AV valves through which the atria empty, and anomalous muscle bands that sometimes traverse the atria often make it difficult to apply conventional terms describing atrial septal defects (ASDs). However, a common atrium (see “Common Atrium”

\textsuperscript{a}Via central confluence.
under Morphology in Chapter 34) is present in nearly half the cases. AV septal defect is present in about 80% of patients, with a higher prevalence in right than in left atrial isomerism (see Table 58-6). Most patients with atrial isomerism and AV septal defects have a common AV orifice (see “Complete Atroventricular Septal Defect” under Morphology in Chapter 34) rather than two AV valve orifices. Rarely the atrial septum is well formed and intact or has only a probe-patent foramen ovale.

**Ventricular Morphology and Ventricular Septal Defects**
Complexities of AV valves and connections and frequent occurrence of solitary ventricular chambers make it difficult to apply conventional terms. Only rarely is the ventricular septum intact; about 80% of patients with a VSD have an AV septal defect, and in the remainder with intact AV septal structures, various types of VSD are present.

**Pulmonary Outflow**
Unobstructed pulmonary outflow is rare in right, but more frequent in left, atrial isomerism. In right atrial isomerism, pulmonary stenosis is present in slightly more than half of patients, and pulmonary atresia in about one third. In left atrial isomerism, pulmonary stenosis is present in about half and pulmonary atresia in less than one tenth (see Table 58-6).

**Ventriculoarterial Connections**
In surgical series, ventriculoarterial connections are most commonly discordant, and an unusually high proportion (33%) of patients have double outlet right ventricle. In autopsy series, about 75% to 90% of specimens with right atrial isomerism have discordant ventriculoarterial connection (transposition) or double outlet right ventricle; in left atrial isomerism, this is true in about 20% to 65% of specimens (see Table 58-6). In some cases, such as double outlet from an indeterminate ventricle, the ventriculoarterial connection cannot be easily characterized.

**Other Coexisting Cardiac Anomalies**
Anomalies other than those inherent in atrial isomerism are infrequent in surgically treated patients. In autopsy series, obstructive lesions on the left side of the heart, excluding left ventricular hypoplasia and mitral stenosis, are common.

**Summary**
In the surgically more common left atrial isomerism, anomalies of systemic venous connection are common, as are abortive forms of cor triatriatum, but extracardiac TAPVCs are not. Common atrium and other types of AV septal defects occur in about half the cases. Univentricular AV connections are uncommon, as are solitary ventricular chambers, but double outlet right ventricle is common. Pulmonary stenosis is present in about half of cases.

In surgical patients with right atrial isomerism, anomalies of systemic venous connection are less common, as are abortive forms of cor triatriatum, but extracardiac forms of TAPVC occur more frequently. Common atrium and other forms of AV septal defect occur in more than 90% of patients, and solitary ventricular chamber occurs in nearly half. The fact that cardiac anomalies are more complex and numerous in hearts with right rather than left atrial isomerism probably explains the higher prevalence of left atrial isomerism in surgical series than in autopsy series.

**Morphogenesis**
The genetic basis of heterotaxy is thought to be related to genetics of ciliary dysfunction on the embryologic midline node.

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**
There are no clinical features absolutely specific to atrial isomerism, because there is no specific functional derangement uniformly associated with the atrial morphology. The clinical sign most intimately related to the atrial morphology itself is presence of abnormal P-wave morphology and slow atrial rhythm associated with left atrial isomerism. Asplenia, commonly associated with right atrial isomerism, is associated with an increased number of Howell-Jolly bodies in the routine blood smear in newborns, or persistent Howell-Jolly bodies in older infants. Clinical features depend, therefore, on the specific cardiac anomalies and the many possible noncardiac anomalies and disorders that may be present, including intestinal malrotation, absence of splenic function, primary ciliary dyskinesia, biliary atresia, central nervous system anomalies, craniofacial anomalies, intraabdominal vascular anomalies such as congenital extral hepatic portosystemic shunt, and musculoskeletal anomalies.

Atrial situs is best diagnosed preoperatively by determining thoracic situs, because atrial and thoracic situs are nearly always the same. Thoracic situs is best indicated by bronchial anatomy, which does not always correspond to

associated with both left and right atrial isomerism and as a result can strongly suggest the diagnosis \(^{17}\) (Figs. 58-2 and 58-3). Echocardiography, however, is limited in delineating all morphologic details related to atrial isomerism, particularly when complex pulmonary artery and pulmonary venous anomalies are present (e.g., pulmonary atresia with discontinuous branch pulmonary arteries, mixed TAPVC). Specific characteristics of the atrial appendages cannot usually be identified with certainty, and the relationship of bronchi to pulmonary arteries cannot be determined. Complex pulmonary artery and pulmonary vein anomalies, and the extra-cardiac thoracic and abdominal features of left and right atrial isomerism, can best be determined by computed tomography and cineangiography (Figs. 58-4 and 58-5). Specific hemodynamic data can only be obtained by cardiac catheterization.

Almost all children with right atrial isomerism are in sinus rhythm, and most have a normal P-wave axis. \(^{\text{W1}}\) Complete AV block coexists in about 10% of patients with left atrial isomerism but is rare in right atrial isomerism. \(^{\text{W1}}\)

At operation, the surgeon must make direct observations of the atrial appendages and atrial walls to confirm or deny the preoperative diagnosis of right or left atrial isomerism.
Atrial isomerism with asplenia (probably bilateral right-sidedness). Echocardiography can reliably identify most cardiovascular defects associated with the various atrial isomerism (heterotaxy) syndromes. Because the constellation of findings is variable and complex, multiple echocardiographic views are required. This subcostal coronal view demonstrates enlarged atrial chamber. Almost complete absence of atrial septum is evident, with only a central band present. There is a large ostium primum defect and a large ostium secundum defect. The single atrioventricular valve and ventricular mass are also seen. Key: AS, Atrial septum; ASD1, ostium primum defect; ASD2, secundum atrial septal defect; V, ventricle.

NATURAL HISTORY

Natural history of patients with atrial isomerism is determined primarily by details of cardiac structures and nature of coexisting cardiac anomalies. However, atrial isomerism itself may contribute to natural history because of its association with neonatal complete heart block and sometimes neonatal death.  

Right atrial isomerism is often accompanied by asplenia, a condition believed to render the patient susceptible to infection, particularly pneumococcal. Left atrial isomerism is often accompanied by polysplenia and a high prevalence of extrhepatic biliary atresia; the polysplenia is also accompanied by splenic incompetence.

TECHNIQUE OF OPERATION

Cardiopulmonary Bypass

In patients with atrial isomerism, cardiopulmonary bypass (CPB) often presents venous cannulation problems because of systemic venous anomalies. Basic venous cannulation techniques are used, as well as those for situations involving three venae cavae (see “Venous Cannulation” under Preparation for Cardiopulmonary Bypass and “Left Superior Vena Cava” under Special Situations and Controversies in Section III of Chapter 2). Direct caval cannulation is particularly advantageous because of complex intraatrial repairs that are often required.

In patients with left atrial isomerism and two superior venae cavae, it must be remembered in selecting venous cannula size that one of the superior cavae is probably returning the entire inferior vena caval flow by way of the azygos continuation as well as its usual flow, and that a larger than usual cannula is required. In such situations, blood returning from hepatic veins connected directly to an atrium is picked up by a pump-oxygenator sump-sucker placed in the depths of the atrium. The hepatic veins, especially if they become confluent before entering the atrium, may also be directly cannulated. Occasionally, patients with right atrial isomerism will have bilateral superior venae cavae as well as hepatic veins that drain to the atrium separate from the inferior vena cava; in this situation, four venous cannulae may be necessary.

In all of these situations, complexity of the cannulation arrangement (and accompanying complexity of the intracardiac repair in many cases) is such that cooling to moderate to deep hypothermia (20°C-24°C) and using aortic clamping and cold cardioplegia are advised to allow maximum visibility and flexibility of the perfusion flow rate. For example, if a complex atrial baffle is required, one or more of the multiple venous cannulae may be temporarily removed and replaced with a cardiotomy suction device to enhance visibility and ensure the baffle is placed without distortion.

One solution to the venous cannulation problem is to use hypothermic circulatory arrest, cooling and rewarming the patient with a single venous cannula through an atrial appendage. (Advantages and disadvantages of this technique are described in Section IV of Chapter 2.) This method is more likely to be chosen for infants.

Intracardiac Repair

A wide variety of intracardiac repairs are required in patients with atrial isomerism, and repair in individual patients may require two or three procedures. These are described under Technique of Operation in chapters on the specific anomaly encountered. Procedures used in repair of AV septal defects, including common atrium (see Technique of Operation in Chapter 54), are particularly important.

Complex Atrial Baffle

In repairing anomalies of pulmonary or systemic venous connections that are frequently part of the cardiac anomaly, a complex atrial baffle is often required. The first step is usually excising remnants of the atrial septum, except for the anterior limbus, which, if present, may contain the AV node or bundle of His. The temptation to retain part of the septum as a flap should generally be resisted because it tends to increase complexity. When a coronary sinus is present, it is usually cut down, as in the Senning or Mustard repair (see Fig. 52-32 in Chapter 52).

Fig. 58-6 shows a complete AV septal defect with bilateral superior vena cavae, interrupted inferior vena cava with azygos continuation to the right superior vena cava, and two separate hepatic venous connections. Spatial arrangements of the orifices of the pulmonary veins, left-sided superior vena cava in the upper left corner of the atrium, right-sided superior vena cava in the upper right atrial corner, and hepatic
After these structures and relationships have been visualized clearly, the proposed suture line of the baffle is marked with four to six interrupted suture markers, and the pericardium that was taken initially and set aside is trimmed to a proper shape and size and sutured into place (Fig. 58-6, B).

This complex atrial baffle is similar to that used for repair of simple unroofed coronary sinus syndrome (see Fig. 33-3 in Chapter 33).

Frequent association of anomalies of venous connection with AV septal defects in patients with atrial isomerism often necessitates combining baffle repair with repair of a complete AV septal defect. In such a procedure, extension of the atrial baffle toward the AV valves is best thought of as simply the intraatrial portion of the two-patch technique used in the repair of complete AV septal defects (see “Two-Patch Technique” under Technique of Operation in Chapter 34).

Techniques have been developed that reduce complexity of the atrial baffle in some circumstances. When bilateral superior venae cavae are present with unroofed coronary sinus, extracardiac connection of the left to the right superior veins lying inferiorly must be visualized in three dimensions and clearly understood (Fig. 58-6, A). Also, the superior vena cava receiving venous drainage from the lower body must be recognized as requiring a larger pathway to the AV valve than usual if flow is to be unimpeded. The relationship of these orifices to left-sided and right-sided AV valves must be clarified, because proper positioning of the atrial baffle depends on this knowledge. Presence of an intact inferior vena cava with separate hepatic venous drainage to the atrium, not shown in this figure, would add further complexity.

In planning the baffle and potential drainage pathways to AV valves, ventriculoarterial connections that will exist at the end of the repair must also be clearly visualized. In this regard, the ventricular situs (handedness or loop) per se is not important, because in what will ultimately be a two-ventricle system, pulmonary venous return must be routed to the ventricle that does (or will) connect to the aorta, regardless of whether it is morphologically right or left. Similarly, systemic venous return must be routed to the ventricle connected to the pulmonary trunk.

After these structures and relationships have been visualized clearly, the proposed suture line of the baffle is marked with four to six interrupted suture markers, and the pericardium that was taken initially and set aside is trimmed to a proper shape and size and sutured into place (Fig. 58-6, B). This complex atrial baffle is similar to that used for repair of simple unroofed coronary sinus syndrome (see Fig. 33-3 in Chapter 33).

Frequent association of anomalies of venous connection with AV septal defects in patients with atrial isomerism often necessitates combining baffle repair with repair of a complete AV septal defect. In such a procedure, extension of the atrial baffle toward the AV valves is best thought of as simply the intraatrial portion of the two-patch technique used in the repair of complete AV septal defects (see “Two-Patch Technique” under Technique of Operation in Chapter 34).

Techniques have been developed that reduce complexity of the atrial baffle in some circumstances. When bilateral superior venae cavae are present with unroofed coronary sinus, extracardiac connection of the left to the right superior veins lying inferiorly must be visualized in three dimensions and clearly understood (Fig. 58-6, A). Also, the superior vena cava receiving venous drainage from the lower body must be recognized as requiring a larger pathway to the AV valve than usual if flow is to be unimpeded. The relationship of these orifices to left-sided and right-sided AV valves must be clarified, because proper positioning of the atrial baffle depends on this knowledge. Presence of an intact inferior vena cava with separate hepatic venous drainage to the atrium, not shown in this figure, would add further complexity.

In planning the baffle and potential drainage pathways to AV valves, ventriculoarterial connections that will exist at the end of the repair must also be clearly visualized. In this regard, the ventricular situs (handedness or loop) per se is not important, because in what will ultimately be a two-ventricle system, pulmonary venous return must be routed to the ventricle that does (or will) connect to the aorta, regardless of whether it is morphologically right or left. Similarly, systemic venous return must be routed to the ventricle connected to the pulmonary trunk.
colleagues have identified characteristics of valve repair that increase the likelihood of success. Multiple techniques were used, primarily including direct leaflet apposition at clefts, scallops, or prolapsing leaflet edges and various forms of reduction anuloplasty. Additional techniques used were the Alfieri suture and chordal shortening.

Palliative Operations

Standard techniques are used for shunting procedures (see “Technique of Shunting Operations” under Technique of Operation in Section I of Chapter 38 and “Systemic–Pulmonary Arterial Shunt” under Technique of Operation in Section II of Chapter 41) and pulmonary trunk banding (see “Pulmonary Trunk Banding” under Technique of Operation in Section II of Chapter 41). Coexisting juxtaductal pulmonary arterial stenosis, not uncommon in these patients, should be corrected at the time of the shunting operation. Occasionally, discontinuous branch pulmonary arteries arising from bilateral ductus arteriosus, in association with pulmonary atresia, must be reconstructed at the time of the shunting procedure. In one series, this morphology was present in 7 of 28 patients (25%) having pulmonary atresia with right atrial isomerism.

If a superior cavopulmonary shunt is being considered, careful consideration must be given to presence of bilateral superior vena cavae or of interrupted inferior vena cava. Bilateral bidirectional superior cavopulmonary shunts are discussed in Section III of Chapter 41. The considerations are purely technical, with no physiologic implications different from those of unilateral bidirectional superior cavopulmonary shunt. In contrast, creating a bidirectional cavopulmonary shunt in the setting of interrupted inferior vena cava has important physiologic implications. Because of azygos vein continuation associated with interrupted inferior vena cava,

Fontan Type of Repair

Frequent occurrence of complex cardiac anomalies means that a Fontan type of repair must sometimes be used. Usual techniques of operation as practiced in the current era (see Technique of Operation in Section IV of Chapter 41) serve well. In most instances, some form of extracardiac conduit or lateral tunnel total cavopulmonary shunt operation is useful (see “Persistent Left Superior Vena Cava with Hemiazygos Extension of Inferior Vena Cava” under Special Situations and Controversies in Section IV of Chapter 41). Several variations of these basic techniques can be used when the hepatic veins enter the atria separately.

Atrioventricular Valve Repair

Repair of a common atrioventricular valve is an important consideration in heterotaxy patients with single ventricle physiology. Valve regurgitation is a consistently cited risk factor for poor outcome (see Results section). Ota and
When a bidirectional cavopulmonary shunt is created in the setting of interrupted inferior vena cava, careful mid- and long-term follow-up is critical to monitor development of pulmonary arteriovenous malformations. These pulmonary vascular abnormalities can develop under various conditions of altered pulmonary blood flow, but their development is particularly rapid and aggressive in this setting. The first sign of pulmonary arteriovenous malformations may be decreased \( \text{Sao}_2 \), although contrast echocardiography may document arteriovenous malformations well before that. At catheterization, angiographic evidence of arteriovenous malformations

**SPECIAL FEATURES OF POSTOPERATIVE CARE**

Usual measures of postoperative care are employed after repair of cardiac anomalies in patients with atrial isomerism (see Chapter 5). Special measures used after the Fontan type of procedure are described under Special Features of Postoperative Care in Section IV of Chapter 41.
and desaturated blood in the pulmonary veins confirm the diagnosis. There is evidence that incorporating splanchnic venous blood into the pulmonary circulation along with the remainder of systemic venous return may reverse pulmonary arteriovenous malformations. Lack of splenic function in heterotaxy patients increases the risk of nosocomial infection and demands exquisite attention to preoperative sterile technique. In a series of 29 heterotaxy patients, seven (24%; CI 15%-35%) developed sepsis during treatment. Six of the seven were on appropriate antibiotic therapy when sepsis developed. Underscoring the fact that polysplenia patients as well as asplenia patients have splenic dysfunction, five of the seven patients with sepsis had polysplenia. Bacterial sepsis was associated with a 44% mortality.

RESULTS

Because of wide morphologic variability in patients with atrial isomerism, it is difficult to summarize overall outcomes. However, several general points can be made. First, overall survival is better with left, compared with right, atrial isomerism (94% vs. 79% at 3 years in one series, and 94% vs. 53% at 1 year in another). Second, in most series survival is better when a biventricular repair is undertaken compared with a management plan that leads to a Fontan procedure (Figs. 58-7 and 58-8). In the large series reported by Serraf and colleagues, however, mortality in these two categories was similar (Fig. 58-9). Points one and two above are somewhat related; in all series of heterotaxy, most biventricular repairs are performed in patients with left atrial isomerism morphology. Third, overall results have improved substantially over time, with current-era outcomes suggesting 7% to 15% early mortality, and long-term survival of 75% (Fig. 58-10). In one large series, all mortality beyond that related to initial neonatal management was due to interstage loss in single-ventricle patients.

Left Atrial Isomerism Outcomes

In left atrial isomerism, several large series suggest that about one third of patients received a biventricular repair. The remainder underwent surgical palliation or did not undergo surgical intervention. Of those not undergoing operation, death was almost certain if important cardiac defects were present. In earlier series, even in patients with normal hearts there was 18% mortality within the first few years of life because of important noncardiac abnormalities, and in those patients undergoing some form of surgical intervention, both short- and long-term outcomes were substantially better in those undergoing biventricular repair (Fig. 58-11; see also Fig. 58-7).

In more recent series, patients undergoing surgical palliation have had excellent survival, as have those undergoing biventricular repair, with no differences noted between these two groups. In fact, these recent outcomes in patients

**Figure 58-7** Flow chart of interventions in 163 patients with left atrial isomerism. *Comprising 9 patients with biventricular hearts, 23 with single ventricle, and 22 with normal hearts. **Four patients had Fontan-type surgery without prior interventions. Fontan-type includes bidirectional cavopulmonary shunt, right atrium to pulmonary artery anastomosis, and hepatic vein to pulmonary artery rerouting. (From Gilljam and colleagues.)
undergoing surgical intervention are substantially better than the 18% mortality in left atrial isomerism patients with normal hearts from older series. Thus, it can be inferred that noncardiac management of heterotaxy patients has also improved. This inference is supported by the fact that noncardiac as well as cardiac risk factors for death were identified in older series (Table 58-7). More recent series show almost no mortality, and understandably: case volumes are small with no identifiable risk factors. One study of 91 biventricular repairs suggests that attempting biventricular repair in the setting of unbalanced AV septal defect is associated with increased mortality.

Right Atrial Isomerism Outcomes

In right atrial isomerism, both short- and long-term outcomes are worse than for left atrial isomerism. Although outcomes have improved in recent series, they still remain worse than in left atrial isomerism. Risk factors in recent series include presence of AV valve regurgitation, obstructed TAPVC, and mixed TAPVC, similar to those identified in earlier series (Table 58-8 and Fig. 58-12). Occurrence of secondary pulmonary vein obstruction after repair of obstructed TAPVC is frequent, adding to the poor prognosis of this association (Table 58-9). Biventricular repair is possible in few patients with right atrial isomerism (see Fig. 58-7). In patients not receiving surgical intervention, death is almost a certainty (Fig. 58-13; see also Fig. 58-8).

In patients undergoing surgical palliation, presence of TAPVC requiring operation creates substantial problems in the setting of single-ventricle physiology. The common occurrence of obstructed outflow into the pulmonary circulation and obstructed pulmonary veins makes management of such infants particularly challenging (see Table 58-8; see also Fig. 58-13).
Figure 58-11  Survival of 163 patients with left atrial isomerism and a normal heart ($n = 22$), a heart suitable for biventricular repair ($n = 71$), and a heart suitable for single-ventricle surgery ($n = 70$). Survivors are denoted by dots. Vertical bars represent 95% confidence limits. Differences between groups were analyzed using the log-rank and Wilcoxon tests. (From Gilljam and colleagues.134)

Figure 58-12  Kaplan-Meier survival of 102 patients with right atrial isomerism, stratified by presence of total anomalous pulmonary venous connection (TAPVC). (From Foerster and colleagues.11)
Other series support the observation that biventricular repair, when possible, can be performed with low mortality, that surgery in the neonatal period for pulmonary venous obstruction in combination with outflow obstruction to the pulmonary circulation in right atrial isomerism carries a dismal prognosis, and that outcomes following surgical intervention are generally better in left, compared with right, atrial isomerism.\textsuperscript{51,52,53,54}

Fontan Outcomes

In several studies, one multicenter, functional outcome and survival after the Fontan operation were similar in heterotaxy and non-heterotaxy patients.\textsuperscript{4,5,6,7} Heterotaxy patients, however, did undergo their procedure at an older age, were more likely to receive an extracardiac conduit Fontan, had more previous operations, had a higher prevalence of sinus node dysfunction and atrial dysrhythmias, and had more AV valve regurgitation.

Atrioventricular Valve Repair Outcomes

Successful repair can be achieved in two thirds of patients.\textsuperscript{2,3} The technique of leaflet apposition (see "Atrioventricular Valve Repair" under Technique of Operation) was associated with successful repair. Successful repair was associated with improved survival.\textsuperscript{4}

INDICATIONS FOR OPERATION

Need for surgical treatment is dictated by associated cardiac anomalies, not by atrial isomerism. Atrial isomerism, particularly right atrial isomerism and asplenia, strongly suggests the presence of complex cardiac anomalies and a higher-than-usual surgical risk, but coexisting anomalies are usually severe and the natural history unfavorable. Therefore, indications for operation are usually clear.
