ing early corrective surgery. The predominant corrective surgery for these variants between 1959 and about 1985 was some form of the atrial switch operation, either Senning or Mustard. The predominant corrective surgery between about 1985 and the present has been the arterial switch. Thus, currently, adults older than about age 25 almost certainly will present with a background of atrial switch surgery, whereas those under age 25 are likely to present with a background of arterial switch surgery. These two populations present distinctly differently in adulthood.

A small but notable subset of the population with prior atrial switch surgery is made up of patients with failing systemic right ventricles (RV) who have undergone pulmonary trunk banding in order to train the morphologic left ventricle (LV) in anticipation of atrial switch takedown and conversion to an arterial switch. These patients may enter adulthood at varying stages of LV training or after conversion to the arterial switch.

Survivors may have a spectrum of conditions, including atrial arrhythmias (most commonly junctional rhythm with sick sinus syndrome [50% at 20 years] but also atrial fibrillation and flutter [35% at 20 years]), ventricular arrhythmias (9%), heart block, systemic and pulmonary venous obstruction within the atrial baffle, atrial septal defect, systemic (morphologic right) ventricular failure, systemic (tricuspid valve) atrioventricular valve regurgitation, and dynamic LV outflow tract obstruction.

Systemic venous baffle obstruction within the superior limb leads to superior vena cava syndrome: swelling of the head and upper body, sometimes accompanied by headache or chylothorax. Systemic venous baffle obstruction in the inferior limb can lead to hepatic congestion, cirrhosis, ascites, and dependent peripheral edema. Baffle leaks will result in shunting, typically physiologically left to right, with pulmonary overcirculation; however, large defects may lead to mixing and systemic cyanosis or paradoxical embolus. Functional status of the systemic RV also influences magnitude and direction of the shunt.

Pulmonary venous pathway baffle obstruction leads to pulmonary venous congestion and pulmonary hypertension. All the sequelae mentioned in the preceding paragraphs may already be well established in childhood, and commonly, pacemaker placement and revision of the atrial baffle, due to either leak or obstruction, may have already been performed before adulthood is reached. These sequelae have a substantial effect on quality of life and survival. These multiple sequelae notwithstanding, systemic right heart function (RV dysfunction, tricuspid valve regurgitation, or both) is the major issue in adults being followed with an atrial switch operation. Some degree of systemic right heart dysfunction is present in most patients by the time they reach adulthood.

Patients with prior arterial switch present in adulthood with fewer sequelae than do those with prior atrial switch. Some studies indicate that patients are physiologically and functionally on par with the age-matched normal popu-
lation. One study of 65 patients shows, however, that exercise capacity was 73% of normal in patients studied at a mean age of 19 years.

Sequelae are not only less prevalent than after the atrial switch, those that occur are also distinctly different, reflecting the differences between the two operations. In a study of 65 patients by Tobler and colleagues, 17% (12/65) of adults had at least one important cardiac lesion. Arrhythmias accounted for 7%, with atrial flutter in three patients, sick sinus syndrome in one, and ventricular tachycardia in one. Structural lesions accounted for the other 10%, with RV dysfunction in three patients, severe pulmonary regurgitation in two, and LV dysfunction, severe tricuspid regurgitation, and LV outflow tract obstruction in one each. They also
noted aortic root dilatation (>36 mm diameter) in 31%, but no intervention was required. Aortic regurgitation occurred in 52%; however, it was mild or less in all. There were no documented coronary artery lesions in this series; however, in other series coronary lesions were noted in 7% of cases at late follow-up.9,25

Other arterial switch series emphasize RV outflow tract obstruction, coronary insufficiency and its sequelae, and aortic root dilatation and aortic regurgitation.14,16,24,26,51,17,32 RV outflow tract obstruction occurs in 5% to 15% of patients and tends to develop within several years of the arterial switch; rarely will this become a new problem late postoperatively. Most patients with serious stenosis will undergo revision of the RV outflow tract during childhood, and some will require multiple revisions. This may ultimately result in important pulmonary regurgitation or need for a prosthetic valve or valved conduit. As adults, these patients require further surgical management of the RV outflow tract for problems related to right-sided conduit failure.

Coronary artery problems develop late in up to 8% of patients after arterial switch.1,16 Some of these patients may be asymptomatic, but most will present with typical signs and symptoms of coronary insufficiency.

Aortic root dilatation is well documented late following the arterial switch, but it occurs in only a small percentage of cases.1,27,18

LV dysfunction may develop in patients with a history of initial atrial switch followed by late pulmonary trunk banding for LV training and conversion to arterial switch. The dysfunction is currently poorly understood, but is probably related to inadequacy of the LV training process in most cases. Coronary artery obstruction is usually not implicated. All patients with a history of LV dysfunction and late conversion to the arterial switch should undergo frequent evaluation to assess LV function.

Diagnosis

Evaluation of the adult with prior atrial switch surgery may include electrocardiogram (ECG), echocardiography, magnetic resonance imaging (MRI), computed tomography (CT), and cardiac catheterization. ECG documents baseline rhythm, status of sinoatrial and atrioventricular nodes, and presence of ventricular ectopy. Holter monitoring is commonly helpful if any disturbance is present.

Echocardiography is the most important tool in assessing the status of both systemic venous limbs of the arterial baffle, pulmonary venous pathway, baffle leakage, systemic RV function, and systemic tricuspid valve function. Transesophageal echocardiography may enhance the findings of surface studies. Nevertheless, it is acknowledged that echocardiography has limited ability to assess RV function.1,28,29 Coronary artery morphology is not well imaged by echocardiography.

MRI and CT provide superior imaging information about the atrial baffle and its pathways and the great arteries and extracardiac central veins, and can provide additional valuable information about the systemic RV and tricuspid valve. In particular, MRI can be used to calculate tricuspid valve mass and volume, ejection fraction, and tricuspid regurgitant fraction. Myocardial delayed enhancement can evaluate RV myocardial viability.1,18

Cardiac catheterization is critical in the evaluation. Angiography is the standard for imaging the coronary arteries. A complete hemodynamic evaluation, and in particular measurement of systemic RV end-diastolic pressure, provides crucial information for managing the systemic right heart.

Electrical, morphologic, and hemodynamic data obtained from these studies are used to determine management of the TGA patient with a systemic RV. Management options include medical (pharmacologic) management of rhythm or ventricular function problems, or both; surgery to correct rhythm and hemodynamic problems (atrial baffle leaks or obstruction, VSD, severe RV-to–pulmonary trunk obstruction, maze procedure for atrial flutter or fibrillation, standard atrioventricular sequential or biventricular pacemaker placement); initiation of a program to train the LV in preparation for conversion to an arterial switch by placing a pulmonary trunk band; completion of conversion to an arterial switch in a previously banded patient; and heart transplantation.

Routine evaluation in the adult with prior arterial switch includes ECG and echocardiography. Cardiac catheterization with coronary angiography should be performed at least once in the adult, and more frequently if coronary insufficiency is suspected by symptoms or by other studies.1,28 More frequent coronary angiography should also be considered if the original operative note from the arterial switch operation indicates an unusual coronary artery pattern or difficulty with coronary artery translocation. ECG is most helpful in showing ischemic changes either at rest or with exercise; however, it will also document atrial and ventricular arrhythmias.

Echocardiography assesses function of all four valves (with particular focus on the semilunar valves), ventricular function, and size of the aortic root. The coronary arteries cannot be fully assessed by echocardiography, but indirect evidence of coronary insufficiency, such as ventricular wall motion abnormalities and mitral regurgitation, can be.

MRI and CT with angiography are also used selectively, for example, when more precise imaging is needed than can be provided by echocardiography (for serial assessment of aortic root size), when qualitative functional valve assessment is needed (for serial assessment of aortic regurgitation), or when functional myocardial evaluation is needed (magnetic resonance myocardial delayed enhancement).

In atrial switch adult patients who are considered candidates for LV training and eventual conversion to arterial switch, baseline evaluation of the morphologic LV and mitral valve is required. This includes ECG for rhythm and ectopy; echocardiography to assess morphologic LV systolic function, wall thickness, and mitral valve function; cardiac catheterization to measure LV end-diastolic pressure; and MRI to determine LV mass. All of these studies are then repeated after placing a pulmonary trunk band according to a specific protocol, to determine if and when the patient becomes a candidate for conversion to arterial switch.

Electrophysiologic evaluation is indicated in all adults with TGA, regardless of the type of surgery, if clinical course, ECG, or Holter monitoring suggests important atrial or ventricular rhythm disturbance.

NATURAL HISTORY

Adults with prior atrial switch surgery survive to adulthood. Twenty-five-year survival is 65%, and is even better (80%) if TGA is not complicated by VSD.2 Late mortality risk after the first 5 years following surgery appears to be linear at 0.5% per year.112 Studies show a concerning trend in measures
using bicaval venous cannulation and aortic clamping with cardioplegia administration. The systemic venous component of the baffle is exposed using an incision into the morphologic right atrial free wall, which is part of the pulmonary venous pathway of the baffle. Patch augmentation of the affected limb of the systemic venous baffle is then performed.

An alternative option for superior limb obstruction is to perform a bidirectional superior cavopulmonary anastomosis. This option may be preferred if there is long-standing long-segment occlusion of the superior limb or very complex non-occlusive obstruction. This option is contraindicated if pulmonary vascular resistance is elevated above about 3 Wood units.

Another option for superior limb obstruction to consider when obstruction is complex is placing an extracardiac polytetrafluoroethylene (PTFE) conduit from the patent superior vena cava to the inferior vena cava at the level of the diaphragm, with the conduit positioned along the right lateral border of the heart. This option should be considered only if the inferior limb of the systemic baffle is fully evaluated and deemed large enough to carry the entire systemic venous output without obstruction. An option that may occasionally be considered for complex inferior limb obstruction is placing an extracardiac conduit in the reverse direction, from the patent inferior vena cava at the diaphragm up to the superior vena cava. The superior limb of the baffle must be large enough to carry the entire systemic venous return without obstruction.

Pulmonary venous baffle obstruction almost always occurs at the midpoint of the pathway as it crosses the plane of the (normal) atrial septum and wraps around the systemic venous component of the baffle. Surgical approach involves CPB as described previously for systemic venous baffle obstruction. Patch augmentation of the external wall of the morphologic right atrium (which is part of the pulmonary venous pathway), with the patch extending down onto the right pulmonary veins, usually relieves the obstruction.

Operation for baffle leakage is performed using the same exposure described previously for systemic venous baffle obstruction. The leak may be at the suture line or through multiple atrial muscle trabeculations remote from the patch suture line. After opening the morphologic right atrial wall and entering the chamber that accepts pulmonary venous blood, suture line leaks are usually obvious and are best closed with additional patch material. Muscular trabeculation leaks are best assessed by performing the additional step of opening the chamber that accepts systemic venous blood and examining the internal surface of the systemic venous pathway. Direct suture closure or patching of all communications from this vantage point is then carried out.

Subvalvar LV-to-pulmonary trunk obstruction is approached using CPB with bicaval venous cannulation and aortic clamping with administration of cardioplegia. Access to the subvalvar obstruction is through an incision in the pulmonary trunk, with retrograde exposure through the pulmonary valve. Muscular and fibromuscular resection is performed using the same techniques used for subaortic obstruction (see Chapter 47).

Tricuspid valve surgery in atrial switch patients is usually not indicated. When it is, it rarely involves valve repair. Very occasionally, a tethered septal leaflet will be an isolated cause of regurgitation in a patient with a history of atrial switch operation.

**TECHNIQUE OF OPERATION**

**After Atrial Switch Repair**

Several surgical options are available for superior and inferior vena caval baffle limb obstruction. The preferred approach involves direct revision of the systemic venous component of the baffle itself. This involves cardiopulmonary bypass (CPB)
Figure 29-39  Takedown of Mustard operation and conversion to arterial switch.  

A, In the months after placing a pulmonary trunk band, patient is followed with echocardiography, cardiac catheterization, and magnetic resonance imaging (see text for details) to assess biventricular function and acquisition of morphologic left ventricular (LV) mass, gradient across band, ejection fraction, LV end-diastolic pressure, and valvar function. If the LV fails to acquire a substantial amount of mass within 6 months and gradient across band predicts LV pressures below 70% of estimated right ventricular pressure, it is necessary to reoperate to tighten pulmonary trunk band. Optimal duration of banding, rate of LV mass acquisition, and gradient across band are likely to vary from patient to patient and have yet to be definitively established. However, compared with the rapid two-stage arterial switch for infants with transposition of the great arteries and intact ventricular septum, the process of LV mass acquisition is much more gradual, and the pulmonary trunk band is left in place substantially longer. The LV should be documented to be working at systemic-level pressure for about 1 year.  

B, After adequate LV mass acquisition, the Mustard configuration is converted to an arterial switch. Arterial switch is performed before Mustard baffle is removed, primarily to ensure that the switch is accomplished successfully before proceeding. Heart, aorta, pulmonary trunk, branch pulmonary arteries, and both cavae are exposed and dissected thoroughly and carefully through a midline sternotomy. Aorta and branch pulmonary arteries are mobilized extensively. Purse-string sutures are placed high in aorta and in both cavae, after which cardiopulmonary bypass is initiated with aortic and bivacal cannulation. Systemic (right) ventricle is vented through appendage of morphologically right atrium. Patient is cooled to 25°C. Aorta is then clamped and cardioplegia administered into aortic root. Aorta and pulmonary trunk are transected, and semilunar valves are inspected. After band around pulmonary trunk is removed, narrowed tissue at band site is excised and proximal and distal edges are trimmed carefully.  

C, After identifying coronary ostia, coronary arteries are mobilized on generous buttons of sinus wall. Counter incisions are made high in the facing sinuses of the proximal neoaorta (pulmonary trunk), and the coronary arteries are reimplanted with continuous 5-0 or 6-0 absorbable monofilament suture. In patients with abnormal coronary artery branching patterns, coronary reimplantation is modified as necessary.  

D, After coronary buttons are reimplanted into neoaortic root, the pulmonary trunk is brought anterior to ascending aorta (Lecompte maneuver). It is important that branch pulmonary arteries have been mobilized to the pulmonary hila to prevent tension on pulmonary trunk anastomosis, which may increase risk of postoperative supravalvar pulmonary stenosis. Distal ascending aorta is then anastomosed to neoaortic root in end-to-end fashion using continuous 4-0 or 5-0 absorbable monofilament suture. Coronary button defects in neopulmonary artery preferably are patched with autologous pericardium, and with allograft or synthetic patch material if pericardium is not obtainable.
Although a standard oblique atriotomy is the most common approach to performing a Mustard operation, other types of atrial incision may be used. In approaching a take-down of the Mustard baffle and reseptation of atria, original atriotomy should be identified and used. On opening pulmonary venous atrium, Mustard baffle is exposed. When Mustard procedure was performed, the coronary sinus septum may have been opened superiorly into the morphologic left atrium to more easily incorporate the coronary sinus into the systemic venous atrium. If that is the case, it will not be visible until the patch is removed. Suture lines are typically easy to identify. After incising the superior baffle suture line, entire patch is removed with sharp dissection using either a knife or scissors. Care should be taken when excising the patch around the opening of the superior vena cava because the sinoatrial node is located in close proximity to the anterior aspect of the suture line. After removing Mustard baffle, mitral valve and caval orifices are exposed. If the coronary sinus was incorporated into the systemic venous atrium, it will also be exposed. It is important to carefully remove as much scar tissue as possible from the suture lines, especially from the orifices of coronary sinus and cavae, to prevent any obstruction. A pericardial or polytetrafluoroethylene (PTFE) synthetic patch is then fashioned to recreate the interatrial septum. Patch is sewn to remaining rim of native atrial septum using continuous 4-0 or 5-0 polypropylene suture. In patients who had coronary sinus septum opened at time of Mustard procedure, the sinus orifice must be reconstructed by bringing the patch down and incorporating it as the posterior wall of the orifice. Alternatively, the patch can be carried along the suture line of the Mustard baffle, such that the coronary sinus drains to the left atrium. Before tightening final sutures, left atrium is de-aired by sustained pulmonary hyperinflation. A left ventricular vent is placed across mitral valve, through either the posterior suture line or a separate purse string. Clamp is removed from aorta, and right atrium is closed and pulmonary outflow tract reconstructed without cardioplegic arrest during rewarming.
Chapter 29 Congenital Heart Disease in the Adult

Right atriotomy is then closed with continuous 5-0 polypropylene as rewarming is commenced. Neopulmonary trunk is then reconstructed by anastomosing distal pulmonary trunk to reconstructed neopulmonary root using continuous 5-0 or 6-0 absorbable monofilament suture. A cardiotomy suction catheter is placed in pulmonary trunk to prevent backflow from obscuring operative field. (From Reddy and colleagues.)

Figure 29-39, cont’d

I. Right atriotomy is then closed with continuous 5-0 polypropylene as rewarming is commenced. J. Neopulmonary trunk is then reconstructed by anastomosing distal pulmonary trunk to reconstructed neopulmonary root using continuous 5-0 or 6-0 absorbable monofilament suture. A cardiotomy suction catheter is placed in pulmonary trunk to prevent backflow from obscuring operative field. (From Reddy and colleagues.)

with concomitant closure of a VSD. The tethered leaflet is iatrogenic. If systolic RV function is normal, repair of the tricuspid valve with partial closure of the septal anterior commissure at the site of tethering may be effective. More complex etiologies of tricuspid regurgitation in the setting of normal RV function are best managed using tricuspid valve replacement. Both bioprosthetic and mechanical valves are appropriate options. The decision is based on the typical advantages and disadvantages of each type of prosthesis.

Atrial switch takedown and conversion to arterial switch technique is shown in Fig. 29-39.

After Arterial Switch Repair

Repair of RV outflow tract problems after the arterial switch can usually be managed using normothermic beating heart CPB with a single venous cannula in the right atrium. Because of the Lecompte maneuver, access to the entire RV outflow tract, including subvalvar, valvar, and supravalvar areas, and branch pulmonary arteries, is excellent. Patch augmentation of obstructive lesions at any level is effective. Valvar obstruction may be managed by valvuloplasty, transanular patch, or valve replacement. Transanular patching will result in some degree of pulmonary regurgitation. Valve options include bioprosthetic valves and pulmonary and aortic allograft valved conduits. Isolated subvalvar obstruction can be resected, working retrogradely through the pulmonary valve, or by a longitudinal infundibular incision with resection or infundibular patching.

Coronary artery obstruction and aortic valve and root problems are managed with techniques described in Chapters 7 and 12. Surgical access to the aortic root, valve, and coronary arteries is more difficult than usual because of their posterior position behind the pulmonary trunk following the Lecompte maneuver. If the pulmonary branches and trunk are mobile, they may be dissected from the underlying aorta intact and retracted, allowing access to the aortic root. Often the pulmonary trunk is not easily mobilized, so it may be necessary to transect it just above the pulmonary valve or to transect the right pulmonary artery at its origin from the pulmonary trunk, mobilizing the pulmonary trunk to access the aortic root. Coronary ostial lesions may be managed by standard techniques of coronary artery bypass grafting or by ostial patching.

The classically described maze procedure is performed in patients with the arterial switch and atrial fibrillation, and an appropriately modified maze procedure is used when there is an atrial baffle in place (see Chapter 16).

Transplantation is performed with the appropriate arterial and venous anastomotic adjustments (see Chapter 21).

RESULTS

There are no large studies of adult TGA patients providing outcomes for the various operations described in this section. Based on outcomes for operations with similar complexity in non-TGA patients, early mortality for most of the procedures in patients with a history of either atrial or arterial switch should be in the range of 1% to 2%. The one exception is the
atrial switch patient undergoing conversion to arterial switch.\(^{14}\) In the series of one of the authors (FLH), early mortality was 20% (1/5; CI 3.2%-53%) among adult patients, with five additional patients not meeting criteria for conversion after LV training. Benzaquen and colleagues report one successful adult conversion.\(^{14}\)

**INDICATIONS FOR OPERATION**

In all adult patients with transposition, regardless of their surgical history, arrhythmias may require intervention. Indications for pacemaker insertion include sick sinus syndrome, symptomatic bradycardia, and selected patients with a stable junctional rhythm that does not meet bradycardia criteria. Although the atrial morphology may be altered, particularly in atrial switch patients, transvenous pacing systems can usually be placed. Surgical placement of epicardial pacing systems remains an option for those with unusual morphology, intracardiac shunts, or occluded central veins, and for those requiring biventricular pacing. Sudden death is described in adult atrial switch patients, mostly related to ventricular tachycardia and fibrillation.\(^{32}\) Placing an internal cardioverter-defibrillator (ICD) is indicated if a sudden death episode is documented or electrophysiologic evaluation demonstrates inducible ventricular tachycardia or fibrillation. The maze procedure, or appropriate modifications if atrial structures are altered, may be indicated for any adult patient with TGA if atrial fibrillation or flutter is present and other cardiac surgery is planned.

**After Atrial Switch Repair**

Both surgical and catheter-based interventional procedures are available for residual and recurrent lesions in adults with prior atrial switch surgery. Intervention for the structural lesions described in the following text is indicated if the lesions cause important symptoms or if hemodynamic alterations caused by these lesions meet standard criteria for intervention.

Catheter-based dilatation or stenting is the preferred method for treating symptomatic superior caval, inferior caval, and pulmonary venous pathway obstruction, and for baffle leaks. It is also an option, but not necessarily the preferred one, for supravalvar pulmonary trunk and branch pulmonary artery stenosis. Surgical intervention is indicated for these same lesions when catheter-based techniques are unsuccessful or contraindicated. As an example, catheter-based therapy may be contraindicated for long-segment occlusion of the superior baffle limb. Many consider surgical reconstruction the preferred method for treating supravalvar and branch pulmonary artery stenosis, whether these lesions occur alone or with valvar and subvalvar stenosis.

Surgical intervention for LV outflow tract obstruction in atrial switch patients is indicated only if LV pressure becomes suprasystemic or symptoms are attributable to the obstruction. Moderate or even severe obstruction, as judged by pressure gradient, may not affect LV function. Additionally, the argument has been made that some elevation of LV pressure may be beneficial, keeping the ventricular septum from bowing away from the RV, thereby stabilizing the subvalvar mechanism of the tricuspid valve and reducing development of systemic tricuspid valve regurgitation.

Surgical intervention may be indicated in selected cases of moderate or severe systemic tricuspid valve regurgitation, but only when systemic RV function is preserved. Repair of the tricuspid valve working under systemic loading conditions remains a challenge. In most cases, tricuspid valve regurgitation is associated with a dilated and poorly functioning systemic RV. The progression may be ventricular dysfunction leading to regurgitation; however, the causality may be the reverse as well. Either way, tricuspid valve repair or replacement is contraindicated when there is associated moderate or severe ventricular dysfunction.

Either pulmonary trunk banding with eventual conversion to an arterial switch or heart transplantation is indicated when RV dysfunction accompanies tricuspid regurgitation. There are no clear guidelines for choosing between these; however, important atrial or ventricular arrhythmias, morphologic LV dysfunction, and mitral valve dysfunction all strongly favor moving toward transplantation. Conversion to arterial switch remains controversial.\(^{112}\) Some institutions never recommend this option. The operation, however, can be performed successfully in highly selected cases in institutions experienced with it. Indications for proceeding with atrial switch take-down and conversion to arterial switch are complex. Several stages of selection are required. In the initial selection process, all patients with an atrial switch procedure can be evaluated. Generally, patients with normal or near-normal function of the systemic RV and tricuspid valve are not considered for conversion. Typically, moderate or severe systemic ventricular dysfunction or tricuspid regurgitation will be present, and these findings lead to further evaluation for conversion. However, other sequelae, such as baffle obstruction or leak, may also lead to additional evaluation. Candidates are eliminated from further consideration if important atrial or ventricular arrhythmias are present or if there is evidence of morphologic LV or mitral valve dysfunction.

In the unusual case that the LV is already working under conditions that will allow it to perform adequately in the systemic circulation (chronic moderate to severe LV outflow tract obstruction, or pulmonary hypertension from atrial baffle obstruction in the pulmonary venous pathway), the patient may proceed directly to atrial switch take-down and conversion to arterial switch without undergoing pulmonary trunk banding. In the more common case the LV will be chronically working under normal afterload conditions of the pulmonary circulation and will not be prepared for systemic workload conditions. These patients must enter a process of LV preparation by pulmonary trunk banding. The aim is to gradually achieve afterload conditions that allow the LV to remodel and hypertrophy such that it will be capable of working efficiently under the conditions of the systemic circulation. The training process takes a minimum of 1 year and may take longer. During this time it is likely that more than one banding procedure will be needed in order to achieve proper training.\(^{514}\) At each stage in the banding process, reevaluation with echocardiography, cardiac catheterization, and MRI is performed to obtain the data required to evaluate LV preparedness. The criteria used by one of the authors (FLH) before the LV is considered prepared are:

- Ventricular ejection fraction of 55% or greater
- Less than mild mitral regurgitation
- Ventricular systolic pressure 90% systemic or greater
- Ventricular end-diastolic pressure 10 mmHg or less
If these criteria are met, conversion is performed. In a series of 31 patients managed by one of the authors (FLH), 42% who began training with the band achieved criteria for conversion. Of those achieving conversion, five were adults aged 22 to 29 years. There was 80% survival in this group. An additional five adult patients who did not meet the criteria were turned down for conversion after attempted LV training. Age was not a deterrent to successful conversion as long as these strict inclusion criteria were adhered to. In the study by Poirier and colleagues of 39 patients undergoing banding, 71% underwent conversion; however, early mortality was 17% (CL 11%-27%) and late cardiac death 13%. This study identified older age as a risk factor, with no successful conversions in patients beyond age 16 years. The differences in these two series may be explained by the stricter training selection criteria used in the series with successful adult conversions.

After Arterial Switch Repair

Indications for surgery in adults with prior arterial switch and RV outflow tract lesions are the same as those for tetralogy of Fallot (see Section XI of this chapter). Indications for coronary artery surgery are similar to those in patients with arteriosclerotic disease (see Chapter 7) and include signs and symptoms of myocardial ischemia and coronary artery luminal narrowing of 50% or greater. Because coronary artery sequelae after the arterial switch are almost always limited to the ostium or adjacent proximal segment, direct ostial augmentation may frequently be indicated, although coronary artery bypass grafting remains an option as well.

Risk of aortic dissection and rupture associated with aortic dilatation after the arterial switch is not known. However, based on physiologic principles, it is reasonable to assume that it is the same as that in native aortic dilatation. Thus, it is reasonable to follow the indications for root replacement recommended for native aortic disease (see Chapters 25 and 12). If aortic valve function is normal, a valve-sparing root replacement should be considered. If root dilatation is accompanied by more than mild aortic regurgitation, root replacement with aortic valve replacement, or aortic valve repair, is indicated.

**Section XIII Congenitally Corrected Transposition of the Great Arteries**

**DEFINITION**

Definition, morphology, and basic physiology of congenitally corrected transposition of the great arteries (corrected transposition, CTGA) are described in Chapter 55. CTGA with pulmonary stenosis or atresia and ventricular septal defect (VSD), the single most common form, is discussed in detail under Special Situations and Controversies in Section XI of this chapter. All other forms are discussed in this section.

**MORPHOLOGY**

CTGA is a rare anomaly and thus is not often found in adults. It may present in adulthood as newly diagnosed disease, previously diagnosed disease with benign physiology, or secondary disease with a history of previous surgery. Presentation will be variable because all but 1% to 2% of patients have one or more major associated structural cardiac anomalies, including pulmonary stenosis, VSD, and systemic atrioventricular (AV) valve abnormalities, and these largely determine the nature of presentation. Even the rare patient without associated structural anomalies will eventually develop problems with conduction or with systemic right ventricular (RV) function.

There are several morphologic variants of CTGA:

- Without associated structural anomalies
- With VSD
- With pulmonary stenosis or atresia
- With structurally abnormal (“Ebsteinoid”) tricuspid valve
- With various combinations of these structural anomalies

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

**Presentation**

Initial presentation may be spontaneous heart block, which is well documented to occur at a rate of about 2% per year in CTGA. Patients with prior history of VSD closure will present in adulthood in the same way as unoperated patients without associated structural anomalies, that is, with systemic RV failure; however, the presentation may be more accelerated. Patients with prior placement of a prosthetic valve in the tricuspid valve position may present with dysfunction or outgrowth of the valve, whether it is a bioprosthetic or mechanical valve. These patients may also present with heart failure from progressive systemic RV dysfunction. Patients with a history of isolated pulmonary stenosis repair may present with recurrent stenosis, or, if one has been placed, with left ventricle–to–pulmonary trunk conduit failure. Patients with a history of double switch (arterial switch–type double switch) will present with a combination of all the sequelae seen after both the arterial and atrial switch (see Section XII, “Transposition of the Great Arteries,” earlier in this chapter). Signs and symptoms of systemic RV failure, systemic tricuspid valve regurgitation, and complete heart block are the same as in any patient with left-sided heart failure or heart block and therefore are nonspecific for CTGA. Evaluation will lead to the diagnosis.

**Diagnosis**

The electrocardiogram will show definitive evidence of ventricular inversion. The chest radiogram is not definitive, but may show abnormal contour of the ventricular shadow, a narrowed superior mediastinal shadow due to the position of the great arteries, and abnormal cardiac position such as mesocardia or dextrocardia. The echocardiogram is diagnostic, identifying AV and ventriculoarterial discordant connections, as well as the major associated anomalies such as VSD, pulmonary stenosis, and systemic tricuspid valve structural abnormalities and function. Apical displacement...
of the tricuspid valve is easily identified, and complexity of pulmonary stenosis, including valvar and subvalvar components, can usually be determined. Quantitative assessment of systemic RV function is often difficult by echocardiography. Magnetic resonance imaging (MRI) is used to assess systemic RV function and volume and to quantify systemic tricuspid valve regurgitation. Cardiac catheterization is often helpful in assessing systemic RV function, using both ventriculography and hemodynamics (RV end-diastolic pressure).

**NATURAL HISTORY**

The undiagnosed asymptomatic adult may present incidentally during evaluation for some other problem.\(^{511,517}\) The asymptomatic adult with known unrepaired CTGA may be referred to the adult congenital cardiac clinic simply because there is a known diagnosis. Most commonly, the unrepaired patient without associated structural anomalies, or with mild associated structural anomalies, will present in the fourth or fifth decade of life with signs and symptoms of systemic RV failure, systemic tricuspid valve regurgitation, or arrhythmias.\(^{511,519}\) In one single-institution study, by age 50 years, 66% of patients were in heart failure, but none died over a 10-year observation period thereafter.\(^{519}\) In a multi-institutional longitudinal study, 25% of patients with CTGA and no other structural anomalies presented with signs and symptoms of heart failure by age 45 years. If associated structural anomalies were present, heart failure by age 45 years increased to 67%.\(^{619}\)

Patients presenting in adulthood without prior surgery rarely have severe pulmonary stenosis, large VSDs, or severely abnormal systemic tricuspid valves, because the natural history of these associated anomalies rarely allows patients to reach adulthood in a healthy state. Isolated moderate, or even moderate to severe, pulmonary stenosis, however, may be well tolerated because the morphologic left ventricle will be working under afterload conditions that it tolerates well.

**TECHNIQUE OF OPERATION**

The surgical techniques recommended in this section—direct repair of associated anomalies and the double switch operation—are described in Chapter 55. Other techniques used to repair sequelae related to atrial and arterial switch operations are described in Chapters 7, 12, and 52.

**RESULTS**

Early surgical mortality in adults after repair of the associated anomalies found with CTGA is not well documented but is likely very low, similar to that associated with repair of these anomalies in younger patients. In the series of 44 patients (mean age 44 years) presenting in adulthood for surgery to correct various associated structural anomalies (atrial septal defect, VSD, severe aortic regurgitation, severe tricuspid regurgitation, severe mitral regurgitation, severe pulmonary stenosis), there were no early deaths (CL 0%-4.2%).\(^{511}\) Four patients who underwent tricuspid valve replacement for severe regurgitation required cardiac transplantation at a mean interval of 56 months after initial surgery. In another series, early mortality for VSD closure and placement of a left ventricular–to–pulmonary trunk conduit in adults was 5.8% (3/52; CL 2.6%-11%).\(^{635}\)

Isolated tricuspid valve replacement can be performed with low mortality. Mongeon and colleagues reported no early deaths (CL 0%-4.0%) in 46 patients (mean age 34 years) and actuarial survival of 69% at 10 years.\(^{531}\) Patients with initial right ventricular ejection fraction greater than 45% had better 10-year survival than those with lower ejection fraction, 94% vs. 55%.

Coronary artery bypass grafting for arteriosclerotic coronary artery disease has been reported in a 47-year-old diabetic adult with CTGA.\(^{84}\)

The double switch in adult patients with naturally prepared left ventricles has an early mortality that is probably similar to that in younger patients, about 2%. Extrapolating from experience with atrial switch conversions, requiring in CTGA left ventricular training, 50% will meet criteria to proceed to the double switch, for which early mortality is about 20%.

**INDICATIONS FOR OPERATION**

Surgery may be indicated in adults with unrepaired CTGA if additional structural anomalies are present and are causing symptoms, or if there are no additional structural anomalies but the systemic RV is failing. Options for surgery if structural anomalies are present include isolated surgical repair of the anomaly or anomalies causing the symptoms, double switch with concomitant management of the associated anomaly or anomalies, and cardiac transplantation.

Criteria for isolated VSD closure, pulmonary stenosis repair, or systemic tricuspid valve repair or replacement for regurgitation are generally similar to the criteria used for similar isolated anomalies in otherwise normal hearts; however, there are some notable modifications. The status of the systemic RV must be considered carefully when a small VSD is present. The already afterload-strained ventricle may not compensate for even a small volume load; thus, small VSDs may require closure if the systemic RV is dilated or dysfunctional. The same argument can be used when assessing systemic tricuspid valve regurgitation. Tricuspid valve repair is difficult in the systemic tricuspid valve, especially if there are structural valve abnormalities. Valve replacement is usually the procedure of choice. Pulmonary stenosis, on the other hand, may be better tolerated with a morphologic left ventricle in the pulmonary circulation, and surgical intervention may not be necessary for moderate or even severe obstruction.

The double switch is an option that should be considered in selected cases. It is an attractive option if the left ventricle is already prepared for a systemic workload due to a combination of VSD and pulmonary or subpulmonary stenosis (see Special Situations and Controversies in Section XI of this chapter). The double switch is less attractive when the left ventricle is unprepared for the systemic workload, as is the case when there are no, or minor, associated structural anomalies. The double switch in this setting will require preparatory left ventricular training (see Section XII, Transposition of the Great Arteries, earlier in this chapter). In unprepared adults without associated structural anomalies, there is no indication for surgery if systemic RV function and tricuspid valve function are normal or near normal. Occasionally, such patients will present with a request for double switch evaluation based on their own research. This approach may be pursued if the patient is fully informed of the left ventricular...
training process, including its risks, time course, likelihood of multiple banding procedures, and likelihood of success to double switch.

In unrepaired adults without associated structural anomalies who have untreated systemic RV failure, the options are left ventricular training and double switch or cardiac transplantation. The considerations are similar to those used to decide between these two options in patients with failing systemic RVs following the atrial switch for simple transposition (see Section XII, Transposition of the Great Arteries, earlier in this chapter). Double switch is not a good option when isolated pulmonary valve stenosis is present. Although the left ventricle is prepared, absence of a VSD renders a Rastelli impossible, and the pulmonary stenosis renders the arterial switch impossible unless a prosthetic root replacement is concomitantly performed. Occasionally, the pulmonary valve itself is normal or near normal, and there is isolated subvalvar left ventricular outflow tract obstruction. The double switch is a good option in this case, because the left ventricle is prepared, the arterial switch is possible, and the left ventricular outflow tract resection is relatively simple.

In selected unrepaired adults without associated structural anomalies who have important tricuspid regurgitation but preserved RV function (ejection fraction > 45%), tricuspid valve replacement may be considered instead of the double switch or transplantation. There is a single case report of a 64-year-old patient who presented with complete heart block and severe tricuspid valve regurgitation who underwent placement of a sequential AV pacemaker, resulting in markedly improved tricuspid valve function.

In adults with previous surgery for CTGA in whom the systemic ventricle remains the morphologic RV, indications for surgery and surgical options are generally the same as for unrepaired patients. Patients with left ventricle-to-pulmonary trunk conduits in place will eventually require conduit replacement for conduit failure. Moderate and severe conduit obstruction may be well tolerated when the left ventricle is in the pulmonary circulation, and in fact some elevation of left ventricular pressure may be beneficial, helping to stabilize the ventricular septum in midposition, thereby preventing systemic tricuspid valve regurgitation. When severe conduit obstruction is present and surgery is necessary, the fact that the left ventricle is prepared for the systemic circulation may make the double switch seem attractive; however, presence of the left ventriculotomy (from the conduit) and lack of a straightforward option for creating left ventricle to aortic continuity make the double switch inadvisable in most cases.

In adults with previous double switch surgery for CTGA, indications for surgery are a combination of the indications for surgery in patients with simple transposition and prior atrial switch and in patients with simple transposition and prior arterial switch. (See Section XII, Transposition of the Great Arteries, earlier in this chapter.)

**Figure 29-40** Probability of death according to severity of tricuspid valve deformity in 72 adult patients with Ebstein anomaly. Tricuspid valve deformity was estimated by echocardiographic measurement of amount of displacement of septal leaflet from true valve annulus. Patients were then placed in Group 1 (mild deformity), Group 2 (moderate), or Group 3 (severe). (From Attie and colleagues.)

### DEFINITION

**Great Arteries**

Prior arterial switch. (See Section XII, atrial switch and in patients with simple transposition and prior indications for surgery are a combination of the indications inadvisable in most cases.

Left ventricular training and double switch or cardiac transplantation. The considerations are similar to those used to decide between these two options in patients with failing systemic RVs following the atrial switch for simple transposition (see Section XII, Transposition of the Great Arteries, earlier in this chapter). Double switch is not a good option when isolated pulmonary valve stenosis is present. Although the left ventricle is prepared, absence of a VSD renders a Rastelli impossible, and the pulmonary stenosis renders the arterial switch impossible unless a prosthetic root replacement is concomitantly performed. Occasionally, the pulmonary valve itself is normal or near normal, and there is isolated subvalvar left ventricular outflow tract obstruction. The double switch is a good option in this case, because the left ventricle is prepared, the arterial switch is possible, and the left ventricular outflow tract resection is relatively simple.

In selected unrepaired adults without associated structural anomalies who have important tricuspid regurgitation but preserved RV function (ejection fraction > 45%), tricuspid valve replacement may be considered instead of the double switch or transplantation. There is a single case report of a 64-year-old patient who presented with complete heart block and severe tricuspid valve regurgitation who underwent placement of a sequential AV pacemaker, resulting in markedly improved tricuspid valve function.

In adults with previous surgery for CTGA in whom the systemic ventricle remains the morphologic RV, indications for surgery and surgical options are generally the same as for unrepaired patients. Patients with left ventricle-to-pulmonary trunk conduits in place will eventually require conduit replacement for conduit failure. Moderate and severe conduit obstruction may be well tolerated when the left ventricle is in the pulmonary circulation, and in fact some elevation of left ventricular pressure may be beneficial, helping to stabilize the ventricular septum in midposition, thereby preventing systemic tricuspid valve regurgitation. When severe conduit obstruction is present and surgery is necessary, the fact that the left ventricle is prepared for the systemic circulation may make the double switch seem attractive; however, presence of the left ventriculotomy (from the conduit) and lack of a straightforward option for creating left ventricle to aortic continuity make the double switch inadvisable in most cases.

In adults with previous double switch surgery for CTGA, indications for surgery are a combination of the indications for surgery in patients with simple transposition and prior atrial switch and in patients with simple transposition and prior arterial switch. (See Section XII, Transposition of the Great Arteries, earlier in this chapter.)

### MORPHOLOGY

A hallmark of Ebstein anomaly is its wide spectrum of morphologic deformity of the tricuspid valve and the associated wide spectrum of physiologic derangement. Severity of morphologic deformity generally correlates with severity of valve regurgitation, but there are exceptions. Unique to adults, the chronic abnormalities of the right heart in this disease may, over time, result in left ventricular alterations due to ventricular-ventricular interaction.

### CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

**Presentation**

Newly diagnosed adults commonly present with palpitations, dyspnea, or fatigue following new onset of atrial tachyarrhythmias, such as atrial flutter, atrial fibrillation, or reentrant tachycardia through an accessory pathway. In a group of
72 unoperated adults aged 25 years or older followed for 8 years, all but 5 patients were initially in New York Heart Association functional class I or II. Atrial arrhythmia was the most common clinical presentation in 51%, with flutter and fibrillation accounting for about half of these. Preexcitation was present in 44% on electrocardiogram. Onset of atrial arrhythmia commonly causes patients to progress to a worse functional class. Occasionally, adults present with untreated severe disease manifested by severe exercise intolerance, cyanosis, low cardiac output due to right heart failure, hepatic and renal compromise, and uncontrolled atrial and ventricular arrhythmias. Sudden death occurs and is associated with arrhythmias. Overall prognosis is poor in this subset of patients (Fig. 29-40).

Adults with previously diagnosed relatively mild disease will not have had prior surgery. These patients may present in adulthood with progression of cyanosis, progression of right heart failure symptoms, new-onset arrhythmias, or occasionally, paradoxical embolism.

Adults with prior surgery that included placing a bioprosthetic valve in the tricuspid position usually present with valve degeneration, manifested by a combination of predominant stenosis and some regurgitation. Adults with prior surgery that included tricuspid valve repair may also present with progressive tricuspid valve disease; however, recurrent regurgitation predominates, although stenosis after aggressive repair can also occur. Cyanosis in previously repaired patients is unusual because most surgical protocols involve closure of atrial-level shunts. Many repaired patients may have received a bidirectional superior cavopulmonary anastomosis as part of initial repair; upper body swelling, headache, and superior caval aneurysm may develop.

Some patients with complex disease have also received right ventricle–to–pulmonary trunk reconstructions in childhood. This will have important implications during adult life, creating sequelae such as pulmonary valve regurgitation, recurrent pulmonary stenosis, or conduit degeneration.

Patients with associated anomalies such as pulmonary stenosis or atresia, and left ventricular myocardial abnormalities such as noncompaction, typically have symptoms early in life and thus do not present in adulthood without prior surgery. Adults with prior surgery may also present with new-onset atrial or ventricular arrhythmias and right heart failure.

Diagnosis

The echocardiogram may show preexcitation due to a right-sided accessory bypass tract, prominent P waves, and right bundle branch block. The chest radiogram will show a variable degree of cardiomegaly due to right atrial enlargement, depending on severity of the morphologic and physiologic derangement. Echocardiography is diagnostic and in many cases is sufficient to proceed to surgery. It shows the structural alterations in the tricuspid valve, including apical displacement of the septal and posterior leaflets and the large abnormal anterior leaflet, the atrialized portion of the right ventricle, enlarged right atrium, and status of the atrial septum. It also provides physiologic information, including amount of tricuspid regurgitation, status of right ventricular function, and presence and direction of atrial-level shunting. Other associated anomalies, such as pulmonary stenosis or regurgitation, ventricular septal defect, and left ventricular noncompaction, can also be identified. Cardiac catheterization may be indicated if there is unexpected ventricular dysfunction or concern for arteriosclerotic coronary artery disease; assessment includes measurement of ventricular end-diastolic pressure and imaging of the coronary arteries. It is also indicated to calculate pulmonary vascular resistance if a bidirectional cavopulmonary anastomosis is being considered as part of the repair. Magnetic resonance imaging is capable of providing definitive information for diagnosis of Ebstein anomaly, including demonstration of all pertinent structural alterations discussed under echocardiography; additionally, it may provide quantitative functional information superior to that provided by echocardiography (Fig. 29-41).

Formal exercise testing may be helpful. In addition to measuring functional capacity, pulse oximetry can demonstrate onset or worsening of cyanosis with exercise. This information may be helpful in determining the best operative approach to the patient, as well as response to therapy.

Electrophysiologic evaluation should be considered in all adults presenting with Ebstein anomaly and is strictly indicated if there is evidence of arrhythmia by history, ECG, or Holter monitoring.

NATURAL HISTORY

Adults with mild deformity of the tricuspid valve may be asymptomatic and have normal survival (see Fig. 29-40). They typically have normal systemic arterial oxygen saturation, either without an atrial septal defect or with an atrial septal defect and left to right shunting. Patients with cyanosis from right to left shunting typically present earlier in life, partly because the cyanosis is obvious, but also because cyanosis is associated with a more severe form of the disease.

TECHNIQUE OF OPERATION

Surgical techniques used in adults with Ebstein anomaly are the same as those used in children (see Chapter 42). Surgery in adults with unrepaired Ebstein anomaly may include the following core procedures in various combinations, with the specific combination of procedures applied to an individual patient depending on the details of that patient’s physiology:

- Tricuspid valve repair
- Tricuspid valve replacement
- Closure of atrial septal defect
- Right atrial reduction plasty
- Bidirectional cavopulmonary anastomosis
- Maze procedure
- Targeted cryoablation
- In adults presenting with unsalvageable right heart dysfunction, the Fontan operation can be considered.

In general, decision making with respect to various core procedures that should be incorporated into the operation in an individual patient is similar to but not exactly the same as that in children. Repair of the tricuspid valve is preferred, with replacement the alternative if repair is not possible. This preference, however, is more difficult to justify in adults than it is in children because growth and rapid calcification of bioprostheses resulting from active calcium metabolism are
Figure 29-41  Magnetic resonance imaging (MRI) in 47-year-old man with unrepaired Ebstein anomaly. A, Gated T1-weighted spin-echo four-chamber view demonstrating right atriomegaly and inferior insertion of tricuspid valve leaflets within atrialized right ventricular cavity. B, Four-chamber view from cine-MRI demonstrating systolic flow dephasing (arrow) arising within right ventricular cavity, suggestive of Ebstein anomaly. C, Sagittal oblique view showing use of a selective saturation pulse through right atrium parallel to atrial septum (curved arrow). Signal loss (arrow) indicates right-to-left shunting through a small atrial septal defect. (From Eustace and colleagues.

Figure 29-42  Survival of 539 Ebstein anomaly patients (mean age 24 years at time of surgery) after surgical correction. (From Brown and colleagues.)

not of concern. In adults with severely deformed tricuspid valves, choice between a marginally adequate repair and a bioprosthesis may favor a bioprosthesis. Interestingly, Dearani and colleagues have shown that in 294 adults (mean age 20 years), 12-year freedom from reoperation was identical in patients with initial valve repair versus replacement (Fig. 29-42). Both bioprosthetic and mechanical valves have been used when valve replacement is required; however, long-term survival is much better when bioprosthetic valves are used.

Surgical electrophysiologic procedures are more likely to be part of the operation in adults than in children because atrial electrical degeneration becomes more frequent over time. A bidirectional superior cavopulmonary anastomosis is less likely to be part of the operation in adults, because individuals who reach adulthood without surgery generally...
have less severe structural changes and thus a more functional right heart.

Occasionally in mild cases of Ebstein anomaly, atrial septal defect may be the dominant structural anomaly. If there is a left-to-right shunt with both rest and exercise, catheter-based intervention and closure is appropriate. If cyanosis at rest is present, catheter-based intervention is contraindicated; surgery with a more extensive procedure than atrial septal defect closure alone is required and commonly will include addressing the tricuspid valve and performing a bidirectional cavopulmonary anastomosis. If there is left-to-right shunting at rest but right-to-left shunting with exercise, surgery is preferred, but catheter-based intervention may be considered in selected cases.

RESULTS

Early mortality following initial surgery to correct Ebstein anomaly in adults ranges from 0% to 5%. In the largest series of adult patients (539 patients, mean age 24 years), early mortality was 5.9% (CI 4.9%-7.2%); however, this experience dates back to 1972. For patients undergoing surgery between 2001 and 2006 in this series, early mortality was 2.7%. Twenty-year survival was 71% (Fig. 29-43). Preoperative risk factors for overall mortality were left or right ventricular systolic dysfunction, increased hemoglobin, male sex, right ventricular outflow tract obstruction, and hypoplastic pulmonary arteries.

In another series of 40 patients undergoing initial surgical correction at a mean age of 41 years, early mortality was 5% (CI 1.7%-11%), and 5-year survival was 84%. Survival was similar for patients receiving a concomitant superior bidirectional cavopulmonary anastomosis (23/40) and those who did not (17/40) (Fig. 29-44). Importantly in this study, the decision to include the cavopulmonary anastomosis was based on preoperative assessment of high operative risk (based on tricuspid valve and right ventricular characteristics), and thus, the authors inferred that the cavopulmonary anastomosis had a beneficial effect on survival. Chauvaud and colleagues prospectively assigned high-risk patients to two groups, those receiving a superior cavopulmonary anastomosis and those who did not. They showed a substantial early survival advantage for the group receiving the cavopulmonary anastomosis. Marianesci and colleagues also showed that use of the superior bidirectional cavopulmonary anastomosis reduced the need for tricuspid valve replacement.

Early mortality in adults undergoing initial surgical repair is lower than that in neonates and infants, and probably lower than that in children. The reason is that a relatively mild form of the disease usually exists in patients who initially present in adulthood. This advantage is partially offset, however, by an increase in associated degenerative changes over time in the myocardium and electrical system.

Functional status, substantially below normal in unrepaired adults, improves following surgery, as measured both by subjective patient response and objective exercise testing.

Khositseth and colleagues reported on 83 Ebstein patients (mean age 28 years) with preoperative indication for concomitant arrhythmia surgery. A variety of surgical arrhythmia procedures were performed, including ablation of accessory pathways, perinodal ablation for atrioventricular nodal reentrant tachycardia, and the maze procedure for atrial flutter or fibrillation. At a mean follow-up of 34 months, there was no recurrence of accessory pathway tachycardia or reentrant tachycardia, and a 25% recurrence of atrial flutter or fibrillation. Early mortality for concomitant arrhythmia procedures was 4.8% (CI 2.5%-8.6%).

Freedom from reoperation after bioprosthetic tricuspid valve replacement was 81% at 15 years in a series of 158 patients (mean age 19 years at surgery).

INDICATIONS FOR OPERATION

In unrepaired adult patients, cyanosis is an indication for surgical intervention. Progressive cardiomegaly due to tricuspid regurgitation, with right atrial and ventricular enlargement, is a relative indication for surgery, even if there are no symptoms. The natural history of the disease suggests that development of atrial flutter or fibrillation is likely if these findings are present. New onset of atrial arrhythmias in previously asymptomatic patients with relatively mild structural
disease is an indication for surgery. Any patient with important symptoms or reduced functional capacity should undergo surgery. These specific indications are no different from those in younger patients with Ebstein anomaly, described in Chapter 42.

In adult patients with prior repair, the preceding indications all apply. Progressive regurgitation of a previously repaired valve has the same sequelae as an unrepaird regurgitant valve. Patients with prior tricuspid valve replacement will eventually present with a degenerated bioprosthesis. Most commonly, stenosis will predominate, but mixed stenosis and regurgitation is almost always present. Occasionally, regurgitation will predominate. Predominant prosthetic valve regurgitation presents like native valve regurgitation, and indications for intervention are similar. Predominant prosthesis valve stenosis is an indication for surgery if the mean gradient is 10 mmHg or greater or if symptoms of reduced functional capacity, peripheral edema, or hepatic congestion are evident.

In adult patients with prior tricuspid valve repair, repeat valve repair may be indicated. However, there is a higher chance that valve replacement will be required than in primary surgery cases. In adult patients with degenerated prostheses, re-replacement is the only option.

Section XV Coronary Artery Problems Related to Congenital Heart Disease

DEFINITION

Definition, morphology, and basic physiology of congenital coronary artery anomalies are described in Chapter 46. Presentation of coronary artery problems related to congenital heart disease in the adult may be as newly diagnosed primary disease (primary congenital coronary anomalies), previously diagnosed primary disease with benign physiology (primary congenital coronary anomalies), or secondary disease (following congenital heart surgery for other anomalies). Coronary artery problems in the adult may also result from sequelae of acquired pediatric diseases in otherwise structurally normal hearts (Kawasaki disease).

MORPHOLOGY

Coronary artery problems related to congenital heart disease in the adult are uncommon and can be categorized into two main groups. One category includes the primary congenital coronary anomalies. The most important of these are coronary artery arising from the wrong aortic sinus, coronary artery arising from the pulmonary artery, and coronary artery fistula. Coronary artery fistulas are the most common of these, accounting for about half of all anomalies in adults. A more complete listing of coronary artery anomalies is shown in Box 29-5. These anomalies can be grouped into a four-tiered clinical-significance–based classification, as shown in Table 29-12. Table 29-13 lists the 62 anomalies (1.2%) found in one study of 5100 coronary angiograms. Mean age of the patients was 65 years. During a 5-year follow-up period, survival was 83%, and 71% of all cardiac events and 100% of all deaths occurred in patient with class III and IV anomalies.

The second category of coronary artery problems related to congenital heart disease encompasses otherwise normal coronary arteries that are at risk, either as a result of surgical procedures used to repair other congenital heart anomalies (e.g., arterial switch operation, Ross operation) or as the natural progression of certain congenital heart diseases (e.g., supravalvar aortic stenosis). Accelerated obstructive arteriosclerotic coronary artery disease, which can develop in patients with left-sided obstructive problems such as aortic coarctation, will not be discussed further in this section (see Section X earlier in this chapter). In patients with a postsurgical etiology, coronary obstruction is usually ostial or very proximal and results from manipulation and translocation of the coronary arteries, which cause some combination of malposition, scarring, torsion, tension, ischemia, or thrombosis. In the cases that occur in supravalvar aortic stenosis, obstruction may occur at the ostium, or even in the sinus, or the problem may be more distal because of arteriopathy.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Presentation

Patients with coronary anomalies of any kind may present with classic signs and symptoms of coronary insufficiency, including angina, ventricular arrhythmia, sudden death, left ventricular dysfunction, or mitral regurgitation, or these anomalies may be more occult if coronary obstruction or insufficiency is less severe, completely absent, or develops slowly, allowing coronary artery collaterals to develop. Many of the more minor coronary anomalies are found incidentally.

Patients with coronary artery fistulas present with chest pain or dyspnea in 71% of cases, and with either fatigue, palpitations, heart failure, or syncope in another 20%. Only 9% are asymptomatic. Symptoms are much more likely in adults than in children, who are asymptomatic 79% of the time. In adults, spontaneous closure occurs in 3%, rupture in 4%, and aneurysm in 14%. Endocarditis has been reported. Fistulas are single in 74% to 90% of cases.

Anomalous origin of a coronary artery from the pulmonary trunk presenting as newly diagnosed disease in the adult will rarely involve the left main coronary artery because the natural history does not allow asymptomatic survival unless there is associated stenosis of the anomalous ostium or pulmonary hypertension. When it does present in the adult, severe left ventricular failure is present (see Chapter 46). Isolated anomalous origin of the left anterior descending, circumflex, or right coronary artery is more likely to present in the adult (Figs. 29-45 and 29-46).

The presentation of a coronary artery arising from the wrong aortic sinus is reviewed in detail in Chapter 46. Both the left main coronary artery arising from the right aortic sinus and the right coronary artery arising from the left aortic sinus can be associated with ischemia, and particularly with sudden death in young adult athletes either during or immediately after exertion.

Kawasaki disease acquired in childhood may result in chronic progressive degenerative changes in the coronary arteries, leading to coronary ectasia, aneurysm formation,
Anomalies of Origination and Course

Absent left main trunk (split origination of LCA)
Anomalous location of coronary ostium within aortic root or near proper aortic sinus of Valsalva for each artery:
- High
- Low
- Commissural
Anomalous location of coronary ostium outside normal coronary aortic sinuses:
- Right posterior aortic sinus
- Ascending aorta
- Left ventricle
- Right ventricle

Pulmonary artery—variants:
- LCA arising from posterior facing sinus (ALCAPA)
- Cx arising from posterior facing sinus
- LAD arising from posterior facing sinus
- RCA arising from anterior right facing sinus
- Ectopic location (outside facing sinuses) of any coronary artery from pulmonary artery:
  - From anterior left sinus
  - From pulmonary trunk
  - From pulmonary branch

Aortic arch
- Brachiocephalic artery
- Right carotid artery
- Internal thoracic artery
- Subclavian artery
- Descending thoracic aorta

Anomalous origination of coronary ostium from opposite, facing coronary sinus (which may involve joint origination or adjacent double ostia)—variants:
- RCA arising from left anterior sinus, with anomalous course:
  - Posterior atrioventricular groove or retrocardiac
  - Retroaortic
  - Between aorta and pulmonary artery
  - Intraseptal
  - Anterior to pulmonary outflow or precardiac
  - Posteroanterior interventricular groove
- LAD arising from right anterior sinus, with anomalous course:
  - Between aorta and pulmonary artery
  - Intraseptal
  - Anterior to pulmonary outflow or precardiac
  - Posteroanterior interventricular groove
- Cx arising from right anterior sinus, with anomalous course:
  - Posterior atrioventricular groove
  - Retroaortic

Single coronary artery

Anomalies of Intrinsic Coronary Arterial Anatomy

Congenital ostial stenosis or atresia (LCA, LAD, RCA, Cx)
Coronary ostial dimple
Coronary ectasia or aneurysm
Absent coronary artery
Coronary hypoplasia
Intramural coronary artery (muscular bridge)
Subendocardial coronary course
Coronary crossing

Anomalous origin of posterior descending from anterior descending branch or septal penetrating branch
Absent posterior descending or split RCA:
- Proximal distal posterior descendings, arising from separate RCA sources
- Proximal posterior descending arising from RCA, distal posterior descending arising from LAD
- Proximal posterior descending arising from RCA, distal posterior descending arising from Cx

Absent LAD or split LAD:
- Large first septal branch and small distal LAD
- Double LAD
- Ectopic origination of first septal branch

Anomalies of Coronary Termination

Decreased number of arteriolar/capillary ramifications (?)
Fistulas from RCA, LCA, or infundibular artery to:
- Right ventricle
- Right atrium
- Coronary sinus
- Superior vena cava
- Pulmonary artery
- Pulmonary vein
- Left atrium
- Left ventricle
- Multiple, right and/or left ventricles

Anomalous Collateral Vessels

Box 29-5 Classification of Coronary Anomalies Observed in Normal Human Hearts

Modified from Angelini and colleagues. 

| Key: Cx, Circumflex; LAD, left anterior descending coronary artery; LCA, left coronary artery; PD, posterior descending branch; RCA, right coronary artery. |

Diagnosis

The electrocardiogram may be normal or may show changes consistent with ischemia or myocardial infarction. Echocardiography and cardiac catheterization are indicated to establish etiology. Echocardiography may confirm the diagnosis, especially if the etiology is a primary coronary anomaly (coronary artery arising from the wrong aortic sinus or from the pulmonary trunk); however, more definitive imaging is almost always required (see Chapter 46). Echocardiography is also performed to assess function of the myocardium and valves. Cardiac catheterization with coronary angiography confirms or establishes the diagnosis, providing important confirmation of the abnormality, whether that is stenosis, and occlusion. Aneurysms have a tendency to thrombose and to develop stenosis at both their proximal and distal ostia.

From Rigatelli and colleagues. Key: CAA, Coronary artery anomaly; CAD, coronary artery disease; LAD, left anterior descending coronary artery; LCA, left coronary artery; LCx, left circumflex coronary artery; RCA, right coronary artery.

**Figure 29-45** Coronary angiography showing retrograde filling of an anomalous left circumflex coronary artery (LCx) through collateral vessels after injection of contrast into (A) left anterior descending coronary artery (LAD) and (B) right coronary artery (RCA). Anomalous origin of LCx from right pulmonary artery is demonstrated. (From Korosoglou and colleagues.)

Asymptomatic adults known to have unrepaired coronary artery origin from the wrong sinus, coronary arising from the pulmonary trunk, or coronary fistula should be evaluated as described in the previous paragraph. If the anomaly involves an anomalous coronary origin, a fistula, an aneurysm, or a coronary obstruction (see Fig. 29-45). Magnetic resonance imaging and computed tomography with angiography may add important details regarding the morphology (see Fig. 29-46).
helpful in determining whether closure is indicated for small or moderate-sized coronary fistulas.

Asymptomatic adults with known history of previous surgery or another condition that puts the coronary arteries at risk should be managed with a high index of suspicion. Patients who have had arterial switch surgery should undergo noninvasive testing for myocardial ischemia every 3 to 5 years. This recommendation is based on the established occurrence of coronary artery occlusion and stenosis found incidentally at cardiac catheterization after this operation. If noninvasive testing is positive, further coronary imaging as described earlier in this section is indicated. Asymptomatic patients who have undergone a Ross procedure should have imaging of their coronary arteries at least once during adult life. Often this can be timed to be part of the preoperative evaluation in preparation for right ventricular outflow tract conduit revision. Asymptomatic patients with a history of repaired or unrepaird supravalvar aortic stenosis should undergo noninvasive testing for myocardial ischemia as adults every 1 to 2 years, based on the known association of diffuse arteriopathy and known occurrence of coronary events associated with this anomaly.

**TECHNIQUE OF OPERATION**

Surgical techniques used to treat adults with primary congenital anomalies of the coronary arteries are described in Chapter 46. Surgical techniques used for coronary artery obstruction in adult patients who have undergone surgery for a congenital heart defect are described in Chapter 7.

**RESULTS**

Early mortality following surgery for congenital anomalies and congenitally associated anomalies of the coronary artery system in adults is not well documented. Based on outcomes for similar problems in children, and on outcomes for adults with arteriosclerotic coronary artery disease and good ventricular function, a mortality of 1% or less represents a reasonable estimate. Long-term outcome in adults is not available. Early mortality for ligation of coronary artery fistulas in adults ranges from 0% to 4%.

**INDICATIONS FOR OPERATION**

Surgical correction is indicated for all coronary arteries arising from the pulmonary trunk, for all symptomatic patients with coronary arteries arising from the wrong sinus, and for asymptomatic patients age 50 years or younger with coronary arteries arising from the wrong sinus if the coronary artery passes between the great arteries, is intramural, or has evidence of angiographic narrowing (see Chapter 46). Coronary artery fistula closure, either by surgery or by catheter-based intervention, is indicated for patients with symptoms attributable to the fistula, regardless of the size of the left-to-right shunt, and for asymptomatic patients if the fistula causes a large left-to-right shunt. Catheter-based closure of a coronary artery fistula can be effective and is indicated if morphologic details allow occlusion without interruption of nutrient branches of the affected coronary artery. Currently, this is possible in a minority of cases. In a literature review of coronary artery fistulas in adults covering 1993 and 2004, 107 fistulas were identified. Definitive
management was noted in 67%, with 38% closed surgically, 24% medically managed, and 5% closed by percutaneous embolization.

If coronary abnormalities are detected in patients with a history of supravalvar aortic stenosis, management will depend on the nature and severity of the abnormality. Obstructive lesions should be managed like other more common arteriosclerotic lesions, with either coronary artery bypass grafting or catheter-based dilatation or stenting (see Chapter 7). Ostial reconstruction for ostial occlusion, more commonly recommended in children, remains an attractive option in the adult, along with bypass grafting.

Indications for intervention for coronary obstructive lesions identified in patients who have undergone an arterial switch operation or Ross procedure are:

- Any obstructive lesion associated with symptoms of ischemia
- Asymptomatic lesions with 50% or greater luminal narrowing
- Asymptomatic lesions with demonstrable flow disturbance

Intervention may be by surgery or catheter-based balloon dilatation or stenting, depending on the position and nature of the lesion (see Chapter 7).A1,H10,R2

Surgical management of coronary involvement in Kawasaki disease is limited and decision making complex. If ischemia is present, bypass grafting or catheter balloon dilatation and stenting may be indicated. Large saccular aneurysms may be asymptomatic but carry a risk of rupture, thrombosis, and occlusion of adjacent coronary arteries. Aneurysm resection and coronary reconstruction or bypass grafting may be indicated.

Section XVI Single Ventricle

DEFINITION

Definition and details of single-ventricle physiology are described in Chapter 41.

MORPHOLOGY

A spectrum of morphologic entities falls under the category of single-ventricle physiology. The most common is hypoplastic left heart syndrome (see Chapter 49), followed by tricuspid atresia (see Chapter 41) and then by less common entities, such as double inlet ventricle and common ventricle (see Chapter 56), unbalanced atrioventricular septal defect (see Chapter 58), certain forms of Ebstein anomaly (see Chapter 42), and certain forms of pulmonary atresia with intact ventricular septum (see Chapter 40). In addition, some patients are managed as having single-ventricle physiology even though their structural anomalies are characterized by two well-formed ventricles and two well-formed atrioventricular valves, because the surgical reconstruction that would be required to septate such hearts is either impossible or inadvisable. An example would be some forms of double outlet right ventricle with noncommitted ventricular septal defect (see Chapter 53). Adults presenting with congenital heart disease uncommonly will have single-ventricle physiology. This is because all morphologic entities that result in single-ventricle physiology combined account for only a small fraction of congenital heart disease. Furthermore, mortality rates are high in infancy and childhood, with fewer than 50% of patients surviving to adulthood. Nevertheless, the palliated state of all survivors dictates that this small group of patients will demand an inordinate amount of resources in the adult congenital heart disease program.

Adults with single-ventricle physiology rarely present with newly diagnosed disease, previously diagnosed disease with benign physiology, or previously diagnosed disease thought to be too complex for intervention; only 13 adult patients with mixed circulation were evaluated over a 10-year period in one large adult congenital referral center.A12 The great majority of patients will present in adulthood with secondary disease following prior surgery. The prior surgery will by necessity be palliative and will result in one of three basic physiologic states:

- Palliation with separated circulations (Fontan circulation)
- Palliation with partially separated circulation (superior cavopulmonary anastomosis, or Glenn, circulation)
- Palliation with completely mixed circulation and controlled pulmonary blood flow (mixed circulation with systemic-to–pulmonary artery shunt or pulmonary trunk band)

The general goal in infancy and childhood is to achieve Fontan circulation in all patients with single-ventricle physiology. Some patients will not meet criteria required to undergo the Fontan and will reach final palliation with a superior cavopulmonary anastomosis. Still others will not meet criteria for a superior cavopulmonary anastomosis and will reach final palliation with a systemic-to–pulmonary artery shunt or a pulmonary trunk band.

A deeper level of complexity exists in this patient population. Patients with Fontan circulation may have an atrio pulmonary Fontan, a lateral tunnel Fontan, or an extracardiac conduit Fontan. Additionally, the circulations may not be fully separated if a fenestration was created as part of the Fontan operation. Patients with Glenn circulation may have a bidirectional cavopulmonary connection or a unilateral cavopulmonary connection, and may or may not have additional sources of pulmonary blood flow through a surgically created systemic-to–pulmonary artery shunt or pulmonary trunk band, or through a congenitally stenotic pulmonary valve. Patients with completely mixed circulation may have a single source of pulmonary blood flow through a shunt or band, or may have multiple sources of pulmonary blood flow through various combinations of shunts and bands. All these variations have particular importance in the adult with respect to the nature of sequelae that will be encountered.

As a final level of complexity, single-ventricle patients with any of these palliated states may have had arch reconstruction, repair of anomalous pulmonary veins, valve repairs or replacements, or subvalvar ventricular outflow tract muscle resections. Some patients may have their morphologic tricuspid valve, pulmonary valve, and morphologic right ventricle functioning in the systemic circulation. All these factors will have management implications in the adult.
Presentation

Single-ventricle patients may undergo evaluation for surgical therapy in a number of circumstances:

- Structural problems such as arch obstruction, bulboventricular foramen obstruction, valve regurgitation, or pulmonary artery obstruction regardless of mixed, partially separated, or separated circulation
- Systemic-to-pulmonary shunt or pulmonary trunk band revision (or rarely, initial placement) in mixed circulation patients
- Advancement of mixed circulation patients to partially separated circulation by performing a superior cavopulmonary anastomosis
- Advancement of patients with partially separated circulation to separated circulation with a Fontan operation
- Addition of a second source of pulmonary blood flow in cyanotic patients with a superior cavopulmonary anastomosis
- Conversion of an atrio pulmonary connection Fontan to an extracardiac conduit or lateral tunnel connection Fontan

Adult patients with mixed circulation can present in a variety of ways. Progressive cyanosis is common, especially in patients with a systemic-to-pulmonary artery shunt. This often is accompanied by increasing exercise intolerance. Heart failure resulting from chronic cyanosis and volume overload is also common. This may be accompanied by onset of arrhythmias, atrioventricular valve regurgitation, and increasing exercise intolerance as well. Patients with chronic unrestricted pulmonary blood flow present with pulmonary hypertension with Eisenmenger physiology. Infective endocarditis may develop, either at the shunt or band site or at an abnormal valve. Paradoxical embolism may occur, resulting in cerebrovascular events or other end-organ dysfunction. Thrombotic complications may develop as a result of increased blood viscosity related to elevated hematocrit. Brain abscess is also described in this population.

Adult patients with partially separated circulation—those with a bidirectional superior cavopulmonary anastomosis—typically present with progressive cyanosis as upper body–to–lower body venovenous collaterals and pulmonary arteriovenous malformations develop. Because of the cyanosis and partial mixing of the circulations, all of the sequelae described for mixed circulation patients can also occur. Unless there is an additional source of pulmonary blood flow, superior cavopulmonary anastomosis patients will not have a volume-loaded ventricle, and thus ventricular failure is less common than in mixed circulation patients.

Adult patients with separated circulation—those with a Fontan—also present in a variety of ways. At baseline, they have greatly diminished lung function and aerobic capacity. Those with anatriopulmonary Fontan connection inevitably develop atrial dilatation, which is associated with atrial arrhythmias, atrial thrombus with possible pulmonary embolism, and right pulmonary venous obstruction. Low cardiac output commonly develops in adult patients, regardless of the Fontan connection, and is associated with exercise intolerance, protein-losing enteropathy, hepatic congestion and dysfunction, peripheral edema, pleural effusion and ascites, and plastic bronchitis. Obstruction in the Fontan pathway may accelerate these signs and symptoms, as may progressive elevation of pulmonary vascular resistance from chronic pulmonary emboli. Atrial shunting resulting in cyanosis is unusual; however, venovenous connection from the systemic circulation to the pulmonary veins may be a cause of cyanosis. Patients with lateral tunnel and extracardiac conduit Fontan connections do not develop atrial dilatation and thus are less likely to develop atrial thrombus with chronic pulmonary emboli and atrial arrhythmias. Atrial arrhythmias, however, such as flutter, fibrillation, and sinus node disease leading to junctional rhythm, can occur. Low cardiac output, and its sequelae as described for atrio pulmonary Fontan connection patients, also develops, but more slowly.

Diagnosis

The main utility of the electrocardiogram (ECG) is to identify atrial and ventricular arrhythmias. Holter monitoring and electrophysiologic evaluation may be indicated based on the ECG or symptoms. The chest radiograph is particularly helpful in identifying and following pleural effusions in Fontan patients. Effusions suggest low cardiac output and failing Fontan circulation, and all of the sequelae associated with it, including protein-losing enteropathy. Echocardiography is the mainstay for evaluating and following single-ventricle patients. The usual intracardiac structural and functional evaluation of the ventricle, valves, aortic arch, and arterial and venous connections is performed. In Fontan patients, additional evaluation of the Fontan pathway is performed, looking for obstruction at the inferior caval and pulmonary artery ends, for thrombus and low flow with spontaneous contrast formation, for flow characteristics and severity of dilatation of the inferior vena cava and hepatic veins, and for the status of a fenestration if one is present.

Cardiac catheterization is indicated in any symptomatic single-ventricle patient to assess a number of variables, including:

- Ventricular hemodynamics
- Coronary arteries
- Pulmonary vascular morphology, pressure, and resistance
- Cardiac output
- Qp/Qs ratio
- Status of surgical shunts
- Bands and cavopulmonary connections
- Assessment of pulmonary arteriovenous malformations, venovenous abnormal connections, and systemic-to-pulmonary artery collateral formation

Cardiac catheterization is a necessity in any single-ventricle patient with previously operated or unoperated mixed circulation, or partially separated circulation, who is being considered for Fontan completion surgery (see Chapter 41 for criteria for proceeding to the Fontan). It is also a necessity for any patient being evaluated for conversion from an atrio pulmonary Fontan to either an extracardiac conduit or a lateral tunnel Fontan.

Magnetic resonance imaging (MRI) and computed tomography with angiography may be useful in single-ventricle patients, usually to augment the structural and functional echocardiographic evaluation, particularly in the pulmonary
arteries and veins. MRI is also useful for functional evaluation of the ventricular myocardium.

**NATURAL HISTORY**

The best prognosis is for patients with S,L,L double inlet left ventricle with moderate pulmonary stenosis. Survival into the sixth decade is possible.\(^{A12}\) Ten-year survival after lateral tunnel and extracardiac conduit Fontan connection, the predominant Fontan operations performed over the last 20 years, is 90% or greater, much better than that observed after the atriopulmonary Fontan.\(^{544}\) Once low output and its sequelae develop, unless there is a structurally correctable problem such as Fontan pathway obstruction, valve regurgitation, or systemic ventricular outlet obstruction or coarctation, survival is limited, with 5-year survival of about 50%. Survival in Fontan patients nevertheless is much better than the approximately 50% 20-year survival for patients with mixed circulation and partially separated circulation.\(^{W13}\)

The chronicity of the abnormal hemodynamic state associated with Fontan circulation leads to additional challenges for adults not generally considered in younger patients. Prevalence and severity of chronic lower extremity venous insufficiency are much greater than in the normal population.\(^{V1}\) Also, intracardiac thrombus formation is noted in 12% of adult Fontan patients when it is looked for, and is attended by significant morbidity.\(^{T23}\) Atrial arrhythmias occur with increasing frequency in adults, noted in 41% of Fontan patients in one study, and arrhythmias were associated with atrial thrombus.\(^{G13}\) In an analysis of all adult Fontan patients presenting to a large clinic, 17% were found to have silent pulmonary emboli.\(^{V11}\)

**TECHNIQUE OF OPERATION**

Surgical techniques, including systemic-to–pulmonary artery shunt, pulmonary artery band, bidirectional superior cavopulmonary anastomosis, and extracardiac conduit and lateral tunnel Fontan operations, are described in Chapter 41. Therapeutic catheter-based procedures may be used to relieve various obstructions and to occlude abnormal venovenous connections, systemic-to–pulmonary artery collaterals, surgical shunts, and Fontan fenestrations.

---

**Figure 29-47** Cryoablation left and right atrial maze (Cox-maze III) procedure in patient with tricuspid atresia undergoing an extracardiac conduit Fontan conversion. A, Superior (SVC) and inferior vena cavae (IVC) have been detached from right atrium in preparation for extracardiac conduit Fontan, and cardiacl stumps of SVC and IVC have been oversewn. Cryolesions are placed in four locations in the right atrium at \(-60^\circ\C\) for 90 seconds each. In this patient with tricuspid atresia, a linear cryoprobe is used to ablate tissue between atrial septal defect (ASD) and SVC stump, ASD and lateral edge of atriotomy, coronary sinus os and IVC stump, and area of atretic tricuspid valve anulus and IVC stump. B, Left-sided cryolesions are placed for patients with preoperative atrial fibrillation. They are placed around the pulmonary veins, at orifice of left atrial appendage, and between inferior pulmonary veins and mitral valve anulus. Appropriate adjustments, while adhering to the basic principles of the maze, must be made in placing the cryolesions for other single-ventricle morphology, for example, in patients with unbalanced atrioventricular septal defect or hypoplastic left heart. (From Weinstein and colleagues.\(^{W18}\))
The maze procedure is modified as appropriate for patients with the variable morphologic features associated with the spectrum of single-ventricle anomalies. Fig. 29-47 shows the cryolesions for a right and left atrial maze procedure applied to a patient with tricuspid atresia who is about to undergo an extracardiac conduit Fontan.

RESULTS
Systemic-to-pulmonary artery shunt and pulmonary trunk band procedures have a low surgical mortality in adults without important comorbid conditions, similar to the mortality of these same procedures in children (see Chapter 41). For shunt procedures it is about 5%, and for bands less than 1%.

Early mortality for the superior bidirectional cavopulmonary anastomosis and Fontan operation in adults is not well documented, but should not differ from outcomes in younger patients, about 2% to 5% for each, as long as selection criteria are met. Observed mortality in most series is higher than this, however, because these series span many decades, and the outcomes often reflect the era. In the largest single-institution study, 132 adults (mean age 23 years) underwent the Fontan procedure between 1973 and 2001, with an early mortality of 8.3% (CL 5.8%-12%). Other studies, including male gender, pulmonary artery pressure greater than 15 mmHg, and age greater than 30 years.

In the next largest series, Veldtman and colleagues reported 61 cases (median age 36 years) with an early mortality of 13% (CL 8.6%-19%); 15-year survival was 67%. Van den Bosch reported on seven adults undergoing the Fontan with one early death (14%; CL 2.3%-41%), and in a mean follow-up period of 15 years, there were two additional deaths and one cardiac transplantation. Gates and colleagues reported on 21 patients with an early mortality of 4.8% (CL 0.8%-15%), with one late death over a mean follow-up time of 7.4 years.

Podzolkov and colleagues reported an early mortality of 6.9% (2/29; CL 2.4%-16%) for the superior bidirectional cavopulmonary anastomosis in adults, and 8.3% for the Fontan in adults. Both values were similar to their outcomes in children. Gates and colleagues reported an early mortality of 6.9% (2/29; CL 2.4%-16%) for the superior bidirectional cavopulmonary anastomosis in adults, and 8.3% for the Fontan in adults. Both values were similar to their outcomes in children.

Early mortality after conversion of the atrioventricular Fontan to the cavopulmonary Fontan ranges from 0% to 25%. The wide range of mortality is likely related to the selection criteria used in individual series. In one of the largest series (containing both children and adults), Mavroudis and colleagues reported no early mortality (CL 0%-4.6%) and one transplant in 40 conversions and concomitant maze procedures (mean age 19 ± 9.0 years at conversion). At a mean follow-up of 2.5 years, functional status was improved, and there was one death and two additional transplants. In another study of 27 conversions in adults (mean age 30 years), there were two early deaths (7.4%; CL 2.6%-17%). Both patients who died had liver cirrhosis and had been evaluated and turned down for transplantation. Functional status improved following conversion. Most patients in this series (78%) also had concomitant maze arrhythmia surgery for atrial flutter or fibrillation, with late arrhythmia recurrence of 14% at 4.2-year follow-up. Another study of 10 adults (mean age 21 years) undergoing conversion and concomitant cryoablation showed one early death (10%; CL 1.6%-30%) and a second midterm death. At follow-up, all survivors improved functionally, and arrhythmia recurrence was 10%.

Sheikh and colleagues reported 15 conversions (mean age 20 years) with no early (CL 0%-12%) or late mortality and improved functional status at a mean follow-up of 43 months. Eleven of the 15 patients had arrhythmia surgery as well, with reduced requirement for medications at follow-up. Mott and colleagues reported no early (CL 0%-12%) or late deaths in 15 conversions with concomitant arrhythmia surgery (mean age 23 years) at 30-month follow-up.

INDICATIONS FOR OPERATION

![Graph showing survival rates after Fontan operation](image-url)
In adults with mixed circulation (usually previously operated, but rarely with no surgical history) and unclear physiology, full evaluation, including cardiac catheterization, will determine whether criteria are met to advance to a state of separated circulation. Criteria for advancing to a superior cavopulmonary anastomosis are the same as those for infants and children (see Chapter 41). If these criteria are met, however, in contrast to the situation in young patients, a superior cavopulmonary anastomosis will rarely be adequate as the sole source of pulmonary blood flow, because of severe cyanosis. A secondary source, either from a new or existing systemic–pulmonary artery shunt or pulmonary trunk band, or from native pulmonary blood flow across a naturally stenotic outflow tract to the pulmonary arteries, will be required.

If the criteria are not met to advance to a separated circulation in the adult with mixed circulation, and the patient is cyanotic due to reduced pulmonary blood flow, then further surgical management with a systemic-to-pulmonary artery shunt, or possibly a pulmonary trunk band revision (if one is in place already), is indicated. If the patient is cyanotic because of pulmonary hypertension, evaluation for heart-lung transplantation is the only surgical option.

If pulmonary overcirculation is present and pulmonary vascular obstructive disease is not, then shunt revision or pulmonary trunk band placement or tightening is indicated as appropriate. Such patients can be further evaluated with catheterization approximately 6 months after shunt or band revision to assess criteria for advancing to a separated circulation. If pulmonary vascular obstructive disease is present in the overcirculated patient, the only surgical option is heart-lung transplantation.

In adult patients with partially separated circulation, if criteria are met at cardiac catheterization (see Chapter 41), advancement to a separated circulation with a completion Fontan operation is indicated. If the patient does not meet criteria for a Fontan and is symptomatic from cyanosis, creation of an additional source of pulmonary blood flow (usually a systemic-to-pulmonary artery shunt) is indicated. If pulmonary arteriovenous malformations are partially the cause of cyanosis, the shunt should be placed to direct the systemic flow primarily to the lung with the dominant malformations. Rarely, large isolated arteriovenous malformations can be closed using percutaneous catheter-based methodology.

In adult patients with separated circulation, surgical intervention may be indicated in several circumstances. Any significant structural cardiac problem or systemic arterial, pulmonary arterial, systemic venous, pulmonary venous, or Fontan pathway obstruction is an indication for surgical correction if catheter-based intervention is contraindicated or unsuccessful. In symptomatic patients with low cardiac output due to elevated pulmonary vascular resistance, a surgical fenestration may be indicated in selected cases. Adult Fontan patients who are fully or nearly fully saturated, however, may not tolerate the increase in cyanosis that attends fenestration. All adult atrio pulmonary Fontan patients with acceptable ventricular function and low pulmonary vascular resistance should be considered for conversion to an extracardiac conduit or lateral tunnel Fontan connection. Conversion is strictly indicated if atrial flutter or fibrillation, pulmonary venous compression, atrial thrombus, or structural problems such as obstruction in the Fontan pathway are present.158,166

In all single-ventricle patients with severe ventricular failure, regardless of mixed, partially separated, or separated circulation, and normal pulmonary vascular resistance, the only surgical option is heart transplantation.62

If atrial flutter or fibrillation is present in single-ventricle patients undergoing surgery to correct structural problems, to advance to a more separated circulation, or to convert from an atrio pulmonary to a cavopulmonary Fontan, a maze procedure or one of its modifications is indicated as a concomitant procedure.166

Section XVII  Other Anomalies Rarely Requiring Surgery in the Adult

ISOLATED PULMONARY STENOSIS

Definition

Isolated pulmonary stenosis is a common congenital heart anomaly; however, it rarely requires surgery in the adult.311 The reasons for this are that the valve obstruction is often mild and self-limited, and percutaneous catheter-based valvotomy is often effective in those who need treatment.

Morphology

Two common morphologic subtypes of isolated pulmonary stenosis are recognized. The predominant type is the doming valve with three fused commissures but underlying well-developed valve cusp tissue. The less common type (=20%) is the dysplastic valve, defined by three cusps with fully formed commissures but thickened immobile myxomatous cusp tissue. This type of valve is associated with Noonan syndrome.311 Occasionally, isolated pulmonary valve stenosis will be caused by a bicuspid valve.

Technique of Operation

Because surgery for pulmonary stenosis in the current era is relegated to a second-choice role behind balloon valvotomy, most patients presenting for surgery will have unfavorable morphology and will likely require pulmonary valve replacement. The occasional patient with a doming valve that does not respond to catheter-based balloon dilatation, and the occasional patient with a doming valve who is undergoing cardiac surgery for another anomaly, are candidates for surgical commissurotomy. Most surgical cases, however, have either dysplastic morphology or one or more associated conditions, such as anular hypoplasia or valve regurgitation, and will require valve replacement. Occasionally, a dysplastic valve without regurgitation and with adequate anular size will respond to surgical valvuloplasty involving shaving of the thickened cusps.

Currently, the replacement option of choice is a bioprosthetic valve placed orthotopically. It may be necessary to patch augment the anular and supravalvular component of the right ventricular outflow tract or to resect muscle in the subvalvar component of the right ventricular outflow tract as well. Surgical reduction of the pulmonary trunk may be considered when there is associated marked post-stenotic dilatation of the pulmonary trunk, but this procedure is truly
In one series of 40 patients (age range 18-56 years), the gradient was reduced by catheter intervention but not eliminated (persistent gradient of $37 \pm 14$ mmHg). All patients had mild or less regurgitation, and there was a tendency for subpulmonic gradients to regress at 24-month mean follow-up (Fig. 29-49). Other studies with follow-up of up to 10 years after balloon dilatation show similar findings. Dysplastic valves are not as effectively treated by catheter-based balloon valvotomy, with generally unacceptable residual gradients.

Balloon valvotomy for the doming valve is currently the first line of therapy. Two studies comparing balloon treatment and surgery suggest that gradient relief and freedom from reintervention are better with surgery (Fig. 29-50); however, although these differences are important, they are small, and thus they are offset by a higher occurrence of important regurgitation, more ventricular ectopy, greater cost, and increased invasiveness associated with surgery.

Surgery (pulmonary valvotomy) for unselected cases of isolated pulmonary stenosis in the adult has an early mortality approaching zero. Long-term survival and freedom from reoperation are also extremely favorable, with no late mortality and 95% freedom from reintervention at 25 years. When valve replacement is necessary, long-term outcomes are similar to those for other patients with bioprosthetic valves in the pulmonary position.

### Indications for Operation

There are several indications for surgical intervention for isolated pulmonary stenosis:

- After catheter-based balloon dilatation with a residual peak echocardiographic Doppler gradient of greater than 60 mmHg in asymptomatic patients or a residual peak gradient of more than 50 mmHg in symptomatic patients
- In any patient with associated severe pulmonary regurgitation, anular hypoplasia, fixed subvalvar stenosis, supravalvar stenosis, or dysplastic valve morphology
- If other cardiac anomalies requiring cardiac surgery, such as coronary artery disease, ventricular septal defect, or tricuspid regurgitation, are present

If there is an associated atrial septal defect, combined catheter-based closure and balloon pulmonary valvotomy may be performed.

### TOTAL ANOMALOUS PULMONARY VENOUS CONNECTION

#### Definition

Definition, morphology, and basic physiology of total anomalous pulmonary venous connection (TAPVC) are described in Chapter 31.

#### Morphology

It is rare for adults with TAPVC to survive into adulthood unrepaired. A few isolated cases are reported. Characteristics

---

*Figure 29-49* Peak pulmonary systolic gradient (PG) by echocardiography from right ventricle to pulmonary artery before, immediately after, and at mean follow-up of 24 months after balloon pulmonary valvuloplasty in 32 adult patients. Bars represent mean ± standard deviation. (From Kaul and colleagues.)

*Figure 29-50* Freedom from reintervention in adults with isolated pulmonary valve stenosis managed by surgery ($n = 54$) or balloon valvuloplasty ($n = 92$). Numbers represent patients remaining at risk. (From Peterson and colleagues.)
of individuals who survive include unobstructed supracardiac form of the disease, large intraatrial communication, and low pulmonary vascular resistance with increased pulmonary blood flow, resulting in only mild cyanosis.\textsuperscript{A17}

Clinical Features and Diagnostic Criteria

Clinical presentation is characterized by varying severity of cyanosis and signs and symptoms of right heart and pulmonary overcirculation. Echocardiography is diagnostic; however, cardiac catheterization is mandatory to assess the status of the pulmonary vascular bed. Magnetic resonance imaging (MRI) and computed tomography (CT) may be helpful.

Natural History

Recurrent pulmonary vein stenosis presenting in adults with a history of infant repair of TAPVC is rare. Recurrent obstruction following infant repair occurs in about 10% of cases in which the total anomalous connection was an isolated lesion (it is higher in single-ventricle and heterotaxy patients). Furthermore, recurrence almost always occurs in the first 6 months after initial infant repair.\textsuperscript{R28,J2,R11}

Technique of Operation

Surgical techniques used to repair this anomaly in adults are the same as those used in infants (see Chapter 31).

Results

Early mortality approaches zero. Arikawa and colleagues report two adult cases, aged 43 and 51 years, without mortality and with uneventful postoperative courses and improved functional status.\textsuperscript{A17} These authors also review the Japanese literature and report on six additional patients over age 40 years, with similar outcomes. John, Sukumar and their colleagues note that presentation in late childhood and adulthood implies a better prognosis than presentation in infancy. They report no early or late mortality in the former groups.\textsuperscript{J8} Berg and colleagues report on three patients, aged 22, 29, and 33 years, all with minimal cyanosis at rest, dyspnea, mild heart failure, and mild to moderate pulmonary hypertension. One patient had gone through an uneventful pregnancy. Another had concomitant important mitral regurgitation that was surgically repaired. There was no early or late mortality after repair, and all patients were functionally improved.\textsuperscript{R17}

VASCULAR RING AND ASSOCIATED ARCH ANOMALIES

Definition

Definition, morphology, and basic physiology of vascular ring are described in Chapter 51. Vascular rings rarely present in adults. Most reported cases are single case reports.

Morphology

In adults, the most common anomaly is double aortic arch (\textsuperscript{\textapprox}45\%), followed by right aortic arch with anomalous left subclavian artery with ligamentum arteriosum (\textsuperscript{\textapprox}30\%).\textsuperscript{G20}

Clinical Features and Diagnostic Criteria

Vascular rings in adults may be found incidentally\textsuperscript{K1,F3} or may present with symptoms of dysphagia lusoria or upper respiratory obstruction.\textsuperscript{J1,G20,G21,M39,N4,S34} It is more common for dysphagia to be the presenting symptom in adults than in children, although respiratory obstruction is still the most common presentation in adults (42% present with respiratory symptoms, 33% with dysphagia). Diagnosis can often be made by chest radiography, contrast esophagogram, and echocardiography; however, MRI or CT are critical, allowing more precise imaging of the vascular anomaly and also imaging of the vasculature relationship to adjacent structures, including the trachea and esophagus.

Pulmonary artery sling is rare in adults. The literature consists of case reports only. Most are asymptomatic, presenting as an incidental finding\textsuperscript{P23,N47}; however, some present with esophageal or tracheal obstructive symptoms, or both.\textsuperscript{J1} Diagnostic evaluation and indications for surgery are similar to those for vascular rings.

Natural History

Presentation in adulthood after vascular ring repair in childhood is rare. Ruzmetov and colleagues followed 183 childhood repairs for up to 35 years with no reports of late complications.\textsuperscript{R24} There is a single case report of late presentation of subclavian steal syndrome in an adult who underwent vascular ring repair in infancy.\textsuperscript{C30}

Technique of Operation

All rings can be approached effectively through a median sternotomy. However, the more traditional approach is through a lateral thoracotomy (see Chapter 51).\textsuperscript{K139}

Surgical management of pulmonary artery sling is described in Chapter 51. In adults, in contrast to infants, tracheal reconstruction is usually not necessary.

Results

There are no reports of perioperative deaths in the modern literature. Symptomatic improvement occurs reliably in patients presenting with dysphagia, but less reliably in those presenting with respiratory symptoms. In the case of late presentation of subclavian steal syndrome, the original repair involved division of the ligamentum and left subclavian artery, without subclavian artery reimplantation.\textsuperscript{C30}

Indications for Operation

Asymptomatic anomalies may be followed. Surgical repair is recommended in the presence of important symptoms.

COR TRIATRIATUM

Definition
There are sporadic reports of cor triatriatum sinister presenting in the adult, either in the form of isolated case reports or included in single-institution (mostly) pediatric series. \cite{C17,H22,K10,K26,O4,S5,V7} Cor triatriatum dexter has been reported in adults, usually as an asymptomatic incidental finding. \cite{M31,S6,Y4} When symptoms are present, they mimic right heart failure.

Morphology

In contrast to children (see Chapter 32), most adults do not have complex associated cardiac anomalies; however, associated cardiac structural anomalies have been found in some patients presenting in adulthood. \cite{C17}

Clinical Features and Diagnostic Criteria

Presentation of isolated cor triatriatum sinister in the adult is identical to that of mitral stenosis, including dyspnea, pulmonary hypertension, atrial fibrillation, right heart failure, and hemoptysis. In mild cases, presentation may be incidental. Thrombus was present in the accessory chamber in one adult. \cite{P10} Diagnosis can be made by echocardiography; however, MRI and CT define the morphologic details with more clarity. Cardiac catheterization is indicated to assess the state of the pulmonary vasculature.

Cor triatriatum dexter has been reported in adults, usually as an asymptomatic incidental finding. \cite{M31,S6,Y4} When symptoms are present, they mimic right heart failure.

Technique of Operation

Surgical techniques are similar to those used in children (see Chapter 32). If chronic atrial fibrillation or flutter is present, a concomitant maze procedure should be performed.

Results

In the few case reports documented in the literature, surgical repair has been performed without early mortality and with improvement in symptoms and reduction in pulmonary artery pressure.

Indications for Operation

Surgical repair is indicated if symptoms are present or if other changes, such as thrombus formation, develop. Surgical excision of cor triatriatum dexter is indicated if symptoms are present.

SINUS OF VALSALVA ANEURYSM

Definition

Definition, morphology, and basic physiology of sinus of Valsalva aneurysm are described in Chapter 36.

Morphology

These anomalies are rare in adults. When they occur, they are often associated with unicusp or bicuspid aortic valves. The aneurysm occurs most frequently in the noncoronary and right coronary sinuses, but can occur in the left.

Clinical Features and Diagnostic Criteria

Sinus of Valsalva aneurysms are generally asymptomatic until they rupture. However, they may cause problems from a mass effect without rupture, including coronary obstruction, aortic regurgitation, right ventricular outflow obstruction, and ventricular tachycardia. Thrombus formation with subsequent embolism can also occur. When rupture occurs, it is usually into a right-sided chamber, creating an aortic to right atrial or right ventricular fistula. Rupture may also cause cardiac tamponade. Rupture usually presents as an emergency with extreme hemodynamic instability. Sinus of Valsalva aneurysms are often detected incidentally or during imaging of abnormal aortic valves.

Natural History

The natural history of small and moderate aneurysms is unknown, and the risk of rupture of large aneurysm, although well documented, is not quantified.

Technique of Operation

The appropriate surgical procedure will vary from simple plication, to resection and sinus patch reconstruction, to aortic root replacement with coronary artery reimplantation. \cite{D10,H3,P11,R10,U1}

Indications for Operation

Treatment options are well defined. If surgery is required for aortic valve disease or any other cardiac problem, sinus of Valsalva aneurysms of any size should be addressed. If no other surgery is indicated, surgical correction of large and moderate-sized aneurysms is the best approach to prevent rupture and other sequelae. Small aneurysms should be followed carefully.

DOUBLE-CHAMBERED RIGHT VENTRICLE

Definition

This anomaly is rare in adulthood in developed countries. Two series with multiple patients are reported in the literature. \cite{L6,M19} Otherwise, there are only occasional individual case reports or mention of an occasional adult in series that include predominantly children. \cite{G1,S32} In the study by McElhinney and colleagues, it is reported that a literature review identified six case reports. \cite{M19} Larger series of adult patients are reported from countries with underdeveloped healthcare systems where this anomaly may go undiagnosed until adulthood. \cite{S33}

Morphology

In adulthood, as in childhood, there are almost always associated structural anomalies. In one series of 11 patients, 10 had associated anomalies, usually a ventricular septal defect, and in a series of 3 adults, all had associated anomalies, either atrial or ventricular septal defects. \cite{L6,M19}

Clinical Features and Diagnostic Criteria
Symptoms in adults are different from those in children. They include syncope, chest pain, and exertional dyspnea. New York Heart Association functional class ranges from II to IV in most patients. Diagnosis in the adult may be difficult. Electrocardiography (ECG) is non-specific, showing evidence of right ventricular hypertrophy, right atrial enlargement, and diffuse ST-wave changes. Transthoracic echocardiography often fails to make the diagnosis. The incorrect diagnosis is often tetralogy of Fallot, ventricular septal defect, or pulmonary valve stenosis. Transesophageal echocardiography may be more accurate. MRI has been reported to establish the diagnosis and may supplement echocardiography. Cardiac catheterization should be performed in all cases and establishes the diagnosis in all. It also should always be performed to assess coronary arteries and overall hemodynamics.

**Technique of Operation**

Surgical techniques are similar to those used in children. Usually a transatrial–transpulmonary artery approach will be effective, with a formal right ventriculotomy unnecessary. Associated anomalies should be addressed as well.

**Results**

Early mortality should be less than 1%. All patients reported in the literature have survived, and follow-up in the two series ranged from 15 to 270 months, with no late mortality, improved functional status, and a low occurrence of recurrent obstruction. Perioperative mortality due to low cardiac output has been reported, but only for patients undergoing surgery prior to 1965.

**Indications for Operation**

Surgery is indicated in the presence of symptoms, signs of myocardial strain or ischemia, or a gradient greater than 40 mmHg.

DEFINITION

An atrial septal defect (ASD) is a hole of variable size in the atrial septum. A patent foramen ovale that is functionally closed by overlapping of limbic tissue superiorly and the valve of the fossa ovalis inferiorly (in response to the normal left-to-right atrial pressure gradient) is excluded. ASDs generally permit left-to-right shunting at the atrial level. Partial anomalous pulmonary venous connection (PAPVC) is a condition in which some but not all pulmonary veins connect to the right atrium or its tributaries, rather than to the left atrium. The term connection is preferred to the term “return,” because connection is anatomical and return is governed by hemodynamic factors. PAPVCs may occur as isolated anomalies or may be combined with ASDs.

These two groups of anomalies are considered together in this chapter because they manifest similar physiology and result in similar clinical findings. Total anomalous pulmonary venous connection is considered in Chapter 31. ASDs typically occur in association with other cardiac anomalies, and these are considered in chapters dealing with those anomalies.

HISTORICAL NOTE

Clinical recognition of an ASD has been possible only in about the past 70 years. Among the 62 recorded autopsy cases of ASD analyzed by Roesler in 1934, only one had been correctly diagnosed during life.\(^\text{56}\) By 1941, Bedford and colleagues were able to make the diagnosis clinically in a number of patients.\(^\text{57}\) When cardiac catheterization came into general use during the late 1940s and early 1950s, secure diagnosis became possible. The first descriptions of PAPVC are attributed to Winslow in 1739\(^\text{115}\) and Wilson in 1798.\(^\text{111}\) The first diagnosis of PAPVC during life was reported by Dotter and colleagues in 1949.\(^\text{107}\)

A number of ingenious closed methods for repair of ASDs and related conditions were proposed and studied experimentally in the productive and expansive surgical era following the end of World War II in 1945. In 1948 in Toronto, Murray reported closing an ASD in a child by external suturing.\(^\text{110}\) Several other closed methods had clinical application, including Bailey and colleagues’ “atriocephoptomy” and Sondergard’s purse-string suture closure.\(^\text{22,51}\) However, limited applicability of these methods was always apparent, and they were soon abandoned.

Hypothermia, induced by surface cooling, and inflow occlusion for repair of ASDs was introduced during the early 1950s (see Historical Note in Section I of Chapter 2). Lewis and Taufic reported the first successful open repair of an ASD with this method in 1953.\(^\text{15}\) At about the same time, Gross invented the ingenious atrial well technique, a semi-open approach in which a rubber open-bottomed well or cone was sutured to an incision in a clamp-exteriorized portion of the right atrial wall.\(^\text{61,19}\) When the clamp was released, the blood rose into the well, and through this pool of blood, the surgeon could place sutures under digital control for direct or patch closure of the defect. Gibbon started the era of open heart surgery in 1953 when he successfully repaired an ASD in a young woman using a pump-oxygenator.\(^\text{69}\) Although these three methods—hypothermia and inflow occlusion, atrial well, and cardiopulmonary bypass (CPB)—were all used during the late 1950s and provided similar early results,\(^\text{58}\) by the late 1960s almost all surgeons used CPB exclusively for these repairs. Percutaneous catheter techniques for closing a fossa ovalis ASD using a polyester double umbrella device were introduced by King and Mills in 1974.\(^\text{124}\)

The first reported treatment for a type of PAPVC was lobectomy in 1950.\(^\text{119}\) In 1958, Neptune and colleagues reported repair using a closed technique in 17 patients with PAPVC of the right lung to the right atrium associated with ASD.\(^\text{55}\) It is not certain who first repaired the sinus venosus syndrome, but the malformation was clearly illustrated by Bedford and colleagues in 1957.\(^\text{114}\) Repair of PAPVC to the inferior vena cava was performed by Kirklin and colleagues at Mayo Clinic in 1960 and was also subsequently reported by Zubiate and Kay in 1962.\(^\text{117,22}\) Correction of anomalous connection of the left pulmonary veins to the left brachiocephalic vein and other forms of PAPVC was reported from the Mayo Clinic in 1953\(^\text{56,15}\) and later in 1956.\(^\text{17}\)

MORPHOLOGY

Types of Atrial Septal Defect

As viewed from the right atrial side (see Fig. 1-2 in Chapter 1), the normal atrial septum may have defects in almost any location (Box 30-1). Although the morphology of these defects has been known since the early descriptions by Robitansky in 1875,\(^\text{85}\) the advent of open heart surgery emphasized their surgically important aspects\(^\text{54,16}\) (Fig. 30-1).

Fossa Ovalis Defect

The most common ASD is the fossa ovalis type, also called foramen ovale type or ostium secundum defect. This defect lies within the perimeter inscribed by the limbus anteriorly, superiorly, and posteriorly (Fig. 30-2). The smallest defects are
Box 30-1  Types of Atrial Septal Defect

- Fossa ovalis defect
- Posterior defect
- Coronary sinus defect
- Sinus venosus defect
- Confluent defect
- Ostium primum defect (absence of atrioventricular septum)

*Fossa ovalis, posterior, and most confluent defects can be classified as secundum type.

*Varies in size from small valvar-incompetent foramina ovale ASD to complete absence of septum primum tissue with resultant ASD extending to inferior vena cava.

essentially valvar incompetent foramina ovale that occur beneath the superior limbus, between it and the valve (floor) of the fossa ovalis. The floor of the fossa ovalis (remnant of septum primum) may in this situation have multiple fenestrations of various sizes (Fig. 30-3). When more of the floor of the fossa ovalis is absent, a larger fossa ovalis defect is present. When all fossa ovalis tissue is absent, the ASD is confluent with the orifice of the inferior vena cava (IVC). The eustachian valve of the IVC then overhangs the ASD and must not be mistaken for its inferior edge at operation. Size of this type of ASD is also affected by any hypoplasia of the limbus that may be present. When the limbus is quite hypoplastic anteriorly, there is only a thin rim of tissue above the atrioventricular (AV) valves (formerly this was called an intermediate defect and was sometimes confused with an ostium primum defect). The limbus may also be hypoplastic superiorly or posteriorly.

Normally the IVC–right atrial junction is partly to the left of the plane of the limbus, so that when the floor of the fossa ovalis is absent and an ASD of fossa ovalis type extends to the IVC, the caval ostium overrides (or straddles) the defect onto the left atrium.\(^7\) This defect results in some right-to-left shunting of IVC blood to the left atrium in virtually all patients with a large fossa ovalis–type ASD (as documented in experimental studies\(^{69,455,510}\)) and severe shunting with cyanosis in a few patients.\(^{455}\) Also, the position of the normally connected right pulmonary veins next to the atrial septal remnant results in preferential left-to-right shunting of their venous drainage.\(^{832,510}\)

Posterior Defect

A defect in the most posterior and inferior part of the atrial septum, with absence, hypoplasia, or anterior displacement of the posterior limbus, is termed a posterior ASD. The orifices of the right pulmonary veins usually open directly into the area of the defect, but true anomalous pulmonary venous connection of the right lung frequently coexists. In the pure form of this type of ASD, the tissue of the fossa ovalis (including the posterior limbus) is present, and the ASD is an oval defect posterior to this tissue (Fig. 30-4).

Sinus Venosus Defect

The ASD that occurs in sinus venosus syndrome (subcaval defect, superior vena cava defect) is located immediately beneath the orifice of the superior vena cava (SVC), superior to the limbic tissue, and is usually associated with anomalous pulmonary venous connection of the right superior pulmonary vein to the SVC near or at the SVC–right atrial junction. The lowermost margin of the defect is a sharply defined crescentic edge of atrial septum, whereas its upper margin is devoid of septum, being continuous with the posterior SVC wall, which in turn is continuous with the upper edge of the left atrium. The SVC usually overrides the atrial septum onto the left atrium to some extent (see “Sinus Venosus Malformation [Syndrome]” later in this chapter).

Coronary Sinus Defect

Coronary sinus ASDs are part of unroofed coronary sinus syndrome. When the sinus is completely unroofed and no partition is present to separate it from the left atrium, the ostium of the coronary sinus is a hole in the atrial septum that permits free communication between left and right atria (see Chapter 33). Occasionally a fenestration may exist in this partition in the midportion of the coronary sinus, particularly in hearts with tricuspid atresia, or rarely the fenestration may be almost at the ostium of the coronary sinus.\(^7\) (Fig. 30-5).

Confluent Defect

Large ASDs may represent a confluence of two of the defects already described. Thus, a fossa ovalis defect coexisting with absence of the posterior limbus can present as a very large ASD with no septal remnant posteriorly. Another confluent defect occasionally seen is a combination of coronary sinus and fossa ovalis ASDs.

Ostium Primum Defect

An ASD occurs anterior to the fossa ovalis (and the anterior limbus) when the AV septum is absent. Such defects are called AV septal defects, AV canal defects, or ostium primum atrial septal defects and are considered in Chapter 34. When essentially the entire atrial septum is absent (common atrium), the defect includes absence of the AV septum (see “Atrial Septal Deficiency and Interratrial Communications” under Morphology in Chapter 34).

Types of Partial Anomalous Pulmonary Venous Connection

Sinus Venosus Malformation

The most common type of PAPVC is the defect present in sinus venosus malformation, in which PAPVC coexists with a superior caval ASD. In sinus venosus malformation, the right upper and middle lobe pulmonary veins (right superior pulmonary vein) attach to the low SVC or the SVC–right atrial junction, an arrangement present in about 95% of patients with a superior caval ASD.\(^{46,34,520}\) Most often, the anomalous pulmonary venous connection is through two anomalous veins from upper and middle lobes, one superior to the other, but there may be three or rarely four veins, with the uppermost entering the SVC near the ayzygos vein entry. Infequently, only part of the right superior vein connects anomalously, with the inferior (right middle lobe) portion of that vein connecting to the left atrium. Rarely, both the right superior and right inferior pulmonary veins connect anomalously to the low SVC or SVC–right atrial junction (Fig. 30-6).

The lowermost part of the SVC that receives the anomalous veins is usually wider than normal, although it may be relatively small, particularly when there is also a well-formed left SVC, which is not uncommon.\(^7\) The SVC typically overrides the atrial septum to some extent and extends partly into...
Figure 30-1  Anatomy of atrial septal defect (ASD), viewed from right atrium.  

Figure 30-2  Specimen with fossa ovalis atrial septal defect, viewed in anatomic orientation with superior vena cava above and inferior vena cava and its eustachian valve below. Limbus forms anterior, superior, and posterior rim of defect, and remnants of the floor (valve) of fossa ovalis form inferior rim. Key: CoS, Coronary sinus; D, atrial septal defect; E, eustachian valve; L, limbus; TV, septal leaflet of tricuspid valve.

Figure 30-3  Specimen with large fossa ovalis atrial septal defect viewed from opened right atrium in same orientation as Fig. 30-2. Thin remnant of septum primum (floor of fossa ovalis) shows numerous perforations. Key: D, Atrial septal defect; IVC, inferior vena cava; SP, septum primum; SVC, superior vena cava; TV, tricuspid valve.

Figure 30-4  Specimen with large posterior atrial septal defect, viewed from opened right atrium. Orientation is as in Fig. 30-2. Fossa ovalis is intact, but there is a patent foramen ovale. Right inferior pulmonary vein certainly drains anomalously, but is probably normally connected. Right superior pulmonary vein is anomalously connected to right atrium. Key: CoS, Coronary sinus; D, atrial septal defect; FO, fossa ovalis; IVC, inferior vena cava; RIPV, right inferior pulmonary vein; RSPV, right superior pulmonary vein; SVC, superior vena cava.
Figure 30-5  Unusual example of small coronary sinus atrial septal defect near ostium. Other anomalies include patent foramen ovale, ventricular septal defect, mild aortic regurgitation, and possible mitral regurgitation. Key: CoS, Coronary sinus; D, atrial septal defect; FO, fossa ovalis; IVC, inferior vena cava; TV, tricuspid valve.

Figure 30-6  Unusual example of sinus venosus malformation. A, Specimen with typical subcaval atrial septal defect (ASD), but with both right superior and right inferior pulmonary veins entering superior vena caval–right atrial junction. In addition, the left pulmonary veins form a common channel connected to left atrium and right superior vena cava. Left superior vena cava and mitral atresia were also present. B, Interior of right atrium showing the subcaval ASD high in the septum and enlarged coronary sinus ostium to which is connected the left superior vena cava. Key: CoS, Coronary sinus; D, atrial septal defect; FO, fossa ovalis; IVC, inferior vena cava; RAA, right atrial appendage; RIPV, right inferior pulmonary vein; RSPV, right superior pulmonary vein; RSVC, right superior vena cava.
the left atrium, resulting in a right-to-left shunt of some SVC blood to the left atrium. In a few patients, SVC overriding is severe enough to produce a large right-to-left shunt and marked cyanosis. The overriding may also be complete, so that the SVC drains directly and completely into the left atrium. The relationship between anomalous connection of the SVC to the left atrium without an ASD and sinus venosus ASD is indicated by connection of pulmonary veins from the right upper lobe to the cardiac end of the SVC in some patients with PAPVC. This relationship also occurs in patients with no ASD but in whom the pulmonary veins from the right upper lobe are connected to the cardiac end of the SVC, with the SVC connected to the left atrium by a large opening, and to the right atrium by a small opening.

Rarely, a typical high superior caval ASD is present without anomalous pulmonary venous connection; right pulmonary veins connect to the left atrium but more superiorly than normal.

**Right Superior Pulmonary Vein to Superior Vena Cava**

Occasionally the entire right superior pulmonary vein connects to the SVC without an associated superior caval ASD. The connection is then usually well above (superior to) the SVC–right atrial junction, and the lower part of the SVC is not dilated. Rarely, even when no superior caval ASD is present, the connection may be in the typical low position of sinus venosus syndrome. At times, only a portion of the right superior pulmonary vein draining one or two segments of the right upper lobe connects directly to the SVC. The PAPVC may be isolated or associated with a fossa ovalis ASD.

**Right Pulmonary Veins to Right Atrium**

Right pulmonary veins may connect directly to the right atrium, either in toto, where they may connect as two or three separate veins, or only through the superior (or rarely inferior) right pulmonary vein. This anomaly may exist as an isolated defect, without an ASD or with only a patent foramen ovale, with the plane of the atrial septum altered from coronal to near-sagittal because of leftward displacement of its lateral attachment. The plane of the right pulmonary vein is actually altered minimally from normal. Because the posterior limbus is present in such defects, the veins are clearly anomalously connected to the right atrium. In ASDs with absence of posterior limbus (posterior ASD), and at times in large fossa ovalis ASDs, the plane of division between right and left atria posteriorly can be questionable, and thus the atrial connection of the right pulmonary veins in this area is debatable. In such defects, however, true anomalous connection of the right pulmonary veins may be present (see Fig. 30-4).

**Right Pulmonary Veins to Inferior Vena Cava**

An anomalous right pulmonary vein, generally draining the entire right lung but occasionally only the middle and lower lobes, may descend in a cephalad-to-caudal direction toward the diaphragm, more or less parallel to the pericardial border but with a crescentic (scimitar) shape, and then curve sharply to the left just above or below the IVC–right atrial junction. The anomalous pulmonary venous trunk usually passes anterior to the hilum of the right lung but occasionally is posterior to it. Entrance into the IVC is just superior to the hepatic vein orifices. The atrial septum may be intact, or a fossa ovalis ASD may be present. Occasionally the anomalous vein also connects to left atrium, and rarely scimitar syndrome can exist with connection of the anomalous vein only to left atrium. Pulmonary venous drainage is then normal. (Rarely, the left lung may connect via a scimitar-shaped vein to the IVC.)

Right-sided scimitar syndrome occurs as an isolated malformation in a minority of cases. In most patients, anomalies of the right lung are also present. The most common anomaly is right lung hypoplasia, which is associated with a marked mediastinal shift and dextroposition of the heart, and in its severe form with the entire heart lying in the right side of the chest. Blood supply to the hypoplastic right lung comes mainly from a branch of the abdominal aorta in the region of the celiac axis, which ascends through the inferior pulmonary ligament to supply the lower lobe, or more often the entire right lung. A small pulmonary artery may be present, but often the central and hilar portions of the right pulmonary artery are absent. Occasionally a true right lower lobe bronchopulmonary sequestration may exist, with secondary intrapulmonary cyst formation.

Associated cardiac anomalies are often present in scimitar syndrome. In one study, for example, 11 of 13 infants had associated malformations, seven of whom had left-sided hypoplastic conditions. Diaphragmatic anomalies occurred in about 20% of the cases reviewed by Kielty and colleagues. These defects included herniation of the right lung through the foramen of Bochdalek and abnormal attachments of the diaphragm.

**Rare Connections of Right Pulmonary Veins**

Rarely, right pulmonary veins connect anomalously to the azygos vein or coronary sinus, with or without a fossa ovalis ASD.

**Left Pulmonary Venous Connections**

Left pulmonary veins may connect to the left brachiocephalic vein by way of an anomalous vertical vein. Anomalous drainage is usually from the entire left lung, but may be only from the left upper lobe. A fossa ovalis ASD coexists in some patients, and in others the atrial septum is intact. Rarely, left pulmonary veins connect anomalously to the coronary sinus, a right-sided SVC, or the right atrium.

**Bilateral Partial Pulmonary Venous Connection**

Partial but bilateral anomalous pulmonary venous connection is rare. The most common variant is probably the defect in which the atrial septum is intact, the left superior pulmonary vein attaches to the left brachiocephalic vein by way of an anomalous vertical vein, and the right superior pulmonary vein attaches to the SVC–right atrial junction. In another form, a common pulmonary venous chamber is present (see “Pulmonary Venous Anatomy” under Morphology in Chapter 31 for definition), and some veins from both lungs connect to it. All but one lobe or only one lobe from each side may connect to the sinus. The common venous sinus may connect to the right atrium or brachiocephalic vein.

**Cardiac Chambers in Atrial Septal Defect and Related Conditions**

Typically in ASD and related conditions, the right atrium is greatly enlarged (at least grade 3 or 4 on a scale of 1 to 6)
and thick walled. The left atrium is not enlarged. This discrepancy occurs in the absence of any flow or pressure restriction between the two, speculatively because the right atrial wall is more distensible than the left.

Right ventricular (RV) diastolic size is increased, often greatly, because of volume overload imposed by the left-to-right shunt. Whereas normal RV diastolic dimensions are between 0.6 and 1.4 cm · m⁻², in patients with large left-to-right shunts at atrial level they average 2.66 cm · m⁻² and may be as large as 4 cm · m⁻². Consequently, the cardiac apex is often formed by the RV.

Morphologically, the left ventricle (LV) is normal or slightly decreased in size. However, important LV dynamic abnormalities are present in most patients (see “Mitral Prolapse”).

Mitral Valve and Atrial Septal Defects

Mitral Prolapse

Mitral valve prolapse occurs in association with fossa ovalis ASD, sinus venosus syndrome, and probably other types of ASDs and related conditions that result in left-to-right shunts at the atrial level. Prevalence of true prolapse is about 20%, increasing with age and with magnitude of the pulmonary-to-systemic blood flow ratio (Qp/Qs).

Schreiber and colleagues have clarified a previously confused subject by relating mitral valve prolapse to abnormalities of LV shape in patients with ASD. Alteration in LV configuration results from leftward shift of the ventricular septum, a process that begins as a slight decrease in the normal rightward convexity and progresses with time to flattening and then reversal, with a resultant central bulge into the LV. This process is a response to RV enlargement, which is secondary to volume overload. This etiologic basis of mitral valve prolapse is supported by its decreased degree or elimination in most cases by ASD closure, with return of LV geometry to normal.

Mitral Regurgitation

Mitral prolapse in ASD can lead to mitral regurgitation, as does ordinary mitral prolapse. True prevalence of regurgitation in unselected patients varies because older patients and those with larger pulmonary blood flows have a higher prevalence of this abnormality and prolapse. Prevalence of mitral regurgitation severe enough to require correction at the time of ASD repair is about 5% or less. The data of Leachman and colleagues strongly suggest that this type of mitral prolapse can also precipitate chordal rupture, as it can in Barlow syndrome.

Cleft Mitral Leaflets

Cleft anterior or posterior mitral leaflets that cause mitral regurgitation are reported to occur occasionally in patients with ASD. However, judging from some of the illustrations of such “clefts,” they may simply be spaces between commissural and main leaflets in prolapsed valves.

Lungs and Pulmonary Vasculature

Pulmonary arteries are considerably dilated and elongated when pulmonary blood flow is increased. This dilatation involves even the smallest branches, which tend to compress the smaller airways, with resultant retention of secretions and bronchiolitis.

Hypertensive pulmonary vascular disease develops infrequently in patients with ASD, and then usually not until the third or fourth decade of life (see “Pulmonary Vascular Disease” under Morphology in Section I of Chapter 35). This contrasts sharply with ventricular septal defects (VSDs), complete AV septal defects, and patent ductus arteriosus, in which pulmonary vascular disease may be present early in life. In ASD, pulmonary vascular disease is caused mainly by secondary thrombosis in the dilated pulmonary artery branches, with changes in the intima and media of vessels usually playing a minor role. Haworth has suggested, however, that an increase in pulmonary arterial smooth muscle may be the only finding.

Associated Cardiac Conditions

ASDs and related conditions may coexist with almost all varieties of congenital heart disease, but such cases are not considered here unless the left-to-right shunt at atrial level is the dominant hemodynamic lesion. A wide spectrum of cardiac anomalies coexist with ASD as the dominant lesion (Table 30-1).

Valvar heart disease may coexist with hemodynamically important ASDs. Six cases with moderate or severe rheumatic mitral stenosis and a hemodynamically significant ASD (Lutembacher syndrome) were observed among 443 patients with an ASD at GLH (1957-1983). Eleven cases of moderate or severe mitral regurgitation were observed; in three, regurgitation was rheumatic in origin. Both mitral stenosis and regurgitation increase left-to-right shunting.

Tricuspid regurgitation of variable severity frequently complicates ASDs in older patients with heart failure, the mechanism generally being RV and tricuspid anular dilatation.

Related Conditions

Rarely, ASD may occur in patients with Marfan, Turner, Noonan, or Holt-Oram syndromes.

*Data from 443 patients undergoing repair at GLH from 1957 to 1983. Some patients had more than one anomaly, so the figures are not cumulative.
CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Symptoms, clinical features, and signs in ASD and related conditions producing left-to-right shunting at the atrial level are related largely to size of the left-to-right shunt. Thus, in general, when $Q_p/Q_s$ is less than 1.5, there are neither signs nor symptoms of the shunt, and this is often true with a $Q_p/Q_s$ up to 1.8. When $Q_p/Q_s$ is larger than this, signs of the shunt are usually present, and symptoms appear eventually (see “Changes in Pulmonary/Systemic Blood Flow Over Time” later under Natural History). Infants present an exception to these generalizations. Their clinical features are often atypical; for example, splitting of the second heart sound is unrelated to $Q_p/Q_s$.

Determinants of Interatrial Shunting

Left-to-right shunting across a nonrestrictive (>2 cm in an adult) ASD under ordinary circumstances is a function of the relative compliance (reflected in the diastolic pressures) of RVs and LVs. RV compliance in particular is unpredictable and is one factor causing variability in $Q_p/Q_s$. A compliant distensible RV (in association with a normal pulmonary vascular bed) will permit a large shunt; a less compliant one (such as may result from pulmonary hypertension or from morphologic RV changes occurring later in life) permits a more modest shunt. LV compliance tends to decrease with age, which tends to increase $Q_p/Q_s$ as patients become older. Shunting is increased by systemic hypertension when this results in decreased LV compliance.

Mitrail regurgitation or stenosis increases $Q_p/Q_s$. When the ASD is small and flow is restrictive, left-to-right shunting is limited. Even then, mitral stenosis may elevate left atrial pressure sufficiently that a large left-to-right shunt through all phases of the cardiac cycle results, leading to a soft continuous murmur.

Symptoms

Symptoms may persist for several decades, but when they occur, they consist of effort breathlessness and a tendency toward recurrent respiratory tract infections. Palpitation from paroxysmal atrial tachycardia or atrial fibrillation may occur later in life. Older adults may present with chronic heart failure with fluid retention, hepatomegaly, and severe cardiac cachexia. Occasionally an infant with ASD and a large left-to-right shunt, often in association with PAPVC, may have heart failure with tachypnea, but this is uncommon. In such infants, other associated malformations may contribute to the heart failure.

Atypical presentations occur. Rarely, an unequivocal history of cyanosis may bring a patient with an uncomplicated ASD to medical attention. For example, a large fossa ovalis ASD extending to the IVC may cause streaming of blood from the IVC into the left atrium, with resultant cyanosis. This coincides with occasional bidirectional shunting in patients with otherwise uncomplicated ASDs, usually older patients. For the same anatomic reasons (see Morphology, earlier), patients may present with paradoxical emboli or cerebral infarctions. This presentation occurred in 9 (2%) of a Mayo Clinic series of 546 patients.

Infrequently the presentation may be modified by presence of severe pulmonary hypertension, in which case cyanosis, effort intolerance, and hemoptyis may be present.

Signs

Clinical signs diagnostic of a large shunt at the atrial level ($Q_p/Q_s > 1.8$ to 2.0) are:

- Overactive left parasternal systolic lift
- Fixed splitting of the second heart sound throughout the respiratory cycle (absent when large $Q_p/Q_s$ is from PAPVC with an intact atrial septum)
- A soft pulmonary midsystolic flow murmur (in second and third left intercostal spaces)
- A mid-diastolic tricuspid flow murmur (in fourth and fifth left intercostal spaces) present in borderline situations only on inspiration

This last sign is occasionally absent, however, particularly in older patients and in those with a larger shunt.

In addition, an extremely large shunt produces a more marked left-sided precordial RV lift, occasionally some prominence of the left anterior chest wall, and leftward displacement of the cardiac apex. Many such patients are short and thin. When heart failure is present, jugular venous pressure is elevated, the liver is enlarged, and there is gross cardiomegaly.

Tricuspid regurgitation produces systolic liver pulsation and a greater tendency to ascites and peripheral edema. Important pulmonary hypertension is evident clinically by accentuation of the second heart sound and a more marked RV and pulmonary artery lift. A pulmonary regurgitation murmur may be heard, as well as a murmur of tricuspid regurgitation.

Chest Radiography

Chest radiography reflects the large $Q_p/Q_s$. The right atrium and right ventricle are large. The pulmonary trunk shadow in the upper left portion of the cardiac silhouette is enlarged, and right and left pulmonary arteries are enlarged to the periphery of the lung field. In general, pulmonary vascular markings are increased, or plethoric. The shadow of the transverse aortic arch is abnormally small. Patients with heart failure may have interstitial pulmonary edema and areas of pulmonary consolidation and atelectasis. These signs are probably secondary to compression of smaller airways by enormously enlarged small pulmonary vessels.

The chest radiograph may suggest the specific anatomic diagnosis. Occasionally the right superior pulmonary vein can be identified lying more superiorly than normal (Fig. 30-7), leading to suspicion of sinus venous syndrome. A crescentic shadow more or less parallel to the right-sided heart border (Fig. 30-8) suggests the diagnosis of anomalous pulmonary venous connection of right pulmonary veins to IVC (scimitar syndrome).

Electrocardiography

Electrocardiogram (ECG) almost always shows the pattern of incomplete right bundle branch block and a clockwise frontal loop. Left axis deviation and a counterclockwise loop strongly suggest an AV septal defect, although this pattern occurs in about 10% of patients with fossa ovalis ASDs.
PART VII Congenital Heart Disease

localization of subcaval defects and anomalous pulmonary venous connection is usually possible. Addition of Doppler color flow interrogation allows a reasonable estimate of $Q_p/Q_s$.

Magnetic Resonance Imaging

Limitations of echocardiography in delineating anomalous pulmonary venous connection can be largely overcome with magnetic resonance imaging (MRI). Anatomic detailing of pulmonary venous connection and calculation of $Q_p/Q_s$ are generally reproducible.

Cardiac Catheterization and Cineangiography

When diagnosis of a typical and apparently uncomplicated ASD has been made by noninvasive methods in children, adolescents, and young adults, cardiac catheterization is not required. The surgeon then becomes responsible for confirming the type of ASD at operation and presence or absence of any anomalous pulmonary venous connections. Cardiac catheterization and appropriate cineangiography are indicated in infants (because of possible associated anomalies), in many adults (for assessing possible pulmonary hypertension and status of mitral valve), and in any patient in whom noninvasive tests suggest PAPVC. Coronary angiography is performed in patients older than 35 to 40 years.

Assessment of operability in patients with pulmonary hypertension is particularly challenging. Even in Eisenmenger syndrome with shunt reversal at atrial level, pulmonary artery pressure ($P_{PA}$) is rarely more than two thirds that of systemic pressure. (There is no transmission of systemic pressure across the defect, as is the case with large defects at ventricular or ductus levels; see “Cardiac Catheterization” under Clinical Features and Diagnostic Criteria in Chapter 35.)

The most reliable criterion of inoperability is the absolute level of pulmonary vascular resistance normalized to body surface area ($R_pI$) and calculated when possible using measured, rather than assumed, oxygen uptake. $Q_p/Q_s$ or resistance ratios are much less discriminating. In fact, precise criteria have not been established as accurately for ASD as for VSD. Using VSD criteria (with no reason to believe these are not equally applicable to ASD), a resting $R_pI$ of 8 U · m$^2$ or more may preclude complete operative closure. In this event, $R_pI$ must also be calculated while using a pulmonary vasodilator (isoproterenol, tolazoline, or 100% oxygen).

If arterial desaturation (<97%) exists when measured by the usual finger sensor, cardiac catheterization is indicated in both adults and children. Interventions such as 100% $O_2$, exercise, and nitric oxide (NO) are appropriate to gauge pulmonary vascular reactivity, response of pulmonary vascular resistance, and reversion to a strictly left-to-right shunt condition. If arterial oxygen saturation ($S_{aO_2}$) increases to normal levels and pulmonary vascular resistance falls, operation can be done even in the presence of intermittent arterial desaturation (right-to-left shunt).

A vasodilator must produce a fall in $R_pI$ to below 7 U · m$^2$ before the patient can be considered operable, because only then can pulmonary vascular disease be expected to regress. Otherwise, disease is likely to progress despite closure of the ASD. Progressive pulmonary vascular disease is less well tolerated when the atrial septum is intact, because the right side of the heart is then unable to decompress.
through a right-to-left shunt at atrial level; thus, ASD closure under such circumstances usually decreases life expectancy.

Cardiac catheterization and angiography are also useful in defining anatomic details of related conditions that can cause shunting at the atrial level. Increased \( \text{SaO}_2 \) in the low SVC provides presumptive evidence of sinus venosus syndrome, and this becomes virtually certain if the catheter can be passed through a subcaval ASD into the left atrium. An indicator dilution curve obtained after injecting dye into the SVC may show some right-to-left shunting, which is generally completely absent in patients with a fossa ovalis ASD (who may have right-to-left shunting from the IVC). In addition, curves obtained after injection into the right pulmonary artery generally show a much larger left-to-right shunt, a result of the anomalously draining right pulmonary veins, than curves obtained after injection into the left pulmonary artery.

Identification of the specific anatomic details of sinus venosus syndrome is best accomplished by angiography after right pulmonary artery injection, because the typical location and drainage of the right superior pulmonary vein can then be seen. Pulmonary artery injection may confirm anomalous connection of the right pulmonary veins to the right atrium or IVC (see Fig. 30-8), of left veins to brachiocephalic or other veins, or of bilateral anomalous pulmonary venous connections. When anomalous connection of the right pulmonary veins to the IVC is demonstrated, aortography should
Survival

In 1970, Campbell published the most detailed study available on survival of patients with ASD treated nonsurgically. Transformation of these findings into conventional survival format and comparison with life expectancy of the general population provide good insight into the life expectancy of patients with ASD (Fig. 30-10). Campbell’s data support the idea that only 0.1% of individuals born with a large ASD and no other important cardiac anomaly die in infancy, and that few who are unrepaired die in the first or second decade. About 5% to 15% die in the third decade, usually with pulmonary hypertension and Eisenmenger syndrome. Premature late death with heart failure occurs in an increasing proportion after the fifth decade. Even so, probably no more than 25% of persons born with a large ASD die from the defect, because lethal manifestations of the disease tend to occur so late in life that other unrelated conditions cause death first.

The natural history of patients with sinus venosus syndrome and most other types of PAPVC and ASD is similar to that of patients with large fossa ovalis ASD. Patients with sinus venosus syndrome in the fourth to sixth decades present with heart failure or severe pulmonary hypertension from pulmonary vascular disease. The natural history of scimitar syndrome is not clear. Presumably, patients

NATURAL HISTORY

The natural history of persons born with ASDs and related conditions producing left-to-right shunts at atrial level is not known precisely, but its general characteristics have been described. Calculations of $Q_p/Q_s$ are of particular importance in patients with isolated PAPVC of only part of one lung. An operation is not indicated when the ratio is less than 1.8 (see Indications for Operation later in this chapter). This approach is especially relevant with isolated connection of some of the right upper lobe veins to the high SVC, because diversion or transfer to the left atrium is quite difficult (and probably needless). Even when only the right superior pulmonary vein is involved and the atrial septum is intact, the shunt may be greater than this, presumably because right atrial and caval pressures are distinctly lower than left atrial pressures, producing a larger-than-usual pulmonary venous gradient.

Figure 30-9 Transesophageal echocardiogram of fossa ovalis atrial septal defect. A, Arrow indicates dropout of atrial septum with clear evidence of tissue superiorly and inferiorly (above atrioventricular valves), diagnostic of fossa ovalis (secundum) defect. B, Blood flow is directed through the defect left to right from left to right atrium. C, Negative image of left-to-right flow during injection of saline (as contrast). Key: LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (From Lang and Marcus.)

also be done to identify any anomalous systemic arteries from the abdominal or thoracic aorta to the right lower lobe. If the right lung is small, if the right lower lobe is contracted or seems otherwise abnormal on chest radiography, or if the patient gives a history of hemoptysis or recurrent pulmonary infections, bronchoscopy or bronchography is also indicated.
without important anomalies of the right lung and with a large left-to-right shunt have a life history similar to patients with a large fossa ovalis ASD. Those with right lung hypoplasia, however, often have a life history dominated by their pulmonary pathology, including hemoptysis and recurrent pulmonary infections. When there is isolated PAPVC of part of one lung and Qp/Qs is less than 1.8, life expectancy may be normal. Rarely, paradoxical emboli occur in patients with sinus venous syndrome (from SVC) as well as in those with fossa ovalis ASDs (from IVC).

Pulmonary Hypertension

In a UAB surgical series, 14% of patients catheterized had pulmonary hypertension with mean PPA greater than 25 mmHg. In a GLH surgical series, systolic PPA was greater than 50 mmHg in 13% of catheterized patients and 11% of the total series (Fig. 30-11). Prevalence of elevated RpI (≥4.5 U · m²) was 4.5%, and rare (1%) in patients younger than 20 years of age. In a few high-altitude locations, however, prevalence of pulmonary hypertension is greater. Cherian and colleagues reported that in their region of India, pulmonary hypertension was present in 13% of patients younger than age 20. Ghisla and colleagues in 14%. Pulmonary hypertension is particularly prevalent in patients with scimitar syndrome, partly due to increased pulmonary blood flow but also to stenosis of the anomalous vein, presence of systemic arterial collaterals to the right lung, or reduction of the pulmonary vascular bed on the right side.

Functional Status

Probably only about 1% of patients born with a large ASD have symptoms during the first year. Most are asymptomatic through the first and second decades, although many are short and thin. Effort intolerance and easy fatigability may develop in the second or third decade or as late as the fifth or sixth decade. These symptoms progress gradually to fluid retention, hepatomegaly, and elevated jugular venous pressure, leading to gradually increasing disability. These phenomena are well exemplified in the surgical experience, in which preoperative New York Heart Association (NYHA) functional class and age at operation are moderately well correlated (r = .61, P < .05) (Table 30-2). When heart failure becomes advanced, both mitral and tricuspid regurgitation are likely to have developed.

Spontaneous Closure

Spontaneous closure of a hemodynamically significant isolated ASD occasionally occurs in the first year. Cockerham and colleagues found closure in 22% of 87 patients, and Ghisla and colleagues in 14%. Smaller left-to-right shunts were present in patients whose defects spontaneously closed than in those whose did not. Spontaneous closure is uncommon after the first year, although Ghisla and colleagues found that closure occasionally occurred in the second year.

Changes in Pulmonary/Systemic Blood Flow Over Time

As already noted, decreasing LV compliance increases $Q_p/Q_s$ in patients with ASD, and this may develop during the fifth and sixth decades. Systemic arterial hypertension accelerates this process and may unmask an ASD that was not an important shunt before onset of decreased LV compliance. It is also likely that most ASDs increase in size as time passes; this has been clearly demonstrated in the case of patent foramen ovale. The direct relationship between $Q_p/Q_s$ and the tendency toward mitral valve prolapse also support the concept that the shunt increases with age. These increases in $Q_p/Q_s$ with time do not occur when the shunt is due to anomalous pulmonary venous connection without ASD. $Q_p/Q_s$ decreases when pulmonary hypertension develops, a result of decreased RV compliance that accompanies RV hypertrophy (see “Determinants of Interatrial Shunting” under Clinical Features and Diagnostic Criteria).

Right Ventricular Function

RV volume overload and consequent increased RV diastolic dimensions are characteristic of patients with a hemodynamically significant ASD or PAPVC. The ventricular septum is displaced posteriorly and leftward under such circumstances, but systolic anterior motion of the septum occurs. These features are well tolerated by the RV for many years, much longer than for the volume-overloaded left ventricle and probably longer than for volume overload produced by acute tricuspid or pulmonary valve regurgitation. RV failure eventually occurs, however, with decreased RV ejection fraction and hypokinesia. Doty and colleagues demonstrated loss of coronary reserve in patients with ASD and volume-induced RV hypertrophy, which contributes further to development of RV failure. Associated signs and symptoms of elevated systemic venous pressure then develop (peripheral edema, elevated jugular venous pressure, hepatomegaly, and finally ascites), often with tricuspid regurgitation.

These RV phenomena have been documented by several studies. Liberthson and colleagues found increased RV volume but normal (64%) ejection fraction in 9 asymptomatic patients with a mean age of 25 years. However, 11 symptomatic patients with a mean age of 52 years had diffuse RV hypokinesia and ejection fraction averaging 36%, in addition to increased RV volume. In a possibly related finding, adult patients with ASD but without pulmonary hypertension occasionally have marked pulmonary valve regurgitation, which disappears after ASD repair.

Left Ventricular Function

Most adult patients with hemodynamically significant ASD or PAPVC have normal LV systolic dimensions but subnormal diastolic dimensions. Some loss of LV functional reserve is present in most adult patients and in some children with ASD. In contrast to normal persons, such individuals do not increase LV ejection fraction during maximal exercise (Fig. 30-12), although resting ejection fraction is usually within normal limits. These preoperative LV abnormalities likely result from effects of the volume-overloaded right ventricle. Even in the absence of symptoms of systemic venous hypertension from RV failure, LV structure and function are influenced by increased RV volume rather than changes in LV compliance.

Ativoventricular Valvar Dysfunction

As discussed earlier, important mitral regurgitation is present in 2% to 10% of adults with large ASDs, and both mitral and tricuspid regurgitation may become prominent in older patients who develop heart failure. When viewed at operation, the tricuspid valve does not appear to be intrinsically abnormal. Presumably, regurgitation develops because of anular dilatation and lack of proper shortening of the tricuspid anulus during systole, secondary to RV enlargement resulting from long-standing volume overload.

Supraventricular Arrhythmias

After the third decade, supraventricular arrhythmias complicate the natural history of patients with large ASDs and related conditions in increasing numbers over time. Most often this begins with paroxysmal atrial fibrillation, which gradually becomes permanent. Atrial fibrillation was present in 15 (20%; CL 15%-26%) of 75 patients over age 40 operated on by Magilligan and colleagues. Of 19 patients preoperatively in NYHA class III or IV, 47% (CL 34%-64%) had this
arrhythmia, compared with 11% (CL 6%-17%) of 56 patients in class I or II. St. John Sutton and colleagues found that 56% of their patients over age 60 had atrial fibrillation at operation.\textsuperscript{S15}

In addition, more subtle abnormalities of conduction system function develop. Benedini and colleagues found concealed sinus node dysfunction in 17 (65%; CL 53%-76%) of 26 adult patients with fossa ovalis ASD, which became evident only with electrophysiologic testing.\textsuperscript{R5} Such abnormalities are less common in children with ASDs.\textsuperscript{R8}

Systemic Arterial Hypertension

Adult patients with hemodynamically important ASDs are likely to have systemic arterial hypertension. In a Mayo Clinic study, 25 (38%) of 66 patients had systemic arterial blood pressure above 150/90, a higher proportion ($P < .01$) than an age-matched general population.\textsuperscript{S15} As noted, this relationship may result partly from the effect of hypertension on shunt size.

**TECHNIQUE OF OPERATION**

Fossa Ovalis Atrial Septal Defect

Anesthetic management, positioning and preparation of the patient, median sternotomy, and preparations for CPB are discussed in detail in Section III of Chapter 2 and in Chapter 4. An alternative to the midline skin incision may be used for cosmetic reasons; in this approach, a bilateral fourth inter-space submammary skin incision is made and a skin flap raised superiorly and inferiorly before the sternum is incised vertically in the usual way. However, some surgeons have expressed concern regarding breast development and symmetry late following right submammary incisions in females. Alternatively, a right anterolateral fifth intercostal space incision may be used if the patient expresses concern about the cosmetic effects of a midline scar. Repair of ASD may also be accomplished using the small lower sternotomy approach and also a small vertical right parasternal incision. Each requires modification of the setup for caval cannulation (see Section III in Chapter 2).

In children and young adults with uncomplicated ASDs, routine placement of a left atrial pressure monitoring catheter is usually unnecessary, but such monitoring should be done routinely in older patients, whose left atrial pressure may be considerably higher than right atrial pressure after repair.

After the incision is made and pericardial stay sutures are placed, intrapericardial anatomy is assessed. The characteristic large right atrium and RV of ASD are noted, as well as the normal-sized left atrium and LV. A left SVC in the fold of Marshall is sought. The external position and connections of the right and left superior and inferior pulmonary veins are noted. Optimally, TEE is available to establish the position of the ASD, relationship of the pulmonary veins, and function of the mitral and tricuspid valves.

The patient is heparinized and arterial cannula inserted. Direct caval cannulation with two angled cannulae is generally employed. CPB is established, with the perfusate temperature at 34°C. The cardioplegic needle or aortic root catheter is now placed in the ascending aorta, the aorta clamped, and cold cardioplegic solution injected. Rewarming of the patient with the perfusate is begun once the heart is cold and isolated. The caval tapes are “snugged,” and the right atrium is opened obliquely (Fig. 30-13). A left atrial suction catheter is not inserted through the left atrial wall in fossa ovalis ASD, because it is unnecessary and imposes a remote risk of cerebral air embolism.

A few fine stay sutures are placed on the edges of the atriotomy incision. Blood in the left atrium is suctioned only enough to clearly expose the edges of the ASD; evacuation of more blood than this from the left side of the heart needlessly exposes the patient to risk of air entrapment and subsequent air embolization. An exception to this policy is presence of mitral valve pathology.

The entire right atrial internal anatomy is examined, particularly identifying the limbus and defining any rim of the ASD. The relationship of the defect to the ostium of the

---

**Figure 30-13** Internal anatomy of a fossa ovalis (secundum) atrial septal defect as seen through usual atrial incision. Key: ASD, Atrial septal defect; IVC, inferior vena cava; SA, sinoatrial; SVC, superior vena cava.
limbic tissue with the first and last bites of this stitch (Fig. 30-14), which must be inferior to any remaining fenestrations. Great care is taken to avoid confusing the eustachian valve of the IVC with the remnant of the floor of the fossa ovalis. Such an error results in connecting the IVC to the left atrium, which can occur when the operation is done under circulatory arrest and there is no IVC cannula, or when direct caval cannulation is used. After this half purse-string stitch is tied, the ASD becomes slitlike. Before last stitch is tied, anesthesiologist places positive pressure on lung to express air from left atrium. Completed repair.

Key: CS, Coronary sinus; RSPV, right superior pulmonary vein.

Possible fenestrations in the valve (floor) of the fossa ovalis are sought; these are usually between the fossa ovalis and limbus anteriorly or near the IVC inferiorly. When present in thin tissue, fenestrations may be joined to the main defect by excising sufficient tissue to create an edge strong enough to hold sutures well, or the fenestrated tissue simply may be imbricated into the suture line.

Usually the fossa ovalis ASD is closed directly (see “Direct Suture versus Patch Repair” under Special Situations and Controversies later in this chapter). The suturing is begun at the inferior angle by placing a half purse-string stitch. Care is taken to catch good, substantial anterior and posterior limbic tissue with the first and last bites of this stitch (Fig. 30-14), which must be inferior to any remaining fenestrations. Great care is taken to avoid confusing the eustachian valve of the IVC with the remnant of the floor of the fossa ovalis. Such an error results in connecting the IVC to the left atrium, which can occur when the operation is done under circulatory arrest and there is no IVC cannula, or when direct caval cannulation is used. After this half purse-string stitch is tied, the ASD assumes a slitlike appearance. The suture line is now carried superiorly, catching tough limbic tissue anteriorly and posteriorly. To avoid damaging the AV node, the sutures must not be placed too far from the edge anteriorly.

Before the last few stitches are pulled up, a clamp or tissue forceps is placed in the aperture, and the anesthesiologist inflates the lung to expel any air from the left atrium. The suture line is snugged while lung inflation is maintained, and

Figure 30-14  Repair of fossa ovalis atrial septal defect (ASD). A, Usual oblique right atriotomy is made and retracting sutures placed. B-C, After exposure is arranged and all structures examined (orifices of pulmonary veins, valve of inferior vena cava [eustachian] coronary sinus), the first sutures are taken as a half purse-string stitch. If ASD extends to inferior vena cava (IVC), initial sutures are placed in floor of the IVC; eustachian valve of the IVC must be noted so that it is not erroneously included. D, After first set of stitches is tied, ASD becomes slitlike. E, Before last stitch is tied, anesthesiologist places positive pressure on lung to express air from left atrium. F, Completed repair. Key: CS, Coronary sinus; RSPV, right superior pulmonary vein.
Coronary Sinus Atrial Septal Defect

Because coronary sinus ASDs are close to the AV node (Fig. 30-15), stitches must be placed near the edge of the defect superiorly in tissue that may not be strong. For these reasons, patch closure is generally advisable. Additionally, when a coronary sinus ASD is identified, presence of a completely or partially unroofed coronary sinus must be ruled out (see Technique of Operation in Chapter 33). 

**Sinus Venosus Atrial Septal Defect**

Preparation and positioning of the patient are as usual. After sternotomy, the pericardium is cleared of pleural reflections bilaterally, and a large pericardial piece is removed and set aside between moist towels or in 0.6% glutaraldehyde. After the remaining pericardium is widely opened, stay sutures are placed and the anatomy examined. The right superior pulmonary vein is easily seen attached to the low SVC or SVC–right atrial junction. At this point, the pulmonary vein (or veins) should be differentiated from the azygos vein, which is slightly more cephalad and directed more medially. Size of the SVC is noted, as is the possible presence of a left SVC, in which case the right-sided SVC is likely to be small. The right atrium and RV are usually considerably enlarged.

**Posterior Atrial Septal Defect**

If the anomaly is a pure posterior ASD, closure by direct suture is possible in a manner similar to that described in the previous text. If the posterior ASD is confluent with a fossa ovalis ASD, the defect may be too large for direct closure. Then a patch of pericardium, knitted polyester velour, or polytetrafluoroethylene (PTFE) is used.
clamped, and cold cardioplegia infused (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3). The caval tapes are secured. In infants, repair may be done with a single venous cannula and hypothermic circulatory arrest. When the aorta is clamped, the perfusate temperature is stabilized at 25°C to 32°C.

When configuration of the superior pulmonary vein is usual and the SVC–right atrial junction is wide, the right atrium is opened through the usual oblique incision beginning at the base of the right atrial appendage and extending down toward the IVC cannula (Fig. 30-16). This does not damage the sinoatrial node or its artery. Stay sutures are placed. A pump sump-sucker is placed across the foramen ovale into the left atrium (or through a stab wound), or no left atrial vent may be used. The repair directs pulmonary venous drainage through the ASD into the left atrium while closing the interatrial communication (see Fig. 30-16). A pericardial baffle forms approximately the anterior half of this internal conduit. Width of the pericardial patch should be about 1.5 times the diameter of the ASD, and length about 1.25 times the estimated length of the distances from the superior edge of the anomalous vein to the inferior edge of the ASD. This ensures an adequate pulmonary venous pathway and does not obstruct the SVC.

After the ASD repair is repaired, the sump (if used) is removed and the created defect closed. Rewarming is begun, and with suction on the needle vent in the ascending aorta, the aortic clamp is released. The right atriotomy is closed, and the operation is completed as usual (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2).

When the right superior pulmonary veins enter more cephalad in the SVC (more than about 2 cm above the cavoatrial junction) or when the SVC is small (as in the presence of bilateral SVCs), the single patch technique described above may require a long tunnel or create possible SVC obstruction, or both. Because of concerns about the potential for sinus node dysfunction with incisions across the cavoatrial junction, the Warden operation may be used (Fig. 30-17). After extensive mobilization and division of the azygos vein, the SVC is divided cephalad to the anomalously connected right pulmonary veins. The central end is closed, and as a final step the distal end is anastomosed to the right atrial appendage. Particular care is needed to completely excise all trabeculated muscle within the appendage and the associated pathway into the right atrial chamber. From within the right atrium, the inferior lip of the subcaval ASD is joined to the right atrial wall, anterior and lateral to the caval orifice. This closes the interatrial communication and diverts pulmonary venous drainage from the anomalously connected right pulmonary veins to the left atrium.

Another alternative is the V-Y-plasty technique. A vertical atriotomy is made posteriorly and extended into the SVC posterior to the sinus node and just in front of the anomalous veins (Fig. 30-18) in preparation for a V-Y-plasty enlargement of the SVC.

Others have recommended near-routine use of a two-patch technique, in which the original incision is extended across the cavoatrial junction below the sulcus terminalis and just anterior to insertion of the anomalous pulmonary veins. After placing the internal baffle, the incision is closed with an autologous or bovine pericardial patch.

Anomalous Connection of Right Pulmonary Veins to Right Atrium

The operation begins exactly as described for sinus venous malformation, including opening the right atrium through the usual oblique incision. The interior of the right atrium is examined, anomalous connections of the right pulmonary veins and normal connections of the left pulmonary veins to the left atrium are confirmed, and any defects in the atrial septum are identified.

When the atrial septum is intact, repair can often be accomplished by making a longitudinal incision in it next to the atrial wall posteriorly and resutting it to the lateral right atrial wall in front of the right pulmonary vein orifices. Alternatively, and particularly when geometry in the right atrium does not lend itself to this simple repair, the fossa ovalis and posterior limbic tissue may be excised and a pericardial, PTFE, or knitted polyester patch used for baffle reconstruction (Fig. 30-19).

When an ASD is present, repair is similar. When the defect is large and of the fossa ovalis or confluent type, a patch similar to the one shown in Fig. 30-19 is used. Occasionally, and particularly when the associated ASD is posterior, repair by direct suture is possible.

Anomalous Connection of Right Pulmonary Veins to Inferior Vena Cava (Scimitar Syndrome)

Initial stages of the operation for scimitar syndrome proceed as described for sinus venous malformation. An internal conduit is then constructed within the right atrium to conduct the right pulmonary venous blood from its entrance into the IVC across the atrial septum into the left atrium.

In small infants, the entire repair may be done during hypothermic circulatory arrest. In older patients, part of the repair can be performed during hypothermic circulatory arrest; alternatively, the entire repair can be performed during conventional CPB at 20°C to 28°C. In the latter approach, the IVC tape may be passed inferior (caudal) to the entrance of the anomalous pulmonary vein into the IVC, and a right-angled metal cannula can be used to cannulate the IVC inferior to this point. This possibility depends on whether the anomalous vein enters at the IVC–right atrial junction. Alternatively, the common femoral or external iliac vein can be cannulated for IVC return.

In any case, CPB is established with two venous cannulae, and if part of the repair is to be made with circulatory arrest, the IVC tape is placed on the cardiac side of the IVC entrance of the anomalous vein. The aorta is clamped and cold cardioplegic solution infused. After caval tapes have been tightened, the right atrium is opened with the usual oblique incision and carried down to the IVC. If present, the valve of the fossa ovalis is completely excised to create a large ASD (Fig. 30-20). The pericardial patch is trimmed according to the measurements made, and stay sutures are applied at the four corners.

Circulatory arrest is established with the patient’s nasopharyngeal temperature at 18°C when this modality is used, and the IVC cannula is removed. Otherwise, repair proceeds during CPB. The pericardial patch is sewn into place so as to form the anterior wall of a conduit between the entrance of the anomalous vein and the defect created in the atrial septum (see Fig. 30-20). If repair has been done during circulatory
Figure 30-16  Repair of sinus venosus malformation, which typically consists of subcaval atrial septal defect (ASD) associated with partial anomalous pulmonary venous connection of right superior pulmonary vein (RSPV) to low superior vena cava (SVC). A, Usual atriotomy is away from sinus node. B, Incision can be extended superiorly and medially to sinoatrial node. Subcaval ASD is superior to limbus. At times the SVC overrides the defect to drain in part directly into left atrium. ASD is far removed from tricuspid valve and atrioventricular node. First stitches for inserting pericardial patch are shown at right lateral edge of SVC orifice at its junction with laterally placed orifice of RSPV. Patch is sewn into place with continuous 4-0 or 5-0 polypropylene suture. Suture line continues medially in an anterior and posterior direction to form a tunnel or roof leading the anomalous RSPV through ASD. C, Convex roof of tunnel has been completed, and blood from anomalously connected RSPV drains beneath this roof into left atrium. Pathway from SVC to right atrium is unobstructed. When SVC is cannulated directly, exposure is good through this incision, and augmentation of the atrial closure is not necessary. D, Transverse section through repair seen from below.
Figure 30-17  Warden operation for sinus venosus malformation with right upper and middle lobe pulmonary veins entering superior vena cava (SVC). A, Right upper and middle pulmonary veins entering SVC. Right atrial appendage is amputated. B, High SVC or innominate vein is cannulated. Dashed line indicates the transecting incision in SVC. C, Cephalad end of transected SVC is anastomosed to amputated right atrial appendage. For mobilization, azygous vein is divided. D, Small incision is made in right atrial wall. Lateral edge of SVC orifice is sutured to lower rim of subcaval atrial septal defect (ASD), or the pathway is completed with a pericardial or polytetrafluoroethylene patch. Cardiac end of transected SVC is closed. E, Right pulmonary vein blood now flows (arrows) across the roofed ASD into left atrium. Key: RA, Right atrium; RAA, right atrial appendage. (From Warden and colleagues.)
Figure 30-18  V-Y atroplasty technique for enlarging superior vena cava (SVC). A, Initial incision is longitudinal and does not cross SVC–right atrial junction unless SVC enlargement is believed to be required. In such cases, a secondary incision is then added to create a V flap of right atrial wall. B, SVC is enlarged by advancing tip of V flap to apex of SVC incision. C, Augmentation is completed with a continuous suture line (X in B is brought to Y in C).

Figure 30-19  Repair of anomalous connection of right superior and inferior pulmonary veins to right atrium without atrial septal defect. A, Right atrial incision is the usual oblique transverse one, and fossa ovalis and posterior limbus are excised. B, Repair is made by replacing excised portion of atrial septum with a patch, sewn to right of (anterior to) the right pulmonary vein orifices. Key: LA, Left atrium; RA, right atrium.
Figure 30-20  Repair of partial anomalous pulmonary venous connection, right pulmonary veins to inferior vena cava (scimitar syndrome).

A, Usual oblique right atriotomy is made, extending it to inferior vena cava (IVC). B, Valve (floor) of fossa ovalis (septum primum) is excised, creating an atrial septal defect that extends almost to IVC. C, During a short period of circulatory arrest or with sucker trickle flow, IVC cannula is removed. Distance between inferior aspect of orifice of anomalous vein entrance into IVC and superior limbus is measured, as is width of fossa ovalis. Pericardial patch is trimmed in a rectangular shape, with length about 1.25 times the measured length and width about 1.5 times the width of the fossa ovalis. Using a continuous polypropylene suture, patch insertion is begun at inferior aspect of orifice of anomalous pulmonary vein in IVC, after this orifice and that of the hepatic vein are positively identified. Suture line between patch and floor of IVC is carried to patient's left and then up toward and onto anterior limbus, where it is held. With the other arm of original suture, patch is attached above orifice of anomalous vein as suture line is carried superiorly. IVC cannula is reinserted, and cardiopulmonary bypass is resumed at usual flow. D, Patch is then attached successively to posterior limbus, superior limbus, and anterior limbus, and tied there to other end of suture. E, Patch now forms approximately half of an intraatrial internal conduit conducting right pulmonary vein blood across defect created in the fossa ovalis into the left atrium. This is drawn in parasagittal section. Key: ASD, Atrial septal defect; LA, left atrium; RA, right atrium; SVC, superior vena cava.
arrest, the IVC cannula is reinserted, caval tape retightened, CPB reestablished, and rewarming with the perfusate begun. The anomalous vein is observed from time to time to ensure pressure in it is not elevated, because its drainage is now temporarily obstructed by the IVC tape. The right atrium is closed and the caval tapes promptly released. With suction on the aortic needle vent, the aortic clamp is released.

Alternatively, the anomalous pulmonary vein can be disconnected from its low insertion at the cavoatrial junction and reimplemented higher on the right atrial wall with connection via a baffle to the left atrium. As a third option, after disconnection, the anomalous vein can be implanted directly onto the left atrial wall at its rightmost aspect because this area is “bare” (having no natural entrance of right pulmonary veins). Usually, repair of the anomalous venous connection should be complemented by interrupting the aberrant systemic subpulmonary collateral supply to the right lower lobe. This can be accomplished by surgical ligation or catheter intervention. In neonates, it may be sufficient simply to interrupt the aberrant arterial supply and leave the anomalous venous connection intact.

Anomalous Connection of Left Pulmonary Veins to Brachiocephalic Vein

When the atrial septum is intact or there is only a valve-competent foramen ovale, operation is performed using a closed technique. The left chest is entered through a posterolateral incision (Fig. 30-21). The left groin should be prepared and draped for possible surgical access in case cannulation of the left femoral artery and vein are needed for CPB bypass. The anomalous left vertical vein is dissected up to the brachiocephalic vein. Left superior and inferior veins are dissected and mobilized as much as possible. A tape is placed around the left pulmonary artery.

The pericardium is opened, usually behind the phrenic nerve, and a large window is made. A clamp is placed across the very base of the left atrial appendage, and most of the appendage is amputated. The left pulmonary artery is temporarily occluded, the left vertical vein is ligated flush with the brachiocephalic vein, a clamp is placed across its proximal portion, and it is divided as near the ligature as safety allows. The vein is positioned with great care to avoid any rotation and is anastomosed to the base of the left atrial appendage. At least part of the anastomosis is made with interrupted sutures to avoid any possible purse-string effect. Before releasing the clamps, care is taken that no air is in the vein.

When there is an associated fossa ovalis ASD, both the left anomalous pulmonary venous connection and ASD should be repaired. (The first patient undergoing repair of this type of anomalous pulmonary venous connection, reported by the Mayo Clinic in 1953, required later closure of the ASD, at which time the previously made anastomosis was functioning well.) This repair can all be accomplished through a median sternotomy with CPB. The anastomosis between the vertical vein and left atrial appendage can be modified when CPB is used. Ports and colleagues make a long incision in the lateral aspect of the left atrial appendage, carrying it down onto the left atrium. The anomalous vein is cut transversely, then a T extension is made posteriorly. The end-to-side anastomosis is thus extremely wide. Alternatively, a side-to-side vertical vein–left atrial anastomosis is made, ligating the vertical vein at its junction with brachiocephalic vein.

Other Anomalous Pulmonary Venous Connections

Bilateral PAPVCs and rare right or left anomalous connections require individual techniques using principles described for standard repairs.

Treatment of Associated Mitral or Tricuspid Valve Disease

Mitral stenosis is treated by valvotomy. Mitral and tricuspid regurgitation are treated by anuloplasty when possible (see “Repair of Mitral Regurgitation” under Technique of Operation in Chapter 11). If mitral valve replacement is necessary, great care is required because the anulus tends to be friable.

SPECIAL FEATURES OF POSTOPERATIVE CARE

Convalescence of most children and adolescents who had repair of an uncomplicated ASD, as well as most adults operated on before they have reached NYHA functional class IV, is uneventful. They are extubated in the operating room or within a few hours of leaving it. Arterial blood pressure is monitored until the next morning via an arterial catheter, and the atrial pressures via any polyvinyl catheters placed at operation.

Occasionally, older patients have unusually high left atrial pressures (20 to 25 mmHg) in the early hours after repair, presumably because systolic and diastolic LV functions are more impaired than usual by the aging process or by coexisting coronary artery disease, systolic arterial hypertension, or residual important mitral regurgitation that has been underestimated preoperatively. In contrast to a few examples reported in the literature, in which urgent reoperation was performed and the ASD reopened because of severe left-sided heart failure with pulmonary edema, in 35 years of experience with this malformation at GLH, Mayo Clinic, and UAB, no ASD has been reopened. A partial explanation for this may be that ASD closure has not been recommended when the primary problem was LV cardiomyopathy. However, because of these considerations, left atrial pressure is routinely monitored intraoperatively and for about 24 hours postoperatively in older patients.

Occasionally, when mitral regurgitation has been underestimated preoperatively and there are signs of severe pulmonary venous hypertension postoperatively, an urgent echocardiographic study may be required. If important residual mitral regurgitation is detected, reoperation may be necessary to repair or replace the mitral valve.

All patients over age 35 years at operation receive sodium warfarin prophylactically beginning on the evening of the second postoperative day and continuing for 8 to 12 weeks after repair. The rationale is that both pulmonary and systemic arterial embolization occur after repair in patients older than 35 years. Occurrence is particularly high in elderly patients in atrial fibrillation (see Results in text that follows), in whom permanent anticoagulation is usually warranted.
RESULTS

Early (Hospital) Death

Hospital mortality for repair of ASDs and related conditions has approached zero for many years in most cardiac surgical centers throughout the world. In the presence of pulmonary hypertension in the elderly, the imponderables are greater in predicting expected early mortality, but in any case it is generally less than about 3%.

Time-Related Survival

Time-related survival of patients with ASD or PAPVC repaired during the first few years of life is that of the matched general population. When operation is performed later in childhood
or in early adult life, survival is nearly as good.\textsuperscript{55} In older patients, repair of ASD improves life expectancy.\textsuperscript{\texttrademark} However, survival is lower than in the matched population.\textsuperscript{\texttrademark} In an observational study, Konstantinides and colleagues compared surgical closure of ASD to medical treatment in 179 patients over age 40 (mean age 56 ± 9 years). Ten-year survival of the surgically treated patients was 95% vs. 84% for those treated medically.\textsuperscript{\texttrademark}\textsuperscript{10}

Modes of Death

The rare patient who dies in hospital after repair of an ASD or PAPVC usually has a serious coexisting condition such as pulmonary vascular disease or old age. The exception is the rare occurrence of death from air embolization, which is about the only risk in repair of ASDs and the reason for using the particular surgical techniques described (see Technique of Operation earlier in this chapter). Premature late death likewise occurs infrequently and almost exclusively in the types of patients just described. Horvath and colleagues found that premature late death occurred more often in patients undergoing surgery in adulthood when preoperative systolic P\textsubscript{A} was 30 mmHg or greater than when it was less (survival 85% ± 1% vs. 99% ± 6% at 10 years; \textit{P} < .0002).\textsuperscript{\texttrademark}\textsuperscript{10}

Neurologic failure from cerebral embolization or hemorrhage is the most common mode of late death in elderly patients, most of whom have hypertension. Heart failure is the next most common mode of death, again in elderly patients. In rare instances, late death results from severe supraventricular arrhythmias.

Incremental Risk Factors for Death

In contrast to most types of congenital heart disease, patients with ASD or PAPVC rarely have serious important coexisting cardiac anomalies. Therefore, this incremental risk factor is absent. Likewise, neither morphology of the ASD nor morphology of most types of PAPVC is a risk factor for death. Again, in contrast to most types of congenital and acquired heart disease, preoperative functional class is not a confirmed
risk factor for death, probably because the operation is relatively atraumatic and requires only a short duration of CPB and global myocardial ischemia.

**Pulmonary Vascular Disease**

Preoperative pulmonary hypertension severe enough to indicate important pulmonary vascular disease is a risk factor for death, and if severe enough, death may occur early after operation.\(^{2,11}\) This risk factor appears in various forms in different analyses; in the study by Murphy and colleagues, for example, pulmonary vascular disease appears as the level of systolic PPA.\(^{11}\) Elevation of RpI becomes a major risk factor when greater than 6 U · m\(^{-2}\) and may be an irreversible risk when it reaches about 12 U · m\(^{-2}\) (see Special Situations and Controversies later in this chapter).

**Older Age at Operation**

Neither older age at operation nor young age at operation is a risk factor for hospital death. Older age is a risk factor for premature late death, identifiable after the first decade and becoming progressively more powerful as age increases.\(^{11,12}\) Patients in the first decade have about a 98% chance of surviving at least 25 years after repair, those in the third decade a 93% chance, and those in the fourth decade an 84% chance; patients older than about 40 years have even less probability of long-term survival.\(^{14}\) St. John Sutton and colleagues found that 10-year survival was 64% after repair of ASD in patients older than age 60, importantly better than that of similar nonsurgically (“Unoperated”). \(^{7,11}\) -2 Fig. 30-22 -

Late survival of patients over age 60 years after undergoing repair of atrial septal defect (hospital survivors only) compared with survival of an age-gender-matched general population (“Expected”) and with that of patients of the same age treated nonsurgically (“Unoperated”). (From St. John Sutton and colleagues.\(^{13}\))

**Anatomic Type of Interatrial Communication**

The anatomic type of interatrial communication or PAPVC does not appear to affect survival.\(^{2,14,15,11,15,16}\) An exception may be scimitar syndrome, with the right pulmonary veins connecting anomalously to the IVC. Increased risk is caused primarily by abnormalities in the right lung rather than by PAPVC itself.

**Functional Status**

Asymptomatic children have no symptoms after operation, but symptomatic infants undergoing repair of ASD may also experience complete relief of symptoms.\(^{2,14}\) Older symptomatic patients typically show improvement.\(^{2,15,16}\) Forfang and colleagues found that ASD closure in patients over age 40 improved symptomatic state by one NYHA functional class in every patient.\(^{14}\) Both Konstantinides and Gatzoulis and their colleagues reported improved functional status in their surgically treated groups that were over age 40.\(^{1,15,16}\) Even patients undergoing surgery after age 60 showed striking functional and symptomatic improvement: \(^{2,14}\) 87% improved at least one NYHA functional class.

Among the 31 patients preoperatively in NYHA class III or IV in the study by St. John Sutton and colleagues, only two (6%) remained severely disabled.\(^{15}\) This striking symptomatic improvement, even in older patients whose cardiomegaly does not always regress, has been documented by Pearlman and colleagues.\(^{14}\) Excellent treadmill exercise performance and normal maximal oxygen consumption were found in all 14 consecutive patients studied late after repair of ASD, despite 9 with persistently large RV diastolic dimensions.

**Hemodynamic Results**

Important hemodynamic changes occur immediately after closure of an uncomplicated ASD. Mean pressure in the ascending aorta increases, as does mean aortic blood flow.\(^{11}\) There is an immediate reduction in pulmonary blood flow.\(^{11}\) Right atrial pressure decreases and left atrial pressure increases; Søndergard and Paulsen found an average immediate rise of 8 mmHg.\(^{14}\) The small amount of available information indicates that in older patients, RpI drops negligibly late after operation.

**Ventricular Function**

RV diastolic dimensions are strikingly decreased after operation\(^{11}\) but are still above normal in many patients\(^{17,11,16}\) (Fig. 30-23). This finding is consistent with Young’s early observation that some children had important residual cardiomegaly years after complete repair of their ASD, which he correctly ascribed to the secondary cardiomyopathy resulting from chronic RV volume overload.\(^{11}\) Pearlman and colleagues showed an effect of older age at operation in this regard; 7 (64%; CL 44%-81%) of 11 patients aged 10 years or younger at operation had normal or near-normal RV diastolic volumes late postoperatively, whereas only 3 (21%; CL 10%-38%) of 14 patients older than age 25 displayed this finding (\(P\) [Fisher] for difference = .04).\(^{14}\)

In adult patients with preoperatively decreased RV wall motion and ejection fraction, most of whom have elevated right atrial pressure and are importantly symptomatic,
Figure 30-23 Effect of atrial septal defect repair on echocardiographic right ventricular internal dimension (RVID) at end-diastole, left ventricular dimension (LVD) at end-diastole (D) and end-systole (S), and left ventricular fractional shortening (FS). Shaded area, Normal range of fractional shortening (29%-45%); open circles with bars, mean values; solid symbols, three symptomatic patients with marked drop in ejection fraction during exercise. Key: LV, Left ventricular; NS, not significant; Pre, preoperative; Post, postoperative. (From Bonow and colleagues.)

Figure 30-24 Left ventricular ejection fraction at rest and during exercise after repair of atrial septal defect. Open circles with bars, Mean values. (From Bonow and colleagues.)

reduction in RV size after surgical repair is less, and ejection fraction, although higher than preoperatively, remains abnormally low (47% in the experience of Libethson and colleagues17). These patients are improved by operation but do not become asymptomatic. Analogies between this and response to surgery of the volume-overloaded LV are apparent (see “Left Ventricular Structure and Function” under Results in Chapter 12).

Postoperatively, in contrast to the preoperative condition, LV ejection fraction increases normally with maximal exercise (Fig. 30-24). Even in patients who have undergone repair in adult life, exercise ejection fraction is usually normal. This favorable change is the result of ablation of the RV volume overload by closure of the ASD. Also, LV diastolic dimensions, when abnormally small preoperatively, increase to normal within 6 months of operation.8,11,31 The abnormalities of LV geometry present preoperatively are also corrected by repair of the ASD.

Arrhythmic Events

Closure of ASDs in children has been shown to improve AV conduction, decrease AV nodal refractory periods, and improve sinus node function in most patients early postoperatively.8,10,31 Presumably this improvement results from reduction in RV and right atrial volume after ablation of the left-to-right shunt at the atrial level. However, Bolens and Friedli found loss of sinus node function after operation and an atrial ectopic rhythm.8,10 Although possibly the result of direct surgical damage to the sinus node, these effects may represent the unmasking of preoperatively concealed sinus node dysfunction.8,15

Little specific information is available on arrhythmias late after repair of ASDs in infants and children, but presumably these are uncommon. Forfang and colleagues, as well as other groups, found that arrhythmic symptoms regress less frequently than other symptoms.15 Thus, most adult patients with atrial fibrillation preoperatively continue to experience it late postoperatively.11,31 Shah and colleagues, however, as well as Konstantinides, noted a persistent occurrence of new arrhythmias and thromboembolic events in adults followed long term after surgical repair.33,34 Furthermore, at least in patients over about age 40, almost half of those not in atrial fibrillation preoperatively develop it late postoperatively.10,31,33 This tendency to atrial fibrillation or flutter late postoperatively may be less when venous cannulation is directly into the venae cavae rather than through the right atrial appendage.33

These same findings apply after repair of PAPVC, particularly of sinus venous malformation, so the pessimistic view expressed by Clark and colleagues is not justified.8,14 Twenty-three (79%; CL 69%-87%) of the 29 patients followed by Trusler and colleagues after repair of sinus venous malformation were in sinus rhythm late postoperatively, and 6 were in junctional rhythm (one of whom had it preoperatively).7,10,33,34

Also, prevalence of changed heart rhythms after repair is similar in patients with fossa ovalis ASDs and those with sinus venous malformation. Twenty-six (84%; CL 74%-91%) of 31 patients undergoing repair of sinus venous malformation had no change in their preoperative rhythm during the first 7 days after operation, compared with 190 (92%; CL 89%-94%) of 207 such patients undergoing repair of fossa ovalis defects (P|χ²| = .16) (Rouse RG, MacLean WH, Kirklin JW;
unpublished study, 1979). Trusler and colleagues reported similar findings; 4 of 29 children had sick sinus syndrome or junctional rhythm late postoperatively, and all 4 had an atriotomy across the cavoatrial junction.\(^{16}\)

**Thromboembolism**

Both systemic and pulmonary emboli tend to occur in patients with ASDs. Among 587 hospital survivors of ASD repair at Mayo Clinic between 1953 and 1963, Hawe and colleagues found postoperative embolization as late as 11 years after repair.\(^{16}\) A higher incidence was found in patients over age 40, especially those with atrial fibrillation (Fig. 30-25).

**Reintervention**

Recurrent ASD has required reoperation in about 2% of patients. Recurrence of ASD is more likely in older patients with heart failure preoperatively. Reoperation is likewise rarely necessary after repair of PAPVC. In the UAB experience, 1 of 56 hospital survivors required reoperation for partial patch dehiscence resulting in partial SVC obstruction and diversion of the SVC largely to the left atrium. At reoperation an entirely new patch was placed with a good result. Two of 12 patients required reoperation after repair of scimitar syndrome because of stenosis of the surgically created channel. Both had right lung hypoplasia with a Qp/Qs of 1.6. Reoperation carries negligible risk. When occurring beneath a pericardial or polyester tunnel, however, stenosis may be difficult to relieve.

**INDICATIONS FOR OPERATION**

Presence of an uncomplicated ASD or of PAPVC with evidence of RV volume overload is an indication for operation. The indication can be restated as a Qp/Qs of 1.8 or more and at times, if the anomaly is uncomplicated, of greater than 1.5. An exception is patients with scimitar syndrome who have severe hypoplasia of the right lung and a Qp/Qs of less than 1.8; operation, usually lobectomy or pneumonectomy with ligation of the anomalous arterial supply, may be required in these patients because of complications of bronchopulmonary sequestration. Isolated PAPVC of a part of one lung without an ASD is not an indication for operation when Qp/Qs is less than 1.8, particularly because the shunt under such circumstances does not increase with age. Isolated PAPVC of a whole lung is an indication for repair; whenever an entire lung drains anomalously and the atrial septum is intact, only the opposite, correctly draining lung can return oxygenated blood to the systemic circuit. If this normal lung is importantly compromised (e.g., by pneumonia, pneumothorax, or atelectasis from inhaled foreign body or tumor), potentially fatal hypoxia occurs.

Optimal age for operation is 1 to 2 years because of the deleterious effects of longer periods of RV volume overload. However, opportunity to intervene surgically as early as age 1 year is not always present, because diagnosis is often made later in life. Very young or very old age is not a contraindication to operation. Mainwaring and colleagues, however, caution that infants presenting with major symptoms and large fossa ovalis defects may not benefit from ASD closure.\(^{13}\) The inference is that these young patients’ failure to thrive is not related to presence of the defect.

Pulmonary vascular disease of sufficient severity to raise RpI to 8 to 12 U · m\(^{-2}\) at rest and to prevent its decrease to less than 7 with a pulmonary vasodilator is a contraindication to operation (see “Cardiac Catheterization and Cineangiography” earlier in this chapter). Such conditions are usually present with a resting Qp/Qs of less than 1.5 in patients with elevated P\(a\)O\(_2\), but may be present with a Qp/Qs of 2.0. These ideas are inferential and based on postoperative studies in patients with VSDs and elevated RpI.\(^{16}\) Of considerable importance is the interaction of pulmonary and systemic vascular resistance with exercise. As a practical consideration, a marked decrease in peripheral pulse oximetry with exercise strongly suggests sufficient increase in pulmonary vascular resistance to cause right-to-left shunting at the atrial level with exertion. This finding indicates need for extreme caution in proceeding with repair, because loss of the “pop-off” hole during exertion could induce syncope or sudden death.

Associated tricuspid or mitral regurgitation, which occurs especially in older patients, is not a contraindication to operation. If important, such conditions are repaired at closure of the ASD. Grading of mitral regurgitation by angiography and echocardiography may be misleading when major runoff occurs from left to right atrium through the ASD, and the regurgitation becomes more important when the ASD is closed. For these reasons, moderate mitral regurgitation is usually an indication for mitral valve repair.

**SPECIAL SITUATIONS AND CONTROVERSIES**

**Closure of Atrial Septal Defects by Percutaneous Techniques**

At least some ASDs can be closed with transcatheter techniques and a device known as the “clam shell,” introduced and manipulated percutaneously.\(^{87}\) The procedure has been successfully performed on an outpatient basis. Currently, 60% to 70% of patients with a fossa ovalis ASD are treated by percutaneous techniques at institutions with the necessary devices and experienced operators. The procedure is limited
to “central” defects with well-defined margins and size of 5 to 20 mm. Potential complications of percutaneous ASD closure include device migration, embolization requiring urgent operation, and residual shunts. With experience, these complications are rare. Simple foramen ovale defects permitting right-to-left shunting and a paradoxical embolus in elderly patients are ideally managed by transcatheter closure.

Direct Suture versus Patch Repair

Cardiac surgeons vary as to the frequency with which they use a patch (usually pericardium, PTFE, or knitted polyester velour) to close ASDs. For example, this approach was used in 17% of patients in a Mayo Clinic experience, approximately 30% of those in a GLH experience, and 3% of those at UAB. Provided a patch is used when the defect is particularly large or the tissues are unduly friable, there appears to be no difference in end results, including early or late thromboembolic complications. Under such circumstances, the ease and simplicity of direct suturing support its use in most patients.

Patch Material in Atrial Septum

Pericardium is the material of choice for interatrial patches (1) when a regurgitant jet may strike the patch, such as after repair of AV septal defects (prosthetic patches may produce severe hemolysis under these circumstances); (2) when pericardium forms part of the wall of an intracardiac conduit, the precise contour (position) of which is primarily determined by pressures on the two sides; and (3) when the patch is sewn to a very delicate area. In other situations, knitted polyester and PTFE patches are suitable alternatives.

Complications after Repair of Sinus Venosus Malformation

When the SVC is normal or enlarged and the pulmonary veins enter at or near the cavoatrial junction, late postoperative narrowing of the SVC is rare after repair of sinus venosus malformation by the techniques described. For this reason, minimal information is available to recommend more complex repairs.

In the unusual situations of a small right SVC (usually in the setting of bilateral SVC) or right pulmonary veins entering well above the cavoatrial junction, controversy exists regarding the optimal repair technique. Evidence exists to implicate occasional SVC stenosis when an autologous pericardial patch has been placed across the cavoatrial junction, and early and late sinus node dysfunction may be more likely secondary to disruption of blood supply to the sinoatrial node. However, several experienced groups report good results with “two-patch” techniques. Others prefer the Warden procedure in this setting (see Technique of Operation earlier in this chapter). Sinus node dysfunction is rare with this technique, but occasional stenosis at the SVC–right atrial connection has been reported. Thus, currently the standard one-patch technique appears optimal for the most common variant of sinus venosus ASD with PAPVC to the cavoatrial junction and a normal or
enlarged SVC. Long-term data have not generated a consensus about the optimal technique in the setting of a small SVC or pulmonary veins entering well above the cavoatrial junction.

Pulmonary Venous Obstruction after Repair of Scimitar Syndrome

The long intracardiac baffle often required to repair anomalous connection of right pulmonary veins to the IVC carries a greater risk of late baffle obstruction compared with other forms of PAPVC. Baffle length, relative stasis caused by the sudden change in direction of blood entering the baffle, and other factors may contribute to this complication. In a series of 15 patients with a baffle repair of scimitar syndrome, Alsoufi and colleagues from Toronto reported pulmonary venous stenosis in 7 of 10 undergoing late cardiac catheterization. Insufficient follow-up data are available to conclude whether alternative techniques, such as direct reimplantation of the anomalous vein, will yield better long-term results.

Repair in Presence of Increased Pulmonary Vascular Resistance

Some information indicates that a few patients with high RpI (>6 U · m²) may benefit from closure of an ASD using a flap-valve patch (Fig. 30-26). The flap opens right to left, such that if right atrial pressure exceeds left atrial pressure in severe pulmonary hypertension, the right atrium will decompress to the left atrium, supporting systemic cardiac output (see “Lateral Tunnel Fontan Operation with Deliberately Incomplete Atrial Partitioning” in Section IV of Chapter 41). It is inferred that as PPA and RpI decrease late postoperatively, the flap valve will close by cicatrix.

Definition
Total (totally) anomalous pulmonary venous connection (TAPVC) is a cardiac malformation in which there is no direct connection between any pulmonary vein and the left atrium; rather, all the pulmonary veins connect to the right atrium or one of its tributaries. Although not part of the malformation, a patent foramen ovale or atrial septal defect is present in essentially all persons with TAPVC and is necessary for survival after birth.

This chapter concerns TAPVC in hearts with concordant atrioventricular and ventriculoarterial connections without other major cardiac anomalies except patent ductus arteriosus. TAPVC can occur in hearts with a wide range of other cardiac anomalies, ranging from ventricular septal defect to tetralogy of Fallot to functional single ventricle. TAPVC in hearts with atrial isomerism is considered in Chapter 58.

Historical Note
TAPVC was apparently first described by Wilson in 1798.1184 In 1951, Muller, while at the University of California Medical Center in Los Angeles, reported the first successful surgical approach.1186 His correction was partial, achieved by anastomosing the common pulmonary venous sinus to the left atrial appendage using a closed technique. In 1956, Lewis, Varco, and colleagues1185 at the University of Minnesota reported successful open repair of TAPVC using moderate hypothermia induced by surface cooling and temporary occlusion of venous inflow to the heart. The same year, Burroughs and Kirklin reported successful repair of TAPVC using cardiopulmonary bypass (CPB).1189 Their report also described a successful operation several years earlier using the atrial well technique of Gross and colleagues.1189 Subsequently, it became apparent that mortality in infants following repair of TAPVC...
using CPB was strikingly higher than in older patients, but attempts to improve results by staged operation or palliative measures were generally unsuccessful.\textsuperscript{6,8,9,10,11} Success was reported from time to time, however, even for critically ill infants with infracardiac connection.\textsuperscript{12} Eventually, improvements in intraoperative techniques substantially improved results in infants. In 1967, Dillard and colleagues achieved good results using hypothermic circulatory arrest without CPB.\textsuperscript{13} and in 1971, Malm, Gersony, and colleagues reported success in a small group of young infants using standard normothermic CPB. Hypothermic circulatory arrest and limited CPB were used in 1969 with strikingly improved results.\textsuperscript{8,9} However, refinements in intraoperative techniques developed over the last 2 decades now allow excellent outcomes using continuous CPB.

**MORPHOLOGY**

**Pulmonary Venous Anatomy**

TAPVC is supracardiac in about 45% of cases, cardiac in about 25%, infracardiac in about 25%, and mixed in about 5% to 10% (Fig. 31-1).\textsuperscript{3,11} The connection in supracardiac TAPVC is usually to a left vertical vein draining into the left brachiocephalic vein, less often to the superior vena cava, usually at its junction with the right atrium, and rarely to theazygos vein. In cardiac TAPVC, the connection is usually to the coronary sinus and less often to the right atrium directly. Connection to the supradiaphragmatic infraventricular vena cava also has been reported.\textsuperscript{3} The most common sites of connection in patients with infracardiac (infraadiaphragmatic) TAPVC are the portal vein (65% of cases, according to Duff and colleagues\textsuperscript{11,12}) and ductus venosus; less common are the gastric vein, right or left hepatic vein, and inferior vena cava. Uncommonly, the pulmonary venous drainage may be through two connections.\textsuperscript{13} Also, part of the pulmonary venous drainage may be to one site and part to another in what is termed mixed TAPVC. At least 15 different morphologic mixed variants have been identified. In the most common form, the left upper lobe of the lung drains to a left vertical vein, and the remainder of both lungs drains to theazygos vein.\textsuperscript{14} Chowdhury and colleagues have categorized this wide assortment of mixed TAPVC into three general groups: the 2+2 pattern, the 3+1 pattern, and thebizarre pattern.\textsuperscript{15}

No matter what the final connection or termination may be, individual right and left pulmonary veins usually converge to form a common pulmonary venous sinus, which in turn connects to the systemic venous system in one of the ways noted earlier. It is usually posterior to the pericardium. Its long axis is usually oriented transversely, with the pulmonary veins of the left lung converging to form its left extremity and those from the right lung to form its right extremity. When the drainage is infracardiac, the right and left pulmonary veins slope downward to converge into a vertical sinus, with the entire arrangement having a Y, T, or treeshape.\textsuperscript{16,17} Rarely, there are two vertical veins that are not confluent until below the diaphragm.\textsuperscript{18} Two vertical veins have also been identified in supracardiac TAPVC.\textsuperscript{19}

A common pulmonary venous sinus may be absent in some cases with cardiac or mixed connections. Its apparent absence in some patients may be an illusion attributable to a defect in the anterior wall of the sinus. That defect is the orifice connecting it to the coronary sinus or right atrium. Pulmonary venous obstruction is a severe associated condition usually resulting from a stenosis involving the vein connecting the common pulmonary venous sinus to the systemic venous system. A localized stenosis may occur at the junction of the left vertical vein with either the left brachiocephalic vein or the common pulmonary venous sinus, or at the junction of a connecting vein that joins the superior vena cava. Severe obstruction may be due to the so-called vascular vice, in which the left vertical vein passes posterior rather than anterior to the left pulmonary artery and is compressed between it and the left main bronchus.\textsuperscript{20}

When TAPVC is to the coronary sinus, a stenosis may occur where the common pulmonary venous sinus joins the coronary sinus or (rarely) at the coronary sinus ostium.\textsuperscript{21} In infracardiac connection, the connecting vein may be similarly narrowed at its junction with the portal vein or ductus venosus, or it may be compressed where it penetrates the diaphragm. In those varieties of infracardiac connection in which the ductus venosus is not available to bypass the liver, the portal sinusoids offer additional important obstruction to venous return. Finally, pulmonary venous obstruction may result simply from the length of a comparatively narrow connecting vein. Rarely, associated cor triatriatum is present and serves as the cause of obstruction.\textsuperscript{22}

Important pulmonary venous obstruction of these various types exists in nearly all patients with infracardiac connection and in almost all with connections to theazygos vein, in 65% of those with connections to the superior vena cava, in 40% of those with connections to theleft brachiocephalic vein, and in 40% with connections of the mixed type.\textsuperscript{23} It is less common in patients with a cardiac connection, although it has been found in 20% of patients in whom the connection is to the coronary sinus. Rarely, pulmonary venous obstruction is the result of stenoses of individual pulmonary veins at or close to their connections to the common pulmonary venous sinus.\textsuperscript{24} Functional pulmonary venous obstruction arguably occurs in patients having a patent foramen ovale rather than an atrial septal defect, although this occurrence may be limited to those with a small orifice at the foramen ovale.

**Cardiac Chamber and Septal Anatomy**

For survival after birth, a communication between systemic and pulmonary circulations must exist. Nearly always, an atrial septal defect or patent foramen ovale is present. However, in the review of Delisle and colleagues, one of 93 autopsy cases was an 11-year-old with an intact atrial septum and multiple ventricular septal defects, and Hastreiter and colleagues reported a 6-week-old patient with TAPVC to the ductus venosus, a patent ductus, and a closed foramen ovale.\textsuperscript{25} Atrial communication in TAPVC is usually of adequate size and not obstructive,\textsuperscript{26,27} although the GLH group reported that the defect was small in about half the infants operated on.\textsuperscript{28} There is frequently no pressure gradient between the two atria even when the defect is small.\textsuperscript{28,29}

The right atrium is enlarged and thick walled in patients with TAPVC, and the left atrium is abnormally small.\textsuperscript{30} Cineangiographic studies by Mathew and colleagues have shown left atrial volume to be 53% of predicted normal.\textsuperscript{31}
Figure 31-1  Classification of total anomalous pulmonary venous connection. A, Supracardiac type (45% of cases), in which the common pulmonary venous sinus connects by a vertical vein on the left side to left brachiocephalic vein. B, Cardiac type (25% of cases), in which the common pulmonary venous sinus connects to the coronary sinus in right atrium. C, Infracardiac type (25% of cases), in which the common pulmonary venous sinus connects to the portal vein or ductus venosus below the diaphragm. D, Mixed type (5%-10% of cases), in which there is no common pulmonary venous sinus, and pulmonary veins connect randomly to the heart.

These investigators noted that the left atrial appendage was normal in size and believed that left atrial smallness could be explained by absence of the pulmonary vein component. In addition, in patients with TAPVC to the right atrium, the posterior attachment of the atrial septum is shifted to the left, so the septum lies nearer to the sagittal than the usual coronal plane. Anatomic studies have shown that the left ventricle (LV) is usually normal in size. Haworth and Reid's quantitative study showed that inflow measurements of the LV were normal in eight of nine infants dying with TAPVC.
In one infant, however, LV inflow measurements were abnormally small, and weight of the free LV wall plus the septum was less than that of a normal fetus at full term. In all nine infants, LV free-wall thickness was normal. In a quantitative autopsy study of infants with TAPVC, Bove and colleagues found LV mass to be normal as well. However, they found the LV cavity was small because of leftward displacement of the septum secondary to right ventricular (RV) pressure-volume overload (see “Mitra Prolapse” under Mor). Correspondingly, Nakazawa and colleagues reported small LVEDV in infants with TAPVC. When both values were measured in the same patient, symbols are connected by solid lines, with two short vertical parallel lines indicating time of repair. X represents values in normal patients. Key: CoS, Coronary sinus total anomalous pulmonary venous connection (TAPVC); Infra, infracardiac TAPVC; RA, right atrial cardiac TAPVC; Supra, supracardiac TAPVC. (From Whight and colleagues.)

The RV varies in size, depending on the magnitude of pulmonary blood flow, presence or absence of pulmonary venous stenosis, and the point at which anomalous pulmonary veins connect. When connection was infracardiac, Haworth and Reid found that the RV was neither hypertrophied nor dilated. When venous connection was supradiaphragmatic, the septum and RV were hypertrophied and the RV dilated.

Pulmonary Vasculature

Because most infants with TAPVC have marked pulmonary hypertension, structural changes are usually found in the lungs of even the youngest infants dying with the malformation. Haworth and Reid demonstrated increased pulmonary arterial muscularity in all infants dying with TAPVC, including an 8-day-old neonate, as shown by increased arterial wall thickness and extension of muscle into

Associated Conditions

Except for an atrial communication, most infants presenting with severe symptoms from TAPVC have either no associated condition or a small or large patent ductus arteriosus. Patent ductus arteriosus is present in nearly all infants coming to operation in the first few weeks of life with pulmonary venous obstruction and, overall, in about 15% of cases. Ventricular septal defects occasionally occur. However, more than one third of cases coming to autopsy, few of which are infants, have other major associated cardiac anomalies. These include tetralogy of Fallot, double-outlet RV, interrupted aortic arch, and other lesions. The combination of TAPVC and other major cardiac anomalies is especially likely to occur when there is atrial isomerism (see Chapter 58). Other associations have been identified. Esophageal varices can occur in obstructed TAPVC, and these are likely caused by obstructed veins. Hypoplasia of the small pulmonary arteries has recently been identified in obstructive TAPVC.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Presentation

Patients with TAPVC present as seriously and often critically ill neonates, especially when a component of obstruction is present. The diagnosis can be missed when obstruction is absent, because of lack of florid signs and symptoms. TAPVC must be suspected in any neonate who has unexplained tachypnea, the cardinal sign of this anomaly. During the first 2 weeks of life, there are other causes of tachypnea that may be impossible to distinguish clinically from TAPVC, particularly a diffuse pneumonic process and retention of fetal lung fluid. Meconium aspiration and myocarditis may also confound the diagnosis. Respiratory distress syndrome should not be difficult to differentiate, because of its classic radiologic features, prematurity, and intercostal and sternal indrawing. Cyanosis is usually unimpressive in TAPVC unless there is marked pulmonary venous obstruction or a widely open ductus arteriosus that permits right-to-left shunting. Both LV and RV functions are depressed compared with normal (P < .001 in both instances) in infants presenting with seriously ill with obstructed TAPVC and marked pulmonary hypertension. Severe metabolic acidosis develops soon after birth when pulmonary venous obstruction is severe, rapidly leading to myocardial necrosis. Some neonates are so critically ill that they require intubation immediately upon hospital admission and before evaluation is begun.

Examination

In neonates and infants, the heart is not particularly overactive on examination. There may be an unimpressive precordial systolic murmur and gallop sound (the latter often proves to be a tricuspid flow murmur). The second heart sound is usually single or narrowly split. In older children, the signs are those of a large atrial septal defect unless there is increased pulmonary vascular resistance.
When the connection is to a left vertical vein, the common pulmonary venous sinus and vertical vein can usually be demonstrated (Fig. 31-5, A). When the anomalous connection is to the coronary sinus, it appears as an ovoid opacification over the left side of the spine within the right atrial contour. When it is infracardiac, the descending vein can usually be demonstrated, although its precise infradiaphragmatic connection may not be seen (Fig. 31-5, B).

Tynan and colleagues have pointed out that in neonates, umbilical vein catheterization permits direct injection of contrast medium into the anomalously connecting infradiaphragmatic vein and an accurate diagnosis of its connections.

Presence of pulmonary venous obstruction is established by demonstrating a gradient between left atrial and pulmonary venous pressure.

**Chest Radiography**

On chest radiography, heart size is usually near normal if there is pulmonary venous obstruction, but it may be large when there is increased pulmonary blood flow. The latter is associated with plethora (Fig. 31-3, A), but the more common pulmonary venous obstruction is evident as a diffuse haziness or, in its severe forms, a “ground glass” appearance. This sign is reduced when the pulmonary circuit can decompress via a patent ductus arteriosus. Older infants with TAPVC to the left brachiocephalic vein have a characteristic “figure-of-eight” or “snowman” configuration on the chest radiograph. A similar chest radiographic appearance is evident in neonates (see previous discussion). When the connection is to a left vertical vein, the common pulmonary venous sinus and vertical vein can usually be demonstrated (Fig. 31-5, A). When the anomalous connection is to the coronary sinus, it appears as an ovoid opacification over the left side of the spine within the right atrial contour. When it is infracardiac, the descending vein can usually be demonstrated, although its precise infradiaphragmatic connection may not be seen (Fig. 31-5, B).

**Echocardiography**

Two-dimensional (2D) echocardiography is remarkably accurate in assessing the morphology of TAPVC (Fig. 31-4). Along with Doppler color flow interrogation, it is almost always diagnostic. Echocardiographic features include criteria for RV diastolic overload and an echo-free space posterior to the left atrium. However, a second drainage site might be overlooked. Echocardiography is commonly accepted as a definitive diagnostic procedure in neonates with important pulmonary venous obstruction, because contrast medium is not required. Cardiac catheterization delays operation and exacerbates myocardial failure and pulmonary edema.

**Cardiac Catheterization and Cineangiography**

Angiograms obtained by pulmonary artery or pulmonary vein injections define the malformation, identify the site of drainage, and often localize the site of pulmonary venous obstruction. This procedure is nearly always diagnostic. However, it should not be used in seriously ill neonates (see previous discussion).
artery wedge pressures. Greene and colleagues employ superimposition digital subtraction angiography to define pulmonary venous anatomy, relationship of common pulmonary vein to left atrium, and size of left atrium.\textsuperscript{G7}

Magnetic Resonance Imaging and Computed Tomography

Because of diagnostic limitations of echocardiography in complex cases and morbidity associated with cardiac catheterization in gravely ill patients, both magnetic resonance imaging (MRI) and computed tomography (CT) have become increasingly important in diagnosing TAPVC. Both modalities should be used selectively, primarily in patients in whom echocardiography is not definitive. When compared with both catheterization and echocardiography, numerous studies have demonstrated the accuracy of MRI and CT in diagnosing TAPVC.\textsuperscript{C4,F1,G8,K5,M2,S14,U1} Several demonstrate improved accuracy of diagnosis using both helical CT angiography, with and without three-dimensional (3D) reconstruction,\textsuperscript{K5} and gadolinium-enhanced 3D cardiac magnetic resonance (CMR) angiography.\textsuperscript{F1,G8}

Physiology of Common Mixing Chamber

In TAPVC, the right atrium is theoretically a common mixing chamber.\textsuperscript{B17} This situation is reflected in the frequent finding of close similarity of oxygen content and saturations from the right atrium, left atrium, pulmonary artery, and systemic artery.\textsuperscript{F4} There is considerable deviation from this pattern, however, because of streaming of systemic venous return in the right atrium, directing inferior vena cava blood through the foramen ovale to the mitral valve, and superior vena cava blood through the tricuspid valve. Thus, in infracardiac TAPVC, systemic arterial saturation is typically higher than pulmonary artery saturation.

Because TAPVC has this common mixing chamber, in most patients who live beyond infancy, a direct relationship exists between the magnitude of pulmonary blood flow and arterial oxygen saturation, assuming a constant oxygen consumption and blood hemoglobin level. This relationship was formulated into a nomogram by Burchell.\textsuperscript{B17} (Fig. 31-6). The upper curve is at rest; the lower is at moderate exercise. Systemic blood flow is assumed to be 25 L · min\(^{-1}\). (From Burchell,\textsuperscript{B17})
NATURAL HISTORY

TAPVC is relatively uncommon, accounting for only about 1.5% to 3% of cases of congenital heart disease.\textsuperscript{89} Infants born with TAPVC have a generally unfavorable prognosis, with only about 20% surviving the first year of life.\textsuperscript{81,83} Only about 50% survive beyond 3 months, with death occurring during the first few weeks or months of life in most neonates in whom tachypnea, cyanosis, and clinical evidence of low cardiac output develop. Such infants usually have pulmonary venous obstruction, long pulmonary venous pathways, and a small patent foramen ovale.\textsuperscript{81} Survival past the critical first few weeks and months does not portend a favorable prognosis, because only about half the patients surviving to age 3 months survive to 1 year. Infants who survive the first few weeks of life usually have cardiomegaly and a large pulmonary blood flow, with mild cyanosis. Most have some degree of pulmonary artery hypertension.\textsuperscript{42} Their clinical syndrome includes tachypnea, recurrent episodes of severe pulmonary congestion, failure to thrive, fluid retention, and hepatomegaly.

Those with TAPVC who survive the first year of life without surgical treatment usually have a large atrial septal defect. Characteristically, they exhibit important physical underdevelopment similar to that of patients with other kinds of large left-to-right shunts, mild cyanosis, and mild exercise intolerance (see “Survival” under Natural History in Chapter 30). Like patients with isolated large atrial septal defects, they tend to have a stable hemodynamic state for 10 to 20 years, with little change in pulmonary vascular resistance and thus little change in pulmonary artery pressure, blood flow, and arterial oxygen levels.\textsuperscript{42} In the second decade of life, pulmonary vascular disease develops in some patients, and there is increasing cyanosis as pulmonary blood flow diminishes (Eisenmenger complex).\textsuperscript{45}

To quantify the natural history, Hazelrig and colleagues analyzed data from 183 autopsied cases of surgically untreated TAPVC reported in the literature.\textsuperscript{1188} Median survival was 2 months, with the shortest survival being 1 day and the longest 49 years; 90% of deaths occurred in the first year of life. Obstruction of the pulmonary venous pathway importantly reduced median survival ($P < .0001$) (Fig. 31-7) from 2.5 months in the nonobstructed group to 3 weeks in the obstructed group. Patients with supracardiac and cardiac connections had a similar history, with median survival of 2.5 and 3 months, respectively, whereas those with infracardiac connections had a worse prognosis, with median survival of 3 weeks (Fig. 31-8). Only three patients had mixed connections; two died at 5 months and one at 3.3 months. Presence of an atrial septal defect (rather than a patent foramen ovale) was associated with increased survival, particularly when the connection was not infracardiac (see Fig. 31-8).

TECHNIQUE OF OPERATION

Operation should be undertaken as an emergency immediately after diagnosis by 2D echocardiography in neonates and infants who enter the hospital critically ill. Preoperative preparation and stabilization should be brief. In stable patients, typically non-neonates without obstruction, the operation can be scheduled electively. Approach is via median sternotomy. The CPB technique can vary depending on surgeon preference, ranging from continuous CPB with either moderate or deep hypothermia to limited CPB with deep hypothermic circulatory arrest. Cardiac arrest using cardioplegia is essential for repair (see Chapters 2 and 3 for a detailed discussion of these techniques).

The ductus arteriosus must be dissected and closed routinely in infants, even if not visualized in preoperative studies.\textsuperscript{811,32} This is usually accomplished just after CPB is established and before cooling is begun. Also, at some point in the operation, the foramen ovale or atrial septal defect must be closed. This is usually done after correcting the anomalous veins. Regardless of the type of TAPVC or type of technical repair, anastomosis of the pulmonary venous sinus to the left atrium is performed with a continuous suture technique using fine polypropylene or polydioxanone suture.

Following completion of the operation, regardless of technical approach to the repair, careful consideration should be given to placing fine polyvinyl pressure catheters into the right atrium, left atrium, and RV or pulmonary trunk for appropriate postoperative monitoring.
Total Anomalous Pulmonary Venous Connection to Left Brachiocephalic Vein

After sternotomy and anterior pericardotomy, the common pulmonary venous sinus, lying behind the pericardium, is identified after lifting up the apex of the heart for a moment to visualize the retrocardiac portion of the pericardium. The right pulmonary artery, running parallel and just cephalad to the sinus, is also identified to avoid confusing it with the common pulmonary venous sinus. The vertical vein connecting the common pulmonary venous sinus to the left brachiocephalic vein can sometimes be seen inside the pericardium, but in most cases the pericardium on the left must be retracted toward the patient’s right and the persistent left vertical vein identified beneath the mediastinal pleura. The vein is isolated after carefully freeing the left phrenic nerve. A ligature is tied to the tip of the left atrial appendage for leftward retraction.

CPB and cardiac arrest are established using the techniques described in the previous section. The ductus arteriosus (if patent) and persistent vertical vein are ligated. The common pulmonary venous sinus can be exposed in several ways. One method approaches the common pulmonary venous sinus from the right side of the heart. The posterior pericardial reflection is opened (Fig. 31-9, A), and the common pulmonary venous sinus is mobilized and opened (Fig. 31-9, B-C). The posterior left atrial wall is opened, and the anastomosis is then made between the common pulmonary venous sinus and left atrium (Fig. 31-9, D-F). The continuous suture line must not be pulled up so tightly as to purse-string the anastomosis and narrow it. The right atrium is opened, the foramen ovale closed, and the atrium closed. The remainder of CPB and reestablishment of myocardial perfusion are completed (see Chapters 2 and 3).

A second method of repairing TAPVC is similar to that just described, but the common pulmonary venous sinus is exposed from the left side of the heart by lifting the cardiac mass out of the pericardial sac by retracting the cardiac apex anteriorly and rightward. This is best achieved by placing a retracting suture into the apical myocardium (Fig. 31-10, A).

This avoids the warming effect on the myocardium that occurs when the surgical assistant’s finger or hand is used to directly retract the heart. The pericardial sac is now essentially vacant, and the incision in the common pulmonary venous sinus is made under direct vision (Fig. 31-10, B). The back of the left atrium is also exposed by this maneuver and is incised. The anastomosis is then made in a fashion similar to that described in the preceding text (Fig. 31-10, C).

A third method of repairing TAPVC to the left brachiocephalic vein is via a right atrial approach. This method has the advantage of allowing the anastomosis of the common pulmonary venous sinus to the left atrium to be performed in precise anatomic relationships, because there is no retraction or displacement of critical structures to gain exposure. The right atrium is incised parallel to the atrioventricular groove (Fig. 31-11, A), exposing the atrial septum. The membrane of the foramen ovale is excised to gain entry to the left atrium. The posterior wall of the left atrium is incised transversely (Fig. 31-11, B) into the free pericardial space behind the atrium. The common pulmonary venous sinus is identified lying beneath the pericardium directly behind the incision in the left atrium. An incision is made in the common pulmonary venous sinus, which extends from the bifurcation on the left side to the bifurcation on the right side (see Fig. 31-11, C). A large anastomosis is constructed between the common pulmonary venous sinus and left atrium (Fig. 31-11, D). This anastomosis has little chance for distortion because it is performed without displacing anatomically adjacent structures. Repair is completed by closing the foramen ovale with a pericardial patch (Fig. 31-11, E). The patch serves both to repair the atrial septum and enlarge the left atrial filling capacity.

Total Anomalous Pulmonary Venous Connection to Superior Vena Cava

A common pulmonary venous sinus is usually present in the rare anomaly of TAPVC to the superior vena cava, providing free communication between right and left pulmonary veins. After the presence of this sinus is confirmed by direct
Figure 31-9  Repair of total anomalous pulmonary venous connection (TAPVC) to left brachiocephalic vein, right lateral approach.  

A, Posterior pericardial attachments of heart are cut, allowing cavae and atria to be lifted completely free of common pulmonary venous sinus, which is behind the pericardium. Left vertical vein is exposed, preferably from within the pericardium. If extrapericardial exposure is required, the phrenic nerve is elevated off the pericardium and vein. This dissection must be done sharply and with perfect exposure and visibility, because damage to this vein might necessitate its premature ligation. In this case, the common pulmonary venous sinus would have to be opened immediately to prevent severe pulmonary venous hypertension. Also, the dissection must identify the site of connection of the uppermost left pulmonary vein so that the vertical vein may be ligated superior to that point.  

B, With ventricles in normal position in the pericardium, exposure for repair (and for repair of other types of TAPVC) is obtained by elevating atria up and to the left. Posterior pericardium over common pulmonary venous sinus and anterior wall of the sinus are opened parallel to long axis of the sinus.
C, Incision should be made over full length of sinus. Orifices of left and right pulmonary veins are located and inspected, and care is taken to avoid damaging them. A corresponding incision is made more or less transversely in the back wall of left atrium. The incision may need to be carried onto the base of the left atrial appendage to gain sufficient length. It is carried to the atrial septum on the right, but care is taken not to enter the septum itself. When in doubt about initial placement of the left atrial incision, it is helpful to pass a small curved clamp through an incision in the right atrial wall and through the foramen ovale so that its tip tents the back wall of the left atrium outward. D, Traction sutures of 5-0 polypropylene are placed on inferior and superior lips of the incision into the common pulmonary venous sinus; both the sinus wall and posterior pericardium are caught with these sutures and with the suture line. Anastomosis is begun at the point shown, with the first stitch placed from outside to inside in the atrial wall, allowing suture line to be made from inside the vessels. E, Suture line is carried toward and around the left-sided angle of the incisions and along most of the superior side. The previously held other end of the double-armed 6-0 or 7-0 polypropylene or polydioxanone stitch is then used to approximate, in similar fashion, the inferior edge. Here the stitches are placed from outside to inside on the sinus and from inside to outside on the atrial wall. Suture line is carried nearly to the right-sided angle. F, Suture line is then completed, either with a few interrupted stitches or as a continuous stitch.
Figure 31-10  A, A retraction suture is placed into the myocardium at the apex and is used to retract the cardiac mass, elevating it superiorly and to the right, out of pericardial space, exposing posterior parietal pericardium. This allows visualization of pulmonary venous sinus lying behind pericardium. B, Cardiac mass is raised and lowered in and out of pericardial sac using retraction suture to identify region of left atrial free wall that lies directly against pulmonary venous sinus. Identifying this region of left atrium is necessary to plan the left atrial incision so that there is no distortion of pulmonary veins after anastomosis. Parallel incisions of equal length are made in the left atrial free wall and pulmonary venous sinus. Incisions are made as large as possible, but the pulmonary venous sinus incision does not extend into individual pulmonary veins. C, Anastomosis is performed using a continuous suture technique.
Figure 31-11 Repair of total anomalous pulmonary venous connection to left brachiocephalic vein, right atrial approach. **A**, Right atrium is incised parallel to atrioventricular groove. Membrane of foramen ovale is excised. **B**, Posterior wall of left atrium is incised transversely into pericardial space behind it. **C**, A long incision is made in common pulmonary venous sinus, which extends from the pulmonary vein bifurcation on the left side to the right side. **D**, Common pulmonary venous sinus is anastomosed to left atrium using continuous stitches of 7-0 polypropylene or polydioxanone suture. Suture line is started at apex of pulmonary venous sinus incision on the left side, placing stitches from inside the pulmonary vein. **E**, Foramen ovale is closed with pericardial patch to increase capacity of left atrium.
both the roof of the coronary sinus, so that it communicates freely with the left atrium, and the fossa ovalis (Fig. 31-12, A-B). The resulting large defect, made up of a confluence between the rim of the fossa ovalis and the coronary sinus ostium, is then closed with a pericardial patch (Fig. 32-12, C).

However, occurrence of stenosis at the repair site late after operation has prompted use of the technique described by Van Praagh and colleagues. The foramen ovale is enlarged to obtain an adequate exposure within the left atrium (Fig. 31-13, A). The wall between the coronary sinus and left atrium is incised (Fig. 31-13, B), and the incision is enlarged as much as possible in both directions. The foramen ovale and coronary sinus ostium are closed separately (Fig. 31-13, C). The pulmonary veins then drain into the left atrium through the surgically unroofed coronary sinus (Fig. 31-13, D). The remainder of the operation is completed as described for other types of TAPVC.

Total Anomalous Pulmonary Venous Connection to Coronary Sinus

The right atrial approach described in the preceding text is used. The right atrium is opened by the usual oblique incision. The repair most commonly used includes excising both the roof of the coronary sinus, so that it communicates freely with the left atrium, and the fossa ovalis (Fig. 31-12, A-B). The resulting large defect, made up of a confluence between the rim of the fossa ovalis and the coronary sinus ostium, is then closed with a pericardial patch (Fig. 32-12, C).

However, occurrence of stenosis at the repair site late after operation has prompted use of the technique described by Van Praagh and colleagues. The foramen ovale is enlarged to obtain an adequate exposure within the left atrium (Fig. 31-13, A). The wall between the coronary sinus and left atrium is incised (Fig. 31-13, B), and the incision is enlarged as much as possible in both directions. The foramen ovale and coronary sinus ostium are closed separately (Fig. 31-13, C). The pulmonary veins then drain into the left atrium through the surgically unroofed coronary sinus (Fig. 31-13, D). The remainder of the operation is completed as described for other types of TAPVC.

Obstructed pulmonary venous drainage can occur in patients with TAPVC to the coronary sinus. Thus, the surgeon must be prepared to abandon usual approaches if a stenosis is proximal to the coronary sinus itself, and proceed to anastomose the common pulmonary venous sinus, which
Figure 31-13  Repair of total anomalous pulmonary venous connection to coronary sinus, Van Praagh method. A, After usual preparations, right atrium is opened obliquely and exposure arranged. Foramen ovale is enlarged cephalad and at times caudad to attain adequate visibility within left atrium. B, An opening is made in the common wall between coronary sinus and left atrium after wall has been tented with right-angle forceps. This opening is enlarged downward and to the left; care must be taken not to go outside the heart in the process. (If this occurs, the opening must be closed at this point from within the heart by a few sutures, because the area is difficult to expose from outside the heart.) The incision is carried anteriorly and to the right to within a few millimeters of the ostium of the coronary sinus.

Continued
Foramen ovale and ostium of coronary sinus are closed, usually individually, with interrupted or continuous suture. Suture line should start inferiorly just below the last tiny coronary vein entering the sinus and, as it proceeds superiorly, should be made with shallow bites and preferably kept within the coronary sinus ostium to avoid the atrioventricular (AV) node. Arrow indicates path of blood flow through the coronary sinus to the right atrium before repair. After repair, blood flow from the coronary sinus is to the left atrium above the mitral valve through the unroofed coronary sinus.
is actually the junction of the right and left pulmonary veins, to the back of the left atrium.\textsuperscript{32}

Total Anomalous Pulmonary Venous Connection to Right Atrium

Initial stages of the operation are as described for other types of TAPVC using the right atrial approach. The right atrium is opened obliquely. The anomalous connection into the right atrium is explored with an instrument to verify the presence of a confluent pulmonary venous sinus. The foramen ovale is then enlarged, and working through it, an incision is made in the posterior left atrial wall. The common pulmonary venous sinus is visualized through this incision, and the anterior wall of the sinus is incised. This opening is enlarged and anastomosed to the left atrial incision, still working from within the atria. The enlarged foramen ovale is closed by direct suture. The original connection of the common pulmonary venous sinus to the right atrium is closed with a relatively small pericardial patch; it must be remembered that the pulmonary venous pathway from the right lung is beneath the patch.

Alternatively, as described for the repair of TAPVC to the superior vena cava, the common pulmonary venous sinus can be detached from the right atrium, the opening in the sinus enlarged and used for anastomosis to the left atrium, and the resulting defect in the posterior atrial wall closed. The remainder of the operation is completed as usual.

Total Anomalous Pulmonary Venous Connection to Infra-diaphragmatic Vein

In TAPVC to an infradiaphragmatic vein, the distal (inferior) portion of the common pulmonary venous sinus is vertical, and proximally (superiorly) it forms a Y or T connection with the left and right pulmonary veins. Therefore, after initial stages of the operation have been performed as described for other types of TAPVC, a decision is made about the approach, which may be similar to that for other types, through the opened right atrium, or through the back of the left atrium directly after tilting the apex of the heart up and to the right. Good results have been obtained by all approaches. The approach using retraction of the cardiac mass out of the pericardial sac is described. The heart is freed from its posterior attachments and the back of the left atrium exposed (Fig. 31-14, \textit{A}). The common pulmonary venous sinus and left atrium are incised (Fig. 31-14, \textit{B}). The common pulmonary venous sinus is Anastomosed to the back of the left atrium (Fig. 31-14, \textit{C}) and is ligated (Fig. 31-14, \textit{D}) and may be divided to allow the anastomosis to conform better.\textsuperscript{74}

Miscellaneous Types of Total Anomalous Pulmonary Venous Connection

Some rare types of TAPVC occur, such as connection to the azygos vein or inferior vena cava, or dual connection from the common pulmonary venous sinus.\textsuperscript{51,56,71,\textit{V2}} These connections can usually be sorted out using MRI or CT. In the rare event that the connection cannot readily be found or dissected out at operation, the common pulmonary venous sinus is opened and the connection(s) identified from within it. After the connection is closed, the usual anastomosis is made between the common pulmonary venous sinus and left atrium.

Mixed Total Anomalous Pulmonary Venous Connection

Patients with mixed TAPVC present a diagnostic as well as surgical challenge. MRI or CT is almost always used to supplement echocardiographic imaging and to provide an accurate characterization of the morphologic details.\textsuperscript{\textit{P1,G8,K5,M2,S14,U1}} Chowdhury and colleagues have recently categorized the spectrum of mixed TAPVC into five major groups.\textsuperscript{\textit{E5,C6}} Each group is characterized by a set of similar general morphologic patterns, but many variations occur from case to case.

Management of each patient must be individualized based on analysis of the mixture presented. A variety of techniques must be used, including many of those already described for TAPVC to the left brachiocephalic vein, right atrium, superior vena cava, and structures below the diaphragm. Combining these techniques with others, such as construction of a right atrial intracardiac baffle for isolated veins to the superior vena cava (similar to repair of partial anomalous pulmonary venous connection) or direct anastomosis of isolated left upper pulmonary vein to the left atrial appendage, will usually allow complete repair.\textsuperscript{\textit{R7,C9,N6,J1,S8}} In some small babies in whom an extensive operation would be required for complete one-stage repair, subtotal repair can be successful, leaving unrepaired, for example, anomalous connection of the left upper lobe to the left brachiocephalic vein.

SPECIAL FEATURES OF POSTOPERATIVE CARE

Overall management of patients after correction of TAPVC is accomplished in the usual way (see Chapter 5). The relationship between left and right atrial pressures is of particular importance. Left atrial pressure may be considerably higher than right when pulmonary artery pressure decreases immediately after repair, particularly when a small and noncompliant left atrium acts more like a conduit than a reservoir.\textsuperscript{\textit{P1}} The left atrial pressure pulse after operation is then characterized by a steep y descent (Fig. 31-15). A small or borderline-sized LV contributes to this situation.

In infants, particularly neonates, who present for operation in critical condition with pulmonary venous obstruction, pulmonary artery pressure and resistance may remain high early postoperatively, which in part may reflect the damaging effects of CPB (see Chapter 2), preoperative lung injury, and postoperative acidemia. Because of this, continuous monitoring of pulmonary artery pressure for at least 48 hours after repair is essential.\textsuperscript{\textit{K9}} When pulmonary artery systolic pressure remains elevated to two thirds or more of systemic arterial systolic pressure, right atrial and RV end-diastolic pressures are usually higher than left atrial pressure, and RV stroke volume is likely to be reduced. When this situation is present, acidemia must be vigorously treated; in addition, PaCO\textsubscript{2} should be kept low (25-30 mmHg) by hyperventilation.\textsuperscript{\textit{J9}}

Fentanyl should be continued for at least 36 hours postoperatively, and all features of the regimen to minimize occurrence of paroxysmal pulmonary hypertension employed (see “Pulmonary Hypertensive Crises” under Pulmonary Subsystem in Section I of Chapter 5). Use of inhaled nitric oxide may be particularly helpful in this setting and has essentially replaced other pulmonary vasodilatory drugs that have important side effects such as systemic hypotension.
Figure 31-14  Repair of total anomalous pulmonary venous connection draining infradiaphragmatically. A, Exposure of common pulmonary venous sinus and posterior wall of the left atrium is obtained by tilting the heart superiorly and to the right. Pulmonary venous sinus is identified behind the pericardium posteriorly. B, Posterior wall of left atrium is incised beginning at base of the appendage and somewhat more vertically than for other types of repair of total anomalous pulmonary venous connection (TAPVC). A long incision is made in common pulmonary venous sinus. Alternatively, common pulmonary venous sinus may be ligated and divided (inset).
C. Anastomosis of common pulmonary venous sinus to left atrium is constructed using 6-0 or 7-0 polypropylene or polydioxanone suture. Anastomosis is started at the apex superiorly, working from within the left atrium and pulmonary venous sinus. The technique with the venous sinus divided is also shown (inset).

D. Common pulmonary venous sinus is ligated below the anastomosis, with care taken to place ligature below any pulmonary vein branch. The sinus may be divided to allow the anastomosis to conform better (inset).

Data from Chowdhury and colleagues.\textsuperscript{c5}  
Key: CL, 95% confidence limits; TAPVC, total anomalous pulmonary venous connection.

and colleagues reported similar findings.\textsuperscript{a2} Other studies indicate a slight drop in survival at mid- to late follow-up. The study by Hancock Friesen and colleagues shows 1-month survival of 90% and 3-year survival of 87%.\textsuperscript{k1} Karamlou and colleagues reported that most deaths occurring outside the perioperative period occurred within a few months of surgery, with essentially no late events.\textsuperscript{k1} In patients with mixed TAPVC, Chowdhury and colleagues demonstrated late mortality of 4.3%, with follow-up of 42 months (median).\textsuperscript{c5}

Modes of Death

The most common modes of hospital death after repair are cardiac failure and hypertensive pulmonary artery crises. Postoperative pulmonary hypertensive crisis can occur in neonates and infants who go into surgery with severe cardiopulmonary instability, even though an adequate vein repair has been achieved, or in patients with postoperative pulmonary venous obstruction. In the modern era, most early and late deaths are associated with some combination of pulmonary venous obstruction, complex mixed TAPVC morphology, and low birth weight.\textsuperscript{a2,c3,k2,k1,k1,k1,k1,k1}

Incremental Risk Factors for Death

Risk factors for early death have been identified. These include earlier year of operation, single-ventricle intracardiac morphology, mixed TAPVC morphology, infradiaphragmatic TAPVC morphology, pulmonary venous obstruction, poor preoperative physiologic state, and lower weight at operation.\textsuperscript{b2,b11,c3,d5,d9,d6,d11,d2,d7,k1,k1,m4,m4} Importantly, many studies cited here are not uniform in identifying all these risk factors. This variability reflects variations in analysis from study to study and also acknowledges that many or most of these risk factors are mutable. For example, Bove and colleagues found severe acidosis on admission to be the most important risk factor for hospital death after repair of infracardiac TAPVC.\textsuperscript{b11} Other studies indicate that preoperative pulmonary venous obstruction is not a risk factor unless accompanied by single-ventricle intracardiac morphology.\textsuperscript{k11} Studies by Bando and colleagues\textsuperscript{b9} and Hyde and colleagues\textsuperscript{c5} argue that preoperative pulmonary venous obstruction and infradiaphragmatic connection have been neutralized as risk factors for death. Risk factors for death in mixed TAPVC have been defined\textsuperscript{c5} (Table 31-1).

Risk factors for late death are difficult to define because late deaths occur so infrequently. Most deaths outside the perioperative period involve recurrent or persistent pulmonary venous obstruction. Possibly, preoperatively small
pulmonary veins predispose patients to develop the lethal postoperative complication of pulmonary vein stenosis. Therefore, this finding may also be a risk factor for death after repair, as may small size of the coronary sinus in cardiac TAPVC.

In older patients presenting for surgical correction, a mild or moderate increase in pulmonary vascular resistance increases the risk of operation, and severe elevation makes older patients inoperable. The situation in these older patients is analogous to that in patients with atrial septal defect (see Indications for Operation in Chapter 30). There may be a few patients with TAPVC in which the LV is so small that it per se represents an incremental risk factor. However, this is rare. More commonly, preoperative LV volume calculations are falsely reduced because of the ventricular septal shift that occurs with pulmonary hypertension. Fortunately, major associated cardiac anomalies in this condition are rare as well.

Functional Status

McBride and colleagues have shown that compared with healthy children, peak oxygen consumption (88% ± 16% of predicted) and ventilatory anaerobic threshold (91% ± 21% of predicted) were mildly reduced in a group of 27 patients with a mean age of 11 years. Chronotropic impairment was observed in seven patients (32%). Neurodevelopmental outcome has been evaluated. Kirshbom and colleagues assessed 30 patients, mean age 11 years, who had undergone TAPVC repair in the neonatal period or infancy. All patients underwent repair using hypothermic circulatory arrest. Microcephaly was present in 28%, and abnormal neuromuscular examination in 27%. Performance IQ, motor skills, and attention were below normal, while full and verbal IQ and memory were normal. In another study of 34 patients at 18 to 24 months of age, all of whom underwent repair using hypothermic circulatory arrest, Mental Developmental Index (87 ± 16) and Psychomotor Developmental Index (89 ± 13) were at the low end of normal.

Hemodynamic Result

Pulmonary artery pressure is normal in patients recatheterized after repair unless there is abnormal cardiac rhythm, and cardiac index is normal, ranging from 2.9 to 5.2 L · min⁻¹ · m⁻² (average 3.7 L · min⁻¹ · m⁻²) in the study of Whight, Barratt-Boyes, and colleagues.

Postoperative cineangiographic studies of infants have shown that left atrial volumes are mostly within normal range, with the exceptions more often large than small. Incorporation of the pulmonary venous sinus, and the coronary sinus in some types of TAPVC, probably increases left atrial size (which was small before repair) to normal for age postoperatively. Some functional left atrial abnormality is present early and late postoperatively, perhaps based on abnormally low compliance of part of the atrium, because left atrial pressure tracings are often abnormal both early and late postoperatively.

RV volume, variable but often increased preoperatively, is normal or only mildly enlarged late postoperatively. LVEDV, abnormally small preoperatively, increases to normal late postoperatively. LV systolic function, often markedly depressed before operation, returns to normal late postoperatively (Fig. 31-16). Part of the explanation for this may be the improved LV geometry resulting from reduction in RV size (see “Ventricular Function” under Results in Chapter 30).

Cardiac Rhythm

Normal sinus rhythm is present in nearly all patients unless there is rhythm abnormality preoperatively. However, at least some of the preferential pathways of conduction from the sinus node to the atrioventricular node (see “Midostral Pathways” under Conduction System in Chapter 1) could be damaged by the repair. Holter monitoring after repair demonstrates that asymptomatic ectopic atrial pacemaker activity and other abnormalities are present in most patients. To date, these conditions appear not to have handicapped patients. McBride and colleagues reported that of 22 patients achieving peak aerobic capacity during late evaluation, 7 (32%) had an attenuated heart rate response (168 ± 14 beats · min⁻¹).

Reoperation and Development of Postoperative Pulmonary Venous Obstruction

Reoperations are performed for two reasons: severe anastomotic stenosis and pulmonary vein stenosis. They have been necessary in every experience. In an early unpublished study by Kirklin, essentially all patients with restenosis required reoperation within the first 6 to 12 months of repair (Fig. 31-17). Karamlou and colleagues, who reviewed 377 cases over a 60-year span, confirmed this
finding. However, other studies imply that need for reoperation may develop later. An analysis from Great Ormond Street Hospital showed that only one third of reoperations (7/20) occurred within 6 months of initial repair.

Patients usually become symptomatic with development of recurrent dyspnea and signs of pulmonary venous congestion, but ideally the diagnosis should be made before that stage. Risk factors for developing recurrent pulmonary venous obstruction include an original diagnosis of infracardiac TAPVC, and obstructed TAPVC. Despite theoretical considerations favoring use of interrupted sutures, there is no correlation between stricture formation and method of suturing. It is likely, however, that the open technique of anastomosis is preferable to use of clamps. Suture material may influence formation of anastomotic stricture. Absorbable polydioxanone suture as a continuous stitch technique of anastomosis is preferable to use of clamps. Absorbable polydioxanone suture compared with nonabsorbable suture.

A powerful tool for evaluating patients after repair of pulmonary venous obstruction but before hospital discharge is 2D pulsed Doppler echocardiography. Ideally, it should be repeated on several occasions during the first postoperative year. High-velocity turbulent flow at either the anastomosis or the pulmonary vein orifices suggests stenosis. Prompt angiographic restudy may further clarify the anatomic point of stenosis. The pulmonary veins are entered retrogradely from the left atrium to make a direct pulmonary vein angiogram and to determine pressure gradient across the anatomic site.

MRI and CT are also useful imaging modalities for defining morphology of the obstruction. According to Ricci and colleagues, about half (10/20) of all cases of recurrence are due to anastomotic stenosis, about one third to combined anastomotic and ostial (6/20) stenosis, and a minority (3/20) to ostial stenosis alone. Risk factors for death following reoperation are earlier age at recurrence and persistence of pulmonary hypertension after reoperation.

Anastomotic Stenosis
In up to 10% of patients, strictures appear to develop at the anastomosis (Table 31-2), usually within a few months of repair. However, results of reoperation are occasionally disappointing, with an important chance of a subsequent restenosis, as reported by Brekenridge and colleagues. Despite theoretical considerations favoring use of interrupted sutures, there is no correlation between stricture formation and method of suturing. It is likely, however, that the open technique of anastomosis is preferable to use of clamps. Suture material may influence formation of anastomotic stricture. Absorbable polydioxanone suture as a continuous stitch has been recommended by Hawkins and colleagues for constructing the left atrium–to–common pulmonary venous sinus anastomosis. Late anastomotic stenosis occurred in 1 (3.2%; CL 0.4%-10%) of 32 survivors having anastomosis with polydioxanone compared with 4 (17%; CL 9%-29%) of 23 patients having anastomosis with nonabsorbable suture. However, groups compared in this series were not concurrent. Based on complete absence of this complication late postoperatively, it is likely that anastomoses grow appropriately as patients grow.

*The variable n refers to number of hospital survivors. Except in the GHE (Whight et al.) patients, in whom routine postoperative cardiac catheterization was performed, the data concern patients dying or requiring reoperation for stricture formation. The 70% confidence limits of the individual proportions all overlap; this overlap and the P value make institutional differences in prevalence unlikely.

P(χ²) .4

Pulmonary Vein Stenosis
Compared with anastomotic stenosis, pulmonary vein stenosis tends to occur later and is less common. In most instances, the stenosis is due to diffuse fibrosis and thickening of the vein wall and often to localized narrowing at the vein–left atrial junction. Pulmonary vein stenosis may or may not be accompanied by anastomotic stenosis.
5.7% of 377 patients undergoing TAPVC repair but do not make a distinction between anastomotic and pulmonary vein stenosis.\textsuperscript{81}

Pulmonary vein stenosis is usually lethal, even with reoperation and extensive attempts at revision or repair. This lack of success has led to alternative treatment such as balloon dilatation and stenting, but these do not appear to provide additional benefit. In 1996, Lacour-Gayet and colleagues described the sutureless repair technique, using in situ autologous pericardium, for recurrent pulmonary vein stenosis following initial TAPVC repair.\textsuperscript{N1} Subsequent reports emphasize the utility of this technique in selected cases.\textsuperscript{1,2,3,7} Following their initial description of the sutureless technique, Lacour-Gayet and colleagues reported that of 178 patients undergoing correction of TAPVC, progressive obstruction developed in 16 (9%) within a median interval of 4 months (range 5 weeks to 12 years) after operation.\textsuperscript{1,2,7} Only 4 of these 16 had isolated pulmonary vein stenosis, with the remaining 12 having either isolated anastomotic stenosis or combined anastomotic and pulmonary vein stenosis. The obstruction was bilateral in 7 patients. Fifteen of the 16 patients underwent reoperation, and 4 (27%) died afterward. The authors used the in situ pericardial patch technique to relieve the stenosis in 7 of the 16 patients.

Despite interest in the sutureless technique, there is little firm evidence that it provides a benefit over conventional techniques. Yun and colleagues\textsuperscript{7,2} used a retrospective analysis to compare the outcomes of death and restenosis after conventional and sutureless techniques. Patients in this series were heterogeneous, and only 17 of the 60 had a history of previous TAPVC repair. By multivariable analysis, there was no statistically significant difference between the conventional and sutureless techniques, although a trend for better outcome using the sutureless technique was observed when all 60 patients were considered.

Development of pulmonary vein stenosis many years after repair is exceedingly rare but has been reported. Kveselis and colleagues reported successful repair of infracardiac TAPVC in a 17-day-old infant who had a demonstrated absence of pulmonary vein obstruction when recatheterized 3.7 years after operation. This patient continued to be healthy without limitations until 12 years of age, at which time he became symptomatic, and important obstruction was demonstrated at the anastomosis.\textsuperscript{8,12} Reoperation successfully corrected the problem.

**INDICATIONS FOR OPERATION**

Investigation must be undertaken promptly in any neonate or infant, no matter how young, who develops signs and symptoms suggestive of TAPVC. Procrastination leads to death in babies with obstructive TAPVC (and in some without it) or to hospital admission in a semimoribund state, which importantly increases operative mortality.

Once the diagnosis is made, operation should be undertaken immediately in any neonate or infant importantly ill with TAPVC. This policy should lead to surgical intervention during the first few days or week of life, frequently in the first month of life, and usually before 6 months of age. In infants in whom the diagnosis is made between 6 and 12 months of age, operation should be undertaken promptly because risk of operation is low, and even infants who appear to be doing well are at risk of dying before age 1 year.\textsuperscript{8,10,34}

Rarely, individuals survive into childhood or early adult life with TAPVC and are first seen for surgical consideration at that time. Operation is advisable if severe pulmonary vascular disease has not developed; the criteria for operability are the same as for patients with atrial and ventricular septal defects (see Indications for Operation in Chapters 30 and 35. In TAPVC, degree of cyanosis is not helpful because of the common mixing chamber, nor is height of mean pulmonary artery pressure relative to systemic pressure, because the shunt is not at systemic level.

When pulmonary vascular disease is suspected clinically, measurement of pulmonary vascular resistance is required at preoperative cardiac catheterization. Using the Fick principle, the patient’s response to 100% oxygen and to inhaled nitric oxide is determined. If pulmonary vascular resistance is less than 8 U - m\textsuperscript{2} using these maneuvers, operation is undertaken. If resistance is higher than 8 U - m\textsuperscript{2}, chronic pulmonary vasodilatory therapy, both pre- and postoperatively, can be considered in an attempt to increase operability.

**SPECIAL SITUATIONS AND CONTROVERSIES**

**Pulmonary Vein Stenosis**

Pulmonary vein stenosis may be either a postoperative complication (as discussed previously) or a primary congenital anomaly.\textsuperscript{87} Congenital lesions are classified as (1) diffuse hypoplasia, (2) long-segment (tubular) focal stenosis, and (3) ostial (discrete) stenosis. Diffusely hypoplastic pulmonary veins extending into the lung parenchyma usually require heart-lung or lung transplantation, and prognosis is poor. Long-segment tubular stenoses of pulmonary veins with normal-caliber intraparenchymal pulmonary veins may be treated, but prognosis is also poor.

Treatment includes operative patch venoplasty, the sutureless technique, catheter dilatation and stent placement, or a combination of therapies. Currently, balloon dilatation and stent placement are not considered effective therapies, because rapid restenosis is the rule. Short-segment discrete stenoses located at or near the left atrial ostium of the pulmonary vein have the best chance for success following surgery. In general, congenital pulmonary vein stenosis has a poor prognosis because of development of pulmonary venous hypertension, followed by pulmonary arterial hypertension.

**Delayed Operation**

In critically ill neonates and young infants whose obstruction is primarily at the atrial level (an unusual situation), balloon atrial septostomy (with a blade if necessary) and delay of operation for 1 to 2 days are reasonable approaches.\textsuperscript{82} Preoperative preparation of the critically ill neonate by infusion of prostaglandin E\textsubscript{1} combined with low-dose dopamine for a few hours has been advised by Serraf and colleagues.\textsuperscript{59} However, such treatment may shunt blood away from the lungs and increase cyanosis in neonates with severe pulmonary venous obstruction and pulmonary venous hypertension.

**Operative Exposure**

Tucker and colleagues described exposing the structures for anastomosis of the common pulmonary venous sinus to the left atrium through the transverse sinus between the aorta...
and superior vena cava. This approach can occasionally be helpful if the pulmonary venous sinus is positioned superiorly.

**Surgical Enlargement of Left Atrium**

Trusler and colleagues found that in dogs, a decrease in atrial volume of more than 50% resulted in an important reduction in cardiac output. Brighton and colleagues, using a mechanical model, obtained substantial improvement in cardiac output by adding a flexible atrium to the inlet of their artificial heart. In studying the effect of atrial compliance on cardiac performance with a mathematical electrical analog, Suga found that cardiac performance was markedly improved by increasing atrial compliance while maintaining constant ventricular contractility. Analysis suggested that increased atrial compliance facilitated the reservoir function of the atrium and maintenance of a relatively high mean atrial pressure during ventricular filling. These facts, combined with the preoperatively observed small left atrium in patients with TAPVC, have made its enlargement by shifting the atrial septum to the right attractive.

Katz and colleagues, on the other hand, found similar survival with and without left atrial enlargement. This may be because surgical efforts to improve left atrial size are not effective, or because adequate left atrial enlargement may result from incorporating the common pulmonary venous sinus into the left atrium. Also, lack of left atrial reservoir function may rarely be critical early or late postoperatively if other aspects of the situation favor survival. Nonetheless, the repair must be done in a manner that does not decrease size of the left atrium.

**DEFINITION**

Classic (or typical) cor triatriatum, or *cor triatriatum sinister*, is a rare congenital cardiac anomaly in which the pulmonary veins typically enter a “proximal” left atrial chamber separated from the “distal” left atrial chamber by a partition in which there are one or more restrictive ostia. In the Congenital Heart Surgery Nomenclature and Database Project, cor triatriatum is classified as a pulmonary venous anomaly, with subclassifications as described in Box 32-1.

**HISTORICAL NOTE**

Cor triatriatum was apparently first described in 1868 by Church. The name *cor triatriatum* was applied to the malformation by Borst in 1905. The angiographic diagnosis seems first to have been made at Mayo Clinic and described by Miller and colleagues in 1964. Echocardiographic diagnosis of this cardiac anomaly was described by Ostman-Smith and colleagues in 1984 and by Wolf in 1986. The first surgical correction is believed to have been performed by Vineberg and Gialloreto in 1956; the second by Lewis and colleagues followed shortly thereafter.

**MORPHOLOGY**

It is unfortunate that cor triatriatum was first defined as “an abnormal septum in the left auricle” and has been described as resulting in a “subdivided left atrium,” because these terms obscure surgically important concepts about cor triatriatum.

**Morphology of Classic Cor Triatriatum**

Typically, the proximal (common pulmonary venous) chamber is somewhat larger than the distal (left atrial) chamber. The common wall partitioning them (“diaphragm” or “membrane”), which may have one or more openings (apertures), is usually thick and fibromuscular (Fig. 32-1). The aperture is typically two dimensional, meaning it has no length, but occasionally it is three dimensional, exhibiting a tubular or tunnel-like configuration.

The proximal chamber contains all pulmonary vein connections and is usually thick-walled, whereas the distal chamber always contains the left atrial appendage and leads into the mitral valve, and is thin-walled (Fig. 32-2). Despite high pressure in the proximal chamber, the pulmonary veins are not dilated. Entry of the right pulmonary veins into the proximal chamber usually bears the same relationship to the right atrium and superior vena cava as in the normal heart (Fig. 32-3).

The right ventricle is usually enlarged, but this enlargement depends on the presence and degree of left-to-right shunting at the atrial level. The left ventricle is usually normal in size or small. The fossa ovalis may be in the septum between the proximal chamber and right atrium, but occasionally it is in the septum between the distal chamber and right atrium. The foramen ovale is usually patent and stretched.

**Relationship of Cor Triatriatum to Partial and Total Anomalous Pulmonary Venous Connection**

In classic cor triatriatum, the right and left pulmonary veins can be considered as not joining the left atrium but rather as entering a chamber, generally posterior and a little superior or medial to the left atrium, that is analogous to the common pulmonary venous sinus found in many patients with total anomalous pulmonary venous connection (TAPVC, see...
Chapter 32 Cor Triatriatum

Box 32-1 Proposed Classification of Pulmonary Venous Anomalies

I. Primary Anomalies of Pulmonary Venous Connection

A. Partially (or partial) anomalous pulmonary venous connection (or return or drainage) (PAPVC, PAPVR)
   1. Non-scimitar
   2. Scimitar (right pulmonary vein[s] draining to inferior vena cava)
B. Totally (or total) anomalous pulmonary venous connection (or return or drainage) (TAPVC, TAPVC)
   1. Supracardiac (supradiaphragmatic, type I)
   2. Cardiac (supradiaphragmatic, type II)
   3. Infracardiac (infradiaphragmatic, type III)
   4. Mixed (type IV)

II. Atresia of the Common Pulmonary Vein

III. Cor Triatriatum (Stenosis of the Common Pulmonary Vein, Triatrial Heart, Cor Triatriatum Sinister)

A. Accessory atrial chamber receives all pulmonary veins and communicates with left atrium
   1. No other connections (classic cor triatriatum)
   2. Other anomalous connections
      a. To right atrium directly
      b. With TAPVC
B. Accessory atrial chamber receives all pulmonary veins and does not communicate with left atrium
   1. Anomalous connection to right atrium directly (cardiac TAPVC with all pulmonary veins first draining to a venous confluence)
   2. With TAPVC (supracardiac or infracardiac TAPVC)
C. Subtotal cor triatriatum
   1. Accessory atrial chamber receives part of the pulmonary veins and connects to left atrium
      a. Remaining pulmonary veins connect normally
      b. Remaining pulmonary veins connect anomalously (partial cor triatriatum with PAPVC)
   2. Accessory atrial chamber receives part of the pulmonary veins and connects to right atrium
      a. Remaining pulmonary veins connect normally (PAPVC with anomalously connected pulmonary veins first draining to a venous confluence)
      b. Remaining pulmonary veins connect anomalously (mixed TAPVC)

IV. Stenosis of Individual Pulmonary Veins

A. Congenital
B. Acquired
   1. Postoperative
   2. Other

From Herlong and colleagues.\(^{11}\)

Chapter 31). Indeed, Van Praagh and Corsini did not use the term proximal left atrial chamber, but called it the common pulmonary vein chamber of cor triatriatum.\(^{12}\) Marin-Garcia and colleagues used similar terminology.\(^{11}\)

From an embryologic standpoint, the confluence of the pulmonary veins is completely incorporated into the left atrium in a normal heart, is not incorporated into the left atrium in TAPVC, and is partially incorporated into the left atrium in cor triatriatum. Just as TAPVC does not always involve all pulmonary veins connecting to a single pulmonary venous sinus (i.e., mixed TAPVC), cor triatriatum does not always involve all pulmonary veins draining to the proximal chamber. There are several examples of cor triatriatum in which some of the pulmonary veins drain to the
proximal chamber, and the remainder have classic anomalous drainage.

Partial anomalous left pulmonary venous connection (from left upper lobe only or from entire left lung) may connect to a left vertical vein that connects to the left brachiocephalic vein, with all other pulmonary veins entering the proximal chamber.\(^{1,2,3}\) Partial anomalous venous connection may consist of all left pulmonary veins connecting to the coronary sinus, with the proximal chamber receiving only the right pulmonary veins and connecting through the usual small orifice into the distal left atrial chamber.\(^2\) Comparisons to partial anomalous pulmonary venous connection (PAPVC)
also exist. In these examples, some pulmonary veins connect to the proximal chamber, and the remainder connect normally to the left atrium.

In “partial” cor triatriatum, the right pulmonary veins alone may connect to the proximal chamber, with the left pulmonary veins connecting normally to the left atrium.\textsuperscript{51} Other unusual variants have been documented. The proximal chamber, receiving all pulmonary veins, may have an imperforate portion between it and a typical distal chamber and instead connect to the right atrium, whereas the right and left atria are in communication through a coronary sinus atrial septal defect, with the coronary sinus itself being completely unroofed (see Chapter 33). In another example, all pulmonary veins may fail to join an otherwise typical proximal chamber separated from the distal chamber by a perforated partition, and instead connect to a common pulmonary venous sinus behind the heart that may connect to the coronary sinus, superior vena cava, or infradiaphragmatically.\textsuperscript{52,56}

**Relationship of Cor Triatriatum to a Left Superior Vena Cava**

A left superior vena cava coexists with cor triatriatum considerably more frequently than with other types of congenital heart disease.\textsuperscript{55,61,62} One proposed pathogenesis of cor triatriatum is impingement of a left superior vena cava on the developing left atrium.\textsuperscript{62} Ascuito and colleagues reported cases in which a persistent left superior vena cava joining a dilated coronary sinus impinged on the posterior wall of the left atrium and divided it into two chambers, both of which had defects that communicated with the right atrium.\textsuperscript{56} It seems clear that a relationship exists between these two anomalies, at least in some patients.

**Associated Anomalies**

In addition to PAPVC and unroofed coronary sinus with a left superior vena cava joining the left atrium, other associated anomalies include ventricular septal defect, coarctation of the aorta, atrioventricular septal defect, tetralogy of Fallot, and (rarely) asplenia and polysplenia.\textsuperscript{51}

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

Infants with classic cor triatriatum, with a small aperture between the proximal and distal chambers, usually present with evidence of low cardiac output, including pallor, tachypnea, poor peripheral pulses, and growth failure.\textsuperscript{51} When there is associated left-to-right shunting due to connection of the proximal chamber to the right atrium or because of associated PAPVC, evidence of pulmonary overcirculation and venous obstruction may be present in the chest radiograph, and right ventricular enlargement is prominent. In children and young adults, the classic presentation is with signs and symptoms of pulmonary venous hypertension. However, like mitral stenosis, cor triatriatum may present with less classic symptoms.\textsuperscript{52}

Diagnosis is usually made by echocardiography\textsuperscript{53,52} (Fig. 32-4). Transesophageal echocardiography has also proven useful in selected cases.\textsuperscript{64} Recently, three-dimensional echocardiography has been used to identify complex morphology in cor triatriatum.\textsuperscript{53,61} Magnetic resonance imaging with three-dimensional reconstruction provides excellent delineation of both simple and complex morphology in cor triatriatum and is the imaging study of choice if standard two-dimensional echocardiography is not definitive.\textsuperscript{12} Cardiac catheterization and cineangiographic studies are no longer considered necessary unless major associated cardiac anomalies are suspected. However, further evidence may be obtained from selective cineangiographic studies and pressure measurements in the proximal and distal chambers. If the catheter cannot be manipulated into the proximal and distal chambers from the right atrium, sometimes an arterial catheter can be advanced into the left ventricle and retrogradely catheter into the mitral valve and into the distal and then proximal chamber.\textsuperscript{51} Gradients of 20 to 25 mmHg have been demonstrated between the two chambers.\textsuperscript{51}

**NATURAL HISTORY**

Natural history depends on the effective size of the aperture in the partition between the proximal and distal chambers. When it is small, the infant becomes critically ill during the early months of life, with signs of pulmonary venous obstruction (Fig. 32-5, A). Without surgical treatment, such patients die at that young age.\textsuperscript{51,61,63,51} If the aperture is larger, the patient presents in childhood or young adulthood with the signs, symptoms, and prognosis of mitral stenosis.\textsuperscript{52}

In most patients, the aperture is severely restrictive, and approximately 75% of persons born with classic cor triatriatum die in infancy. However, when the proximal chamber communicates with the right atrium through a fossa ovalis atrial septal defect, the prognosis is better because the proximal chamber decompresses into the right atrium (Fig. 32-5, B). These patients present with signs of a large left-to-right shunt and generally survive longer than those with an obstructive aperture. Rarely, cor triatriatum may be discovered in an adult.\textsuperscript{2,61,62,63} Delay in diagnosis may be accounted for by a lesser degree of obstruction by the partition or by a unilateral pulmonary venous obstruction.\textsuperscript{51}

**TECHNIQUE OF OPERATION**

**Classic Cor Triatriatum**

Treatment of cor triatriatum is primarily by operation. In small infants, approach through the right atrium is preferable. In older patients, especially when the proximal chamber is
enlarged and no other cardiac anomalies exist, approach through an incision in the right side of this chamber is recommended.

After usual preparations, moderately hypothermic cardiopulmonary bypass (CPB) using two venous cannulae is established (see Section III of Chapter 2). Alternatively, hypothermic circulatory arrest may be employed according to surgeon preference. Cold cardioplegia is established as usual after clamping the aorta (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3).

When the approach is through the proximal chamber, a vertical incision is made in the chamber anterior to the right pulmonary veins (Fig. 32-6, A) exactly as for mitral valve surgery (see Technique of Operation in Chapter 11). After insertion of an appropriately sized Richardson retractor or similar instrument, the diaphragm is exposed and apertures in it identified. A preliminary incision out from the apertures improves exposure for the definitive excision (Fig. 32-6, B). Orifices of the pulmonary veins on both sides are located. Position of the atrial septum is also identified, if necessary, by opening the right atrium and inserting a curved clamp to displace the atrial septum into either the distal or proximal chamber. Most of the partition between these chambers is then excised to make as large an opening as possible (Fig. 32-6, C). This procedure is usually easily and quickly done.

When an approach through the right atrium is used, its free wall is incised as in atrial septal defect closure. The right side of the atrial septum is examined and the fossa ovalis identified. If a foramen ovale or atrial septal defect is present, this is enlarged by incision to gain access into the left-sided chamber with which it communicates, either proximal or distal. If there is no atrial septal defect, the septum primum within the fossa ovalis is incised. The partition between the proximal and distal chambers is then identified. In Fig. 32-7, the exposure provided by an atrial septal incision leading into the proximal chamber is shown (Fig. 32-7, A). The partition is easy to identify and expose by this approach (Fig. 32-7, B). The procedure described for the left-side approach is carried out and the opening in the atrial septum closed with a pericardial patch (Fig. 32-7, C). The cardiotomy is closed, the heart having been filled with blood or saline solution before the last few sutures were placed. The remainder of the operation is completed in the usual fashion (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2).

In the rare case in which there is a specific contraindication to CPB, percutaneous balloon dilatation is possible using a double balloon technique similar to that proposed for mitral valve stenosis. Relief of symptoms is good, but follow-up is too short (3 months) to establish confidence in this treatment.

Atypical Cor Triatriatum
As noted earlier under Morphology, patients occasionally present for treatment with atypical forms of cor triatriatum, or other important cardiac anomalies may coexist. A persistent left superior vena cava may be present, connecting to the coronary sinus or directly to the upper left atrium, with “unroofing” of the coronary sinus. Because almost any number of specific combinations may be encountered, the general surgical approach is described rather than a detailed description of each possible combination.

Before operation, the surgeon must determine with reasonable certainty the connections and drainage of all pulmonary and systemic veins, including the possible presence and connection of a left superior vena cava. The possible presence

---

**Figure 32-5** Morphology of cor triatriatum. A, Cor triatriatum with patent foramen ovale below obstructing partition. Proximal chamber is separated from distal chamber by an obstructing partition. Partition is attached to the atrial septum medially and immediately below left inferior pulmonary vein laterally. The lateral attachment is also closely related to the mitral valve. Left atrial appendage is in the distal chamber. Clinical presentation is that of pulmonary venous obstruction (like mitral valve stenosis) when the aperture in the partition is small. Distal chamber communicates with right atrium through foramen ovale, but left-to-right shunt is small. B, Cor triatriatum with patent foramen ovale above obstructing partition, through which the proximal chamber may communicate with the right atrium. Clinical presentation in this situation is that of a large left-to-right shunt or may mimic total anomalous pulmonary venous connection. Right ventricle may be enlarged.
RESULTS

Early (Hospital) Death

Hospital deaths are uncommon after repair of classic cor triatriatum. Those that occur are in critically ill infants and should be considered to be related to inadequate myocardial management. Seven separate single-institution retrospective studies constitute a combined total of 96 surgical cases of classic cor triatriatum with six early deaths (6.2%; CL 4.1%-9.4%) (Table 32-1).

Atypical cor triatriatum can also be successfully repaired. Many of the studies documented in Table 32-1 report successful repairs in patients in this more complex subset but also emphasize that mortality is higher than for classic cor triatriatum.

Time-Related Survival and Functional Status

Life expectancy after repair of classic cor triatriatum approaches that of the general population, especially when the operation is done in infancy. Richardson and colleagues

SPECIAL FEATURES OF POSTOPERATIVE CARE

Postoperative care is as usual (see Chapter 5), with special attention given to support of the respiratory system, which may be compromised by pulmonary venous obstruction existing before operation.
survival was 96% at 5 years and 88% at 15 years. The association of pulmonary vein stenosis with cor triatriatum reinforces the interrelationship between cor triatriatum and TAPVC (see “Pulmonary Vein Stenosis” under Reoperation and the Development of Pulmonary Venous Obstruction in Chapter 31). Another unfavorable late event is restenosis of the orifice between the proximal chamber and left atrium. This may be the result of an inadequate original operation in which the common wall between the two chambers was incompletely resected. Most follow-up studies suggest that essentially all patients are either described as asymptomatic or are documented to be in New York Heart Association functional class I.

reported one late death attributed to pulmonary vein stenosis in their group of eight hospital survivors. Qethamy and colleagues reported no late deaths in 20 patients with a mean follow-up of 31 months. Alphonso and colleagues reported 27 patients with a mean follow-up of 98 months; survival was 96% at 5 years and 88% at 15 years. The association of pulmonary vein stenosis with cor triatriatum reinforces the interrelationship between cor triatriatum and TAPVC (see “Pulmonary Vein Stenosis” under Reoperation and the Development of Pulmonary Venous Obstruction in Chapter 31). Another unfavorable late event is restenosis of the orifice between the proximal chamber and left atrium. This may be the result of an inadequate original operation in which the common wall between the two chambers was incompletely resected. Most follow-up studies suggest that essentially all patients are either described as asymptomatic or are documented to be in New York Heart Association functional class I.

INDICATIONS FOR OPERATION

Classic cor triatriatum with a restrictive aperture in the partition between the proximal and distal chambers is an urgent indication for operation, because 75% of patients with such malformations die in infancy. When older patients present with chronic symptoms, operation is also urgently indicated.
In atypical cor triatriatum, when the proximal chamber opens into the right atrium, a restrictive opening or no opening is present between the proximal and distal chambers, and only a small patent foramen oval exists between the right atrium and distal chamber, physiologic instability will be present. A large left-to-right shunt combined with restricted left atrial and left ventricular inflow produces severe symptoms during the early months of life, and operation is urgently indicated.

**Definition**

Unroofed coronary sinus syndrome is a spectrum of cardiac anomalies in which part or all of the common wall between the coronary sinus and left atrium is absent. Hearts with atrial isomerism and a left-sided superior vena cava (LSVC) entering a left-sided atrium are included in this chapter, despite the controversy concerning proper classification of such anomalies (see “Atrial Isomerism” under Morphology later in this chapter; see also Chapter 58).

**Historical Note**

Unroofed coronary sinus syndrome was unknown to cardiac pathologists before the era of cardiac catheterization and cardiac surgery. In 1954, Campbell and Deuchar referred to instances of LSVC attached to the left atrium. Although they did not have such an example in their own series of LSVC, they appreciated that in such cases there was no true coronary sinus. That same year, Winter, a radiologist at Hahnemann Hospital in Philadelphia, published a report that identified persistent LSVC attached to the left atrium, and 2 years later, Friedlich and colleagues identified by cardiac catheterization LSVC entering the left atrium in four patients. An isolated case was also reported by Tuchman and colleagues in 1956. However, true understanding of the morphology of the syndrome awaited the classic paper by Raghib, Edwards, and colleagues in 1965. The descriptive phrase “unroofed coronary sinus” was first used by Helseth and Peterson in 1974.

In cyanotic patients with a communication between the left and right SVC, the LSVC was first ligated (appropriately) by Hurwitt and colleagues in 1955 and then by Davis and colleagues in 1959. In 1965, Taybi and colleagues reported a ligation and mentioned “transferring the left SVC to the right atrium,” but presumably this was unsuccessful, because no further details were given. The first report of successful repair was from the Mayo Clinic in 1963. In this case, a tunnel was constructed from the posterior wall of the left atrium. In a second case, a large pericardial atrial baffle was constructed that corrected the anomalous connection of both the SVC and the inferior vena cava (IVC) to a left-sided atrium. This procedure was also described by Helseth and Peterson in 1974.

**Morphology**

Completely Unroofed Coronary Sinus with Persistent Left Superior Vena Cava

In one form of unroofed coronary sinus syndrome, the coronary sinus does not exist, because the common wall between it and the left atrium is absent. A persistent LSVC, which usually becomes continuous with the coronary sinus, connects to the left upper corner of the left atrium. The site of connection of the LSVC to the left atrium appears to be constant and lies between the opening of the left atrial appendage anteriorly and slightly superiorly, and the opening of the left pulmonary veins posteriorly and inferiorly. The
pulmonary veins may enter the left atrium more superiorly than usual in this form of the syndrome.

A coronary sinus atrial septal defect (ASD) is present in the posteroinferior region of the atrial septum in the usual position of the ostium of the coronary sinus (see Chapter 20, Fig. 30-5). The ASD is separated from the atrioventricular (AV) valve ring by a remnant of atrial septum (in contrast to an ostium primum ASD), and its posterior margin is formed by the atrial wall where it joins the IVC. There may be a separate foramen ovale ASD or a single large ASD formed by the confluence of both defects. The coronary sinus ASD may be confluent with an ostium primum ASD, or there may be a common atrium. Because the coronary sinus does not exist, individual coronary veins connect separately to the inferior aspect of the left atrium. Some also connect to the right atrium.

Of considerable surgical importance is the fact that the left brachiocephalic vein is absent in 80% to 90% of cases of unroofed coronary sinus syndrome and LSVC. The right SVC is frequently small and may be absent. The IVC not infrequently crosses to the left side below the diaphragm to enter the left hemiazygos vein, which joins the LSVC. The hepatic veins usually enter the inferior aspect of the right atrium, but they too may enter the inferior wall of the left atrium. When all the systemic veins enter a morphologically left atrium, total anomalous systemic venous connection is present (see Chapter 31).

**Completely Unroofed Coronary Sinus without Persistent Left Superior Vena Cava**

In some cases, the syndrome is characterized by a completely unroofed coronary sinus without a persistent LSVC. Such cases consist of a coronary sinus type of ASD and total absence of the coronary sinus because of absence of the partition between it and the left atrium.

**Partially Unroofed Midportion of Coronary Sinus**

Another form of the syndrome is characterized by a partially unroofed midportion of the coronary sinus (also called biatrial opening of coronary sinus or coronary sinus to left atrial window or fenestration). In this anomaly, an aperture is present in the midportion of the wall between the coronary sinus and left atrium. Through this aperture, a left-to-right or right-to-left shunt occurs, depending on whether obstruction is present to left atrial or right atrial outflow. When this rare form of unroofed coronary sinus syndrome occurs as an isolated lesion, there may be a large left-to-right shunt. It has also been reported as a major cardiac anomaly associated with tricuspid atresia, recognized only after the Fontan repair has elevated the right atrial pressure and produced a right-to-left shunt.

When midportion unroofing occurs in the presence of LSVC, there is a right-to-left shunt into the left atrium.

**Partially Unroofed Terminal Portion of Coronary Sinus**

Particularly in the presence of an atrioventricular septal defect (see “Completely Unroofed Coronary Sinus with Left Superior Vena Cava” under Morphology in Chapter 34), the coronary sinus ostium may open into the left atrium rather than the right. Also, a localized unroofing of the sinus may occur just before it enters the ostium of the coronary sinus, resulting in a coronary sinus ASD with preservation of the coronary sinus (see “Coronary Sinus Defect” under Morphology in Chapter 30). Such anomalies can be considered to be unroofing (or absence) of the terminal portion of the coronary sinus.

**Relationship of Unroofed Coronary Sinus Syndrome to Cor Triatriatum and Atrioventricular Septal Defect**

As indicated, when a completely unroofed coronary sinus with persistent LSVC is present, both the left and right pulmonary veins may enter the left atrium more superiority than usual. Sometimes this condition is accompanied by a mild or moderate narrowing between the portion of the left atrium to which the pulmonary veins are attached (the common pulmonary venous chamber) and that to which the LSVC, left atrial appendage, and mitral valve are attached (see “Relationship of Cor Triatriatum to a Left Superior Vena Cava” under Morphology in Chapter 32).

Unroofed coronary sinus syndrome has as its most common major associated cardiac anomaly an atrioventricular septal defect, not infrequently with a common atrium (see Chapter 34). Interestingly, atrioventricular septal defects are more commonly associated with persistent LSVC than are other types of ASD.

**Atrial Isomerism**

Many patients with an LSVC connecting to a left-sided atrium have atrial isomerism (see Chapter 58), and the majority of such patients have an atrioventricular septal defect. In an unpublished autopsy series from GLH of 26 hearts with the LSVC connecting to the left-sided atrium, only 3 were examples of classic unroofed coronary sinus syndrome; 23 hearts had atrial isomerism, 17 with bilateral morphologically right atria (most with asplenia) and 6 with bilateral morphologically left atria (most with polysplenia). Of the 23, 20 had an atrioventricular septal defect in addition to numerous other cardiac anomalies. When bilateral morphologically right atria are present, the LSVC enters the left-sided right atrium behind a typical crista terminalis and is not therefore an example of unroofed coronary sinus, even though the coronary sinus is usually absent. When bilateral morphologically left atria are present, the LSVC may or may not be part of an unroofed coronary sinus syndrome. In such cases, however, the coronary sinus is frequently absent.

**Clinical Features and Diagnostic Criteria**

In most cases, diagnosis of unroofed coronary sinus syndrome is made by two-dimensional echocardiography and confirmed at operation (Fig. 33-1). Demonstration of an LSVC by catheter passage into the vein or by cineangiography suggests the diagnosis, which is confirmed at operation if the LSVC can also be shown to drain into the left atrium. Diagnosis of a partially unroofed midportion of the coronary sinus can be made by cineangiography after injection into the right atrium, when right atrial pressure is higher than left (e.g., after the Fontan operation). Konstam and colleagues have pointed out that radionuclide angiography can be diagnostic, because intravenous injections into the left arm show much larger right-to-left shunting than those into the right arm. Diagnosis sometimes can be made by cross-sectional, contrast, and
transesophageal echocardiography.\textsuperscript{2,3} Contrast-enhanced gated multidetector computed tomography is also useful for diagnosis (Fig. 33-2). Often, however, the diagnosis is made by the surgeon viewing external and internal morphology of the heart at operation.

**NATURAL HISTORY**

Cyanosis from right-to-left shunting dominates the clinical picture of isolated completely unroofed coronary sinus with persistent LSVC and determines its natural history. In the series of Quaegebeur and colleagues, cyanosis was mild (all patients were younger than 17 years), but it was severe in some older patients in other series.\textsuperscript{91}

Cerebral embolization manifested by transient ischemic attacks or stroke and brain abscess complicate the life history in 10% to 25% of patients\textsuperscript{91} (Table 19-1). This situation is similar to that in other types of right-to-left shunting. Presumably, life expectancy is considerably reduced by these complications and by other problems associated with increasing cyanosis and polycythemia.

**TECHNIQUE OF OPERATION**

Isolated Completely Unroofed Coronary Sinus with Persistent Left Superior Vena Cava

Anesthesia and preparation of the patient for repair of isolated completely unroofed coronary sinus with persistent LSVC are as described in Section III of Chapter 2. When the diagnosis is known preoperatively, the anesthesiologist inserts a pressure-monitoring line into the left external or, preferably, internal jugular vein.

Operation may be done with cardiopulmonary bypass (CPB) at 25°C and the usual direct caval cannulation (see “Clinical Methodology of Cardiopulmonary Bypass” in Section III of Chapter 2); venous blood from the LSVC is collected with a sump sucker connected to the pump oxygenator. Alternatively in infants, a single venous cannula and repair during hypothermic circulatory arrest may be used. Myocardial management is conducted as for other cardiac operations (see “Methods of Myocardial Management during Cardiac Surgery” in Chapter 3).

**Intracardiac Repair**

After sternotomy, a large piece of pericardium is excised and set aside (see Chapter 30). Following aortic clamping and infusion of cardioplegic solution, the right atrium is opened through the usual oblique incision. Orifices of the three vena cavae are identified with certainty. Repair can be accomplished satisfactorily using one of two methods (the original method of “reroofing the coronary sinus”\textsuperscript{Q1,R2,S3} is no longer used because of its technical difficulty and because the left pulmonary veins are at risk of obstruction by the baffle). One method consists of excising the entire atrial septum except for the anterior limbus, which is preserved to protect the AV node and bundle of His.\textsuperscript{C3,M2} A pericardial patch is sutured into place as a repositioned atrial septum, and all three caval orifices are positioned on the right side of this septum (Figs. 33-3 and 33-4). This method is particularly useful when a common atrium is part of the cardiac anomaly.

A second method, described by Sand and colleagues, consists of “rerouting the coronary sinus”\textsuperscript{S1} to the roof of the left atrium (Fig. 33-5) and then reconstructing the atrial septum.\textsuperscript{51}

After the right atriotomy is closed, the caval tapes are released and aortic clamp removed. Usual de-airing maneuvers are performed (see “De-airing the Heart” in Section III of Chapter 2), and the operation is completed.

**Extracardiac Repair**

A third method involves extracardiac correction of the unroofed coronary sinus in combination with the associated intracardiac repair. If the brachiocephalic vein is absent, the LSVC is divided at its junction with the left atrium, and the...
A continuous 6-0 or 7-0 absorbable monofilament suture is used for these anastomoses.

If the brachiocephalic vein is present but restrictive, it can be enlarged with a patch of autologous pericardium.\textsuperscript{V2} The LSVC is then divided at its junction with the left atrium, and both ends are oversewn.

These extracardiac techniques eliminate the need for constructing an intraatrial baffle or tunnel. They can be performed during the period of rewarming after correction of opening in the left atrium is oversewn. The divided end of the LSVC is anastomosed to the side of the right SVC either anterior or posterior to the aorta.\textsuperscript{R3,V3} Alternatively, the LSVC can be anastomosed to the right atrial appendage or left pulmonary artery as a bidirectional superior cavopulmonary shunt.\textsuperscript{F1,R3,S4,T1,V4}
Chapter 33 Unroofed Coronary Sinus Syndrome

1221

Patch used to close the interventricular communication (complete atrioventricular septal defect) (see Fig. 33-4; see also Chapter 58 and Fig. 58-6).

Completely Unroofed Coronary Sinus Associated with Other Complex Cardiac Anomalies

No simple description can be given of repairing complex anomalies in which unroofed coronary sinus syndrome is but a part. Such cases are often unique, and the surgeon must study the malformation in detail and plan the repair according to the findings. General comments concerning atypical cor triatriatum may be applicable (see Chapter 32). The types of procedures performed in two large surgical series of uncomplicated unroofed coronary sinus are shown in Tables 33-1 and 33-2.

RESULTS

Early (Hospital) Death

Risk associated with repair of simple unroofed coronary sinus syndrome is low. No deaths occurred among 18 patients (0%; CL 0%-10%) reported by Quaegebeur and colleagues (Table 33-3). In two subsequent series reported by Ootaki and colleagues and Attenhofer Jost and colleagues, early mortality was 0% (0 of 11 patients; CL 0%-16%) and 4.3% (1 of 23 patients; CL 0.7%-14%), respectively.

When the syndrome is part of a complex anomaly associated with atrial isomerism, risk has been much higher. Three of six patients (50%; CL 24%-76%) reported by Quaegebeur and colleagues died (see Table 33-3). A similar experience was reported by Cherian and Rao. Better understanding of morphology and improved operative methods, including avoidance of intracardiac repair, should result in improved outcomes (for further details, see Chapter 58).
Figure 33-4  Autopsy specimen showing a pericardial baffle that corrects an unroofed coronary sinus syndrome (left superior vena cava [LSVC] to left atrium) in association with a common atrium and partial atrioventricular septal defect. Operation was performed on a patient 20 months of age; the child died at 13 years of age, probably from arrhythmia. In both views, the pericardial baffle suture line is identified by a dashed line. A, Exposure from opened right atrium and right ventricle. Baffle suture line passes behind the LSVC ostium to reach the ventricular septal crest between right and left atrioventricular valves and then behind inferior vena caval ostium. There is no right superior vena cava in this heart. B, Viewed from opened left atrium. Key: A, Anterior leaflet of right atrioventricular valve; CoV, opening of large coronary vein into atrium; IVC, inferior vena cava; LA, left atrium; LPV, left pulmonary veins; LSL, left superior atrioventricular valve leaflet; RA, right atrium; RIL, right inferior atrioventricular valve leaflet; RPV, right pulmonary veins; RV, right ventricle.
Time-Related Survival and Functional Status

No late deaths occurred after repair of simple unroofed coronary sinus syndrome in the series of Quaegebeur and colleagues, but one patient required reoperation after 8 years because of tunnel obstruction. No late deaths occurred among the patients reported by Ootaki and colleagues (mean duration of follow-up, 85.5 months), and one late death occurred among 22 hospital survivors (mean duration of follow-up, 85 months) in the series of Attenhofer Jost and colleagues. In the series of Cherian and Rao, one of eight hospital survivors required reoperation for closure of a coronary sinus ASD. At the time of the reports, surviving patients in all series were without symptoms, including the ones who required reoperation.

INDICATIONS FOR OPERATION

When diagnosis of isolated completely unroofed coronary sinus with persistent LSVC is made, operation is advisable because of arterial desaturation, risk of cerebral emboli, and satisfactory results of operation. Indications for repair of the rare isolated completely unroofed coronary sinus without persistent LSVC (coronary sinus ASD) are the same as for other
Figure 33-5, cont’d  
C. Elliptical contoured patch (of pericardium, polyester, or polytetrafluoroethylene) is sutured into place posteriorly to begin creating a pathway for diverting blood from LSVC to right atrium. Care is taken to avoid encroachment of suture line or patch on orifice of left superior pulmonary vein. D, Atrial flap has been laid back into position. Posteriorly and inferiorly, it is resutured to remnant of atrial septum to close the coronary sinus atrial septal defect. Superiorly, the flap is sewn to the other edge of contoured patch; before this, the patch is trimmed to be as narrow as possible to avoid any encroachment on pulmonary veins. Note free access of all three caval orifices to the right atrium. Key: IVC, Inferior vena cava; SVC, superior vena cava.

SPECIAL SITUATIONS AND CONTROVERSIES
Ligation of Left Superior Vena Cava

When the brachiocephalic vein is absent or restrictive, some surgeons ligate the LSVC in this and other conditions even when the jugular venous pressure goes as high as 30 mmHg after temporary occlusion of the LSVC. No ill effects have been reported late postoperatively, although venous engorgement, facial edema, and chylothorax may be early complications.\textsuperscript{12}

We do not recommend ligation in this circumstance, because the other methods described are safe and widely applicable. An alternative practice, when correction of unroofed coronary sinus may complicate intracardiac repair of a coexisting condition and extracardiac repair is not possible, involves temporarily occluding the LSVC and ligating it if the increase in left jugular venous pressure does not types of ASD\textsuperscript{11} (see Chapter 30). When unroofed coronary sinus is associated with complex cardiac anomalies, the associated anomaly usually presents a clear indication for operation.

Modified from Attenhofer Jost and colleagues. PSVC ligated in 5 patients (4 left, 1 right) and anastomosed to LPA in 1 patient.

Key: CS, coronary sinus; LPA, left pulmonary artery; PSVC, persistent superior caval vein.

exceed 15 to 20 mmHg. Even in this setting, however, creating an LSVC–to–left pulmonary artery anastomosis (bidirectional Glenn) would seem preferable to ligating the LSVC. This procedure is technically simple and is feasible in essentially all circumstances except in the presence of pulmonary hypertension. Increasing experience with the bidirectional pulmonary shunt as part of a two-ventricle repair (the “one-and-a-half ventricle repair”) has shown that this physiologic arrangement is well tolerated when applied to a variety of morphologic conditions (see Chapters 34, 40, 41, and 55).

**DEFINITION**

Atrioventricular (AV) septal defects are characterized by a deficiency or absence of septal tissue immediately above and below the normal level of the AV valves, including the region normally occupied by the AV septum, in hearts with two ventricles. The AV valves are abnormal to a varying degree.

These defects have also been called AV canal defects, AV defects, endocardial cushion defects, ostium primum atrial septal defects (when there is no interventricular communication), and common AV orifice (when there is only a single AV valve orifice).  

**HISTORICAL NOTE**

**Morphology**

Abbott apparently recognized ostium primum atrial septal defect (ASD) and common AV canal defect, but it was Rogers and Edwards who in 1948 recognized their morphologic similarity. This concept was further elaborated by Wakai and Edwards in 1956 and 1958. The terms partial and complete atrioventricular canal defects were introduced by these investigators, who realized nonetheless that not all cases fit their definitions. During this period, Lev was formulating his concepts of ostium primum ASD (or partial AV canal) and common AV orifice (or complete AV canal), and he described the position of the AV node and bundle of His in these malformations.  

Wakai and Edwards and later Bharati and Lev became dissatisfied with trying to compress all cases into two categories and added the term transitional. During this period, Van Mierop’s scholarship added a great deal of knowledge about the overall anatomic features of AV septal defects.

By the early 1960s, surgical treatment of these defects provided a stimulus to further morphologic studies. In 1966, Rastelli and colleagues at the Mayo Clinic described in more detail the morphology of AV valve leaflets in cases with common AV orifice. The error made in this study was to compress into the designation common anterior leaflet a leaflet that was in fact divided in two by a commissure (i.e., the divided common anterior leaflet of type A). The description of AV valve leaflets by Rastelli and colleagues was accepted for some years, but in 1976 a publication by Ugarbe and colleagues emphasized the idea of leaflets bridging the ventricular septum, a concept also held by Lev. Meanwhile, based on anatomic and cineangiographic studies and in accordance with the description of Baron and colleagues and Van Mierop and colleagues, it was recognized in the late 1960s that the basic defect in these malformations was absence of the AV septum. This concept is particularly important because the AV septum can be imaged by echocardiography and in the left ventriculogram in the right anterior oblique projection. These concepts were further expanded by Piccoli and colleagues under the direction of Anderson, who further emphasized that all the variations of the defect were part of a spectrum (Fig. 34-1).

**Surgical Treatment**

In 1952 at the University of Minnesota Hospital in Minneapolis, after a long period of laboratory investigation, Dennis and Varco attempted for the first time a cardiac operation in a human using a pump-oxygenator. The preoperative diagnosis was ASD, and at operation the defect was thought to be closed. The patient died, and autopsy showed the true diagnosis to be partial AV septal defect (Edwards JE: personal communication, 1980). The first successful repair of a complete AV septal defect was performed by Lillehei and colleagues in 1954, using cross-circulation and direct suture of the atrial rim of the septal defect to the crest of the ventricular septum. In 1954, Kirklin and colleagues successfully repaired a partial AV septal defect through the atrial well of Watkins and Gross, and in 1955 began repairing AV septal defects by open cardiotomy and use of the pump-oxygenator.

Early experiences with complete AV septal defects were all associated with a high hospital mortality, often related to complete heart block, postrepair left AV valve regurgitation, or creation of subaortic stenosis. Interestingly, in many of these early operations, a two-patch technique was used (see “Two-Patch Technique” under Technique of Operation later in this chapter). In 1958, Lev’s description of the location of the bundle of His provided the basis for repair techniques that avoid heart block. In 1959, Dubost and Blondeau reported their early experience and emphasized that the “cleft” in the “mitral leaflet” need not be sutured in repairing partial AV septal defects, a concept currently challenged. In 1962, Maloney and colleagues described two cases in which a single patch was used to close both
defects and with the valve tissue suspended from the patch. This technique was again described by Gerbode in 1962 and was associated with decreased in-hospital mortality. McGoon recognized the importance of “taking from the tricuspid valve” to leave sufficient tissue from which to create an adequate left AV valve. These technical advances allowed repair of even the more complex variants of the defect. Subsequently, good results were obtained in patients older than about 2 years of age, but results in infants remained relatively poor. Between 1968 and 1971, Barratt-Boyes successfully repaired this anomaly in four severely ill infants; subsequently, improved results in infants were reported by many others.

In 1978, Carpentier again emphasized (as did Dubost and Blondeau) that generally, the left AV valve functions best when repaired as a three-leaflet valve. As a result of these advances, risks of operation for nearly all types of AV septal defect are now low.

**MORPHOLOGY**

**General Morphologic Characteristics**

AV septal defects have as defining characteristics a deficiency or absence of the AV septum, resulting in an ostium primum defect immediately above the AV valves and a deficiency (or scooped-out area) in the inlet (basal) portion of the ventricular septum immediately below the AV valves. Patients with partial AV septal defects have a normal length of atrial septum, and the ostium primum ASD is the result of absence of the relatively small AV septum plus some deficiency in the inlet portion of the ventricular septum. The deficiency in the inlet portion of the ventricular septum is variable, but on average is greater in patients with complete AV septal defects than in those with partial defects.

These septal deficiencies may or may not result in interatrial or interventricular communications, depending on configuration and attachments of the AV valves (Tables 34-1 and 34-2). Whereas the basic defect in these malformations is absence of the AV septum, whether the ventricular septal or atrial septal deficiency or the AV valve abnormality is the result only of AV septal absence is still debated.

Five or more AV valve leaflets of variable size are usually present (see Fig. 34-1), but there is often variability in completeness of commissures and prominent crenations in the leaflets (Fig. 34-2). For example, among the 43 hearts with all types of AV septal defects and 2 ventricles in the GLH autopsy series in which the number of leaflets could be accurately assessed, 10 (23%) had 4 leaflets, 18 (42%) had 5 leaflets, 14 (33%) had 6 leaflets, and 1 (2%) had 7 leaflets. When a large interventricular communication was present (complete AV septal defect), the most common number of leaflets was 5 (16 of 28, or 57%).
The left superior leaflet (LSL) and left inferior leaflet (LIL) are particularly variable in size, connections one to another (Table 34-5), and degree of bridging across the crest of the ventricular septum (Table 34-4; see Figs. 34-1 and 34-2). There may be one or two AV valve orifices (Table 34-5).

Hearts with AV septal defects are also characterized by absence of the usual wedged position of the aortic valve above the AV valves. Instead, it is elevated and deviated anteriorly.\textsuperscript{53,63,73,74} Details of the aortic-mitral fibrous continuity often differ from those in the normal heart. Thus, continuity was abnormal in more than half of 21 specimens with normally related great arteries in the GLH autopsy series; continuity was to the base of the noncoronary cusp in only 5 (24%) and to both the noncoronary and right coronary cusps in 7 (33%). In addition, the left ventricular (LV) inflow tract is shortened in length to the outflow portion, and there is a related reduction in length of the diaphragmatic wall of the LV.\textsuperscript{3,16} The LV outflow tract is also narrowed, although rarely is the narrowing sufficient to be of hemodynamic importance in the unrepaired heart.\textsuperscript{57}

AV septal defects include a spectrum of malformations. At one end is the simplest type, in which there is an interatrial communication but no interventricular communication and a connection of variable width between the LSL and LIL; this is called a partial AV septal defect or ostium primum defect. At the other end of the spectrum is the most extreme form, with large deficiencies in atrial and ventricular septa, a common AV valve orifice, and large interatrial and interventricular communications; this is called a complete AV septal defect. Because a continuous spectrum of gradations lies between these extremes, some anomalies have been grouped.

\textsuperscript{a}Prevalence
Figure 34-2  Atrioventricular (AV) valves in AV septal defects viewed from atrial aspect in a series of fixed specimens. A, Specimen with partial AV septal defect in which left superior (LS) and left inferior (LI) leaflets are adherent to crest of ventricular septum and there is no interventricular communication. Arrow marks line of closure between LS and LI leaflets, formerly called the “cleft in the anterior mitral leaflet.” Note that as usual, LS leaflet does not bridge septum (there is no leaflet tissue in the position of the superior portion of the normal tricuspid septal leaflet). In this heart, as is not uncommon, there are two left lateral and two right lateral leaflets. B, Specimen with complete AV septal defect in which there are interventricular communications beneath LS and LI leaflets. LS leaflet does not bridge crest of septum. Right superior (RS) leaflet is characteristically large. LI leaflet is bridging (grade 2) and very distinct from right inferior (RI) leaflet. C, Specimen of a complete AV septal defect in which LS leaflet markedly bridges crest of septum. Correspondingly, RS leaflet is small. LS leaflet is characteristically larger than LI leaflet. Key: LA, Left atrium; RA, right atrium.
as intermediate or transitional AV septal defects. Definitions of these intermediate types have varied but usually include presence of two AV valve orifices and a restrictive inlet ventricular septal defect (VSD), with dense chordal attachments to the ventricular septum (see “Unusual Atrioventricular Combinations” under Morphology). Added complexity is provided by occurrence of a large variety of major and minor associated cardiac anomalies (Tables 34-6 and 34-7). In addition, Down syndrome is common, particularly in patients with an interventricular communication.

Because it is virtually impossible to subdivide the spectrum of AV septal defects into satisfactory noncontroversial subgroups, this chapter describes cases based on morphologic and functional variables rather than categorizing them into subgroups. The older imprecise terms continue to be useful as shorthand, and in this chapter, partial AV septal defect refers to a malformation with two AV valve orifices and no interventricular communication, whereas complete AV septal defect refers to a malformation with a common AV valve orifice and large (grade 2 or more) nonrestrictive interventricular communication.

Chapter 34  Atrioventricular Septal Defect

Common Atrium
Deficiencies in the anterior limbus or fossa ovalis may be associated with AV septal defects, resulting in a larger interatrial communication. Occasionally the entire limbus and fossa ovalis are absent, along with the AV septum. The condition is then termed common atrium (see Table 34-1).

Absence of Interatrial Communication
Rarely, AV valve tissue is attached completely to the edge of the atrial septum, and no interatrial communication exists despite the deficiency in the septum (see Table 34-1). In this unusual variant, the characteristic deficiency of the inlet (basal) portion of the ventricular septum is also present and associated with a large interventricular communication beneath the leaflets. The functionally left AV valve, consisting only of those portions of the LSL and LIL on the left side of their attachment to the atrial septum, tends to be competent. As seen from a right atrial approach, part of the right AV valve may have chordal attachments across the ventricular defect to the left side of the septum—that is, it is straddling. When viewed from the ventricular side, the appearance is typical of a complete AV septal defect. It is distinct from an inlet type of perimembranous VSD that is sometimes called inlet septal, AV septal, or AV canal type of VSD, which is unrelated to deficiency of the AV septum (see “Inlet Septal Ventricular Septal Defect” under Morphology in Chapter 35.

Atrial Septal Deficiency and Interatrial Communications

Partial Atrioventricular Septal Defect
Usually there is an interatrial communication related to deficiency of the AV septum, the so-called ostium primum ASD (Fig. 34-3). The defect is bounded below by the inferiorly displaced AV valve leaflets and above by a crescentic ridge of atrial septum that fuses with the AV valve anulus only at its extremities.

Generally, there is little atrial septal tissue at the superior point of fusion of the atrial septum with the valve anulus adjacent to the aorta, but more tissue is usually present inferiorty adjacent to the coronary sinus (Fig. 34-4). The distance between the crescentic atrial margin of the defect and the AV valves (and thus the size of the interatrial communication) is variable. In most cases, the fossa ovalis is normally formed and there is a patent foramen ovale or an associated fossa ovalis ASD. Usually the interatrial communication through the ostium primum defect is moderate in size. When the interatrial communication is small, the atrial septal deficiency is restricted to the area normally occupied by the AV septum (26). The communication may be still smaller due to fusion of the base of the LSL or LIL to the edge of the adjacent portion of the atrial septum. Rarely, there may be an accessory “parachute” of fibrous tissue that narrows or obstructs the defect. Under such circumstances, a pressure difference exists between the two atria.

Figure 34-3  Partial atrioventricular (AV) septal defect. A, View from right atrium and right ventricle. Large ostium primum atrial septal defect is seen above AV valve leaflets. No interventricular communication is present beneath the leaflets. However, deficiency of basal (inlet) portion of ventricular septum is apparent. Left superior (LS) leaflet is attached firmly by fibrous tissue to crest of septum (dashed line) and does not bridge onto right ventricular side. There is thus a bare area on right side of superior aspect of ventricular septum (arrow). Left inferior (LI) leaflet bridges on right ventricular side. Right superior (RS) leaflet is clearly visible, but right lateral and inferior leaflets are not in photograph. B, Left ventricular outflow view. LS and LI leaflets are firmly attached to crest of ventricular septum. Narrowing and elongation of left ventricular outflow tract are apparent. This figure makes clear why, in describing position of the two leaflets attached to the ventricular crest, the terms superior and inferior are preferable to anterior and posterior, terms that lead to confusion with normal mitral leaflets. (Courtesy Dr. Maurice Lev.)
and “Inlet Septal Type of Ventricular Septal Defect” in text that follows).

Ventricular Septal Deficiency and Interventricular Communications

Partial Atrioventricular Septal Defect
Some degree of deficiency of the inlet portion of the ventricular septum immediately beneath the AV valves is a constant finding. Thus, the inlet portion of the ventricular septum is shortened. There is usually no interventricular communication when the LSL and LIL are connected and attached to the downwardly displaced crest of the septum throughout its length (Fig. 34-5; see also Fig. 34-3), the situation described as a partial AV septal defect. Occasionally, one or several small interventricular communications are present beneath the attachment of the AV valve to the septum (Fig. 34-5, B).

Complete Atrioventricular Septal Defect
With ventricular septal deficiency generally greater than that in a partial AV septal defect, a moderate or large interventricular communication may be present, and usually the LSL and LIL are separate. This anomaly is described as a complete AV septal defect (Fig. 34-5, C). Deficiency of the inlet portion of the ventricular septum (the “scoop”) is generally deeper in hearts with complete AV septal defects than in those with partial AV septal defects.\(^{A10,B1,F2}\) Often the communication is particularly large beneath the LSL and smaller beneath the LIL (see Table 34-2), whereas in about 5% of cases there is a larger interventricular communication beneath the LSL and none beneath the LIL. Rarely, there is no VSD beneath the LSL and a large one beneath the LIL.

A remnant of the membranous ventricular septum may be present (see Fig. 34-5, B). This was the case in 8 of 27 (30%) GLH autopsy specimens of AV septal defect with normally related great arteries; in 19 specimens the membranous septum could not be identified.

Atrioventricular Valves
Attachments of the AV valves to the crest of the ventricular septum in partial AV septal defects, as well as their chordal attachments in complete AV septal defects, are displaced toward the apex of the heart because of deficiency of the inlet (basal) portion of the septum. This alters orientation of the AV orifices relative to the aortic orifice (i.e., the aortic valve is no longer wedged between the AV valves) and provides an important diagnostic imaging criterion of this malformation.\(^{E5,E6,F2}\)

Two Atrioventricular Valve Orifices
Typically when two AV valve orifices are present, as in partial AV septal defects, the LSL and LIL are joined together to a variable extent anteriorly by leaflet tissue near the crest of the ventricular septum (see Figs. 34-1 and 34-3). Together they resemble an anterior (septal) mitral leaflet with a cleft, but in fact the left AV valve is tricuspid and oriented differently from the normal valve (see Figs. 34-1 and 34-2). The connection between the LSL and LIL may be only a thin strand of tissue (complete cleft), but more commonly it is 2 to 4 mm or more deep (see Table 34-3). This connection, too, is usually fused to the crest of the ventricular septum in partial AV septal defects. Occasionally, chordae pass from opposing edges of the LSL and LIL to the muscular ventricular septum beneath.\(^{E5}\) Yilmaz and colleagues identify a difference in this area of separation and distinguish between a commissure supported by chordal apparatus on either side of the gap and a cleft that is relatively unsupported and bereft of chordae at its edges.\(^{F2}\) In addition, the chordae that originate from the central edges of the LSL and LIL attach to different papillary muscles, which can cause a distracting force on the leaflets during closure. This contrasts with the normal commissure in which the chordae from adjacent leaflet edges attach to a single papillary muscle, encouraging coaptation. Rarely, separation into LSL and LIL is represented only by a notch in the center of the free edge of a nearly normal “anterior mitral leaflet.” The left lateral leaflet (LLL) is usually smaller than the other two leaflets and is triangular.

In aggregate, these left AV valve leaflet anomalies may make the valve regurgitant to a variable degree, sometimes severely (Table 34-8). When LSL and LIL are nearly completely separated (connection grades 1 and 2; see Table 34-3), an appreciable gap may occur during systole, producing regurgitation. When there is failure of valve coaptation at this site, leaflet tissue forming the margin usually becomes thickened and rolled. In other cases, regurgitation appears to be due to deficiency of leaflet tissue, particularly in the LIL.\(^{B16,M10}\) The mechanism of severe left AV valve regurgitation is, however, not evident in some cases. The jet of regurgitation is usually directed into the right atrium. Rarely, the left AV valve is stenotic, but this usually is associated with hypoplasia of the LV.\(^{B18}\)

---

**Figure 34-4** Right atrial view of a specimen of a partial atrioventricular (AV) septal defect. Coronary sinus ostium (CoS) is seen inferior and posterior to ostium primum (P) defect in atrial septum. Approximate position of AV node and bundle of His is shown as a dashed line. Placement of inferior part of patch suture line is shown by the line of x’s. Key: EV, Eustachian valve of inferior vena cava; FO, fossa ovalis; SVC, superior vena cava.
Figure 34-5  Left ventricular aspect of atrioventricular (AV) septal defects.  
A, Partial AV septal defect viewed from opened left ventricle.  
Left superior (LS) and left inferior (LI) leaflets are completely attached to crest of a deficient ventricular septum (VS).  
Area of contact or closure between left superior and left inferior leaflets is indicated by arrow.  
In this specimen, only the anterior papillary muscle (APM) is present (“parachute” mitral valve).  
B, Intermediate type of AV septal defect from left ventricular view.  
Numerous small interventricular communications are present between thick, short chordae that tether both LS and LI leaflets to ventricular crest.  
Fibrous tissue extending from superior leaflet to below right coronary aortic cusp (RC) represents remnant of membranous septum.  
C, Complete AV septal defect viewed from left ventricular aspect.  
LS and LI bridging leaflets are free floating, and there is a large interventricular communication between them and the underlying crest of the ventricular septum.  
This specimen also has double outlet right ventricle.  
Key: AoV, Aortic valve; LI, left lateral leaflet; NC, noncoronary aortic cusp.
The right AV valve is also abnormal when there are two AV orifices, although less attention has been paid to it. It may consist of three leaflets—right superior leaflet (RSL), right lateral leaflet (RLL), and right inferior leaflet (RIL)—or of two or four leaflets (see Figs. 34-1 and 34-2). Leaflet tissue attached directly or by chordae to the crest or right side of the crest of the septum, and thus contributing to closure of the right AV valves, is considered to represent bridging of the LSL or LIL (see Fig. 34-1).

Usually in cases without an interventricular communication, the LSL does not bridge at all (previously, this finding was interpreted as absence or hypoplasia of the superior part of the tricuspid septal leaflet) and the LIL bridges moderately (see Fig. 34-2, A). Even with abnormalities of the right AV valve, regurgitation is rare (unless right heart failure develops).

**Common Atrioventricular Orifice**

When the AV valve orifice is a common one and the interventricular communication is large (complete AV septal defect), the LSL and LIL are separate, and a bare area is exposed on the crest of the ventricular septum (Fig. 34-6; see Figs. 34-1 and 34-5, C). The LSL may be entirely on the LV side of the septum or may, to a variable degree, bridge the septum and extend onto the right ventricular side (see Fig. 34-2, B-C and Table 34-4). This variability formed the basis for the classification by Rastelli and colleagues into types A, B, and C.\(^2\) Chordal attachments of the right ventricular extremity of the LSL vary according to degree of bridging (Fig. 34-7). When there is no bridging, chordal attachments are to the ventricular crest (Fig. 34-7, A). With mild bridging, they are to the medial papillary muscle in the right ventricle; with moderate bridging, to an accessory (often large) apical papillary muscle (Fig. 34-7, B); and with marked bridging, to the normally positioned (although often bifid) anterolateral papillary muscle of the right ventricle (Fig. 34-7, C). When the LSL bridges the septum moderately or markedly and extends into the right ventricle, it is usually unattached to the underlying ventricular crest (free-floating), but it may occasionally be attached by chordae (tethered). Length of the chordal or fibrous attachments to the right side or crest of the ventricular septum varies according to size of the interventricular communication or the position of the leaflet.

Data from Studer and colleagues.\(^11\)

\(^a\) No information on five patients.

\(^b\) \(\chi^2\) for difference = .007.

![Image](image)

The LIL typically bridges moderately, but it too varies in this respect. It is not uncommon for a bridging LIL to be attached to the underlying ventricular crest either completely or by short, thick chordae with interchordal spaces.

Chordal attachments of the leftward components of the common AV valve in the LV are usually relatively normal, although the posterior papillary muscle is displaced more laterally than normal and a third papillary muscle may be present.\(^2\) There may be only one papillary muscle, producing a parachute-type valve that is difficult to repair.\(^2\) This was true in 7 of 53 (13%) cases in the GLH autopsy series, in 14% of the specimens described by David and colleagues, and in 4% of 155 surgical cases reported by Ilbawi and colleagues.\(^12\)
The right ventricular portion of the common AV valve has superior, lateral, and inferior leaflets, but as in partial AV septal defects, they vary considerably in number and size (see Fig. 34-2). When bridging of the LSL is absent or mild, the RSL is large, whereas with more extensive bridging, it is smaller.78

When leaflets of the common AV valve close appropriately during ventricular systole, AV valve regurgitation is absent or mild. However, important left AV valve regurgitation may be present (see Table 34-8). The mechanism of the regurgitation is often not clearly understood.

Anatomic studies by Kanani and colleagues have emphasized the marked valvar abnormalities in this malformation, not only of the anular component but also of the subvalvar apparatus (with deficiency of chordal arrangement) and leaflet tissue (which is often deficient in coaptation surface and pliability following repair).75
Accessory Orifice

An accessory orifice (double left AV valve orifice) is present in the commissure on one side, usually the inferior side, of the LLL in about 5% of cases. A ring of chordae surrounds the orifice, and a very small papillary muscle is usually beneath it. The accessory orifice may be conceptualized as an incomplete commissure, and the fibrous tissue “bridge” between the accessory orifice and main orifice

Unusual Atrioventricular Combinations

Other unusual combinations of size, connections, attachments, and degree of bridging of AV valve leaflets in the spectrum of AV septal defects prompted Wakai and Edwards, Bharati and colleagues, and others to use a transitional or intermediate category. Rarely in patients with two AV valve orifices with no interventricular communication beneath the LSL and LIL, these leaflets are connected only by a fibrous strand adherent to the ventricular septal crest, forming what Bharati and colleagues have called a “pseudomitral leaflet,” rather than an “anterior mitral leaflet with a complete cleft.”

In such patients, deficiency of LIL tissue and severe left AV valve regurgitation are common. Occasionally when the LSL and LIL are connected (and thus two AV valve orifices are present), one or multiple small interchordal interventricular communications are present beneath the leaflets (see Tables 34-2 and 34-5), and occasionally one or two larger holes may be present (Fig. 34-8; see Fig. 34-5, B). In about 1% of cases, the connected LSL and LIL have large interventricular communications beneath them; in these patients, the connection is a thin strand of valve tissue beneath which there is also a large interventricular communication (Fig. 34-9), but two AV valve orifices can be said to be present (see Table 34-5). Bharati and colleagues have referred to this as intermediate type C.

### Accessory Orifice

An accessory orifice (double left AV valve orifice) is present in the commissure on one side, usually the inferior side, of the LLL in about 5% of cases. A ring of chordae surrounds the orifice, and a very small papillary muscle is usually beneath it. The accessory orifice may be conceptualized as an incomplete commissure, and the fibrous tissue “bridge” between the accessory orifice and main orifice

Data from Studer and colleagues. $^{115} \chi^2$ for difference = .3.
which case it overrides the left AV valve to a varying degree and may be associated with hypoplasia of the left atrium. This variant is therefore sometimes included in “hypoplastic left heart physiology” (see Chapter 49).

The right ventricle has no specific anomalies, but is usually enlarged secondary to the left-to-right shunt. Its size is also variable, and occasionally it is importantly hypoplastic.

S15

Ventricles

The LV outflow tract is characteristically elongated and narrowed (Fig. 34-10) in all types of AV septal defect (see “General Morphologic Characteristics” under Morphology earlier in this chapter).

In AV septal defect with large interventricular communications, the LV may be abnormally large, but its size is variable, both absolutely and in relation to the right ventricle. In the severely right-dominant type of AV septal defect, the LV is severely hypoplastic (Fig. 34-11). In such cases, the atrial septum may be displaced leftward in relation to the plane of the ventricular septum, in which case it overrides the left AV valve to a varying degree and may be associated with hypoplasia of the left atrium. This variant is therefore sometimes included in “hypoplastic left heart physiology” (see Chapter 49).

The right ventricle has no specific anomalies, but is usually enlarged secondary to the left-to-right shunt. Its size is also variable, and occasionally it is importantly hypoplastic.

The LV or right ventricle is severely hypoplastic in about 7% of patients born with complete AV septal defect. Prevalence of the two types is similar. Presence of severe ventricular hypoplasia can increase risk of surgical correction and may demand a Fontan-type repair, alone or with a technique for correcting the hypoplastic left heart physiology (see Special Situations and Controversies later in this chapter and Chapter 41).

Septal Malalignment

Usually the two AV valves or common AV valve orifice lies in proper proportion over the two ventricles. When one ventricle is hypoplastic, the ventricular septum is malaligned and lies more to the side of the hypoplastic ventricle (see Fig. 34-11).
Less commonly, the atrial septal remnant is malaligned, and then usually leftward. When this is severe, both AV valves (or common AV valve orifice) are accessible only from the right atrium, and blood exists from the left atrium only through the ostium primum defect (so-called double outlet right atrium).66,15,51

Left Ventricular Outflow or Inflow Obstruction

Important LV outflow tract obstruction occurs rarely in unoperated hearts (about 1% of cases) in all types of AV septal defect.8,11,31,11 It more often becomes apparent as a postoperative complication. It is surprising that it is not more frequent, in view of the elongation and narrowing of this area in affected hearts.66,64

Part of the elongation and narrowing is due to the more extensive area of direct fibrous continuity between the aortic valve and the LSL than is present normally between the aortic and mitral valves.53 This is caused in part by the short, thick chordae that often anchor the LSL to the crest of the ventricular septum.34,35 Also, the anterolateral muscle bundle of the LV (muscle of Moulaert) bulges more into the LV outflow tract in hearts with AV septal defects than in normal hearts, contributing to the tendency to outflow obstruction after repair.36 In addition to these basic arrangements tending to narrow the LV outflow tract, LV obstruction may be contributed to by morphologically discrete subaortic stenosis or by excrescences of AV valve tissue heaped up in the LV outflow tract.51,61,77,73 It may also result from abnormally positioned papillary muscles.87 Occasionally, its presence is overlooked preoperatively, and it becomes apparent or develops only after operation.

Important LV inflow obstruction may occur rarely.87 This may be from simple narrowing of the AV valve entrance into the LV, usually associated with marked right ventricular dominance. It may be related to presence of an accessory AV valve orifice on the left side, or it may result from cor triatriatum (see Chapter 32) or a supravalvar fibrous ring.76 These associated cardiac anomalies appear to be more prevalent in patients without Down syndrome.33,65

Conduction System

The defect in the AV septum often displaces the coronary sinus ostium inferiorly, which may appear to lie in the left atrium, especially when the ostium primum atrial defect is particularly large. The AV node is also displaced inferiorly (caudally) and lies in the posterior right atrial wall between the orifice of the coronary sinus and ventricular crest.15 (Fig. 34-12) in what has been termed the nodal triangle.75 The bundle of His passes forward and superiorly from the node to the ventricular crest, reaching it where the crest fuses posteriorly with the AV valve anulus.81 It then courses along the top of the ventricular septum beneath the bridging portion of the LIL, giving off the left bundle branches. As it reaches the midpoint of the crest of the ventricular septum, it becomes the right bundle branch, which continues along the crest a little farther before it descends toward the muscle of Lanclusi and moderator band. These anatomic find- ings have been supported by electrophysiologic studies at operation.14,11 This morphology of the conduction system is a determinant of the electrocardiographic pattern usually seen in AV septal defects.1,75

Major Associated Cardiac Anomalies

Table 34-6 presents the prevalence of the major cardiac anomalies associated with AV septal defects.

Patent Ductus Arteriosus

A patent ductus arteriosus is present in about 10% of patients with AV septal defects. It is particularly common in those with an interventricular communication.

Tetralogy of Fallot

Typical tetralogy of Fallot is present in about 5% of patients with complete AV septal defects, and about 1% of patients with tetralogy of Fallot have associated complete AV septal defects.81,8,71 The LSL bridges markedly and is free-floating over the crest of the ventricular septum, and the interventricular communication beneath it is large and juxtaaortic.81,64 An interventricular communication beneath the LIL is present in only about half of cases.79 Rarely the LSL and LIL are connected by a fibrous (or valvar) band, beneath which also is a large interventricular communication. The right ventricular outflow tract has typical tetralogy morphology (see Chapter 38) that may be so severe that pulmonary atresia is present. Localized narrowing occasionally occurring in that portion of the LV outflow tract just upstream from the recess formed by the subaortic deficiency of the ventricular septum further complicates the situation in rare cases.

Double Outlet Right Ventricle

Double outlet right ventricle (DORV) without pulmonary stenosis complicates complete AV septal defect in about 2% of cases.86,8,11,11,51,72 As in tetralogy of Fallot, usually...
deficiency of the ventricular septum is large and juxtaaortic beneath the extensively bridging and free-floating LSL. However, occasionally the interventricular communication is far from the aortic and pulmonary valves and is “non-committed.” Rarely, Taussig-Bing type of DORV is present.\textsuperscript{8,13,12} DORV combined with severe pulmonary stenosis coexists with complete AV septal defects in about 1% of cases.\textsuperscript{315} These combinations of DORV and AV septal defect with large interventricular communication frequently also have atrial isomerism or situs inversus, common atrium, completely unroofed coronary sinus with left superior vena cava, azygos extension of the inferior vena cava, or total anomalous pulmonary venous connection.\textsuperscript{2,312}

**Transposition of the Great Arteries**

Very rarely, transposition of the great arteries (discordant ventriculoarterial connection) is associated.\textsuperscript{313}

**Completely UnroofedCoronary Sinus with Left Superior Vena Cava**

Completely unroofed coronary sinus with persistent left superior vena cava (see Chapter 33) attached to left atrium occurs in about 3% of patients with an interventricular communication and in about 3% without, and is more frequent when common atrium is present.\textsuperscript{91} A partially unroofed distal end of the coronary sinus resulting in drainage of the coronary sinus into the left atrium occasionally occurs, but is a minor and unimportant associated anomaly.\textsuperscript{15} When complete AV septal defect is associated with persistent left superior vena cava and unroofed coronary sinus, atrial isomerism is also frequent (see Chapter 58).\textsuperscript{34}

**Minor Associated Cardiac Anomalies**

Table 34-7 lists minor cardiac anomalies associated with AV septal defects.

**Pulmonary Vascular Disease**

In partial AV septal defects, as in other types of ASDs, pulmonary vascular disease is uncommon, whereas in complete AV septal defects, as with large VSDs, pulmonary vascular disease usually appears early in life and progresses.\textsuperscript{313}

Morphologically, pulmonary vascular disease associated with complete AV septal defects is similar to that associated with large VSDs (see “Pulmonary Vascular Disease” under Morphology in Section I of Chapter 35). However, it tends to progress more rapidly in patients with complete AV septal defects. Correlation between histologic findings and pulmonary vascular resistance is similar in the two conditions.\textsuperscript{315} The pulmonary vascular changes probably are more frequent and occur at an earlier age in patients with Down syndrome with complete AV septal defects compared with patients without Down syndrome.\textsuperscript{19,31}

**Down Syndrome**

Down syndrome is rare in patients with partial AV septal defects but common (about 75%) in those with complete AV septal defects.\textsuperscript{199} Left-sided obstructive lesions are 10 times less common in Down syndrome patients\textsuperscript{2,31,35} whereas advanced pulmonary vascular disease may be more frequent.\textsuperscript{31}

Inlet Septal Type of Ventricular Septal Defect

It is important to note that an isolated inlet (AV septal) type of VSD (see Morphology in Section I of Chapter 35) occurs without any of the features of an AV septal defect as defined in this chapter, except that it involves the inflow portion of the ventricular septum beneath the septal tricuspid valve leaflet and usually also the area of the membranous ventricular septum. The AV septum, however, is intact, and the mitral and tricuspid annuli and aortic orifice lie in normal positions. This feature allows these VSDs to be readily differentiated echocardiographically and angiographically from AV septal defects. Interestingly, in isolated inlet VSD, the anterior mitral leaflet is occasionally cleft.

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

Pathophysiology

Left-to-right shunting is present in AV septal defects unless severe pulmonary vascular disease has developed or important right ventricular outflow tract obstruction or pulmonary valve stenosis coexists. When there is no interventricular communication, the shunt is at atrial level and usually large, but it may be small or moderate; in such cases, a pressure gradient can be demonstrated between left and right atria. When the shunt is large and left AV valve regurgitation is mild or absent, the hemodynamic state of the patient is identical to that in isolated ASD (see Clinical Features and Diagnostic Criteria in Chapter 30); only right ventricular stroke volume is increased. When important left AV valve regurgitation is present, the left-to-right shunt becomes much larger; in fact, the regurgitation jet usually goes directly from LV to right atrium. Left as well as right ventricular stroke volume is increased, and marked cardiomegaly and heart failure develop early in life.

When a large interventricular communication is also present (complete AV septal defect), the left-to-right shunt is large, and right ventricular and pulmonary artery pressures approach or equal systemic pressures (Table 34-10). Pulmonary vascular resistance rises rapidly and is usually importantly elevated after age 6 to 12 months and sometimes before.\textsuperscript{31}

Data from Studer and colleagues.\textsuperscript{315}

\textsuperscript{a}Data not available for 43 patients.

\textsuperscript{b}Data not available for 23 patients.

Key: AO, Aortic; PA, pulmonary artery.
When present, AV valve regurgitation adds greatly to ventricular volume overload. For some reason, however, the overload usually seems to enlarge the right ventricle more than the left.

**Atrioventricular Valve Regurgitation**

Prevalence of regurgitation at the left AV valve or common AV valve is considered to be less than before echocardiographic studies were available. Probably 10% to 15% of patients with partial AV septal defect have important regurgitation, not 40% as was estimated earlier (see Table 34-8). Moderate AV valve regurgitation is present in about 20% of infants with complete AV septal defects and severe regurgitation in only about 15%. AV valve regurgitation may be considerably more common in older patients with complete AV septal defects.

A not-uncommon site of regurgitation is through the gap between the LSL and LIL, particularly near the leaflet hinge or base; partly for this reason, regurgitant flow frequently goes directly into the right atrium. Under such circumstances, the left atrium remains small and the right becomes large; but when the interatrial communication is smaller or the regurgitation is sited elsewhere, regurgitation may enter the left atrium, which enlarges.

Although the precise mechanism of AV valve regurgitation is often unclear, it apparently varies considerably, as would be expected from variations in the number, size, and configuration of the leaflets and their chordal attachments. In patients with partial AV septal defects and important left AV valve regurgitation, the LIL is commonly severely hypoplastic.

**Symptoms and Physical Findings**

Patients without an interventricular communication (partial AV septal defect) and with absent or mild left AV valve regurgitation often present in the first decade of life but may remain asymptomatic well beyond that age. Their clinical presentation is virtually identical to that of patients with the more common fossa ovalis ASD (see “Fossa Ovalis Defect” under Morphology in Chapter 30), except that they may have an apical systolic murmur when mild left AV valve regurgitation is present, and left axis deviation and a counterclockwise frontal plane loop.

Moderate or severe (grade 3, 4, or 5) left AV valve regurgitation in patients with partial AV septal defects may produce symptoms earlier, and progressive severe heart failure may require treatment in infancy. In addition to the usual signs of ASD, the heart is more active in association with a loud apical pansystolic murmur, and the apex of the LV may be palpable. Tachypnea and hepatomegaly are often evident.

In patients with complete AV septal defect, presentation is usually in the first year of life, frequently during the first months, as a result of progressive severe heart failure, which may not be controllable medically. There is associated tachypnea, poor peripheral perfusion, and failure to thrive. Occasionally, heart failure is minimal early in life, and presentation may be delayed until some years later, by which time there is almost always severe hypertensive pulmonary vascular disease and Eisenmenger complex (see “Clinical Findings” under Clinical Features and Diagnostic Criteria in Section I of Chapter 35). On physical examination, cardiomegaly with increased ventricular activity is apparent. The second heart sound at the base is split and usually fixed, with accentuation of the second component caused by elevated pulmonary artery pressure. A systolic murmur is audible over the left precordium from the shunt at ventricular level and is increased in intensity and nearer the apex when there is important AV valve regurgitation. A mid-diastolic flow murmur is characteristically widely heard both over the lower left precordium and at the apex secondary to the large diastolic flow across the malformed AV valve leaflets (depending on both the left-right shunt and any AV valve regurgitation).

In those patients with morphology intermediate between the partial and complete AV septal defects, clinical features depend on size of the interventricular communication and severity of left AV valve regurgitation.

**Chest Radiograph**

In patients without an interventricular communication or important left AV valve regurgitation, the chest radiograph is the same as in other large ASDs. When moderate or severe left AV valve regurgitation is present, the radiograph usually shows marked cardiomegaly with evidence of LV, right ventricular, and right atrial enlargement and marked pulmonary plethora. Left atrial enlargement is not apparent unless the ostium primum defect is restrictive.

In complete AV septal defect, cardiomegaly and pulmonary plethora are evident in infants and young children presenting with heart failure. In patients who survive beyond this age, severely increased pulmonary vascular resistance usually dominates, and the heart is less enlarged, central pulmonary arteries are large, and lung fields are clear.

**Electrocardiogram**

Electrocardiographic findings are rather specific. They usually indicate marked right ventricular hypertrophy and may show LV hypertrophy as well. The PR interval is frequently prolonged. Of considerable diagnostic importance is the vectorcardiogram. Ongley and colleagues conclude that a counterclockwise frontal plane loop anterior and to the right strongly suggests, but does not prove, the diagnosis.

**Two-Dimensional Echocardiogram**

In AV septal defects without an interventricular communication or important left AV valve regurgitation, two-dimensional echocardiography, together with clinical presentation, chest radiograph, and electrocardiogram, is diagnostic, and cardiac catheterization with cineangiography is not necessary. Two-dimensional echocardiography, particularly with Doppler color flow imaging and, when possible, with a transthoracic window, can also provide full information for complete AV septal defects.

The common AV orifice is easily seen in the four-chamber view (Fig. 34-13). Characteristically, left and right AV valves (separated or common) exist at the same level, in contrast to the cephalad displacement of the normal mitral valve. The elongated outflow septum and unwedged position of the aortic valve are also identifiable. Chordal attachment and degree of leaflet bridging can also be assessed. Finally, the degree of AV valve regurgitation is assessed with color flow.
Figure 34-13  Echocardiograms of atrioventricular (AV) septal defects. **A**, Apical four-chamber view of a heart with an unbalanced AV septal defect. In this figure, the common AV valve (arrow) is positioned such that there is malalignment between interatrial septum and interventricular septum and a disproportionate size of the ventricles. Smaller arrow shows primum atrial septal defect. **B**, Apical four-chamber view showing common AV valve (arrows) with virtual absence of interatrial septum. **C**, Parasternal long axis view showing a “gooseneck” appearance of left ventricular outflow tract caused by displacement of left-sided portion of a common AV valve (arrow). **D**, Coronal image of heart as viewed from apex (apical four-chamber view). This heart has a complete AV septal defect. There are both primum and secundum atrial septal defects. **E**, Coronal image of a heart with a complete AV septal defect as viewed from the apex (apical four-chamber view). Arrows point to the common AV valve. There are both primum and secundum atrial septal defects. **F**, Coronal image of a heart with a partial AV septal defect as viewed from the apex (apical four-chamber view). Thin arrows point to common AV valve. Thick arrow points to tissue occluding the inlet ventricular septal defect right AV valve pouch formation. Key: Ao, Aorta; IVS, interventricular septum; LA, left atrium; LV, left ventricle; RA, right atrium, RV, right ventricle; V, inlet ventricular septal defect; 1°, primum; 2°, secundum.
With subcostal views, the degree of balance in the commitment of the common AV orifice to right and left ventricles can be ascertained (see “Unbalanced Atroventricular Septal Defects” under Special Situations and Controversies).

Limitations of echocardiography include lack of sensitivity for double orifice left AV valve and inability to assess quantitatively pulmonary vascular resistance and reactivity.

Cardiac Catheterization and Cineangiogram

Direction and magnitude of shunting; pulmonary and systemic pressures, resistances, and flows; and right and left ventricular pressures can be measured and calculated from data obtained at cardiac catheterization (see “Cardiac Catheterization” under Clinical Features and Diagnostic Criteria in Section I of Chapter 35). P4 However, these studies are now required only when major cardiac anomalies coexist and when operability is questioned because of evidence of pulmonary vascular disease.

Angiocardiographic features of AV septal defects were well described by Baron and colleagues in 1964 and further refined by the work of Brandt and colleagues, Bargeron and colleagues, and Macartney and colleagues. B3,B4,B20,M1,S10 Both oblique and axial views are used. B3,R20 They demonstrate absence of the AV septum and deficiency of the inlet portion of the ventricular septum, elongation of the LV outflow tract in relationship to the inflow tract, elevation and anterior displacement of the aortic valve vis-à-vis the AV valves, and the anomalous relationship of anterior components of the left AV valve to the aorta. These are well portrayed by the line drawings of Baron and colleagues and representative cineangiograms (Figs. 34-14 through 34-16). The anomalous left AV valve’s relationship to the aorta results in change in direction of left AV valve movement. Interaltrial and interventricular shunting can also be demonstrated, as can presence of one or two AV valve orifices. With high-quality studies, leaflets of the left AV valve often can be visualized in motion to delineate the degree, location, and mechanism of valvar regurgitation.

The relative size of the two ventricles and of AV orifices must be determined by whatever technique—echocardiography or angiography—is preferred. Severe hypoplasia of one or the other ventricle must be identified preoperatively, because such hypoplasia makes it less likely anatomic correction will be successful. C8,M1

Special Situations and Associated Defects

Presence of common atrium generally can be identified preoperatively by echocardiography or a cineangiogram, which show nearly complete absence of both atrial and AV septum (see Fig. 34-13). Finding mild arterial desaturation in a patient with clinical findings of an AV septal defect, but without an interventricular communication or pulmonary artery hypertension, suggests presence of common atrium. C9,M18,R2,R5 Presence of a left superior vena cava in such a setting suggests both unroofed coronary sinus syndrome and common atrium, because they frequently coexist. Q1,R5 In patients with common atrium and atrial isomerism, even more complex associations occur, including DORV, partial or total anomalous pulmonary venous connection, and azygos extension of the inferior vena cava D7,K16,P2,S13,T1 (see Morphology in Chapter 58).

A patent ductus arteriosus can be identified on aortography. Likewise, associated malformations such as tetralogy of Fallot, DORV, transposition of the great arteries, and additional VSDs are identified by a combination of echocardiography and cineangiography.

It is essential to recognize functionally important LV outflow tract obstruction. Narrowing of this tract is inherent in AV septal defects but rarely results in a systolic pressure gradient. Distortion results from the shortened inflow axis of the LV and anterior displacement of the left AV valve complex (Fig. 34-17). Thus, LV outflow obstruction is most prevalent in patients with Rastelli type A valve morphology. P7,S17 This distortion is rarely evident preoperatively as LV outflow obstruction. More frequently, important obstruction becomes evident postoperatively, both early and later. Usually it takes the form of subaortic discrete membranous stenosis, but the process may be relatively diffuse along the outflow tract. Infrequently, it occurs as a result of the ventricular patch component pulling the left AV valve apically and anteriorly such that the new “mitral” valve apparatus narrows the outflow tract. Thus, the initial AV septal repair must place the left AV valve at the appropriate level: caudad toward the apex may result in LV outflow tract obstruction; cephalad toward the atria may result in left AV valve regurgitation.

NATURAL HISTORY

The life history of patients with surgically untreated AV septal defects depends on morphologic and functional details of their malformation. When there is a partial AV septal defect, only mild left AV valve regurgitation, and no major associated cardiac anomaly, life history without surgical treatment is similar to that of patients with large fossa ovalis ASDs (see Natural History in Chapter 30). Important pulmonary vascular disease develops in a small number of patients in their 20s, 30s, and 40s. P4 As in other types of large ASD, symptomatic deterioration of patients in adult life often coincides with development of atrial fibrillation (Fig. 34-18).

Patients with a partial AV septal defect and moderate or severe left AV valve regurgitation have a different natural history. Because of a nonrestrictive interatrial communication, severe left atrial and pulmonary venous hypertension are absent, but the left-to-right shunt is large and pulmonary artery pressure usually at least moderately elevated. Probably at least 20% of such individuals are severely symptomatic in infancy, and without surgical treatment, many would die in the first decade of life.

Patients with a complete AV septal defect have a still more unfavorable natural history. Because no group of infants known to have this malformation has been followed from birth without surgical intervention, the ideal database for delineation of their natural history does not exist. The closest approach is the prospective study of 56,109 live births by Mitchell and colleagues that included 10 infants judged to have isolated complex AV septal defect (excluding four stillbirths with the malformation), 4 of whom died within the first 3 years of life. M15 This information is inconclusive, however, because of the small number of patients involved; failure to obtain a positive diagnosis by surgery, autopsy, or cardiac catheterization in all patients in the study; use of surgical intervention in some cases; and nonreporting of specific ages of the six survivors.
Figure 34-14  Diagrams of altered attachment of left atrioventricular (AV) valve leaflets in AV septal defect compared with normal heart. Heart is shown in its in vivo position as seen in a frontal angiogram. Right ventricle (RV) and most of the ventricular septum and right atrium have been removed. Dashed line indicates portion of line of attachment of left AV valve hidden by other structures. A, Normal heart. Attachment of anterior mitral leaflet (A) begins at anterolateral commissure (AL) and runs anteriorly for a short distance along free wall of left ventricle (LV). It is then continuous with root of aorta in relation to adjacent portion of left coronary (L) and noncoronary (N) aortic cusps. Line of attachment proceeds downward along AV septum to posteromedial commissure (PM). Attachment of mitral valve to AV septum is profiled in right anterior oblique view (see Fig. 34-15). B-C, Partial AV septal defect shown in diastole (B) and systole (C). Scooped-out crest of basal portion of ventricular septum is shown considerably thinner than it actually is. Right AV valve leaflets are shown only at their sites of attachment. Diastolic figure (B) depicts left superior and left inferior leaflets as open; their line of attachment to aortic root is nearly normal, but it then passes along the superior rim of the scooped-out ventricular septal crest. Left superior leaflet is displaced upward into the left ventricular outflow tract, narrowing it. Left inferior leaflet is folded back against left ventricular aspect of sinus septum. In systolic figure (C), left superior and inferior leaflets are closed. Increased left ventricular pressure balloons them toward the atria. Arrow marks their point of coaptation. Key: AP, Anterior papillary muscle; AV, atrioventricular septum; L, left inferior leaflet of atrioventricular valve; LA, left atrium; MS, muscular ventricular septum; P, posterior mitral leaflet; PP, posterior papillary muscle; R, right aortic cusp; S, left superior leaflet of atrioventricular valve; T, tricuspid valve. (From Baron and colleagues.13)
Figure 34-15  Diagrammatic representations of cineangiograms of a normal heart and hearts with atrioventricular (AV) septal defects, in oblique and axial views. A, Mitral valve orifice and leaflet attachments (interrupted line) in right anterior oblique (RAO) and left anterior oblique (LAO) projections. (1) Normal mitral orifice is approximately profiled in 40-degree RAO projection, but is overlapped by left ventricular (LV) outflow tract. Rightward posterior border of normal LV outflow tract is formed by AV septal tissue, not mitral valve. (2) In 50-degree LAO projections, the rightward anterior margin of the normal outflow tract consists of the basal ventricular sinus (inlet) septum: membranous above, muscular below. Mitral valve attachments do not reach the septal margin. (3, 4) In AV septal defects, absence of AV septum and adjacent deficiency of basal (inlet) ventricular septum modify left AV valve attachments and position and shape of left AV orifice and LV outflow tract. B, LV cineangiograms in 40-degree RAO projections. (1, 2) Normal features can be compared with those of typical partial (3, 4) and complete (5, 6) AV septal defect in systole and diastole. In the normal heart, mitral (left AV valve) leaflets contribute only to the lowest portion of rightward posterior LV outflow margin in systole, the relatively immobile AV septum forming the remainder of this margin throughout cardiac cycle in diastole. Line of attachment (m) of mural (posterior) leaflet of mitral valve can be identified, because contrast is trapped between leaflet and adjacent LV wall. In AV septal defects, rightward posterior margin of LV outflow tract consists of mobile leaflet tissue: left superior leaflet (s) above and left inferior leaflet (i) below. AV septum is absent. Mural leaflet attachment lies in relatively normal position. When there is complete attachment of left superior and inferior leaflets to septal crest (dashed line), LV outflow tract deformity is well marked in systole, and position of septal crest can be identified in diastole, with contrast being trapped between open leaflets and septum. When there is a large interventricular communication with superior and inferior leaflets free-floating or attached to septal crest by thin chordae only (5, 6), systolic deformity may be less marked and septal crest may be invisible, because contrast is washed away by non-radiopaque inflow. RAO view separates an AV regurgitant stream (AVR) from an interventricular shunt (VS).
Figure 34-15, cont’d  C, Left ventricular (LV) cineangiograms in 50-degree left anterior oblique (LAO) projection. (1, 2) In normal heart, septal margin of LV outflow tract is uninterrupted in systole and diastole. In AV septal defect (3-8), septal margin is interrupted by defect in basal (inlet) ventricular septum, the defect being continuous with left AV orifice. (3, 4) When left superior (s) and inferior (i) leaflets are completely attached to septal crest, as in partial AV septal defect, leaflet tissue bulges into defect in systole, and position of septal crest (c) can be identified in diastole. (7, 8) When there is a large interventricular communication, systolic flow into right ventricle can be observed passing beneath left superior (upper arrow) or left inferior (lower arrow) leaflets. In diastole, a common AV orifice is identified. (5, 6) In some cases, attachments to septal crest are present but leave smaller interventricular communications. AV valve regurgitation tends to obscure valve detail as overlying atria opacify.

D, LV or left atrial cineangiograms of AV septal defect in 50-degree LAO with cranial angulation (axial, hepatoclavicular, or four-chamber view). (1) Arrows in 40-degree RAO view illustrate why conventional LAO (part C) shows full height of the AV orifice, providing the best separation of left superior from left inferior leaflets. Cranially tilted version of LAO (CR LAO) foreshortens AV orifice and tends to superimpose these leaflets. (2, 3) However, the characteristic deformity of septal and AV orifice anatomy seen in conventional LAO view can be appreciated in axial LAO views, which are shown in both systole and diastole. In addition, midmuscular and apical parts of the sinus septum are better separated from basal defect so that additional muscular defects in cross-hatched area (e.g., at x) may be identified. AV valve regurgitation obscures detail, but partial separation of atria from ventricles improves differentiation of regurgitation from interventricular shunting. With a left atrial or right upper pulmonary venous injection in 50-degree LAO with cranial angulation (4), contrast flow (arrows) early in the sequence shows position of atrial septal defect adjacent to AV valves. Contrast enters right atrium, right ventricle, and left ventricle. Cranial angulation rarely achieves a perfect profile of AV anulus, and ventricular opacification obscures detail later in the sequence. Key: AV, Atrioventricular septum; AVR, atrioventricular regurgitant stream; bs, basal (inlet) portion of ventricular septum; c, septal crest; CR LAO, cranial left anterior oblique; i, left inferior leaflet; l, left coronary sinus of aortic root; LA, left atrium; LAO, left anterior oblique; LV, left ventricle; m, line of attachment of posterior mitral leaflet; N, noncoronary sinus of aortic root; R, right coronary sinus of aortic root; RA, right atrium; RUPV, right upper pulmonary venous injection; RV, right ventricle; s, left superior leaflet; VS, ventricular shunt.
An important event in the natural history is development of severe pulmonary vascular disease. This complication becomes apparent at 7 to 12 months of age in up to 30% of patients with complete AV septal defect and is probably present in 90% of such patients by age 3 to 5 years.\textsuperscript{F3,N2} Thus, its prevalence in early life is higher in patients with complete AV septal defect than in those with large VSD.

In the absence of a definitive prospective study, approximation of natural history of complete AV septal defect has been constructed from 39 patients in two reports of

---

**Figure 34-16** Cineangiograms of atrioventricular (AV) septal defects. A, Partial AV septal defect shown by left ventriculogram in four-chamber position: diastolic frame (left) and systolic frame (right). Loss of straight line contour from aortic valve to crux cordis indicates absence of major part of AV septum. B, AV septal defect with two AV valve orifices and an interventricular communication.
This analysis indicates that about 80% of patients who do not undergo operation die by age 2 years (Fig. 34-19). A child surviving to age 1 year has only about a 15% chance of living to age 5. Those who die in the first 1 to 2 years of life usually do so with heart failure, with or without recurrent pulmonary infections, as a result of the large left-to-right shunt and moderate-to-severe AV valve regurgitation present in 60%. The high incidence of death in the first year of life has been confirmed by Samanek. Thereafter, valve regurgitation and increasing pulmonary vascular disease become dominant factors in the natural history. Newfeld and colleagues showed histologically that advanced pulmonary vascular disease (Heath-Edwards grade 3 and 4; see “Pulmonary Vascular Disease” under Morphology in Section I of Chapter 35) is occasionally present in such infants, even in the first year of life. However, it is...
uncertainty as to the appropriateness of analyses underlying their inferences, however.\textsuperscript{K8,W9}

Another aspect of the natural history of patients with AV septal defects is the tendency of their offspring to have similar defects or other congenital cardiac malformations. Emanuel and colleagues found that 14% of children of mothers with AV septal defects have congenital heart disease; half have tetralogy of Fallot, and half have AV septal defects. This prevalence is much higher than the 2% to 4% among children of parents with other types of congenital heart disease.\textsuperscript{N4}

**TECHNIQUE OF OPERATION**

Surgical treatment of AV septal defects is directed toward (1) closing the interatrial communication, which is virtually always present; (2) closing the interventricular communication if one is present; (3) avoiding damage to the AV node and bundle of His; and (4) maintaining or creating two competent, nonstenotic AV valves.

Repair techniques vary considerably, but when used properly, all appear to provide good results.\textsuperscript{B1,L1} For example:

- One or two patches may be used to repair the malformation when there is large interventricular communication.\textsuperscript{R3}
- A markedly bridging LSL may be divided to facilitate the repair, or it may be left intact.\textsuperscript{B17,R4,S15}

![Figure 34-17 Anatomic specimens (above) and drawings of them (below) contrasting outflow angle in a normal heart compared with that in atrioventricular (AV) septal defect. A, Wide angle between plane of outlet septum and plane of septal crest (outflow angle) in a normal heart. B, Narrow angle in a heart with AV septal defect. Septal crest is scooped out, shortened, and anteriorly displaced; outflow axis is elongated. (From Van Arsdell and colleagues.\textsuperscript{V1})](image)

![Figure 34-18 Cardiac arrhythmias in surgically untreated patients with a partial atrioventricular septal defect according to age. Increased prevalence in older patients is striking. (From Somerville.\textsuperscript{S9})](image) present in nearly 90% of patients older than age 1 year (7 of their 8 specimens).

Bull and colleagues dispute these inferences and deduce a more favorable prognosis for infants with complete AV septal defects based on a study of patients with Down syndrome and this anomaly.\textsuperscript{B21} Careful study of their report generates
in this regard the results are imperfect, particularly in patients without interventricular communications. The same improvements have been obtained while retaining the single-patch technique. Addition of intraoperative transesophageal echocardiography (TEE) to assess completeness of repair provides a further safeguard against an imperfect anatomic and functional result.

**Figure 34-19** Life expectancy without surgery of patients with complete atrioventricular septal defects. A, Plus signs represent nonparametric survival estimates; solid line, with its 70% confidence limits (dotted lines), represents parametric survival estimates. Note that probability of surviving beyond 6 months is 50%, and beyond a year is only 30%. B, Hazard function according to age. Note that risk of dying is highest in the first few months of life. (From Berger and colleagues.)

Methods described in this chapter are the product of experiences in several centers and have improved surgical results. They avoid functionally important damage to the conduction system, provide complete and permanent closure of interatrial and interventricular communications, and are suitable for the many variations across the spectrum of AV septal defects. They are well adapted to cases with major associated cardiac anomalies. They retain AV valve competence when it is present, minimize occurrence of valve repair dehiscence, and generally abolish or lessen AV valve regurgitation, although

---

- The AV node and bundle of His may be avoided by staying on the LV and left atrial side (McGoon DC: personal communication, 1978) or by staying on the right side of the septum.
- Contiguous surfaces of the LSL and LIL may be sutured together, or the left AV valve may be left as a tricuspid structure.
- The patch may be attached to leaflet tissue by simple sutures or by pledgeted mattress sutures with some sort of sandwich method, with assortment of techniques employed to establish AV valve competence.

Methods described in this chapter are the product of experiences in several centers and have improved surgical results. They avoid functionally important damage to the conduction system, provide complete and permanent closure of interatrial and interventricular communications, and are suitable for the many variations across the spectrum of AV septal defects. **Repair of Complete Atrioventricular Septal Defect with Little or No Bridging of Left Superior and Left Inferior Leaflets: Rastelli Type A**

**Two-Patch Technique**

After the usual preparations, a median sternotomy is made, a large piece of pericardium is removed and set aside, and pericardial stay sutures are applied. External cardiac anatomy is evaluated and a left superior vena cava sought. If one is present, there is a 50% chance of associated unroofed coronary sinus syndrome. Purse-string sutures are placed.

In patients weighing less than 5 kg, repair may be performed with limited cardiopulmonary bypass (CPB) with a single venous cannula and hypothermic circulatory arrest; in larger patients, standard CPB is used. Alternatively, in both infants and older children, hypothermic CPB at 20°C and cold cardioplegia may be used. In this method, the cavae are cannulated directly with thin-walled, right-angled metal cannulas (see “Venous Cannulation” in Section III of Chapter 2). CPB flow is reduced to about 1.2 L · min⁻¹ · m⁻² when the patient’s temperature reaches 20°C. Short periods of circulatory arrest or low flow perfusion are occasionally used if visibility is not excellent. As cooling proceeds, the aorta is clamped, and cold cardioplegic solution is injected. The right atrium is opened widely, and a sump sucker is passed through the foramen ovale into the left atrium. Stay sutures are applied.

The malformation is examined and each morphologic detail noted (Fig. 34-20). Morphology of the LSL and LIL is noted carefully with the leaflets in both the closed and open positions. Cold saline solution is injected once or twice through the valve and the closure pattern and any regurgitant leaks studied (Fig. 34-21, A-C). The most anterior point of LSL-LIL opposing edges is found, and a double-armed 6-0 or 7-0 polypropylene suture is placed through it. Leaflet stay and marking sutures are placed, measurements are made, and the polyester interventricular patch is trimmed.

The patch is sutured to the right side of the crest of the ventricular septum with continuous polypropylene suture (Fig. 34-21, D and E). Chordae of the RSL and RIL stay on the right ventricular side of the patch; those of the LSL and LIL stay on the LV side, and some may be cut if they interfere with the suturing, because the anterior edges of these leaflets will be sutured to the polyester patch.

When this phase is completed, the marking suture on the anterior edges of the coapting surfaces of the LSL-LIL complex is passed through the appropriate point of the edge of the polyester ventricular defect patch. The pericardial interatrial patch is then trimmed to appropriate shape and size, and the first part of its insertion is accomplished (Fig. 34-21, F). For this, interrupted mattress sutures of 5-0 or 6-0 polyester are placed to enclose anterior edges of the LSL and LIL between the polyester patch below and pericardial patch above. Alternatively, left-sided leaflet tissue is anchored as a separate maneuver to the polyester patch; the pericardial atrial
The interventricular patch is in place to study its closure pattern and competence. A few additional “tailoring sutures” are placed without tension along the coapting surfaces of the LSL and LIL near the patch, if needed, to prevent systolic eversion or prolapse; usually they are not required. If a central leak (at the point of junction of LSL, LIL, and LLL) persists, an additional septal patch is then sewn to the leaflet-patch line of attachment. Great care is taken to ensure alignment of left AV valve leaflets is perfect and without distortion during this process.

Saline solution is again injected through the left-sided portion of the AV valves (two orifices are present once the interventricular patch is in place) to study its closure pattern and competence. A few additional “tailoring sutures” are placed without tension along the coapting surfaces of the LSL and LIL near the patch, if needed, to prevent systolic eversion or prolapse; usually they are not required. If a central leak (at the point of junction of LSL, LIL, and LLL) persists, an

**Figure 34-20** Repair of complete atroventricular (AV) septal defect; right atrial view, showing two variations of bridging. **A**, Bridging grade 1. **B**, Bridging grade 4. In both there is a common AV orifice and interventricular communication. AV node lies on right side of inferior (caudal) atrial septal remnant at its junction with floor of right atrium over crux cordis. Node pierces abnormally formed central fibrous body to become the short penetrating portion of bundle of His. This structure immediately becomes the branching bundle, which gives off left bundle branches earlier than normal as it travels along crest of ventricular septum. **C**, Cross-section through AV septal defect with common AV valve orifice showing mild bridging of left inferior leaflet (LIL) and scooped-out crest of ventricular septum. View is anterior to posterior. Key: **CS**, Coronary sinus; **LSL**, left superior leaflet; **RSL**, right superior leaflet.
Figure 34-21  Repair of complete atrioventricular (AV) septal defect. A, After right atrium is opened, valve leaflets are often closed exactly as they are in systole. If, instead, they are open, saline is injected into left ventricle to close them. At this point, morphology of the leaflets, particularly their closure pattern, is studied and information obtained is used to plan repair of any regurgitation present or accommodate any lack of left AV valve tissue. B, A fine polypropylene suture is placed between left superior leaflet (LSL) and left inferior leaflet (LIL) in position shown (anterior aspect) and left loose. C, Leaflets are allowed to open, and details of atrial and ventricular septal deficiencies and of interatrial and interventricular communications are studied. Position of coronary sinus (CS) is noted, and course of the unseen AV node and bundle of His is conceptualized by surgeon from knowledge of the anatomy. Leaflets are retracted as much as possible and projected width (shown here) and depth of AV patch estimated. Planned suture line of interventricular patch to ventricular septum and free wall is thus visualized by surgeon. D, Polyester ventricular patch is trimmed to a flat, rectangular-pyramidal shape. Suture line may begin anywhere along ventricular septum, but it must be on the right ventricular side of all chordae from left-sided leaflets, including those from any bridging components of the LIL. Retractor in right inferior aspect of the common valve marks position in which base of right inferior leaflet (RIL) is sandwiched between ventricular and atrial patches. Suture line here stays well back from crest of interventricular septum and catches some of the base of the RIL to avoid the bundle of His.

Continued
E. Suture line for interventricular patch is completed anteriorly, retracting defect posteriorly and elevating the RSL to expose the aspect of the defect closest to left ventricular outflow tract. Width of patch at the valve level will be less than its width deeper on ventricular septum level. 

F. Left superior leaflet (LSL) and left inferior leaflet (LIL) are precisely anchored to ventricular septal patch using fine interrupted simple or mattress sutures. It is here that care is taken to ensure that the left-sided valve apparatus at the patch is appropriately narrow so as not to create regurgitation and at the correct height so as not to produce left ventricular outflow tract narrowing (too low) or left AV valve regurgitation (too high). To provide accuracy, the previously placed fine stay suture joining LSL and LIL is positioned approximately at midpoint of the suture line. 

G. Pericardial patch for closure of the atrial defect is trimmed to size and a new suture line is begun with bites incorporating pericardial patch, left AV valve tissue (at its junction with the top of the polyester patch), and polyester patch, sandwiching delicate left AV valve tissue between pericardium and fabric. Initial suturing at crest of polyester patch can be done with the pericardial patch folded leftward toward left AV valve. Conduction system is avoided by extending the pericardium to the right of the coronary sinus, leaving its drainage to left atrium. Competence of left (and right) AV valve is next tested with saline injection. If necessary, small anuloplasty sutures can be placed between LSL and left lateral leaflet (LLL) and between LIL and LLL. 

H. Remainder of pericardial patch is sutured inferiorly and then superiorly to rim of atrial defect, often also incorporating closure of foramen ovale defect. 

Key: RLL, Right lateral leaflet; RSL, right superior leaflet.
acceptable if within 2 SD of normal for the size of the patient (z value is −2 or greater; see Chapter 1, Appendix 1D, Table 1D-2).

Repair is completed by suturing the rest of the pericardial interatrial patch in place, with the suture line passing around the AV node and bundle of His and not across them (Fig. 34-21, G and H). The right-sided leaflets are usually not sutured to the patch because they close competently without this. If any commissural tissue between the LSL and RSL or LIL and RIL is cut, the right side of this (as well as the left side) is sutured to the patch.

Rewarming of the patient is begun (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2). A few sutures are placed, but not pulled up or tied, for closure of the foramen ovale. Air is evacuated through the foramen ovale, and the aortic clamp is removed with suction on the needle vent.

The first stitch for closure of the right atriotomy is placed at its inferior angle, and closure of the right atriotomy is continued up to the midportion. Usually, cardiac action has begun by then, so the pump sump-sucker is removed from the right atrium and sutures closing the foramen ovale are tied, with care taken to avoid trapping air in the left atrium. The remainder of the right atrium is closed and caval tapes released. Assessment at this stage of the morphologic and functional result by two-dimensional color flow Doppler TEE is useful.37 If important abnormalities are present, CPB and cardioplegia are reestablished and corrections made. Otherwise, the remainder of the operation is completed in the usual manner (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2 and “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3). Left and right atrial and pulmonary artery pressure-monitoring catheters are placed.

Alternatively, when hypothermic circulatory arrest is used in infants, circulatory arrest is continued until the right atrium is closed, provided the procedure can be completed within 45 minutes (which is usually possible). The single venous cannula is then reinserted, the heart is de-aired, CPB for rewarming is begun, and the remainder of the procedure continues as usual. (For repair that requires more than 45 minutes, the sequence described in Chapter 2, Section IV, is adopted.)

Repair of Complete Atrioventricular Septal Defect with Bridging of Left Superior Leaflet: Rastelli Type B or C

Repair is similar to that just described, but special consideration is given to the LSL. Whether bridging is moderate (Rastelli type B) or marked (Rastelli type C), the commissure between it and the RSL is generally only slightly on the right ventricular side of the intersection of the atrial (and ventricular) septum with the anulus. This location is critically important because, again, suturing for insertion of the interventricular polyester patch usually begins in the anulus at the level of this commissural tissue. If suturing in the anulus is too far anterior—that is, too far on the right ventricular side of the junction of anulus with atrial septum—either by error or because the LSL-RSL commissure is far anterior, the right AV valve orifice will be too narrow. Narrowing of its orifice can also be produced by attaching the interventricular polyester patch too far to the right of the crest of the septum with the first few superior (cephalad) stitches. Compensation too far leftward narrows the LV outflow tract.

The interventricular patch is slid beneath the chordae going from the right extremity of the LSL to right ventricular papillary muscles. The interventricular patch must have appropriate dimensions and configuration (Fig. 34-22). If the patch is excessively wide (in a superior-inferior direction), there is greater likelihood of postoperative LV outflow tract obstruction. If the patch is excessively long (deep, in a caudad-cephalad direction), there is a greater likelihood of left AV valve regurgitation.

Incising the LSL from its free edge to the anulus is rarely necessary, although in extreme cases in which a small right AV valve would otherwise result, it may be done, with both divided edges later sutured onto the interventricular polyester patch.

Repair of Complete Atrioventricular Septal Defect with Single-Patch Technique

Repair using a single patch differs from the two-patch technique in the following ways: (1) the single patch is almost always pericardium, (2) tailoring the waist of the patch (at the level of the AV valves) is critical, and (3) both the LSL and RSL and the LIL and RIL are sutured to the patch. Setup using bicaval cannulation is the same as for the two-patch technique, making sure that the inferior vena cava cannula is placed well caudad at the cavoatrial junction. CPB is established at 20°C to 24°C, and antegrade cardioplegia is infused after aortic clamping. The right atrial incision is made and atrial exposure is arranged as for the two-patch technique. The most anterior point of LSL-LIL apposing edges is identified, and a 6-0 polypropylene suture is placed to retain that apposing relationship. Bridging leaflets superiorly and occasionally inferiorly are incised laterally to the valve anulus (Fig. 34-23, A). This maneuver allows easy later exposure for closing the intraventricular portion of the defect and accommodating the waist of the patch.

The patch for the ventricular septal closure is inserted using continuous polypropylene or interrupted synthetic braided mattress sutures. Generally the initial suture is placed at the midpoint of the ventricular defect and is continued upward anteriorly (Fig. 34-23, B). Posteriorly, the suture line stays behind the rim of the defect to avoid conduction fibers. Both left and right AV valve leaflets are then anchored to the waist of the patch using double-pledgeted horizontal mattress sutures (Fig. 34-23, C). Pledgets are
Figure 34-23 Complete atrioventricular (AV) septal defect repair, single-patch technique. A, Right atriotomy is made as for two-patch technique and AV valves are inspected. Saline is infused into ventricles as for two-patch technique, and apposition point of left superior leaflet (LSL) and left inferior leaflet (LIL) is identified as the leaflets float up to their systolic position. A fine guy suture is placed for alignment and left loose. Frequently, the bridging LSL or LIL is incised to gain access to the anterior portion of interventricular defect. Later, each cut edge of the superior leaflet will be attached to pericardial patch at its waist. B, Fresh or glutaraldehyde-treated pericardial patch is trimmed partially after measuring height and width of interventricular communication. Generally, ventricular portion of patch is attached to right side of crest of ventricular septum using a continuous suture initiated at the deepest aspect (midpoint) of the rim of the ventricular septal defect (VSD). Usual precautions are taken as in the two-patch technique to avoid the bundle of His at posterior-inferior aspect of ventricular defect. C, AV leaflets, both left and right, are attached to pericardial patch at appropriate level. As in the two-patch technique, the central guy suture, which approximates the gap between LSL and LIL, helps position the AV valves at correct height and midpoint on the single pericardial patch. Interrupted horizontal mattress sutures incorporate bites of right-sided valve tissue, pass through pericardium, and end with bites of left-sided valve tissue. Small pledgets of pericardium may be used to buttress sutures on left and right AV valve tissue. Several additional sutures complete closure of gap between LSL and LIL.

generally of pericardium; often a single strip is used on the left-sided aspect. The strip is made a little shorter than the anteroposterior width of the anulus to somewhat narrow the anulus and contribute to AV valve competency. The level of this suture line (in a cephalad-caudad direction) must ensure that height of the AV valve anulus is such that left AV valve regurgitation is avoided (patch too high) and LV outflow obstruction is not produced (patch too low). At this point, the LV is loaded by saline injection to test valve competency and VSD closure. The left AV valve cleft is closed.
with fine interrupted sutures at its opposing edges to the previously placed marking suture. At this point if necessary, anuloplasty sutures (horizontal mattress) are placed at the two lateral commissures. Repair of the remaining atrial defect proceeds as for the two-patch technique (Fig. 34-23, D), outside the rim of the coronary sinus and including the foramen ovale defect. The completed single pericardial patch has a lopsided, dumbbell-shaped configuration (Fig. 34-23, E).

Repair of Complete Atrioventricular Septal Defect with Modified Single-Patch Technique

In 1997, Wilcox and colleagues reported direct suturing of the AV valves to the ventricular septum in complete AV septal defects with a small ventricular component. Others extended the application of this technique to all forms of complete AV septal defects, with no division of valve leaflets or chordae, and reduced operative time.

Key features of the procedure are illustrated in Fig. 34-24. Interrupted pledgeted 5-0 braided sutures are placed on the right side of the interventricular septal crest (as in the ventricular septal suture line of the standard ventricular patch technique) and passed through the bridging LSL and LIL. These sutures are then passed through the edge of the autologous pericardial patch used to close the atrial defect and through a thin strip of polyester whose length is slightly shorter than the corresponding ventricular septum, with the intent of producing a central anuloplasty of the LSL and LIL. These sutures are tied, and the remainder of the operation proceeds as in the single- or two-patch techniques.

Nunn and colleagues reported uniform application for all patients with complete AV septal defects, 30-day mortality of less than 2%, no reoperations for residual VSDs, and no reoperations for LV outflow tract obstruction out to a median follow-up of 7.3 years. This procedure has now been widely applied in the setting of shallow ventricular defects. General acceptance of its wider application to all defects awaits analyses from other institutions.

Repair of Partial Atrioventricular Septal Defect with Little or No Left Atrioventricular Valve Regurgitation

Repair is similar to that described for complete AV septal defects, but no interventricular polyester patch is required. After CPB is established, intraatrial exposure is arranged, cold cardioplegic solution infused, and morphology studied. Attachments of the LSL and LIL to the crest of the ventricular septum are probed to be certain there are no small interventricular communications.

The “cleft” in the AV valve is then identified and its medial and septal extremities noted (Fig. 34-25, A-C). In the past, if there were no left AV valve regurgitation, nothing was done to the valve at the cleft (commissure). More recently, most surgeons obliterate this gap (close the cleft) using several interrupted simple sutures or pericardial pledgeted mattress sutures. The margins here are characterized by slightly thickened and rolled edges, and it is at these margins that sutures are based.

An anuloplasty stitch may also be placed at the LSL-LLL commissure. The intraatrial pericardial patch is sewn into place in the same way used for repairing complete AV septal defect (Fig. 34-25, D; see also Fig. 34-21). Small, pledgeted mattress sutures of 5-0 or 6-0 polyester are passed from the right ventricular side through the base of the RIL and the
bridging part of the LIL and through the pericardial patch. More cephalad, the patch is sewn to fibrous valvar tissue attached to the crest of the ventricular septum in this reinforced manner, analogous to its suturing to the top of the polyester patch (see Fig. 34-21).

Repair of Atrioventricular Septal Defect with Small Interchordal Interventricular Communications (Intermediate Form)

When two AV valve orifices are present but small interventricular communications exist between thick, short chordae attaching the LSL to the crest of the ventricular septum, repair is simple. The interventricular communication is simply closed by taking the anterior portion of the pericardial patch just to the right side of the septal crest, catching the base of the LSL with each stitch.

When the interventricular communications are beneath the LIL, the same maneuver may be followed. However, because of the bundle of His, care must be taken to keep the suture line well away from the crest of the septum and to attach the patch in the same manner in which the interventricular patch is attached in repair of complete AV septal defects.

Repair of Atrioventricular Septal Defect with Common Atrium

When a common atrium is present, either with or without an interventricular communication, special effort is made to ensure that there is no left superior vena cava or, if one is present, that there is not a completely unroofed coronary sinus, which would change the repair (see Technique of Operation in Chapter 33).

Repair is accomplished by sewing an appropriately larger pericardial patch to the atrial wall on the left atrial side of the orifice of the inferior vena cava, to the right of the right pulmonary veins, and beneath the superior vena cava (where there is usually a small septal remnant).

Repair of Complete or Partial Atrioventricular Septal Defect with Moderate or Severe Left Atrioventricular Valve Regurgitation

For repair of an AV septal defect with moderate or severe left AV valve regurgitation, results seem to vary from one institution to another, even when the same techniques have apparently been used.

In the repair of complete AV septal defects, the primary determinant of left AV valve competence, particularly when preoperative AV valve regurgitation is moderate or less, is accurate sizing of the ventricular patch (or patch component) to produce an anuloplasty effect (width somewhat less than the combined width of the LSL and LIL) and avoiding elevation by the patch of the LSL and LIL above their pre-repair level (see Fig. 34-22). If the size and placement of the patch have been imperfect, this should be corrected.

If the patch and its placement are considered optimal, the basic options depend on observations about location and mechanism of regurgitation by filling the LV with saline:

- If the major leakage is between the LSL and LIL, the “clef” is partially or completely closed with interrupted 5-0 polypropylene or braided sutures, which may be reinforced with small bovine pericardial pledgets if the leaflet tissue is fragile.
If the leakage is central or at the commissure between the LLL and LSL or between the LLL and LIL, anuloplasty sutures (with or without pledgets) are placed to reduce anular circumference. In cases of marked central leakage and an enlarged orifice, a more extensive anuloplasty of the LLL and its commissures using a polytetrafluoroethylene band has been reported.\textsuperscript{K5}

If leakage is through accessory clefts, they may be partially closed. When the repair is completed and leakage is trivial or absent by saline injection, the remaining orifice is sized with Hegar dilators; a measured diameter yielding a $z$ value of $-2$ or greater is generally adequate to avoid valve stenosis.

In the presence of persistent moderate to severe residual regurgitation (particularly in the reoperative setting) despite the maneuvers described above, two other more radical techniques may be applied:
When there is severe central regurgitation, particularly in the presence of leaflet prolapse, the LLL and the reconstructed anterior leaflet may be approximated with a pledgeted mattress suture, creating a double orifice valve. To avoid physiologic stenosis, care must be taken that the orifice of the reconstructed “mitral” valve is somewhat larger than normal (probably a z value of +1 or larger) before placing the approximation suture.

An additional procedure in the presence of leaflet deficiency that has reported short- and mid-term success is patch augmentation of the neoanterior leaflet.

If moderate or severe left AV valve regurgitation remains, repair should be immediately reassessed. If, in the surgeon’s judgment, improvement by further repair is possible, the patient is returned to CPB. If no further repair is likely, valve

**Figure 34-25, cont’d**  
C, Cleft is closed with interrupted sutures; if necessary, anuloplasty sutures are added. D, Defect is closed with a pericardial patch, placed in a fashion similar to that used in the two-patch technique for repair of complete AV septal defect. It is inserted using fine continuous polypropylene suture. Suture line begins at the confluence of left- and right-sided AV valves over ventricular septum and passes rightward and caudally over right inferior leaflet to surround the coronary sinus (CS), leaving coronary sinus draining to left atrium. E, An alternative to avoid the conduction system is the McGoon technique. Patch is sutured to base of left-sided valve tissue, and in area near conduction system, superficial bites are taken. Key: *LIL*, left inferior leaflet; *LSL*, left superior leaflet; *RIL*, right inferior leaflet; *RSL*, right superior leaflet.

**Figure 34-26**  
Creating a double orifice valve for persistent severe left ventricular valve regurgitation. Lateral leaflet and reconstructed anterior leaflet have been approximated. (From Mitchell and colleagues.)
areas are larger than usual and handicap exposure. Then they may be incised back to the anulus, once it is certain that this is commissural tissue! Tissue on the LV side is incorporated into the repair along with the LSL or LIL. That on the right side should be reattached to the patch with a few sutures at the end of the repair.

Replacement of Left Atrioventricular Valve

When severe left AV valve regurgitation cannot be repaired, or when it persists or develops postoperatively, left AV valve replacement may be necessary. Because the left AV valve nearly always encroaches on the LV outflow tract (see Figs. 34-5, A and 34-10), valve replacement may accentuate or produce subaortic stenosis. The prosthesis must therefore be kept away from the subaortic area. This may be accomplished by attaching a rectangular piece of polyester to the anulus of the left AV valve in the subaortic area (Fig. 34-28). (Poirier and colleagues describe the outcome of eight patients in which similar augmentation was used at reoperation to increase deficient bridging leaflet coaptation without valve replacement.) The prosthesis is then sutured to this artificial mitral-aortic anulus and to the natural anulus for the rest of its circumference. To minimize the chance of damage to the AV node and bundle of His, particular care is taken anteriorly and inferiorly to sew only to the fringe of left AV

Right Atrioventricular Valve

In hearts with or without interventricular communications, the right AV valve usually does not require attention. Two-patch repair leaves this valve without a complete “septal leaflet,” but in this and other situations, regurgitation does not result. The RSL and RIL (and the RLL) are well supported by chordae, and this, combined with their closure against the polyester patch or bare ventricular septum, generally results in adequate valve function. However, the right AV valve should be analyzed separately with saline injection and Hegar sizing (valve diameter should provide a z value of −2 or greater). If important leakage is identified, it should be surgically addressed. Often, attachment of the RIL to the VSD patch will correct the leakage.

Left Superior Leaflet–Right Superior Leaflet and Left Inferior Leaflet–Right Inferior Leaflet Commisures

Generally, repair of LSL-RSL and LIL-RIL commissures can be made without disturbing the commissural leaflet tissue in these areas. Occasionally, however, these commissural leaflet replacement is performed. If the patient is small, no further intervention is feasible, and the infant is managed as well as possible postoperatively.

Figure 34-27 Leaflet augmentation technique using glutaraldehyde-treated autologous pericardium for severely dysplastic left atrioventricular valves. A, Radial incision adjacent to anulus is made in superior and inferior bridging leaflets from commissure to commissure. B, Abnormal secondary chords to ventricular side of leaflet are divided. C, Patch of autologous glutaraldehyde-treated pericardium is sutured in place, augmenting anterior leaflet. Tension-free closure of cleft is now possible. Key: LIL, Left inferior leaflet; LLL, left lateral leaflet; LSL, left superior leaflet.
and anterior deviation of the infundibular septum is always present and must be considered in the repair. Preoperative cineangiographic studies are often necessary to delineate the surgically important details of right ventricular outflow obstruction and morphology of the pulmonary arteries.

Operation is begun as for repair of any complete AV septal defect. Before heparinization, however, if a right ventricular outflow patch is required, an appropriately sized patch is prepared as described in Section I of Chapter 38 (see “Decision and Technique for Transanular Patching” under Technique of Operation). The VSD patch is trimmed with a wide superior aspect, which is important in preventing left ventricular outflow obstruction.

Usually the anteriorly deviated parietal extension of the infundibular septum (band) can be seen through the AV valve, and it is cut and mobilized (see “Repair of Uncomplicated Tetralogy of Fallot with Pulmonary Stenosis via Right Atrium” under Technique of Operation in Section I of Chapter 38). Other muscular infundibular obstructions can be visualized and resected. The pulmonary valve can be visualized and fused commissures opened. The right ventricular outflow tract is sized with Hegar dilators. At this point the surgeon may decide on a combined right atrial–right ventricular (RA-RV) approach. If so, a small vertical incision is made in the right ventricular outflow tract, and parietal and septal extensions are mobilized and partially resected. This incision is later closed with a small patch.

Repair of Complete Atrioventricular Septal Defect with Tetralogy of Fallot

In complete AV septal defect associated with tetralogy of Fallot, the large VSD is also juxtaaortic. The LSL bridges moderately (grade 3) or markedly (grades 4 or 5) and is not attached to the crest of the ventricular septum. Any of the types of right ventricular outflow tract obstruction associated with tetralogy of Fallot may be present (see “Convenient Morphologic Categories of Right Ventricular Outflow Obstruction” under Morphology in Section I of Chapter 38), and anterior deviation of the infundibular septum is always present and must be considered in the repair. Preoperative cineangiographic studies are often necessary to delineate the surgically important details of right ventricular outflow obstruction and morphology of the pulmonary arteries.

Operation is begun as for repair of any complete AV septal defect. Before heparinization, however, if a right ventricular outflow patch is required, an appropriately sized patch is prepared as described in Section I of Chapter 38 (see “Decision and Technique for Transanular Patching” under Technique of Operation). The VSD patch is trimmed with a wide superior aspect, which is important in preventing left ventricular outflow obstruction.

Usually the anteriorly deviated parietal extension of the infundibular septum (band) can be seen through the AV valve, and it is cut and mobilized (see “Repair of Uncomplicated Tetralogy of Fallot with Pulmonary Stenosis via Right Atrium” under Technique of Operation in Section I of Chapter 38). Other muscular infundibular obstructions can be visualized and resected. The pulmonary valve can be visualized and fused commissures opened. The right ventricular outflow tract is sized with Hegar dilators. At this point the surgeon may decide on a combined right atrial–right ventricular (RA-RV) approach. If so, a small vertical incision is made in the right ventricular outflow tract, and parietal and septal extensions are mobilized and partially resected. This incision is later closed with a small patch.
The interventricular communication is closed by suturing into place a polyester or pericardial patch from this right atrial approach, sequencing the repair exactly as described for other complete AV septal defects. This can be accomplished with a single- or two-patch technique. With either, the shape of the ventricular component of the patch must be modified to account for the anterior-superior extension of the interventricular communication. Familiarity with the atrial approach for repair of isolated VSD (see Technique of Operation in Section I of Chapter 35) and for repair of the VSD in simple tetralogy of Fallot (see “Repair of Uncomplicated Tetralogy of Fallot with Pulmonary Stenosis via Right Atrium” under Technique of Operation in Section I of Chapter 38), as well as familiarity with repair of uncomplicated complete AV septal defects, are important preparations for this procedure. Stay sutures are placed as usual for transatrial repair. Repair is begun at the AV valve anulus superiorly, where the atrial septal remnant meets the anulus.

Care must be taken that repair does not begin too far rightward, in which case the right side of the surgically partitioned AV valve orifice will be too small. Because of the dextroposed aorta, attachment of the VSD patch to tissue over the aortic root (and beneath the commissural tissue and RSL) is particularly important. The patch is generally beneath (on the left ventricular side of) chordae attached to the right extremity of the bridging LSL and beneath this leaflet itself. Because this leaflet will be attached to the VSD patch, some of these chordae may be cut to facilitate exposure. In the single-patch technique, the entire bridging leaflet is incised. The suture line is then carried around the interventricular communication and along the base of the RIL as described earlier for the usual complete AV septal defect. When the aorta overrides the interventricular septum to a considerable degree (and when DORV is present), the juxtaaortic portion of the repair may be completed through a small infundibular incision. Remainder of the AV septal defect is repaired as described earlier.

The right ventricular outflow tract is again sized with Hegar dilators. If it is adequate, nothing further is done. Otherwise, it is enlarged by an infundibular patch, or, if necessary, a transanular patch (see “General Plan and Details of Repair Common to All Approaches” under Technique of Operation in Section I of Chapter 38). Moderate or severe pulmonary regurgitation should be avoided because associated right ventricular dilatation may result in severe right AV valve regurgitation from deficiency of right-sided AV valve tissue. Therefore, the threshold for inserting a valve (monocusp or allograft) in the right ventricular outflow tract is lower than usual.

Repair of Complete Atrioventricular Septal Defect with Double Outlet Right Ventricle

When the interventricular communication is large and subaortic, configuration and insertion of the interventricular patch are similar to that just described for tetralogy of Fallot. Pulmonary stenosis, when coexisting, is also treated similarly.

When the interventricular communication is not subaortic and cannot be converted into one by septal excision (see “Intraventricular Tunnel Repair of Double Outlet Right Ventricle with Noncommitted Ventricular Septal Defect” under Technique of Operation in Chapter 53), a Fontan repair (see Technique of Operation in Section IV of Chapter 41) is necessary if pulmonary stenosis coexists.

Repair with Transposition of the Great Arteries

When size of the LV allows it, usual repair of the AV septal defect is carried out and an arterial switch operation is performed (see “Arterial Switch Operation” under Technique of Operation in Chapter 52).

SPECIAL FEATURES OF POSTOPERATIVE CARE

Usual care as described in Chapter 5 is accorded patients after repair of AV septal defects, but certain features require emphasis. Because of the complexity of repair and despite the generally good results now obtained, vigilance must be exercised to detect any important imperfections in the repair. Thus, TEE or transthoracic echocardiography (if the infant is small) is of great help in the operating room and a few hours after the patient’s return to the intensive care unit to verify complete closure of the interatrial and interventricular communications and absence of important AV valve regurgitation. Left atrial pressure more than 6 mmHg higher than right atrial pressure raises the possibility of either severe left AV valve regurgitation or stenosis, although it can result simply from small size and low compliance of the LV (see Chapter 5). Height of the r wave is not helpful because, as in all circumstances, this correlates more with height of mean left atrial pressure than with degree of regurgitation. Usual prophylaxis is taken against pulmonary hypertensive crises. Generally this includes introducing a pulmonary artery catheter intraoperatively. Because average age at repair has decreased, this complication is seen less frequently now (see “General Care of Neonates and Infants,” Section IV of Chapter 5).

If the patient’s condition is not optimal and important residual left AV valve regurgitation is suspected—particularly if deterioration continues over several hours—repeat echocardiographic study in the intensive care unit is advisable. If results of this study are inconclusive, left ventriculographic studies (or some other reliable method of quantifying left AV valve regurgitation) should be considered. Indirect indications, both in the operating room and early postoperatively (including absence of a murmur), are unreliable. If severe regurgitation is demonstrated, reoperation is indicated. Likewise, if the patient’s condition is unsatisfactory and a large residual left-to-right shunt is present, reoperation is indicated.

When the patient does not convalesce normally, echocardiographic and possibly left ventriculographic studies before hospital discharge are indicated. Because left AV valve repair failure predisposes the patient to death within the first year after operation, consideration should be given to early reoperation if severe regurgitation is found.

RESULTS

Survival

Early (Hospital) Death

Hospital mortality after repair of partial AV septal defects has been low for a long time, dating back to the early experience reported from the Mayo Clinic. In the current era, hospital mortality generally is 1% or less. 

\footnote{M13}
Hospital mortality after repair of uncomplicated complete AV septal defects was 30% to 50% during the early years of cardiac surgery, but has declined steadily in recent years. This has been the result of greatly improved understanding of the morphology of this complex malformation, better surgical techniques, and general improvements in cardiac surgery in infants. These improvements are evident in most major pediatric cardiac surgical programs. Improvement in hospital mortality has been particularly evident in infants.

Major congenital heart disease centers report mortality of under 3% for patients with complete AV septal defects with balanced ventricles undergoing repair in the first 3 to 6 months of life. As is often the case, results from individual centers of excellence are superior to results from unselected institutional studies. The Pediatric Cardiac Care Consortium reported results of 10 years of activity in 25 institutions within the United States. Overall operative mortality was 14% and did not differ between Down and non-Down patients. There were a total of 768 cases, averaging three cases per year per institution. This report should be contrasted with individual institutional reports demonstrating low mortality representing caseloads of 20 to 50 yearly.

Even when complete AV septal defect coexists with other major cardiac anomalies such as tetralogy of Fallot, hospital mortality remains generally low. However, other less common major associated anomalies with both partial and complete AV septal defects impose a considerable increase in hospital mortality.

**Time-Related Survival**

Late outcomes are generally good, with reported 15-year survival of 80% to 90%.

### Incremental Risk Factors for Premature Death

#### Earlier Date of Operation

An earlier date of operation as a risk factor in a surgical experience that covers a large number of years, as that at UAB (Table 34-11), demonstrates that many risks of repair have been neutralized across the experience. Others report similar experiences. The effect of date of operation on outcome is just as evident in long-term events as it is in hospital mortality. This is dramatically evident in predicted 10-year survival after repair of partial and complete AV septal defects in patients operated on in 1967 versus 1977 and 1985 (Fig. 34-29).

#### Higher New York Heart Association Functional Class

As in most cardiac surgery, severe preoperative disability (higher New York Heart Association [NYHA] functional class) is a risk factor for premature death in both the early and constant hazard phases (see Table 34-11).

#### Important Pre-Repair Atrioventricular Valve Regurgitation

Important pre-repair regurgitation of either the left AV valve in partial AV septal defects or the common AV valve in complete AV septal defects increases risk of premature death, but only in the constant hazard phase (see Table 34-11). This suggests that post-repair moderate regurgitation, the prevalence of which is almost surely increased by severe preoperative regurgitation in patients with partial AV septal defects but probably less so in patients with complete AV septal defects, is reasonably well tolerated early postoperatively but becomes more serious several months later. However, severe left AV valve regurgitation is poorly tolerated in infants post-repair and is a risk factor for early mortality (see Table 34-11).

#### Interventricular Communication

An interventricular communication (complete AV septal defect) has been an important risk factor, but only in the early declining hazard phase. The effect of this aspect of morphology indicates that outcomes after repair of complete AV septal defects currently approximate those of partial AV septal defects, which have been excellent for many years (see Fig. 34-29). Residual interventricular communication after repair of complete AV septal defect may be an infrequent cause for reoperation and a risk factor for premature death. Early postoperative residual VSD should be suspected in the presence of “pulmonary hypertensive crisis” and low cardiac output.

Data from Kirklin and colleagues and Hanley and colleagues. Key: AV, Atrioventricular; LV, left ventricular; NYHA, New York Heart Association; VSD, ventricular septal defect.
Unbalanced Atrioventricular Septal Defects

From Kirklin and colleagues.

Late death from mitral regurgitation. The left AV valve may also be easier to repair, lessening the likelihood of survival than patients without Down syndrome. The left AV valve function considerably. Also, decreased prevalence of LV inflow and outflow obstruction affects risk of premature death early or late after repair, except for complete AV septal defects with or without major associated cardiac anomalies, according to year in which operation was performed. Solid lines are survival estimates, and dashed lines are 70% confidence limits. (See original publication for details, risk factors, coefficients, and $P$ values of multivariable equation.) (From Kirklin and colleagues.)

Accessory Valve Orifice

An accessory valve orifice is an incremental risk factor for premature death (see Table 34-11), almost surely because of its potentially adverse effect on function of the surgically created left AV valve (see description under Morphology earlier in this chapter). Despite the realization that the accessory orifice should not be “tampered with,” this risk factor has not been neutralized.

Major Associated Cardiac Anomalies

Included among important risk factors are major associated cardiac anomalies (see Table 34-11), but some of them, particularly tetralogy of Fallot, have been largely neutralized. Young Age

Young age has been an incremental risk factor for death, usually hospital death, in all experiences that go back 30 years or so. However, it has been virtually eliminated as a risk factor, primarily because of overall improvement in knowledge and repair techniques, but also because of advances in intraoperative and early postoperative care of infants. However, despite low hospital mortality, lower weight among infants is associated with more frequent postoperative complications and longer hospital stay.

Down Syndrome

Risk-adjusted analysis does not show that Down syndrome affects risk of premature death early or late after repair, except when complete AV septal defect is associated with tetralogy of Fallot. However, in view of the considerably decreased prevalence of LV inflow and outflow obstruction in patients with AV septal defects and Down syndrome, these patients may in fact have a better early and intermediate-term survival than patients without Down syndrome. The left AV valve may also be easier to repair, lessening the likelihood of late death from mitral regurgitation.

Need for Reoperation

The need for reoperation to insert a pacemaker, close a residual interventricular communication, or deal with important left AV valve regurgitation has been associated with added risk of death.

Other Risk Factors

Other incremental risk factors for premature death after repair have been reported. A single papillary muscle (see description under Morphology earlier in this chapter) becomes a serious problem after repair because of its tendency to result in LV inflow obstruction. It may therefore be a contraindication to typical two-ventricle repair. Severe ventricular hypoplasia is a risk factor for hospital death after a two-ventricle repair. Severe LV hypoplasia is more common in patients with complete AV septal defects than is severe right ventricular hypoplasia (see "Unbalanced Atrioventricular Septal Defects" under Special Situations and Controversies). Most hearts with severe LV hypoplasia are properly classified and treated as part of hypoplastic left heart syndrome (see Chapter 49).

Heart Block and Other Arrhythmias

Since Lev described the architecture of the conduction system in AV septal defects in 1958, prevalence of surgically induced permanent complete heart block has been approximately 1%. Avoiding heart block is generally facilitated by incorporating the coronary sinus on the left atrial side of the atrial patch. An equally low occurrence of heart block can also be accomplished by maintaining the coronary sinus on the right atrial side as long as appropriate attention is given to the anatomy of the conduction system (see also discussion under Special Situations and Controversies). Heart block is more frequent after repair of AV septal defect associated with tetralogy of Fallot and after AV valve replacement.

First-degree AV block, present in about 30% of patients preoperatively, has been found in about 50% of patients after repair. Right bundle branch block is common after repair of complete AV septal defects but uncommon after repair of partial AV septal defects.

In an earlier UAB experience, when left AV valve replacement was required, heart block occurred in 4 of 20 patients (20%; CL 10%-33%). This is because sutures placed in the left AV valve anulus at about the 2-o’clock position overlie the AV node. A fringe of AV valve tissue must be left in this area so that valve replacement sutures can be placed there and more anteriorly in the interatrial pericardial patch, rather than along the ventricular septal crest. Placing the prosthesis in supraanular position is also helpful. With these precautions, complete heart block is minimized.

Functional Status

Most long-term survivors are in excellent health. In one center, 88% of surviving patients were in NYHA functional class I, and 11% were in class II.

Atrioventricular Valve Function

Doppler color flow interrogation combined with two-dimensional echocardiography have increased the knowledge about postrepair left AV valve function considerably. Also,
About 10% to 20% of infants and older patients have moderate or worse postoperative left AV valve regurgitation late postoperatively in about half of patients,

Partial Atrioventricular Septal Defects

After repair of partial AV septal defects, about 10% of patients have late severe left AV valve regurgitation, and such patients are more likely to have had severe regurgitation prior to the repair. Generally these patients have a deficiency of the LIL of the AV valve; to date, valve replacement has been the only certain method of achieving left AV valve competence in such patients. Lesser degrees of regurgitation are present late postoperatively in about half of patients; 30% to 40% have essentially no left AV valve regurgitation late postoperatively. Recent studies suggest that moderate or worse postoperative left AV valve regurgitation is more common in children repaired after about 4 years of age, possibly related to longer exposure to LV volume overload and anular dilation induced by the regurgitation.

In patients undergoing repair of complete AV septal defects, there appears to be little relationship between preoperative severity of AV valve regurgitation and that present late postoperatively in some studies, but in others, an association is suggested. Use of single- vs. two-patch technique of repair does not increase the likelihood of early or late post-repair left AV valve regurgitation.

More severe abnormalities of left AV valve morphology, including deficient LLL, papillary muscle abnormalities of the LLL, incomplete commissures, double orifice valve, and severe disparities in length of the LSL and LIL contributing to the “cleft,” have been associated with a greater likelihood of postoperative left AV valve regurgitation. Absence of “cleft” closure has been identified as a risk factor for late reoperation for valve regurgitation.

About 10% to 20% of infants and older patients have important regurgitation late postoperatively, with the remainder having little or none. Despite general improvements in surgical techniques, late reoperation for left AV valve regurgitation has remained a challenge. When reoperation is necessary, left AV valve repair is possible in about half the patients; the rest require valve replacement. Stulak and colleagues at the Mayo Clinic found no difference in subsequent survival or freedom from additional operations according to whether valve repair or replacement was performed.

Repair of uncomplicated partial and complete AV septal defects uncommonly results in stenosis of the left AV valve. More often, this complication results when an accessory valve orifice or single papillary muscle coexists with the AV septal defect.

Important regurgitation or stenosis of the right AV valve is rare after repair of AV septal defects.

Left Ventricular Outflow Tract Obstruction

Uncommonly, LV outflow tract obstruction develops after repair of AV septal defects. As predicted on anatomic grounds by Ebels and colleagues, the AV septal defect has usually been the partial form. Prevalence of clinically significant late outflow obstruction is probably about 5% after repair of partial AV septal defect, which is up to three times more frequent than with the complete form.

When LV outflow obstruction develops, it may be associated with worsening left AV valve regurgitation; its relief usually permits regression of the regurgitation.

Prevalence of subaortic LV outflow tract obstruction late after repair of complete AV septal defect is not precisely known, but not negligible. Obstruction may have the appearance characteristic of discrete subaortic stenosis, with an “acquired fibromuscular ridge” (see “Resection of Localized Subvalvar Aortic Stenosis” in Section II of Chapter 47), or it may appear to result from the long, narrow LV outflow tract itself. In either case, simple resection rarely suffices. Extensive transaortic myectomy or the modified Konno operation, without aortic valve replacement, is indicated (see “Modified Konno Operation” in Section II of Chapter 47). Other techniques have been described that specifically address the scooped-out deficiency in the ventricular septum by detaching the LSL attachments to the crest of the ventricular septum and augmenting the anterosuperior aspect of the VSD patch or the LSL with a pericardial patch, followed by reattachment of the LSL. This moves the left AV valve farther into the left atrium during systole.

Residual Pulmonary Hypertension

When important pulmonary hypertension is present preoperatively, it can be expected to regress postoperatively if pulmonary blood flow is large and the patient receives a timely operation, usually when younger than age 6 months.

INDICATIONS FOR OPERATION

Presence of an AV septal defect indicates need for operation, because an important hemodynamic derangement is nearly always present, and spontaneous closure does not occur.

Partial Atrioventricular Septal Defects

In partial AV septal defects, pulmonary hypertension is usually absent, and the optimal age for operation is 1 to 2 years, assuming a competent left AV valve. If AV valve regurgitation...
is present, earlier operation is indicated to prevent further damage to valve tissue. Also, when heart failure or severe growth failure is evident earlier in life, operation is indicated at that time.

Complete Atrioventricular Septal Defects

Operation is indicated early in the first year of life. When the infant’s general condition is good, repair can be delayed until about age 3 to 6 months. When refractory heart failure or severe growth failure is evident at an earlier age, repair at that time is indicated. Often in patients who are older than 1 year, and occasionally in those in the last part of the first year of life, pulmonary vascular disease may already be too severe to permit repair. Criteria of inoperability are the same as described for patients with VSD (see Indications for Operation in Section I of Chapter 35). Lung biopsy is not recommended as an aid in grading severity of pulmonary vascular disease because of its associated morbidity and mortality and because of the scatter between histopathologic findings and pulmonary vascular resistance.

Coexisting Cardiac Anomalies

Although certain major associated cardiac anomalies increase risk of repair of AV septal defects, their presence rarely alters the indication for operation. Thus, although a coexisting large patent ductus arteriosus has in the past increased risk of repair of complete AV septal defects, it increases the urgency of early repair rather than contraindicating it. When tetralogy of Fallot coexists, indication and timing of repair are similar to that for tetralogy of Fallot in general (see Indications for Operation in Section I of Chapter 38), although some favor elective operation for tetralogy of Fallot with complete AV septal defects at age 9 to 12 months. When complete AV septal defect with juxtaaortic VSD is combined with DORV without pulmonary stenosis, life history and indications for operation are the same as for isolated complete AV septal defect; in the past, risk of repair has been high, but in the current era, early risk has been much less and intermediate-term results good.²²,³³

SPECIAL SITUATIONS AND CONTROVERSIES

Pulmonary Trunk Banding

Pulmonary trunk banding has been used episodically as initial management for small infants with complete AV septal defects, and some excellent results have been reported.⁵⁹ This approach has been used only sparingly in recent years. However, Silverman and colleagues, as well as Williams and colleagues, demonstrated in the early era that some very sick, small infants can be well managed initially by banding and deferral of repair for 6 to 18 months.⁵⁵,⁵⁸ In the absence of other contraindications to repair (unbalanced ventricles, comorbid conditions), banding is not indicated, because age, left AV valve regurgitation, and many other risk factors have been neutralized, and overall results of complete repair are excellent. In the rare instances in which preliminary pulmonary banding is elected, a device that is adjustable by remote control has provided encouraging results.⁵¹,⁵⁴,⁵⁵

Septal Patches

There have been several reports of near-fatal hemolysis from the regurgitant jet of a left AV valve striking a synthetic interatrial patch after repair of AV septal defect.⁴⁴,⁵²,⁵⁶ Therefore, for maximal safety, the interatrial patch material should be pericardium.

Avoiding Heart Block

For years, McGoon and colleagues successfully used a method that involved keeping the suture line on the left and superior sides of the conduction tissue, rather than on the right side and inferiorly.⁴⁷ Starr’s group has used the same general method with good results.⁴³ The patch is sutured to the LSL-LIL complex on the left ventricular side of its attachment to the crest of the ventricular septum. Inferiorly, the suture line then goes to the edge of the ostium primum defect, posterior and central to the AV node and bundle of His, and posteriorly along the atrial septal edge. This method keeps the suture line to the left of, and away from, the AV node and bundle of His (see Fig. 34-25, E).

Unbalanced Atrioventricular Septal Defects

In about 10% of patients with complete AV septal defects, the common AV valve is unequally balanced over the right ventricle or LV. The majority of cases are right dominant with associated LV hypoplasia.⁴⁴,⁵⁶ The surgical options include biventricular repair or single-ventricle strategies. When one ventricle is severely hypoplastic, a repair resulting in a two-ventricle system frequently fails. Theoretically, a Fontan-type repair should be applicable to patients with this type of major associated cardiac anomaly. In the small number of patients treated in this manner, however, hospital mortality has been high.⁴⁸,⁵⁸ This may be related to very early development of pulmonary vascular disease in patients with complete AV septal defects.

Echocardiographic analyses have been proposed that define the degree of “balance” of the AV valve over each ventricle. Using the subcostal view, the area of the common orifice can be divided into right and left AV valve orifices by a line drawn from the caval septum to the crest of the muscular septum.⁴¹,⁵⁴ Cohen and colleagues used this method to calculate an AV valve index using the ratio of the left AV valve area divided by the right AV valve area in patients with a larger right AV valve (left/right valve area). In general, patients with a balanced complete AV septal defect have an area ratio greater than 0.67, and a value less than 0.67 indicates right ventricular dominance. Approximately one third of patients with right ventricular dominance have Down syndrome.⁴¹ Patients with Down syndrome frequently have traits that increase the risk of single-ventricle palliations, such as lung hypoplasia, increased pulmonary vascular resistance, hypotonia with hyperventilation, and upper airway obstruction with nocturnal hypercarbia.⁴¹ Additional left-sided anomalies are also common in patients with right-dominant complete AV septal defects. Precise guidelines have not been established for the degree of RV dominance that is consistent with a successful two-ventricle repair. Available analyses are also confounded by the important additional risk imposed by additional major anomalies.⁴¹
In data from Cohen and colleagues on patients undergoing two-ventricle repairs with left AV valve/right AV valve ratio between 0.27 and 0.65, the specific ratio failed to predict survivors. Similarly, a study by Van Son and colleagues examined outcomes with two-ventricle repair among five patients with a diameter ratio (left/right valve diameter) of 0.23 to 0.39. All survived hospitalization, but one died late from left AV valve dysfunction.

Others have examined calculated LV volumes in decision making. Van Son and colleagues suggested that the actual LV volume may be underestimated in right ventricle–dominant AV septal defects secondary to leftward septal bowing, and they introduced the concept of “potential LV volume” to predict the volume of the LV post-repair that could be accomplished with only a change in shape. Patients with a potential volume of 15 mL · m⁻² have survived repair. Individual reports have shown dramatic increases in LV size of twofold to threefold after repair. A small interventricular communication may be a favorable prognostic factor.

Another method of assessing dominance is the ratio of the left AV valve area to the total AV valve area. A ratio of 0.4 or less indicates right ventricular dominance, and a ratio of 0.6 or more indicates LV dominance. In a multicenter study from the Congenital Heart Surgeons Society, a ratio less than 0.2 (severe right ventricular dominance) uniformly predicted a single-ventricle strategy. A valve ratio of 0.4 to 0.6 indicated a “balanced” defect, and a two-ventricle repair was performed. A ratio of 0.2 to 0.4 represented the “gray zone” of moderately severe right ventricular dominance, in which either single- or two-ventricle strategies were applied, with a disproportionately high number of deaths in that range.

If biventricular repair is undertaken, placing a left atrial catheter for postoperative monitoring is advisable. A persistently elevated left atrial pressure and signs of low cardiac output, persistent pulmonary edema, or failure to wean from ventilator indicate need for reoperation and conversion to single-ventricle palliation. Unfortunately, outcomes after single-ventricle palliation in this setting are generally worse than for most other single-ventricle cohorts. Owens and colleagues noted a midterm survival of only 50% among 32 patients with severe right-dominant unbalanced AV septal defects, worse than that of a contemporary cohort of hypoplastic left heart syndrome patients. Thirty percent of the unbalanced AV septal defect patients required replacement or repair of their systemic AV valve.

**Left-dominant unbalanced complete AV septal defect** may be defined by a right AV valve area/left AV valve area less than 0.5 or a left AV valve area/total valve area greater than 0.6. Down syndrome has been reported in 80% of this subset. When the valve ratio is less than 0.5, risk of biventricular repair may carry an increased risk. De Oliveira and colleagues reported improved outcomes with a restrictive atrial fenestration intended to lower right atrial pressure and increase cardiac output with some degree of desaturation.

The general surgical strategies in this patient group are similar to those for pulmonary atresia with intact ventricular septum (see Chapter 40). When right ventricular hypoplasia is severe and success of biventricular repair is in question, a “one-and-a-half ventricle repair,” as suggested by Alvarado and colleagues and others, may be appropriate. In this repair, the usual procedure to correct the AV septal defect is accompanied by a bidirectional cavopulmonary anastomosis. Pulmonary blood flow is augmented, and the right ventricle is unloaded. A potential but unusual problem is pulmonary artery–to–right atrial circular flow if superior vena cava–to–right atrium continuity is maintained.

**Late Reoperation**

The only residual condition that remains an important cause of late reoperation is left AV valve regurgitation. Najm and colleagues reported that 9.4% of 363 patients operated on for complete AV septal defect underwent subsequent repair or replacement of the left AV valve; 3 of 34 (8.8%; CI 3.9%–17%) patients died. Intraoperative echocardiography reduces the occurrence of residual important left AV valve regurgitation. The report of Reddy and colleagues is illustrative: 72 infants (median age 3 to 9 months) underwent repair of complete AV septal defect, and cleft closure or anu-loplasty was done in 70. Based on TEE, 10 were returned to CPB for revision of the left AV valve. Among all 72 patients, there was 1 early death. There were 5 late reoperations with a median follow-up of 24 months; 2 were for AV valve regurgitation and 3 for subaortic obstruction. Although there may have been mild deterioration of AV valve function in patients with mild to moderate regurgitation early postoperatively, there was a 90% probability of not having severe late AV valve regurgitation at a mean follow-up of 45 months (range 3 to 169 months).

Section 1  Primary Ventricular Septal Defect

**DEFINITION**

Ventricular septal defect (VSD) is a hole or multiple holes in the interventricular septum. This chapter discusses VSDs that occur as the primary lesion, recognizing that hearts with primary VSDs may have minor coexisting morphologic abnormalities. VSD may be part of another major cardiovascular anomaly, such as tetralogy of Fallot (see Chapter 38), complete atroventricular (AV) septal defect (see Chapter 34), anatomically corrected malposition of the great arteries (see Chapter 57), truncus arteriosus (see Chapter 43), tricuspid atresia (see Chapter 41), sinus of Valsalva aneurysm (see Chapter 36), and interrupted aortic arch (see Chapter 48). VSDs also may be acquired, as discussed in Chapters 9 and 17.

**HISTORICAL NOTE**

In 1954, Lillehei, Varco, and colleagues at the University of Minnesota in Minneapolis began to repair VSDs using normothermic, low-flow, controlled cross-circulation based on the so-called azygos flow principle, with an adult human as the oxygenator (see Historical Note in Section II of Chapter 2). This was the beginning of the era of cardiac surgery using cardiopulmonary bypass (CPB), a term coined by Cooley a few years later. Five of the first eight patients were in their first year of life, and only two (40%; CL 14%-71%) of the five died, a tribute to surgical skill, lack of cardiac ischemia (the aorta was not clamped), and quality of their human oxygenator. The dramatic weight gain of the surgical team and interrupted aortic arch (see Chapter 48). VSDs also may be acquired, as discussed in Chapters 9 and 17.

Kirklin and DuShane developed a surgical technique that avoided producing heart block during VSD repair.

Lillehei showed the feasibility of an atrial approach to VSD in 1957. The technique of hypothermic circulatory arrest, with rewarming by a pump-oxygenator, was applied successfully to infants with VSD by Okamoto. Kirklin and DuShane (1961) and Sloan’s group (1967) reported the feasibility of primary repair of VSD in infants.

Barratt-Boyes and colleagues (1969-1971) found that routine primary repair of VSD in sick, small infants was superior to pulmonary artery banding.

**MORPHOLOGY**

Although this chapter considers VSD that occurs as the primary lesion, the method of morphologic description is applied in other chapters to VSDs that are part of other major cardiac malformations. The morphologic classification described here represents an attempt to simplify VSD classification by encompassing all variations of the lesion while conforming to other systems of classification (Table 35-1). This classification conforms generally with the consensus of the Congenital Heart Surgery Nomenclature and Database Project and includes many of the concepts of Anderson and Wilcox.

**Size**

VSDs are highly variable in size, and their division into size groups is arbitrary but useful. The echocardiographic criteria for VSD size are discussed in “Two-Dimensional Echocardiography” under Clinical Features and Diagnostic Criteria.

![Table 35-1 Morphologic Classification of Ventricular Septal Defect](image-url)
Large VSDs are approximately the size of the aortic orifice or larger. They offer little resistance to flow, and thus their VSD resistance index\(^1\) is less than 20 units \(\cdot\) m\(^2\) in situations in which the calculation of the index is valid.\(^{1,13,53}\) Right ventricular (RV) systolic pressure approximates left ventricular (LV) pressure, and the pulmonary to systemic blood flow ratio \((Q_P/Q_S)\) is increased to a degree dependent on the level of pulmonary vascular resistance \((R_p)\).

Moderate-sized VSDs, although still restrictive, are of sufficient size to raise RV systolic pressure to approximately half LV pressure and \(Q_P/Q_S\) to 2.0 or greater.

Small VSDs are of insufficient size to raise RV systolic pressure, and \(Q_P/Q_S\) is not increased above 1.75. Small VSDs have a VSD resistance index greater than 20 units \(\cdot\) m\(^2\).\(^{1,13}\) Multiple small defects behave in aggregate as a large defect.

Location in Septum and Relationship to Conduction System

VSDs can occur in all portions of the ventricular septum\(^2\) (Fig. 35-1). VSDs with entirely muscular borders (muscular VSDs) may occupy several areas of the ventricular septum; other VSDs have one or several nonmuscular borders consisting of spaces or structures against which they are juxtaposed (Table 35-2). These nonmuscular borders may be a semilunar valve, an AV valve, or the crux cordis (intersection of the posterior aspect of the interventricular septum and AV junction). Some VSDs in the periphery of the ventricular septum are bordered by the ventricular free wall, but such VSDs are conventionally considered to be muscular. VSDs in the category of subarterial may be (1) juxta-aortic, (2) juxta-arterial (bordered by both pulmonary and aortic valves), or (4) juxtaapical (bordered by the valve of a common arterial trunk). Subarterial VSDs are typically associated with some degree of overriding of the related arterial trunk, and the margin of the VSD is actually a space over which is a semilunar valve(s).\(^{3,9}\)

Many VSDs are associated with malalignment of portions of the ventricular septum or atrial septum relative to the interventricular septum, in which case an AV valve usually overrides the VSD. Malalignment VSD terminology results from two-dimensional (2D) echocardiographic examination of the heart regarding alignment of the trabecular and the outlet (conal) septum. In some cardiac anomalies, the aorta seems displaced relative to the VSD. The malalignment is referred to as anterior when the outlet septum appears anterior to the trabecular septum, with the VSD interposed. Tetralogy of Fallot–type defects are considered anterior malalignment types, with the aorta “overriding” the VSD (see Fig. 35-18, C). Malalignment is posterior when the outlet septum appears posterior to the trabecular septum in anomalies such as interrupted aortic arch and severe coarctation of the aorta. There may also be a rotational malalignment in anomalies characterized under the broad category of Taussig-Bing heart.

Anatomic location of the VSD determines its relation to the conduction system.

VSDs may also be characterized according to their commitment to the great arteries (Lev and colleagues\(^{4,10}\)): subaortic, subpulmonary, doubly committed, and noncommitted.

---

\(^1\) VSD resistance index = \(\frac{\Delta P_LV - \Delta P_RV}{\Delta Q + \Delta Q_s} \times BSA\)

where \(BSA\) is body surface area, \(\Delta P_LV\) is left ventricular systolic pressure, \(\Delta P_RV\) is right ventricular systolic pressure, \(\Delta Q\) is pulmonary blood flow, and \(\Delta Q_s\) is systemic blood flow.

\(^2\)The location is described in words that are relevant to the RV aspect of the VSD (see “Right Ventricle” under Cardiac Chambers and Major Vessels in Chapter 1), because most reparative procedures are performed from that aspect.
This type of characterization—which is relational, not morphologic—preferably is restricted to hearts with double outlet ventricles, because its use in other situations has resulted in considerable confusion.

All these features of the location of VSDs should be included in descriptions of these defects.

**Perimembranous Ventricular Septal Defect**

Approximately 80% of patients operated on for primary VSD have a perimembranous VSD. These defects could be called *junctional VSDs* because they are in the junctional area between the trabecular (sinus) and outlet (conal) portions of the ventricular septum (Fig. 35-2) and usually appear to be between the posterior and anterior divisions of the trabecula septomarginalis (septal band). Thus, these VSDs are between the outlet (conus) and inlet (ventricular) portions of the right ventricle, but characteristically they are in the outlet portion of the left ventricle.

Perimembranous VSDs are often associated with anomalies of the outlet septum and other adjacent structures, although when small, they may be truly isolated anomalies. Some perimembranous VSDs are *juxtaticuspid* (abutting the tricuspid valve), *juxtamitral*, and *juxta-aortic*. These perimembranous VSDs are also *conoventricular* (conotruncal) (Fig. 35-3). Such defects abut the commissural area between the noncoronary and right coronary cusps of the aortic valve. Others are only juxtaticuspid (conotruncal), and in hearts with these as well as in hearts with perimembranous VSDs, the bundle of His passes along the posteroinferior border of the defect. Some perimembranous VSDs abut none of these valvar structures and are separated from the tricuspid anulus posteriorly by a band of muscle that is part of the posterior division of the trabecula septomarginalis joining with the ventriculoinfundibular fold. The bundle of His is not in this muscular band but is in its usual position more posteriorly. Technically, although this type of defect is located in a perimembranous position, it is better classified as *muscular inlet-type VSD* because all borders are muscle.

VSDs have also been described in the past as *typically high, infracristal, membranous, or perimembranous*, without the original specific description.

As already indicated, the AV node and penetrating portion of the bundle of His are in their normal position in hearts with perimembranous VSDs. As the bundle penetrates the fibrous right trigone of the central fibrous body at the base of the noncoronary cusp of the aortic valve, it lies along the posteroinferior border of perimembranous and inlet-type VSDs. As the bundle continues along the inferior border of the VSD (at times slightly to the left or right of the free edge), the left bundle branch fascicles emerge from the branching portion. Only the right bundle branch remains when the bundle reaches the level of the muscle of Lancisi.

Abnormalities of the ventricular portion of the membranous septum are often associated with perimembranous VSDs. The membranous septum may be absent or nearly so, and then the right trigone (beneath the nadir of the noncoronary aortic valve cusp and base of the septal and anterior leaflets of the tricuspid valve are exposed and form the posteroinferior rim of the VSD (see Fig. 35-3). The bundle of His, as it penetrates the fibrous right trigone at the base of the noncoronary cusp, is intimately related to the posteroinferior angle of such a defect. This is associated with a deficiency in the posterior limb of the trabecula septomarginalis. Rarely the ventricular portion of the membranous septum may be well developed, thickened, and perforated by one or many holes, forming an *aneurysm of the membranous septum* that bulges toward the right in systole. This so-called aneurysm is simulated on angiography by the much more common tethered anterior leaflet and the involved and usually fused chordae. Accessory fibrous tissue not part
Thus, it is useful to Fig. 35-5 - Fig. 35-9 (arrows) are present. B, Same defect viewed from left ventricle. VSD lies below noncoronary cusp of aortic valve and is not juxta-aortic. Arrow indicates cleft in anterior mitral leaflet. Key: ALMV, Anterior leaflet of mitral valve; AV, aortic valve; LV, left ventricle; PV, pulmonary valve; RA, right atrium; SLTV, septal leaflet of tricuspid valve.

of the tricuspid valve mechanism may lie along the posterior or superior margin of the defect. This phenomenon is most marked in the flap valve VSD.

Not surprisingly, in hearts with perimembranous VSDs, still other adjacent structures may be abnormal. The medial papillary muscle characteristically joins the anteroinferior angle of the defect and receives chordae from adjacent portions of the tricuspid anterior and septal leaflets. These chordae may be increased in number and abnormally positioned around the edges of a perimembranous VSD, attached to the posterior edge, superior edge (Fig. 35-5), or most often anterior edge. A thick leash of chordae joining the center of the anterior edge of a large defect may produce an appearance on angiography or even at operation of a double defect. Chordae from the anterior leaflet may attach to all three margins, and the anterior leaflet then limits the shunt from left to right through the defect, as well as hinder its repair.

Close association of some perimembranous VSDs with the commissure between anterior and septal tricuspid leaflets sometimes results in adherence of leaflet tissue to edges of the defect and shunting directly from LV into right atrium (Fig. 35-6). This so-called LV–right atrial defect, which constitutes fewer than 5% of perimembranous VSDs in this region, rarely involves the AV septum. Adherence of tricuspid leaflet and chordal tissue is also an important mechanism of spontaneous closure of these VSDs.

**Ventricular Septal Defect in Right Ventricular Outlet (Doubly Committed Subarterial Ventricular Septal Defect)**

Some 5% to 10% of patients treated operatively have a single VSD, usually of moderate or large size, within the outlet portion of the RV. VSDs in this location are also in the outlet portion of the LV and, in contrast to perimembranous VSDs, are more beneath the right aortic cusp than the commissure between it and the noncoronary cusp. In the past, these have also been termed conal, infundibular, supracristal, and intracristal defects. The complex morphology of the ventricular septum in the outlet portion of the RV and many controversies concerning the term “outlet septum” support use of a simple descriptive terminology for this group of VSDs.

VSDs in this general location are bordered in part by a space over which lie the pulmonary and aortic valves (Fig. 35-7). As such, these VSDs are subarterial. VSDs of this type are more common in Asians than in white or black races. Subarterial VSDs may be circular, diamond shaped, or oval with the long axis lying transversely (Fig. 35-8). When viewed from the LV aspect, these defects are in the outflow portion of the ventricular septum (see Fig. 35-7, B), beneath the right coronary cusp (or commissure between it and the left cusp). The aortic and pulmonary valve cusps are separated by only a thin rim of fibrous tissue. The right aortic cusp and (less often) noncoronary cusp may prolapse into the upper margin of the defect, with or without aortic regurgitation (see Section II later in this chapter).

The posteroinferior margin of RV outlet VSDs is usually well separated from the tricuspid valve anulus by a band of muscle and is consequently well above the bundle of His. Occasionally, however, a particularly large confluent VSD may be both subarterial and perimembranous (Fig. 35-9). The conduction system is related to such a VSD as it is to other perimembranous defects. This particular type of VSD is sometimes associated with severe overriding of the aorta, and the cardiac anomaly is then termed double outlet right ventricle (DORV) with doubly committed VSD. The same type of VSD may also be seen in double outlet left ventricle (DOLV), in which the pulmonary artery severely overrides the VSD.

Morphology of these subarterial VSDs has been well elucidated by 2D echocardiography and color Doppler examinations. Despite the potential confusion of using Lev’s relational terminology in a morphologic sense, in the echocardiographic literature, subarterial defects are usually referred to as doubly committed VSDs. Thus, it is useful to
Figure 35-5 Perimembranous ventricular septal defect (VSD) associated with anomalous leaflet tissue. **A**, VSD viewed from right ventricle. Note chordal attachment (arrow) of anterior tricuspid leaflet to anterosuperior margin of defect. Normal position of infundibular (outlet) septum between two limbs of trabecula septomarginalis (septal band) is well seen. **B**, Same defect viewed from right atrium. VSD is partly obscured by tricuspid leaflet tissue, but its extent is indicated by dashed line. **C**, Same defect viewed from left ventricle. VSD is immediately beneath aortic valve (juxta-aortic), and its extent is indicated by dashed line. Abnormal tricuspid valve attachments are obvious and on an angiocardiogram are indistinguishable from an aneurysm of the membranous ventricular septum. Key: ALMV, Anterior leaflet of mitral valve; AV, aortic valve; InfS, infundibular (outlet) septum; PV, pulmonary valve, RA, right atrium; RV, right ventricle; TS, trabecula septomarginalis (septal band); TV, tricuspid valve.

combine morphologic and echocardiographic descriptions to characterize these VSDs occurring in the RV outlet as **doubly committed subarterial VSDs**. Echocardiography has demonstrated that aortic and pulmonary valves are frequently at the same level in the presence of subarterial (or doubly committed) VSDs, rather than the pulmonary valve being elevated above (cephalad to) or offset relative to the aortic valve, seemingly by the RV infundibulum. This description often provides a diagnostic tool useful in both echocardiography and angiography, along with the finding that the outlet septum appears to be absent and the subpulmonary infundibulum deficient. Echocardiography has also demonstrated the frequently associated prolapse of an aortic cusp and aortic regurgitation present in up to half of patients with this type of VSD. Aortic cusp prolapse may nearly close the VSD during diastole. At times the fibrous raphe between the arterial valves is displaced relative to the ventricular septum, resulting in overriding of one arterial valve and narrowing of the other.

Some VSDs in the RV outlet are only **juxta-aortic** and abut the nadir of the right coronary cusp. The cusp typically prolapses through this type of VSD, and aortic regurgitation frequently develops. Rarely, VSDs in the RV outlet are only juxtapulmonary and lie far to the left. Some defects in the outlet portion of the septum have **muscular** borders and lie in the substance of the infundibulum (muscular VSD, outlet type), with a muscle bridge of infundibular septum superior to the defect. The superior muscular bridge may be malaligned and displaced leftward into the aortic outflow tract (posterior malalignment type of VSD), producing muscular subaortic stenosis that lies above the VSD. This anomaly occasionally occurs in association with interrupted aortic arch and with coarctation, although perimembranous VSDs are more common in both settings.

Inlet Septal Ventricular Septal Defect

Five percent or less of surgical patients have *inlet septal VSD* (or *AV septal type* or *AV canal type of VSD*). This defect involves the RV *inlet septum* beneath the tricuspid septal leaflet and LV *outlet septum*. Its posterior margin is formed by the exposed AV valve anulus (juxtapacustricuspid), and its
Figure 35-6 Type of perimembranous ventricular septal defect (VSD) that ejects directly into right atrium, a so-called left ventricular–right atrial defect. A, VSD viewed from right atrium. Posterior part of tricuspid anulus is marked by dashed line. Tricuspid septal leaflet is anomalously adherent to underlying ventricular septum and edges of VSD, which is juxtraticuspid. Intact atrioventricular septum lies on atrial side of tricuspid anulus (beneath letters VSD). Bundle of His is along posterior angle of defect. B, Same defect viewed from left ventricle. VSD is juxta-aortic and beneath commissure between right and noncoronary aortic cusps. Figure 35-7 Doubly committed subarterial ventricular septal defect (VSD) in outlet portion of ventricular septum. A, VSD viewed from right ventricle. Its inferior margin is formed of thick septal tissue and its superior margin by confluent right pulmonary and right aortic cusps, which are separated by a thin ridge of fibrous tissue. B, Same defect viewed from left ventricle. VSD is beneath right coronary cusp of aortic valve and more anterior than a conoventricular VSD. Key: ALMV, Anterior leaflet of mitral valve; InfS, infundibular (outlet) septum; L, left pulmonary cusp; NC, noncoronary aortic cusp; R, right pulmonary cusp; TSM, trabecula septomarginalis (septal band).
Figure 35-8  Doubly committed subarterial ventricular septal defect (VSD) viewed from right ventricle. VSD lies immediately beneath pulmonary valve (and, although it is unseen, aortic valve). Inferior to defect are infundibular septum and trabecula septomarginalis (septal band). Tricuspid valve, papillary muscle of conus, and bundle of His are far from defect. Key: InfS, infundibular septum; PMC, papillary muscle of Lancisi; PV, pulmonary valve; TSM, trabecula septomarginalis (septal band); TV, tricuspid valve.

Figure 35-9  Large confluent ventricular septal defect (VSD) that is both subarterial and perimembranous, extending downward to reach tricuspid anulus. This type of VSD is also seen in double outlet right ventricle with doubly committed VSD and in double outlet left ventricle. A, VSD viewed from right ventricle. At superior margin of VSD, pulmonary and aortic cusps are in fibrous continuity. Arrow points toward aortic valve. B, Same defect viewed from left ventricle. Note additional small trabecular muscular defect. Key: Ao, Aorta; IS, infundibular septum; PA, pulmonary artery; PV, pulmonary and aortic cusps.

The anterior margin is muscular and crescentic (Fig. 35-10). Superiorly, inlet septal defects usually extend to the membranous septum. The AV septum is intact, in contrast to the situation in hearts with AV canal septal defects (see Morphology in Chapter 34). The anterior (septal) mitral leaflet occasionally may be cleft, either partially or completely, with associated mitral regurgitation. Rarely, VSDs in the inlet portion of the septum extend completely to the crux cordis and thus are also juxtacrural in position. The tricuspid valve is overriding and usually straddling.

In inlet septal VSDs, the AV node lies more laterally and anteriorly along the tricuspid anulus than normal and at the point at which the tricuspid anulus meets the underlying ventricular septum, because of straddling of the tricuspid valve. The bundle of His lies along the posteriorinferior rim of the inlet septal VSD, slightly on the LV side, as in juxtratricuspid VSDs.

A muscular VSD can occur in the inlet portion of the ventricular septum beneath the tricuspid septal leaflet (Fig. 35-11). The posterior margin of such a defect is separated from the tricuspid ring by muscle. A muscular VSD must be distinguished from the inlet septal type of VSD because the conducting tissue runs superior and anterior to a muscular defect.

Muscular Ventricular Septal Defect
VSDs in other locations are generally muscular VSDs. Such defects are frequently multiple and may be associated with perimembranous or subarterial VSDs. Single or multiple muscular defects in the trabecular septum are more common
Figure 35-10  Inlet septal ventricular septal defect (VSD) beneath septal leaflet of tricuspid valve. Posterior margin of defect is formed by tricuspid anulus. VSD is juxtratricuspid. A, VSD viewed from right ventricle. Note crescentic anterior margin of defect. (A previously placed polyester patch has been removed.) B, Same defect viewed from left ventricle. Superiorly, defect reaches almost to aortic valve; posteriorly, it extends to mitral valve. Key: AV, Aortic valve; MV, mitral valve; PV, pulmonary valve; RA, right atrium; SLTV, septal leaflet of tricuspid valve; TV, tricuspid valve.

Figure 35-11  Single, moderate-sized, muscular inlet septal ventricular septal defect (VSD) lying beneath tricuspid septal leaflet. A, VSD viewed from right ventricle. Note septal muscle between VSD and tricuspid valve. Bundle of His lies superior to VSD. This defect can easily be closed from a right atrial approach. B, Same defect viewed from left ventricle. VSD is in posterior part of nontrabeculated portion of left side of ventricular septum. Key: ALMV, Anterior leaflet of mitral valve; AV, aortic valve; LV, left ventricle; PV, pulmonary valve; TV, tricuspid valve.
Muscular defects can occur anywhere in the ventricular septum (see Fig. 35-1). Those in the middle portion of the trabecular septum are the most common (Fig. 35-12) and may be overlaid by the trabecula septomarginalis; thus, even when single on the LV side, these defects have at least two openings on the RV side. Anterior muscular defects are usually multiple and most often in the apical and outlet portions of the septum. They may extend all along the anterior part of the septum from apex to outlet septum. Typically there are more openings on the RV than LV side.

A particularly important group of patients are those with Swiss cheese defects (Fig. 35-13), many defects of variable size, not only along the anterior portion of the septum but throughout the midportion as well. These defects often pass obliquely through the septum to appear on both sides of the trabecula septomarginalis or in the anterior part of the septum. They may be associated with large or small perimembranous or subarterial defects. Major associated cardiac anomalies are common, especially severe coarctation of the aorta.

The bundle of His is not closely related to the borders of any muscular VSD.

**Confluent Ventricular Septal Defect**

Some unusually large, single confluent VSDs involve more than one area of the septum. Rarely a confluent VSD may involve most of the septum (Fig. 35-14), but hearts with such defects should not be classified as having a single ventricle.

**Ventricular Septal Defect with Straddling or Overriding Tricuspid Valve**

In rare instances, tricuspid valve chordae may straddle the ventricular septum in association with a large inlet septal defect resembling an inlet septal-type VSD but extending to the crux cordis. The tricuspid valve usually overrides both ventricles. When overriding is severe, the tricuspid anulus is usually very large, and many chordae from it are attached to the LV side of the septum (a combination of straddling and overriding). The atrial septum is malaligned relative to the ventricular septum. The RV is often hypoplastic. The tricuspid valve may be regurgitant.

**Associated Lesions**

Nearly half of patients undergoing surgical treatment for a primary VSD have an associated cardiac anomaly. A moderate-sized or large patent ductus arteriosus (PDA) is
Figure 35-13  “Swiss cheese” type of multiple ventricular septal defect (VSD) associated with a large perimembranous VSD. A, VSDs viewed from right ventricle. Perimembranous defect shows anomalous chordal attachment from tricuspid valve to posterosuperior margin of defect (arrow). Probes demonstrate five separate openings of small defects, one above and four below trabecula septomarginalis (septal band). B, Same defects viewed from left ventricle. Perimembranous defect is seen. Probes demonstrate three separate openings of Swiss cheese defects, but many more lie in grossly trabeculated lower portion of septum. Key: ALMV, Anterior leaflet of mitral valve; AV, aortic valve; InfS, infundibular septum; PV, pulmonary valve; TV, tricuspid valve.

Figure 35-14  Large confluent ventricular septal defect (VSD) is perimembranous and occupies upper half of muscular septum beneath infundibular septum (anterior extension). It is associated with Swiss cheese VSDs. A, VSD viewed from right ventricle. Surgeon’s initial impression would be that patient had a single ventricle. B, Same defect viewed from left ventricle. Malformation is clearly not a single ventricle. Key: ALMV, Anterior leaflet of mitral valve; AV, aortic valve; PV, pulmonary valve; TV, tricuspid valve.
Figure 35-15  Inlet septal type of ventricular septal defect (VSD) with posterior extension and straddling tricuspid valve.  

A, VSD viewed from right atrium.  Crest of ventricular septum forming lower boundary of defect (black arrow) crosses almost beneath center of large tricuspid orifice, indicating severe malalignment of atrial and ventricular septa.  

B, Same defect viewed from left ventricle.  Chordal attachments of tricuspid valve cross VSD to attach to septal surface of left ventricle.  This heart also exhibits transposition of the great arteries, with pulmonary trunk above left ventricle.

present in about 6% of patients of all ages, but about 25% of infants in heart failure.  VSD occurs in combination with moderate or severe coarctation of the aorta in about 5% of patients.  This combination is also much more common among infants with large VSD coming to operation younger than age 3 months.

Congenital aortic stenosis occurs in about 2% of patients requiring operation for VSD.  Subvalvar stenosis is more common than valvar and may also occur in association with infundibular pulmonary stenosis.  Subvalvar stenosis can be due to (1) a discrete fibromuscular bar lying inferior (caudal or upstream) to the VSD; (2) a discrete fibromuscular bar located distal (downstream) to the VSD, often consisting of displacement of infundibular septal muscle into the LV outflow tract (posterior malalignment), and often associated with aortic coarctation and interrupted arch; (3) pulmonary artery banding; and (4) excrescences of AV valvar tissue.

Congenital mitral valve disease occurs in about 2% of patients.  One of the pulmonary arteries may be absent or severely stenotic.  Severe peripheral pulmonary artery stenoses occur rarely.

Although atrial septal defects in general are not considered major associated anomalies, they may coexist with a large VSD in small infants and may be important lesions.

Severe positional cardiac anomalies (e.g., isolated dextrocardia, situs inversus totalis) are uncommon in patients with VSD.

Pulmonary Vascular Disease

The classic description of the pathology of hypertensive pulmonary vascular disease is that of Heath and Edwards (Box 35-1).

$\text{Rp}$ in patients with large VSD (and those with large PDA) is positively correlated with histologic severity of the hypertensive pulmonary vascular disease, classified by Heath and colleagues (Fig. 35-16).  A close positive correlation also exists between lowest $\text{Rp}$ at rest or with isoproterenol infusion and Heath-Edwards grade of vascular disease.  Heath-Edwards grades above 3 were not found in patients with $\text{Rp}$ index less than 7 units · m$^2$, whereas those with $\text{Rp}$ greater than 8.5 units · m$^2$ showed changes characteristic of grade 4 or greater.  Similarly, Fried and colleagues found a rather close negative correlation ($P = .001$) between magnitude of left-to-right shunt and Heath-Edwards grade in infants and children coming to VSD repair.  Variability in these matters is not unexpected because Heath-Edwards classification is based on the most severe lesion seen, regardless of its frequency.  As noted by Wagenvoort and colleagues and
Yamaki and Tezuka, grading should include assessment of the number of vessels affected. In addition, calculation of Rp is open to errors.

Hislop and colleagues provide a different view of hypertensive pulmonary vascular disease in infants with large VSD. Other investigators had noted earlier that intimal proliferation (and thus Heath-Edwards changes of grade 2 or greater) rarely develops in patients with large VSD until 1 or 2 years of age, despite infants occasionally having severely elevated Rp. Hislop and colleagues found that infants dying at 3 to 6 months of age with large VSD and high (>8 units · m²) Rp with intermittent right-to-left shunting have marked medial hypertrophy affecting both large and small pulmonary arteries, including those less than 200 µm in diameter. The usual number of intraacinar vessels was present. By contrast, these investigators found that infants 3 to 10 months of age with large VSDs dying with a history of large Qp and heart failure and normal or slightly elevated Rp have medial hypertrophy affecting mainly arteries larger than 200 µm. The intraacinar vessels were fewer than usual, so-called lessened arterial density. These histologic features have been shown by Rabinovitch and colleagues to correlate with pulmonary hemodynamic findings after repair of VSDs.

Histologic reversibility of pulmonary vascular disease after closure of VSD has not been documented. Favorable results in infants may be from an increase in arterial density as growth proceeds. Presumably, pulmonary vascular disease of Heath-Edwards grade 3 or greater severity is not reversible.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Clinical Findings

In infants, signs and symptoms of heart failure include tachypnea and liver enlargement, often associated with poor feeding and growth failure, and physical findings of a precordial pansystolic or more abbreviated systolic murmur and a hyperactive heart. These findings suggest the diagnosis of a large VSD. An apical diastolic murmur suggests large flow across the mitral valve during diastole, the result of a large Qp. Cardiomegaly and evidence of large Qp are seen on the chest radiograph (Fig. 35-17). The electrocardiogram (ECG) usually shows biventricular hypertrophy. In older patients with large VSD, the history is often nonspecific, but
examination also shows evidence of LV and RV enlargement and a systolic murmur usually best heard in the third and fourth left interspaces. In patients with doubly committed subarterial VSDs, the systolic murmur is maximal in the second and third interspaces, and in defects shunting mainly into the right atrium, in the fourth and fifth interspaces.

A high Rp from severe pulmonary vascular disease changes the hemodynamic state and clinical findings in patients with large VSDs. A large left-to-right shunt is no longer present because output resistances of the two pathways for LV emptying are similar, and the shunt is bidirectional and of about equal magnitude in both directions. The heart is not enlarged or hyperactive. A systolic murmur (produced by the large flow across the VSD) is soft or absent, and no apical diastolic murmur is heard. The pulmonary component of the second sound at the base is loud and sometimes palpable. Chest radiography reflects these features (see Fig. 35-17). ECG shows severe RV hypertrophy rather than combined ventricular hypertrophy, and evidence of LV volume overload. When pulmonary vascular disease is even more advanced, cyanosis develops (Eisenmenger complex) because the shunt across the VSD becomes right to left as RV output resistance through the pulmonary vascular bed becomes higher than that through the VSD and aorta.

Patients with small VSDs have small shunts and often no abnormal signs or symptoms other than a pansystolic murmur. Chest radiography and ECG both may be normal. When the defect is moderate in size, the LV is mildly or moderately enlarged (shown by physical examination, chest radiography, and ECG), and the volume of the RV is increased.

When there is associated pulmonary or aortic stenosis, diagnostic features are changed. Thus, with important pulmonary stenosis, Qp is reduced, and the shunt may even be right to left. RV hypertrophy is increased. With important aortic stenosis, the load on the LV is increased, and if the obstruction is cephalad to the VSD, left-to-right shunt is also greater, resulting in more than the expected degree of LV hypertrophy on ECG. Coarctation of the aorta may also produce these features in older children.

Two-Dimensional Echocardiography

Two-dimensional echocardiography imaging of the VSD with color Doppler flow evaluation of shunt flow by proximal isovelocity surface area (PISA) has changed traditional views about preoperative studies. Thus, cardiac catheterization and cineangiography are not necessary before closure of primary VSDs when (1) the clinical syndrome in neonates and infants indicates a large Qp/Qs; (2) noninvasive imaging clearly defines the morphology, including that of the aortic arch and ductus arteriosus; and (3) the surgeon is experienced in surgical identification and repair of congenital heart disease.

For identifying a large single perimembranous VSD, combined 2D echocardiography and Doppler flow interrogation is highly reliable in combination with clinical criteria (Fig. 35-18). Echocardiography adds to anatomic clarification, particularly in the case of doubly committed subarterial VSDs. Particularly for small VSDs and multiple muscular defects, 2D Doppler color flow echocardiographic imaging increases the sensitivity of echocardiography (Fig. 35-18, A and B). However, and particularly in the presence of a single large VSD, multiple muscular defects can go undetected even with refined techniques of echocardiography. Because perimembranous VSDs are infrequently (<3%) accompanied by additional muscular VSDs, this does not contraindicate proceeding to repair in infants without cardiac catheterization. Malalignment VSD is diagnosed by 2D echocardiography by the appearance of the alignment of the RV and pulmonary semilunar valves. Malalignment may be anterior as in tetralogy of Fallot (Fig. 35-18, C), posterior as in interrupted aortic arch, or rotational as in Taussig-Bing heart.

Size of a VSD is generally categorized echocardiographically as small, moderate, or large for purposes of decisions regarding surgery (see Morphology and Indications for Operation later in this chapter). A large defect has a diameter of 75% or greater of the aortic anulus and low-velocity flow by Doppler, measuring no more than 1 m · s⁻¹. A moderate defect has a diameter of 33% to 75% of the aortic anulus and flow velocity of 1 to 4 m · s⁻¹, indicating moderate flow restriction. (By the modified Bernoulli equation, gradient across the defect is calculated by multiplying velocity squared times 4.) A small defect has a diameter less than 33% of the aortic anulus and a flow velocity of 4 m · s⁻¹ or greater. When considering Rp, it is important to note that as resistance (or obstructions in the RV outflow tract) increases, flow velocity across the VSD decreases.

Other Noninvasive Diagnostic Methods

Other noninvasive imaging modalities may come into use. At present, only magnetic resonance imaging (MRI) has shown promise to provide accurate information about the morphology of all types of VSDs. Dynamic three-dimensional echocardiographic reconstructions may refine ability to image and portray VSDs spatially.

Cardiac Catheterization

When surgical intervention is under consideration in older children, cardiac catheterization and angiography are generally indicated to assess Rp and precisely identify location, size, and number of VSDs and any associated anomalies. Furthermore, preoperative sizing of VSDs is often important in arriving at management decisions. Sizing can be especially difficult when the VSD is associated with another lesion such as coarctation or pulmonary stenosis. The most reliable way to size the defect is to measure its diameter either by 2D color flow Doppler echocardiography or cineangiography. With cineangiography, the VSD must be accurately profiled and the measurement either corrected to allow for magnification or compared with aortic root diameter. In applying this method to perimembranous VSDs, the defect is smaller in a cranially tilted left anterior oblique (LAO) projection than in the conventional LAO position.

Cardiac catheterization should include both right-sided and left-sided heart studies, the latter mainly to obtain LV angiograms. Basic data obtained at cardiac catheterization should include oxygen consumption (VO₂); systolic, diastolic, and mean pulmonary arterial, pulmonary artery wedge, and systemic arterial pressures; oxygen content and saturation in right atrial, pulmonary arterial, aortic, or peripheral arterial blood and, when possible, left atrial blood. Pulmonary (Qp) and systemic (Qs) blood flows and Qp/Qs...
are calculated\(^3\) with Rp (Table 35-3). When left atrial (or pulmonary arterial wedge) pressure is not available, only total pulmonary resistance (TPR)\(^4\) can be calculated. Rp in absolute units \(\times\) body surface area is of more value in predicting operability than is the ratio of resistances in pulmonary and systemic circuits.\(^5\) When Rp is elevated, further information concerning operability should be obtained by assessing response to exercise and to isoproterenol (see Indications for Operation later in this chapter).

### Angiography

Angiographic assessment of VSD is best performed using biplane techniques in appropriate projections.\(^6\)\(^7\) Whereas cardiologists and radiologists carry primary responsibility for these studies, appreciation of their findings and limitations is essential to the surgeon, who must also understand when the study is incomplete.\(^8\)

Fig. 35-19 summarizes the surgically important features of angiograms of VSD by diagram. Fig. 35-20 presents representative angiograms of the various types of VSDs.

### NATURAL HISTORY

#### Spontaneous Closure

VSDs tend to close spontaneously.\(^9\) This is relevant to decisions about operation and explains, for the most part, the infrequency with which large VSDs are encountered in adults.\(^10\) Spontaneous closure can be complete by 1 year of

---

\(\frac{Q_P}{Q_S} = \frac{V_o_1}{(C_a_0_1 - C_p_0_1)}\) in L·min\(^{-1}\)

where \(P_r\) is pulmonary vein and \(P_a\) is pulmonary artery. \(Q_P\) may be expressed as index \(L\cdot\text{min}^{-1}\cdot\text{m}^{-2}\) by dividing by body surface area (BSA) expressed in square meters.

\(Q_s = \frac{V_o_2}{(C_a_0_2 - C_v_0_2)}\) in L·min\(^{-1}\)

where \(a\) is aorta or arterial and \(v\) is mixed venous.

\(\frac{Q_P}{Q_S} = \frac{(C_a_0_1 - C_p_0_1)}{(C_a_0_2 - C_p_0_2)}\)

Note that total oxygen consumption is not needed for this calculation.

Chapter 35 Ventricular Septal Defect

A. Interrelationships of left ventricle (LV) and aortic root (thick line) with right ventricle (RV) and pulmonary trunk (thin line) in 40-degree right anterior oblique (RAO), 50-degree left anterior oblique (LAO), and 40-degree cranially tilted (CR. LAO) projections. RAO view profiles infundibular (conal) and high anterior portions of RV outlet septum below and in front of right coronary sinus and profiles atrioventricular (AV) septum beneath noncoronary sinus of aortic root. Both LAO views profile apical trabecular portion of septum. LAO view also partly profiles RV outlet septum but superimposes it on LV outflow tract and aortic root. CR. LAO projection views RV outlet septum en face and superimposes it on LV. Because orientation shows a horizontally lying heart, LAO view depicts full length (cranial to caudal) of apical and anterior trabecular portion of ventricular septum and AV valve anuli (interrupted lines), whereas CR. LAO view depicts full length of sinus portion of trabecular septum from base to apex. B. Both cranially tilted (CR. LAO) and conventional LAO views are required for a complete assessment of sinus septum. Basal (inlet) (O, x) VSDs are separated from more apical (o) VSDs by CR. LAO projection, whereas high (x) VSDs are separated from low (O) VSDs by LAO view. C, Anatomic and hemodynamic features of VSDs shown by LV angiograms. LAO diagrams show a compromise between conventional and cranially tilted options. LV and aorta are shown by thick lines, RV and pulmonary trunk by thin lines, and AV valves and nonprofiled VSDs by interrupted lines. C1, Perimembranous VSD. LAO view profiles VSD just beneath parietal band (ventriculoinfundibular fold) at upper margin of inlet septum. Flow enters base of RV above tricuspid valve, filling base before reaching infundibulum. Tricuspid valve is well seen in diastole, and lower margin of defect can be accurately related to tricuspid anulus in LAO. RAO view does not profile defect unless it extends into outlet septum. Note intact AV septum beneath noncoronary sinus of aortic root. Shunt enters RV infundibulum, crossing but not interrupting intact superior margin of LV, indicating intact conal and high anterior septal regions. C2, Doubly committed subarterial VSD (labeled conal septal VSD). LAO view shows an intact septum from aortic valve to apex. RV sinus usually fills only faintly by diastolic mixing from infundibular region, and tricuspid valve may not be seen. Defect is superimposed on aortic root. RAO view profiles defect beneath contiguous parts of aortic and pulmonary valves. Systolic streaming through RV infundibulum to pulmonary trunk is well shown, with some mixing to more anterior part of RV in diastole, but high anterior septal region is intact.

Figure 35-19 Line drawings of angiographic projections for assessment of ventricular septal defect (VSD). A, Interrelationships of left ventricle (LV) and aortic root (thick line) with right ventricle (RV) and pulmonary trunk (thin line) in 40-degree right anterior oblique (RAO), 50-degree left anterior oblique (LAO), and 40-degree cranially tilted (CR. LAO) projections. RAO view profiles infundibular (conal) and high anterior portions of RV outlet septum below and in front of right coronary sinus and profiles atrioventricular (AV) septum beneath noncoronary sinus of aortic root. Figure 35-19, cont’d  C3, Inlet septal VSD (labeled basal muscular VSD). VSD is adjacent to tricuspid valve (AV septal type) or separated from it by a rim of muscle (muscular VSD). These two types of VSDs are not readily distinguished radiologically. In LAO view, defect is profiled between AV valves, replacing full height of basal septum (conventional LAO view), perhaps extending into adjacent middle portion of ventricular septum but not into apical region (cranially tilted LAO view). Contrast medium streams directly into base of RV sinus in systole, providing a good depiction of tricuspid orifice in diastole. Separate AV valves are present, in contrast to the finding in a complete AV septal defect (see Chapter 34). In RAO view, VSD is not profiled. Intact AV septum distinguishes this defect from a true AV septal defect. Note intact conal and high anterior septal regions. C4, Muscular, trabecular VSD (labeled mid-muscular VSD). LAO views show an intact inlet septum and no extension into apical region, although a small additional defect is seen in diastole, closing in systole. Some of the contrast medium streams directly into RV outflow during systole. Height of defect from floor of ventricle (bottom of AV valve) is appreciated in LAO view, and separation from basal and apical regions in cranially tilted LAO view. RAO features are as in parts C1 and C3. C5, Multiple muscular anterior and apical VSDs. Muscular VSDs in these regions frequently coexist and, if numerous, form a continuous series throughout trabeculated septum from high in RV infundibulum to apical sinus septum. For clarity, only highest and lowest are shown here. In LAO view, intact basal and middle septal regions are profiled. Apical defects are profiled, but high anterior defects are superimposed on LV outflow region. Contrast medium tends to stream to RV outflow tract without filling basal parts. In RAO view, high anterior defects are profiled, interrupting superior margin of LV anterior to intact outlet septum. More defects are open in diastole than in systole. Key: CR.LAO, Cranial left anterior oblique; L, left coronary; LAO, left anterior oblique; LV, left ventricle; N, noncoronary; R, right coronary; RAO, right anterior oblique; RV, right ventricle. (From Brandt.31)
A1, 40-degree cranially tilted 60-degree left anterior oblique (LAO) projection, systolic frame, early in perimembranous angiographic sequence. VSD (arrow) lies in basal part of ventricular septum adjacent to aortic root. No additional defects are seen in middle and apical portions of septum (catheter to LV through atrial septum and mitral valve). A2, 30-degree right anterior oblique (RAO) projection, systolic frame, slightly later than A1 in sequence. Patient was positioned to achieve cranial tilting of simultaneously exposed LAO view shown in A1. Note intact atrioventricular septum beneath noncoronary aortic sinus and intact outlet septum (C). Contrast medium from shunt through nonprofiled VSD fills right ventricular (RV) outflow tract, crossing (arrow) but not interrupting high anterior margin of LV. A3, 50-degree LAO projection, systolic frame early in sequence (second injection). Perimembranous VSD is profiled as in A1 beneath aortic root. Large arrow indicates flow into base of RV above tricuspid valve (identified in diastole but not illustrated). Downward extent of VSD (small arrow) is accurately shown, and there are no additional defects lower in septum. Perimembranous defects are frequently small, of dimensions profiled in cranially tilted LAO projection in A1, compared with LAO.

Figure 35-20 Angiograms of patients with ventricular septal defect (VSD). A, Left ventricular (LV) angiograms of a perimembranous VSD. A1, 40-degree cranially tilted 60-degree left anterior oblique (LAO) projection, systolic frame, early in perimembranous angiographic sequence. VSD (arrow) lies in basal part of ventricular septum adjacent to aortic root. No additional defects are seen in middle and apical portions of septum (catheter to LV through atrial septum and mitral valve). A2, 30-degree right anterior oblique (RAO) projection, systolic frame, slightly later than A1 in sequence. Patient was positioned to achieve cranial tilting of simultaneously exposed LAO view shown in A1. Note intact atrioventricular septum beneath noncoronary aortic sinus and intact outlet septum (C). Contrast medium from shunt through nonprofiled VSD fills right ventricular (RV) outflow tract, crossing (arrow) but not interrupting high anterior margin of LV. A3, 50-degree LAO projection, systolic frame early in sequence (second injection). Perimembranous VSD is profiled as in A1 beneath aortic root. Large arrow indicates flow into base of RV above tricuspid valve (identified in diastole but not illustrated). Downward extent of VSD (small arrow) is accurately shown, and there are no additional defects lower in septum. Perimembranous defects are frequently small, of dimensions profiled in cranially tilted LAO projection in A1, compared with LAO.

Continued
Figure 35-20, cont'd  B, LV angiograms of doubly committed subarterial VSD. B1, 60-degree LAO projection, systolic frame early in sequence. Pulmonary arteries are filled by shunt through RV outlet defect superimposed on LV outflow tract. Only slight contrast medium is seen in RV sinus, and whole of sinus septum is shown to be intact. B2, 30-degree RAO projection, diastolic or very early systolic frame early in sequence. Doubly committed subarterial VSD is profiled immediately beneath contiguous parts of aortic and pulmonary valves, still closed. Arrows show streaming from VSD toward pulmonary valve, with some filling of remainder of RV infundibulum, but high anterior LV margin is intact. C, LV angiocardiograms of muscular VSDs. C1, Muscular anterior VSD. 30-degree RAO projection, diastolic or very early systolic frame early in sequence. Shunt through large, high-anterior muscular VSD fills anterior part of RV infundibulum. Arrows show the main stream toward pulmonary valve, which is still closed. There is a little mixing in RV sinus, but outlet septum is intact. C2, Multiple muscular VSDs (Swiss cheese septum); 40-degree cranially tilted 60-degree LAO projection, systolic cine frame. Large muscular trabecular VSD (large arrow), accompanied by numerous small muscular apical defects (small arrows), is profiled, but basal part of ventricular septum beneath aortic root is intact. In diastole (not shown), more numerous apical defects were apparent. C3, 30-degree RAO projection, diastolic frame in same patient as in C2. Numerous muscular anterior VSDs (arrows) interrupt LV margin. Note intact outlet septal margin of LV near aortic valve. Earlier in sequence, intact atrioventricular septum was identified, but base of filled RV overlaps base of LV in this frame. Note that position of large muscular VSD is incompletely evaluated (trabecular); an LAO view would be necessary. Note surgically banded pulmonary trunk. Key: A, Aortic valve; Ao, Aorta; C, septum; D, subarterial ventricular septal defect; P, pulmonary valve; PT, pulmonary trunk; R, right ventricle; V, atrioventricular septum.
close than juxtaglutaric or subarterial muscular VSDs.  
Perimembranous VSD with LV-to–right atrial shunt (Gerbode defect) in infancy is also associated with less chance of spontaneous closure.

Inferences about the tendency toward spontaneous closure seem to be in disagreement with the results of some studies. Hoffman and Rudolph’s data (one of the sources for Fig. 35-21) indicate that 80% of infants aged 6 weeks with large VSDs will experience spontaneous closure or reduction in size of the VSD. Rowe found that none of 11 infants (mean age 46 days) with a VSD 80% or greater in diameter than that of the aorta showed subsequent reduction in size during the period of observation. These apparent discrepancies may be explained by lack of information about location or size of VSDs.

Pulmonary Vascular Disease

A large VSD exposes the patient to risk of developing increased Rp from hypertensive pulmonary vascular disease, which tends to worsen with age. Thus, the proportion of patients with large VSDs who have severely elevated Rp is directly related to age (Fig. 35-22). The statement that some infants younger than 2 years of age with large VSDs have severely elevated Rp is doubted by some, but its occurrence is well documented.

Some infants and children with severely elevated Rp have not undergone the usual fall in Rp a few weeks to a few months after birth. Others have undergone this decrease, but later in the first 2 years of life, they have developed a rapid increase in Rp.  
Some infants with large VSDs and most of those with moderate-sized VSDs have normal or mildly elevated Rp and retain this through the first decade of life. Then, if their VSD is still large, more severe pulmonary vascular changes may or may not develop as they age. In infants with small VSDs, pulmonary vascular disease does not develop.

Infective Endocarditis

Infective endocarditis is rare in patients with VSD, occurring at a rate of about 0.15% to 0.3% per year. Its prevalence is greater in males and individuals older than 20 years of age. Infective endocarditis is more common in small and moderate VSDs than in large VSDs. Often a pulmonary process is the presenting feature, presumably developing from emboli secondary to right-sided bacterial vegetations or bacteria carried to the lungs by left-to-right–directed flow through the VSD. Prognosis with modern antibiotic treatment regimens is good.

Premature Death

Past experience and reports in the literature indicate that without surgical treatment, about 9% of infants with large VSDs die from them in the first year of life. Death may also result from recurrent pulmonary infections, often viral in origin, secondary to pulmonary edema from high pulmonary venous pressure. Death is most likely to occur in those infants with large VSDs who have associated conditions of major anatomic or functional importance, such as PDA, coarctation of the aorta, or large atrial septal defect.

After the age of 1 year, few if any patients die of their VSD until the second decade of life. By then, many patients whose VSDs have remained large have pulmonary vascular disease and ultimately die with complications of Eisenmenger complex (Fig. 35-23). These include hemoptysis, polycythemia, cerebral abscess or infarction, and right-sided heart failure.

Patients with small VSDs die very rarely as a result of bacterial endocarditis. However, in common with patients with larger VSDs, some of these patients may develop disturbed systolic function and increased compliance in both ventricles.

Figure 35-21 Probability of eventual spontaneous closure of a large ventricular septal defect (VSD) according to age at which patient is observed. Dotted lines enclose 70% confidence limits. Specific ratios, with 70% confidence limits, reported by Hoffman and Rudolph and Keith and colleagues are shown centered on mean or assumed ages of patients in their reports. P for age <.0001. See original sources for equations and statistics. (From Blackstone and colleagues.)

Figure 35-22 Estimated (not calculated) probability of developing severe pulmonary vascular disease (pulmonary vascular resistance 8 units · m-2 or greater) in patients with large ventricular septal defects, according to age. (From Keith and colleagues.)

Chapter 35 Ventricular Septal Defect
as well as some of the more important pulmonary stenoses, probably develop in this way. Stenosis may become severe enough to produce shunt reversal and cyanosis, and the condition then can properly be termed tetralogy of Fallot (see Chapter 38). Those who undergo the transformation probably are born with a mild degree of anterior displacement of the infundibular septum and its extensions.

**TECHNIQUE OF OPERATION**

VSDs are repaired either through the right atrium, RV, or in special circumstances, LV or pulmonary trunk. Currently, RV and LV approaches are rarely used. Repair is done on conventional CPB at 20°C to 28°C, with direct caval cannulation and brief periods of low flow perfusion or (rarely) total circulatory arrest (see Sections III and IV of Chapter 2). For infants weighing less than about 3 kg, a single venous cannula may be used, and the repair is performed during hypothermic circulatory arrest (see Section IV of Chapter 2). Cold cardioplegia is used in all cases.

After the usual anesthetic and surgical preparations (see Chapter 4), a median sternotomy is made. Presence of anomalies of pulmonary or systemic venous return is determined. It should be known from preoperative study whether the ductus arteriosus is open or closed. An open ductus during open cardiotomy, particularly during hypothermic circulatory arrest, allows air to enter the aorta and later migrate to the brain; during CPB an open ductus increases intracardiac return and overdistends the pulmonary circulation. A patent ductus is ligated from the anterior approach, usually during cooling. In neonates and infants undergoing hypothermic circulatory arrest, the ductus is ligated as a routine procedure.

**Repair of Perimembranous Ventricular Septal Defect**

After CPB (with or without circulatory arrest) has been established, the aorta is occluded, cold cardioplegic solution injected, and the right atrium opened obliquely. A suction device is placed across the naturally present or surgically created foramen ovale (Fig. 35-24). Before repair is started, the defect is carefully examined to establish that all margins can be seen and reached. In rare circumstances in which this is not possible because of chordal arrangement, an incision is made to disconnect a portion of the tricuspid valve from the annulus, and the VSD is exposed through the resulting aperture. Particular attention is directed toward determining whether the VSD is juxtratricuspid, in which case it abuts the tricuspid valve in the region of the commissure between septal and anterior leaflets. If the VSD has a bar of muscle of varying width between it and the tricuspid valve, it is not juxtratricuspid. Relationship of the bundle of His to the posterior and inferior margins of the defect must be clearly understood (see Morphology earlier in this section) to accomplish a safe repair (Fig. 35-24, A).

In older infants and children, the VSD is repaired with a polyester patch sewn in place with continuous polypropylene sutures (Fig. 35-24, B), a technique confirmed to be entirely adequate in such patients. In neonates and small infants, the technique may not be adequate because of the delicate nature and friability of the structures. In these patients, the patch may be sewn into place using a combination of continuous and interrupted pledgeted mattress sutures or, alternatively,
Employing exclusively interrupted mattress sutures reinforced with small pledgets.

A ventricular approach may be used when the VSD cannot be well visualized from the right atrium. An RV approach is performed through a transverse incision. The patch is sewn into place with continuous or interrupted sutures (Fig. 35-25). Technique of repair and sequence for suturing shown in Fig. 35-25 are slightly different from those shown for the atrial approach. Suturing begins at the transition point between the septal leaflet of the tricuspid valve and the...
ventricular septum, 5 to 7 mm below the edge of the septal defect. This critical point is given attention by all experienced surgeons.  

Usual de-airing procedures are performed, and the remainder of the operation is completed as usual.

Repair of Doubly Committed Subarterial Ventricular Septal Defect

Transverse incision in the RV infundibulum is the classic approach for repair of doubly committed subarterial VSDs  
(Fig. 35-26). These defects should always be closed with a patch to reduce the possibility of distorting the semilunar valves. A continuous stitch technique is employed. When pledged sutures are used, they are placed from just above the pulmonary valve leaflets, and pledgets come to lie in the pulmonary valve sinuses. Care is taken not to damage the left main coronary artery. An approach through the pulmonary trunk is also convenient for repairing doubly committed subarterial VSDs.

Repair of Inlet Septal Ventricular Septal Defect

Inlet septal (AV septal type) VSD is most easily repaired through the right atrium (see Technique of Operation in Chapter 34). Such defects are always repaired with a patch. The defect lies beneath the septal leaflet of the tricuspid valve, and care is taken to avoid damage to the leaflet or its chordae and to tailor the patch such that it is not too bulky beneath the leaflet. One method of avoiding damage to the leaflet and improving exposure is to temporarily detach the base of the septal leaflet and a portion of the anterior leaflet of the tricuspid valve and retract the leaflet anteriorly.

Repair of Muscular Ventricular Septal Defect

A right-sided approach is used for repair of muscular VSDs. Left ventriculotomy provides excellent exposure, and although it has been reported not to be disadvantageous in infants, it can produce ventricular aneurysm and important LV dysfunction early and late postoperatively. Therefore, use of left ventriculotomy is not recommended. Defects in the lower part of the muscular septum may be obscured by trabeculations and thus difficult to visualize, resulting in incomplete closure. Wollenek and colleagues found that an apical left ventriculotomy was a useful approach in 23 patients, and in follow-up over 3 to 18 years (mean 11 years), echocardiography showed no residual VSD, normal LV shortening, no regional wall motion abnormality, and small LV aneurysm in only two patients.

Single or multiple muscular defects in the inlet and trabecular septum (see Figs. 35-1 and 35-12) are approached through the right atrium. When a single defect is slitlike or oval, direct suture (often in part at least with pledged mattress sutures) is satisfactory, but when it is large and circular, a patch is used. A cluster of defects can be closed with a single patch or individually.

Division of RV trabeculations can aid exposure of the defects, which may be difficult to close because of multiple
sites of jet penetration. A heavy traction stitch passed through the defect and back through the left side of the defect may improve exposure. A single patch of autologous pericardium supported by pledget-reinforced sutures covering an extensive portion of the trabecular septum is useful when there are multiple defects. Kitagawa and colleagues described resection of trabeculations to expose the defect and attaching an oversized patch to the left side of the ventricular septum by sutures passed through the septum from the left side. They also described placing pledget-supported sutures through the rim of an anterior muscular defect, passing the sutures to the outside and tying down on the epicardial surface.

When a muscular VSD coexists with a perimembranous VSD, a single patch may be used to avoid damaging the bundle of His.

VSDs with a single LV opening but two or more openings into the RV on both sides of the trabecula septomarginalis

---

5The pledget is a “firm” polyester mini-pledget, 3/16 inch × 3/16 inch × 3/16 inch.
Figure 35-25, cont’d  C, Septal leaflet of tricuspid valve is retracted to expose junction of tricuspid anulus with ventricular septum. A pledget-reinforced mattress stitch of 4-0 polypropylene suture is placed to create a transition from septal leaflet to ventricular septum. One arm of suture is placed entirely on septal leaflet, and other arm is placed into ventricular septum at hinge point of septal leaflet on ventricular septum. Stitch is at least 5 to 7 mm below rim of VSD. Suture is passed through a knitted double-velour polyester patch fashioned to be somewhat larger than VSD. Alternative patch material could be pericardium or polytetrafluoroethylene. D, Several pledget-reinforced mattress stitches are placed around perimeter of VSD. Stitches are placed entirely in septal leaflet tissue between transition stitch and junction of septal and anterior leaflets of tricuspid valve. Stitches are placed 5 to 7 mm below rim of defect between transition stitch and papillary muscle of Lancisi, which demarcates anterior extent of specialized conduction system. Rest of stitches may be placed in rim of septal defect. All stitches are placed through ventricular septum and septal leaflet of tricuspid valve before approximating patch to ventricular septum. E, Patch is attached securely to ventricular septum by tying all sutures. Key: Ao, Aorta; PT, pulmonary trunk; RA, right atrium.
are also approached through the right atrium. The defect is converted into a single LV orifice by detaching the lower end of the trabecula septomarginalis and moderator band from the septum and retracting them (see Fig. 35-12). The VSD is closed with a patch. The trabecula septomarginalis then falls back into place.

Multiple defects in the anterior portion of the septum may be closed through a high transverse ventriculotomy. At times, VSDs may be considered too numerous to close individually; these VSDs are simply compressed and often totally closed by interrupted mattress sutures between a felt strip on the anterior ventricular wall (away from the left anterior descending coronary artery) and pledges inside the RV and inferior to the VSDs. This repair may be done from the right atrium or through a right ventriculotomy.

Apical muscular VSDs can be exposed through the right atrium and tricuspid valve or through a low vertical right ventriculotomy. This can be extended around the apex for a short distance onto the posterior wall.

The rare Swiss cheese septum, with features resembling ventricular noncompaction (spongy ventricular septum) and defects involving all components of the ventricular septum,
may not be correctable through the right side. Its repair requires an LV approach, and a patch over the entire muscular septum may be necessary. An associated perimembranous defect should be repaired through the right atrium because its repair from the LV side increases risk of heart block. Incisions into both ventricles are avoided whenever possible. Great care is used in making and closing the left ventriculotomy incision so as not to damage coronary artery branches. A continuous mattress suture over fine polytetrafluoroethylene (PTFE) felt strips plus an over-and-over stitch give a secure closure. Mace and colleagues used a right atrial approach and inserted a single large patch to cover the right side of the trabecular septum, adding several intermediate fixation stitches to prevent septal bulging. Regardless of the approach employed, these patients often have poor LV function after repair and may ultimately require transplantation for heart failure. This group of patients may be better served by pulmonary trunk banding with the hope that some of these defects may close as a result of ventricular hypertrophy.

Although it is important to avoid residual shunts, multiple incisions and a prolonged search for a few small additional muscular VSDs are generally not advisable. Preoperative echocardiography should accurately delineate the size as well as position of all the defects.

Closure of Associated Patent Ductus Arteriosus

Dissection of the ductus arteriosus is done after establishing CPB; this reduces the risk of hemorrhage should an error in dissection occur because of exposure, which can be difficult. After establishing CPB with the perfusate temperature at about 34°C, with caval tapes still unsnugged (so the heart will not distend) and right atrial pressure at zero, the ductus is dissected. The heart must continue to beat; otherwise a large shunt will rapidly overdistend the right side of the heart and lungs as it steals from the systemic and cerebral circulation. If the heart does fibrillate, CPB flow is immediately reduced while the dissection is rapidly completed. With downward traction on the pulmonary trunk (see Technique of Operation in Chapter 37), the ductus can usually be seen through its pericardial reflection and surrounding adventitial tissue. The left pulmonary artery and undersurface of the aorta—both proximal and distal to the ductus—are clearly identified to prevent these structures from being damaged or ligated after being mistaken for the ductus. The delicate pericardial reflection and adventitial tissue on both sides of the ductus are sharply dissected from it. The adventitia of the ductus itself and of the adjacent pulmonary artery and aorta must not be entered. The recurrent laryngeal nerve is not seen. Only when the dissection is complete, the left pulmonary artery visualized, and the ductus identified with absolute certainty is a right-angled clamp passed behind it to grasp the 2-0 silk ligature. One ligature, tied on the ductus side of the pulmonary trunk banding with the hope of reducing while the dissection is rapidly completed. With subsequent adhesions, the pericardial incision should be limited to the area needed to expose the great vessels. The pulmonary trunk is separated from the aorta by dissecting close to the aorta. A right-angled clamp is passed around and behind the aorta to grasp one end of the band and pull it through. The other end of the band is retrieved by a clamp passed through the transverse sinus. Small angiocatheters are placed in the aorta and left pulmonary artery for pressure monitoring. Transesophageal echocardiography (TEE) may be useful during the procedure to estimate gradient across the band.

With the band now safely around the proximal portion of the pulmonary trunk, the marked points on the band are joined temporarily with a hemoclip to produce the desired circumference. With proper band tightening in patients with a two-ventricle circulation, systolic and mean blood pressures will be less than 1, and the band is too tight. The distal pulmonary artery systolic pressure should be less than 50% of systemic systolic blood pressure. In cases of complete mixing, arterial oxygen saturation will vary with band tightening and should be set at 80% to 85% by pulse oximetry with FiO₂ of 50%. This implies a Qp/Qs of about 1 (see "Pulmonary Trunk Banding in Section II of Chapter 41"). If bradycardia or cyanosis develops, the band must be slightly loosened by placing a hemoclip more distally and removing the initial clip. If the narrowing is insufficient, as judged by the criteria mentioned earlier, it is tightened by adding a hemoclip more proximally.

When the ideal diameter is obtained, the band is joined by sutures. It is essential that stitches be placed between the band and the pulmonary trunk adventitia to prevent migration of the band. The pericardium is loosely closed to facilitate dissection at subsequent operation.

Pulmonary Trunk Debanding

When a pulmonary trunk band has been properly applied for 6 months or less, simple band removal may be all that is necessary. When the band must remain in place longer, reconstruction of the pulmonary trunk is usually required.
The band can almost always be cut and removed without damaging the underlying artery. The tip of the left atrial appendage actually is more likely to be damaged, because it is always adherent to the banded area. Dissection is usually delayed until CPB has been established, when if necessary, CPB flow can be reduced to facilitate exposure and dissection.

The VSD is usually closed after repair of the pulmonary trunk. The pulmonary trunk is usually reconstructed. The most satisfactory technique is local excision of the short, narrowed, scarred segment of artery and reanastomosis of the divided pulmonary trunk using a continuous polypropylene suture.28 This technique can usually be employed even when the band lies close to the pulmonary valve, by extending the incision vertically into the most anterior sinus between the valve commissures to enlarge the diameter of the proximal end. A similar technique can be used to enlarge an orifice stenosis involving only one branch of the pulmonary trunk. When the pulmonary valve cusps have become excessively thick, their edges may require excision. If an adequate diameter is unobtainable by the technique of excision and end-to-end anastomosis, an oval-shaped patch is inserted. To adequately enlarge the stenotic area, the patch (autologous pericardium, bovine pericardium, pulmonary allograft, or thin PTFE) should extend from within the sinus of Valsalva of the pulmonary trunk proximally and across the anastomosis to the distal trunk. Extensive reconstruction (see “Repair of Tetralogy of Fallot with Bifurcation Stenosis of Pulmonary Trunk” in Section I of Chapter 38) is required when the band constricts the origin of the pulmonary arteries.

**SPECIAL FEATURES OF POSTOPERATIVE CARE**

General measures and management of complications described in Chapter 5 are used for postoperative care of patients undergoing repair of primary VSD.

Hemodynamic state typically is good early postoperatively after closure of VSD. In the unusual situation of poor hemodynamic performance, the possibility of residual left-to-right shunting must be considered, particularly if left atrial pressure is considerably higher than right atrial pressure.6 Also, the finding of a considerably higher oxygen content or saturation in blood from the pulmonary artery than that from the right atrium establishes existence of a shunt.28 Two-dimensional Doppler color flow echocardiography can be used to settle the matter.1,18 Although some shunting may occur for 12 to 24 hours after VSD closure with a porous patch, the usual cause of poor hemodynamic state from a left-to-right shunt is patch dehiscence. Thus, if the hemodynamic state is poor or a large left-to-right shunt is present, prompt reoperation is probably indicated. Intraoperative echocardiography at the original operation, if done, will usually have indicated residual shunting, as confirmed by postoperative echocardiography, which may be done transesophageally for greatest resolution and quality of images.

It is prudent to place temporary pacing wires on the RV after VSD repair. Complete AV dissociation is often present for a short time intraoperatively. Even if this resolves promptly to normal sinus rhythm, it is advisable to leave pacing wires in place and have an external pacemaker available while the patient is hospitalized, because AV dissociation may occur temporarily.

**RESULTS**

**Early (Hospital) Death**

Hospital mortality is low for repair of single large VSDs, most of which are now repaired in early infancy. In the current era in experienced centers, hospital mortality for isolated VSD closure is 1% or less.30 Risk is higher when VSDs are multiple and when major associated cardiac anomalies coexist.

**Mode of Early Death**

The most common mode of death after repair of a primary VSD is acute cardiac failure.36 This may be related to failure of intraoperative myocardial protection in the face of myocardial dysfunction, often present in sick small patients coming to operation. Occasionally, paroxysms of pulmonary arterial hypertension (see “Pulmonary Hypertensive Crises” under Pulmonary Subsystem in Section I of Chapter 5) precipitate acute cardiac failure.321 Persisting severe pulmonary dysfunction, often from viral pneumonitis present before operation, characterizes death of a few infants after repair of VSD.

**Incremental Risk Factors for Hospital Death**

Studies of experiences extending back a number of years permit identification of incremental risk factors. With death after repair now less common, risk factors are now more difficult to identify.

Risk of repair has decreased, and thus early date of operation is an incremental risk factor.320,322,328 Improvement from an original risk of hospital death of 20% began in the experience at the Mayo Clinic during the early 1960s. This type of improvement has been demonstrated in other centers.1,18,37

In previous eras, **young age** increased the risk of operation.87,14 However, in the current era at experienced centers, this risk factor has been neutralized.15,35 Young age may still be an incremental risk factor when major associated anomalies coexist.

**Multiple VSDs** increased risk of operation in the past,1,17,12 but risk has declined considerably in the current era. However, multiple VSDs complicated by additional cardiac anomalies impose a higher risk of hospital death than uncomplicated ones.87 This again may not be an immutable risk and may be improved by better myocardial management, avoidance of ventricular incisions, and device closure.37
Changes in weight after repair of ventricular septal defect in 96 patients aged 10 years or less, with ratio of pulmonary and systemic pressures greater than 0.45 and ratio of pulmonary and systemic resistances less than 0.75 preoperatively. (From Cartmill and colleagues.)

**Survival**

Premature late death occurs in less than 2.5% of patients when Rp is low preoperatively. Presumably, the few deaths in this setting are from arrhythmias, either ventricular fibrillation or sudden development of heart block late postoperatively. Patients with a high Rp preoperatively often die from progression of pulmonary vascular disease.

Repair of VSD during the first 1 or 2 years of life is curative for most patients, resulting in full functional activity and normal or near-normal life expectancy.

**Physical Development**

A prominent feature of the late postoperative course after repair of large VSDs in infants is improved physical development, and an impressive increase in weight may also be seen, as Lillehei and colleagues first showed in 1955. There is a less impressive increase in length and head circumference. This improved physical development is usually associated with complete relief of symptoms. Postoperative weight increase also occurs in children in whom a large VSD is repaired later in the first decade of life (Fig. 35-27).

These generalizations were refined by Weintraub and Menahem in a definitive study. They confirmed that repair of a large VSD in the first 6 months of life results in near-normal long-term growth in most patients, so that by age 5 years, weight, length, and head circumference are normal. Low-birth-weight infants were an exception, and catch-up occurred only in their weight.

**Conduction Disturbances**

Conduction disturbances are frequent after repair of VSDs.

**Right Bundle Branch Block**

Right bundle branch block (RBBB) is present late postoperatively in many patients in whom VSDs are repaired via right ventriculotomy. In one series of infants, prevalence was 80% (CL 72%-86%). Based on their studies, Gelband and colleagues concluded that the cause is the ventriculotomy. However, Weidman and colleagues at Mayo Clinic reported that 44% (CL 35%-54%) of 36 patients undergoing repair of perimembranous VSDs through a right atriotomy developed new RBBB. Rein and colleagues reported RBBB in 34% (CL 26%-43%) of infants undergoing repair via right atriotomy. Thus, in some patients, RBBB must result from damage to the right bundle by sutures along the inferior border of perimembranous VSDs. In any event, RBBB is less prevalent when the right atrial approach is used for VSD repair. Although an adverse effect on late ventricular function has not been established, at least one study has associated RBBB with increased risk of late diastolic dysfunction.
techniques through the right atrium or RV. Others have found persisting abnormalities of LV size and function after repair of large VSDs at an older age, although all patients were asymptomatic. This information suggests that in general, patients with large VSDs should be operated on before they reach 2 years of age, preferably during the first year of life.

Experience with LV function after left ventriculotomy for repairing VSDs in infants has been sobering; in some patients, cardiac output has been low and left atrial pressure high despite absence of a shunt. False aneurysm has occurred after closure of VSD through a left ventriculotomy.

Residual Shunting
Postoperative left-to-right shunts large enough to require reoperation are uncommon when proper techniques are used. In experienced centers, reoperation for residual VSD should be 2% or less. Small but hemodynamically unimportant residual VSDs cannot be entirely ignored; theoretically, the possibility of infective endocarditis at such sites exists. Accurate estimation of their prevalence would require routine postoperative left ventriculography, however, and this has not been done. With near-routine intra- and postoperative assessment of cardiac function, such shunts are usually detected.
reparations by echocardiography, detection of even small residual defects late after operation is uncommon. Among early residual defects of less than 2 mm detected by echocardiography, greater than 80% are undetectable at 1 year.

Pulmonary Hyperinflation Syndrome

When pulmonary hyperinflation syndrome is present in infants before VSD repair, it usually resolves within 1 to 2 months after repair.

Surgically Produced Aortic or Tricuspid Regurgitation

As complications of repair of primary VSD, surgically produced aortic and tricuspid regurgitation are rare.

Rarity of surgically induced tricuspid regurgitation is surprising considering how often abnormal chordae are attached around the defect. Aortic valve regurgitation occurring after patch closure of doubly committed subarterial VSD may be a special problem. Tomita and colleagues reported that aortic valve regurgitation was detected by echocardiography in 6 of 23 patients (26%; CI:16%-39%) having neither aortic valve prolapse nor regurgitation before operation. Among early repairs by echocardiography, detection of even small residual defects late after operation is uncommon. Among early residual defects of less than 2 mm detected by echocardiography, greater than 80% are undetectable at 1 year.

Pulmonary Hypertension

When severe pulmonary hypertension persists after operation, it may worsen with passage of time and may cause premature late death. About 25% of patients with preoperative pulmonary hypertension and high Rp (at least 10 units · m⁻²) die with pulmonary hypertension within 5 years of operation (Fig. 35-29). However, some patients with pulmonary hypertension and elevated Rp late postoperatively have neither progression nor regression of their disease for as long as 20 years, although they have some limitation in exercise tolerance.

In general, the younger the child at time of repair, the better are the chances of surviving and having an essentially normal PPA 5 years and more later. The lower the Rp at repair, the better the chances of having normal pressure late postoperatively (Fig. 35-31). These two factors, age and preoperative Rp, interact in determining late postoperative PPA.

A more specific correlate of survival and good outcome in patients with important preoperative pulmonary hypertension is preoperative response to infusion of a pulmonary vascular dilator such as isoproterenol. Generally, outcome is good in patients of all ages when preoperative Rp is only mildly or moderately elevated (<8 units · m⁻²; see Table 35-3). Outcome is good in patients with severely elevated Rp only
when it drops below 7.0 units · m$^{-2}$ with preoperative infusion of isoproterenol. Sodium nitroprusside infusion or nitric oxide may also be used and has the advantage of not producing tachycardia.

**Surgical Cure**

Combining data on PPA late postoperatively with the proportion of patients dying early and late postoperatively, chances of “surgical cure” (defined as surviving the early postoperative period and being alive late postoperatively with essentially normal PPA) can be estimated for an individual patient (Fig. 35-32). If repair of a large VSD is performed in a patient at 6 months of age, there is at least a 95% chance of surgical cure, unless preoperative Rp is greater than about 8 units · m$^{-2}$ and does not fall to less than 7 units · m$^{-2}$ with infusion of isoproterenol (which is rare at that age). This is supported by studies by Rabinovitch and colleagues, in which it was also found that surgical cure is likely to result in any infant in whom the VSD is repaired before age 6 to 9 months, irrespective of degree of pulmonary vascular disease. In a 2-year-old patient, chances of cure are this good only if preoperative Rp is less than about 5 units · m$^{-2}$. In a patient operated on for repair of large VSD at age 4 years, chances are that good only if Rp is normal preoperatively (which is unusual). This unfavorable effect of older age has been confirmed by John and colleagues. This finding supports the practice of repair of large defects at least by age 12 months and can be used to predict results of operation in individual patients.

**INDICATIONS FOR OPERATION**

In earlier eras, great emphasis was placed on details of calculated Rp and $Q_p/Q_s$ in determining appropriate timing of surgical intervention or whether continued observation was advisable. In the current era in which hospital mortality after surgical closure of isolated VSD approaches 1% or less, and the majority of infants and children undergo transthoracic echocardiography (without cardiac catheterization) as the definitive diagnostic study, the decision-making process has evolved away from these hemodynamic measurements.

Decisions regarding operation vary somewhat among experienced institutions, but generally relate to size of the defect as assessed echocardiographically (see “Two-Dimensional Echocardiography” under Clinical Features and Diagnostic Criteria), morphologic characteristics related to likelihood of spontaneous closure (see Fig. 35-32), estimated Rp, and presence or absence of Down syndrome.

Infants with an isolated large VSD are rarely truly asymptomatic in the absence of elevated Rp, which results in lower $Q_p$. In addition to overt signs of heart failure or failure to thrive, the experienced pediatric cardiologist will note subtle signs of failure such as enlarged tachypnea or decrease in the slope of the growth curve even with adequate feeding. Left atrial enlargement detected echocardiographically supports the presence of LV volume overload secondary to increased $Q_p$. In the presence of a large defect and absence of such symptoms or signs, specific echocardiographic interrogation for signs of elevated Rp or associated obstructive lesions in the RV outflow tract is warranted. In infants with a large VSD and major symptoms of heart failure or failure to thrive, operation is advisable irrespective of age. In the presence of mild symptoms, elective repair of isolated large VSD is advisable during the first 6 months of life or at the time of diagnosis if older. Infants with Down syndrome and large VSD are likely at increased risk for developing pulmonary vascular disease; therefore, operation should be undertaken within the first few months of life.

Infants with a moderate or large perimembranous VSD associated with aneurysm of the membranous system or a VSD partially covered by accessory tricuspid valve tissue have increased likelihood of spontaneous closure, and operation can be deferred for 6 to 12 months in the absence of symptoms, with planned reevaluation for signs of decreasing size. A VSD of moderate size still carries an ongoing risk of pulmonary vascular disease, and surgical closure is recommended by 12 months of age (or at the time of diagnosis if older) unless there are signs of decreasing defect size. Appearance of decreasing flow velocity in the absence of decreasing size suggests increasing Rp, although such findings may appear transiently in the face of bronchiolitis or other self-limited reasons for increased Rp. If increasing Rp is identified, prompt surgical closure is advisable.

Exceptions to this general practice are made for rare infants with Swiss cheese septum, who present a special problem because of higher risk of surgery. In this setting during the first 3 months of life, pulmonary trunk banding may be indicated; when there are no complications from the band, repair of the Swiss cheese septum and debanding are postponed until age 2 to 4 years. This general plan is also followed when Swiss cheese septum coexists with coarctation of the aorta. Other exceptions to primary repair during the first 3 months of life include infants with straddling tricuspid valve.

In patients with evidence of important elevation of Rp by echocardiography, cardiac catheterization is advisable. When Rp is truly and precisely measured at preoperative cardiac catheterization and is only mildly or moderately elevated (<8 units · m$^{-2}$), operation can be undertaken with near certainty that the early and late outcome will be good (Fig. 35-33). Such patients usually have a large $Q_p/Q_s$. 

---

**Figure 35-32** Probability of overall surgical cure (survival at least 5 years postoperatively with a mean pulmonary artery pressure of <25 mm Hg) according to age (months) at repair for all patients with single large ventricular septal defects (VSD). Dashed lines enclose 70% confidence limits. Analysis is based on data of DuShane and Kirklin. Natural history is also shown, with vertical axis the probability of long-term survival and ultimate spontaneous closure of the defect and horizontal axis the age at observation of a patient with a large VSD. (From Blackstone EH, Kirklin JW: Unpublished study, 1982.)
In older patients, operation is generally advisable with a $Q_p/Q_s$ above 1.5 in the absence of additional major operative risk factors. However, in patients with a large VSD, a $Q_p/Q_s$ of 1.5 to 1.8 at rest that becomes 1.0 or less during moderate exercise (from systemic peripheral vasodilatation, increased $Q_s$, and a fixed and high $R_p$ preventing increased $Q_p$) is an indication of probable inoperability. An important fall in $S_aO_2$ during exercise (from right-to-left shunting across the VSD for the reasons described) also suggests inoperability, but a more complete investigation with determination of response to nitric oxide is required for a final decision. Response of $R_p$ to inhalation of mixtures high in oxygen alone is not useful in determining operability in borderline situations.

Children with small VSDs can be safely observed unless other cardiac anomalies (e.g., aortic regurgitation from aortic cusp prolapse, subaortic stenosis, subpulmonary stenosis) are observed. Periodic reevaluation is advisable to verify that observed clinical and echocardiographic findings are compatible with safe continued observation.

Doubly committed subarterial and juxta-aortic VSDs constitute a special situation. Even though apparently small, they should not be left untreated if there is any aortic cusp deformity on 2D echocardiography or cineangiography; development of aortic regurgitation must be prevented (see Section II). These defects should be repaired promptly if an aortic diastolic murmur develops.

### SPECIAL SITUATIONS AND CONTROVERSIES

#### Ventricular Septal Defect and Patent Ductus Arteriosus

Combination of large VSD and moderate-sized or large PDA is particularly likely to cause severe symptoms and require operation early in infancy. During the first 6 to 8 weeks of life in patients with a very large ductus and only a moderate-sized or small VSD, the PDA alone may be repaired because the VSD may narrow or close spontaneously. If this does not occur, the VSD is closed at an appropriate time. When the VSD is large, both it and the PDA are closed simultaneously if operation is required in early life. Risk of operation should not be higher than that for isolated VSD.

#### Ventricular Septal Defect and Coarctation of Aorta

Combination of VSD and aortic coarctation frequently causes severe symptoms in infancy. Both coarctation and VSD are variable in severity. Clearly, the worst combination is a large VSD and severe coarctation, but even a small VSD in association with important coarctation may produce heart failure early in life.

Management options for this combination of defects include simultaneous repair of both lesions, sequential single-stage repair through separate incisions, initial repair of the coarctation alone, initial coarctation repair and pulmonary trunk banding, or initial VSD closure alone. With a large VSD and severe coarctation, repairing the VSD first has certain theoretic advantages but has been practiced.
rarely under such circumstances. Repair of the coarctation only as the initial operation has the advantage of reducing afterload on the LV and, theoretically at least, reducing shunt through the defect. It also avoids a second operation if the VSD closes spontaneously. Mortality with repair of aortic coarctation in this setting has been high in the past, but more recent experience has been good. The results have also been good with initial coarctation repair with pulmonary trunk banding.

Simultaneous repair of both the coarctation and a large VSD in early infancy in the current era in experienced institutions carries a low risk, with hospital mortality of about 5%. The operation is generally performed via a median sternotomy and combined regional perfusion and circulatory arrest. Alternatively, the operation can be performed as a single stage with repair of coarctation through a left thoracotomy followed by repair of a VSD via median sternotomy using standard CPB. Kanter and colleagues have reported excellent survival with this method. In the current era, the following practice can be recommended:

1. When the VSD is large, the coarctation is severe, and the infant presents with severe heart failure, a single-stage repair of coarctation and VSD is advisable, using one of the techniques described previously. When multiple VSDs or Swiss cheese septum is present, the pulmonary trunk is banded, and debanding and repair are delayed if possible until the patient is about age 3 years.
2. When the coarctation is severe and VSD small or moderate-sized, only the coarctation is repaired, and subsequent repair of the VSD is performed according to standard indications.
3. When the coarctation is moderately severe and VSD large, the VSD may be repaired initially and the coarctation repaired either at the same operation or as a second procedure within a few months. Techniques of CPB are standard, with perfusion of the lower body satisfactory in this situation.

**Pulmonary Trunk Banding**

Civin and Edwards noted good prognosis and freedom from pulmonary vascular disease in patients with single ventricle and moderate pulmonary stenosis. Based on that observation, Muller and Dammann performed pulmonary trunk banding in 1952. For many years thereafter, this procedure was used by many for infants who required operation for large VSD, thereby allowing deferral of the intracardiac repair until an older age.

For several reasons, banding is seldom indicated for primary isolated large VSDs. Hospital mortality of patients with pulmonary trunk banding has been substantial, and a second operation, which carries additional mortality, is always required. Early mortality is independent of type of VSD. It is difficult to adjust the tightness of the band perfectly, and reentry a few days later may be needed to modify the tightness. Furthermore, good palliation is not always achieved by banding, and there may be important intermediate mortality before second-stage repair. Complications result from banding in some patients, including development of infundibular and valvar pulmonary stenosis, subaortic stenosis, and migration of the band to the pulmonary trunk bifurcation (Fig. 35-35). Although hospital mortality from pulmonary trunk debanding and VSD repair is low, combined mortality of the banding procedure and subsequent debanding and VSD closure is at least as high as primary VSD repair. Furthermore, restenosis of the pulmonary trunk may follow debanding and VSD repair, necessitating a third operation.

Pulmonary trunk banding as an initial palliative procedure in very young or very small patients with refractory heart failure may still be appropriate in some centers. For a number of years, however, there have been only two standard indications for pulmonary trunk banding in infants with primary VSD: (1) severe heart failure from Swiss cheese septum and (2) associated severe coarctation of the aorta and severe heart failure during the first few months of life. The second is no longer an indication for banding.
Right Atrial versus Right Ventricular Approach for Perimembranous Ventricular Septal Defect

The RV approach may be used for repair of perimembranous VSDs and results in low hospital mortality even in patients with high Rp. The RV approach has the advantage that the nadir of the noncoronary cusp of the aortic valve, which is the area of the right trigone and bundle of His, can be accurately visualized, which may be helpful in choosing the suture technique that will minimize prevalence of heart block (see Fig. 35-25). The RV approach has the disadvantages of (1) leaving a scar in the RV, (2) being associated with a higher prevalence of complete RBBB than with an atrial approach, and (3) possibly resulting in more ventricular arrhythmias late postoperatively.

The right atrial approach may be used almost exclusively, a practice begun in about 1960 at the Mayo Clinic. An accurate repair can be obtained through a right atrial approach in nearly all cases. Associated infundibular pulmonary stenosis can be excised. An RV scar is avoided, and occurrence of RBBB is lower than with the transventricular approach. With the right atrial approach, however, techniques must be accurate to avoid damaging the tricuspid valve leaflets or chordae.

Closure of Ventricular Septal Defect Through Less Invasive Approaches

Smaller incisions (less invasive approaches) have been used for closure of VSDs. Although it is technically feasible to close a VSD successfully through a variety of these techniques, no advantages have been demonstrated other than the smaller incision.

Percutaneous Closure of Ventricular Septal Defects

In selected cases, especially in patients with complex cardiac anomalies (e.g., multiple muscular VSDs) and those with overlooked VSDs after surgical repair of a large defect, transcatheter closure of the VSD by a percutaneously placed double umbrella can be considered. This may be particularly advantageous in apical muscular defects. This method in general should be considered only when surgery is contraindicated or has unusually high risks and when suitable skill and equipment are available.

A current perception is that primary multiple muscular VSDs, particularly those near the apex, are more suitable closed by a percutaneous catheter technique than by operation. This remains unproven, however, particularly for multiple muscular VSDs that can be closed from the right atrium after taking down the trabecula septomarginalis. The technique is a promising one, but additional experience and information are required for definitive evaluation.

These devices may also be deployed intraoperatively.

Closure of Ventricular Septal Defect When Pulmonary Resistance Is High

Patients with VSD in which pulmonary hypertension is severe, with PPA at or above systemic blood pressure, have traditionally been thought to be inoperable because of the high risk of operation. Zhou and colleagues reported use of unidirectional valve patch closure of cardiac septal defects with severe pulmonary hypertension. There was a VSD in 22 of 24 patients in the series, all with marked elevation of PPA (80 ± 12 mm Hg) and increased Qp/Qs (1.1 ± 0.11). SaO₂ was reduced to 88% ± 4%. The patch consisted of polyester fabric with a 0.5- to 1.0-cm hole covered by a pericardial patch left open at one side to function as a one-way valve, placed on the systemic side of the defect. Two patients died after operation (8.3%). PPA fell to 56 ± 19 mm Hg and Qp/Qs to 0.7 ± 0.1, while SaO₂ rose to 96% ± 1%. Excellent improvement of functional state was noted. These results were corroborated by Ad and colleagues while claiming earlier right of discovery of this method (see Fig. 30-26 in Chapter 30).

Section II Ventricular Septal Defect and Aortic Regurgitation

DEFINITION

Ventricular septal defect and aortic regurgitation (VSD-AR) syndrome includes hearts in which AR is of congenital origin, although rarely present at birth, and caused by cusp prolapse or a bicuspid aortic valve. The VSD is doubly committed subarterial, perimembranous (with outlet extension or simply juxta-aortic), or rare, outlet muscular. These locations are in fact a continuum, with the subarterial VSD lying farthest to the patient’s left (and anteriorly), the perimembranous VSD with outlet extension lying more rightward (and slightly inferior) than the subarterial, and the perimembranous juxta-aortic VSD lying still more rightward (and inferiorly). VSD-AR syndrome is related to congenital sinus of Val-salva aneurysm (see Chapter 36) and tetralogy of Fallot with AR (see Chapter 38).

HISTORICAL NOTE

Initial description of VSD-AR syndrome due to aortic cusp prolapse is attributed to Lauby and Pezzl’s publication in 1921. First reports of operative correction were those of Garamella and Starr and their colleagues in 1960. On review of this experience in 1965, of the 30 patients in whom the aortic valve cusps were reconstructed and repaired, 10 (33%; CL 24%-44%) still had important AR. This and other reports in which results of cusp reconstruction were equally unsatisfactory led to adoption of aortic valve replacement using either an allograft or prosthetic valve. During this period, operations were delayed beyond childhood whenever possible to avoid valve replacement at a young age. Renewed interest in use of cusp reconstruction dates from publications of Spencer and Trusler and their colleagues in 1973, which followed the work of Frater. Tatsuno and colleagues in Japan have done much to elucidate the nature of the anomaly and document the good results obtained by VSD closure alone when AR is mild.
MORPHOLOGY AND MORPHOGENESIS

Perimembranous VSDs are most prevalent among predominantly white patients with VSD and AR. Among Asians with VSD and AR, VSDs are more prevalent in the RV outlet, particularly doubly committed subarterial VSDs. Rarely, the defect may be a muscular outlet (also called “intracristal”) defect in which the superior rim is formed by the remnant of a deficient subpulmonary infundibulum. The posteroinferior margin of the defect is formed by fusion of the posteroinferior rim of the trabecula septomarginalis with the ventriculoinfundibular fold. AR is most often caused by prolapse of the right cusp of the aortic valve (about two thirds of patients); the remaining third have prolapse of the noncoronary cusp or of both noncoronary and right coronary cusps, with about equal prevalence. The common feature of all these defects associated with AR is that the affected cusp or cusps lack the normal muscular support provided by attachment of the sinus of Valsalva to the muscular ventricular septum. Infrequently, no cusp is prolapsing, but the aortic valve is bicuspid and regurgitant.

Variable degrees of RV outflow obstruction are present in many patients. The infundibular septum may be underdeveloped and displaced anteriorly and leftward (malaligned as in tetralogy of Fallot), a feature responsible for mild infundibular stenosis that may be present. Occasionally, RV trabeculae near the junction of the infundibular septum and free wall may contribute to infundibular stenosis, as may hypertrophy of the moderator band at a lower level. Typical low-lying infundibular pulmonary stenosis (double-chambered RV) accounts for the gradient in some patients.

The aortic root and valve exhibit a variety of anomalies. Cusps may prolapse not only into but at times through the VSD. Prolusion through the VSD increases during diastole and effectively plugs the defect, limiting the shunt even when the defect is large. Extensive cusp prolapse through a large VSD can also produce some obstruction to RV outflow. In advanced cases, the center of the prolapsed free margin of the cusp is thickened and retracted, a feature that makes resuspension of the leaflet less effective. Some patients have additional damage produced by endocarditis.

The sinus of Valsalva adjacent to the prolapsed leaflet is enlarged, often considerably. This enlarged sinus is associated with asymmetric splaying and dilatation of the aortic “anulus,” a feature aggravated by severe AR and volume changes in the LV. It is virtually impossible to distinguish the junction between the prolapsed cusp and dilated sinus at cineangiography and at times at operation. The wall of the enlarged sinus may be thinned and aneurysmal adjacent to the cusp hinge line and rarely may protrude into the RV immediately above the prolapsed cusp. Such a finding indicates the close similarity between this condition and that of ruptured congenital sinus of Valsalva aneurysm with VSD.

Mechanism of Aortic Regurgitation

The mechanism for cusp prolapse remains speculative; multiple theories have been proposed. Prolapse may result in part from lack of support of the aortic sinus of Valsalva and “anulus” by the infundibular septum, although because most large perimembranous defects are closely adjacent to the aortic “anulus” and very few have associated regurgitation, this cannot be the entire explanation. A structural defect in the base of the sinus itself may also play a role, particularly when the VSD is small. Loss of continuity of the aortic media from the aortic “anulus” and the ventricular septum has also been proposed. Hemodynamic influences during both systole and diastole aggravate the tendencies toward AR. Such influences are more marked once AR develops, resulting in progressive prolapse and distortion.

The most widely accepted predominant mechanism of cusp prolapse is the Venturi effect, which describes changes in velocity and pressure that occur when fluid passes through conduits of varying diameter. As conduit caliber decreases, fluid velocity increases and pressure decreases. If there is restriction to flow through a VSD and an aortic valve cusp is adjacent to the defect, it is vulnerable to being drawn into the high-velocity, low-pressure jet as blood shunts left to right through the restrictive VSD (Fig. 35-36). This tends to displace the unsupported “anulus” outward and downward into the RV. Later in systole, the aortic cusp prolapses into the VSD and is acted upon by direct pressure from the cavity of the LV, displacing both “anulus” and cusp into the RV. During diastole, the high pressure in the aortic root distends the dilated sinus, with further displacement of the aortic “anulus” toward the RV. As the sinus dilates, the distending force becomes greater from increase in wall tension.

Observations supporting the Venturi effect as the predominant cause of aortic cusp prolapse and subsequent AR include:

- The Venturi effect requires a restrictive VSD. Previous studies in the era of near-routine cardiac catheterization indicate that with occasional exceptions, most
such defects are restrictive, and PTA is usually near normal. In a study from Taiwan, Chiu and colleagues found that among patients who developed aortic valve prolapse, mean $Qp/Qs$ for perimembranous VSDs was 1.7; for subarterial defects, 1.6; and for muscular outlet VSDs, 1.45. 

- There appears to be a minimum shunt size required to induce sufficient cusp distortion for development of prolapse. The lower limit of $Qp/Qs$ among patients with VSD and aortic valve prolapse or AR appears to be about 1.4. 

- AR in association with VSD is an acquired lesion. AR or prolapse with VSD is not present at birth and is rarely diagnosed in infancy.

- The nadir of the affected leaflet would be expected to lie within the stream of the shunt. This is consistent with observations that overriding of the involved cusp is commonly noted, and override of the aortic cusp in perimembranous VSDs has been identified as a risk factor for developing cusp prolapse and subsequent AR. 

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Potential for development of AR can be assessed by noting the possible presence of aortic cusp prolapse at echocardiography or cineangiography. Studies in such patients should include 2D echocardiography with Doppler flow velocity evaluation. Anatomic relationships of the aortic valve and VSD should be easily demonstrated. AR is estimated qualitatively. Aortic root dimensions are measured accurately. Usually, echocardiography provides sufficient information on which to base clinical decisions.

In some patients, it is desirable to have cardiac catheterization, which should include (1) right-sided heart catheterization (for calculating shunt and measuring pressures in the pulmonary artery and RV), (2) right ventriculography (for studying possible infundibular pulmonary stenosis), (3) left ventriculography (for identifying location and size of VSD), and (4) aortography (for estimating magnitude of AR and morphology of aortic root). Finding a normal aortic root diameter without cusp prolapse suggests that AR is caused by a bicuspid valve and may not be amenable to repair. Anatomic size of the VSD cannot be demonstrated angiographically when, as often occurs, it is occluded throughout the cardiac cycle by the prolapsed aortic cusp.

In patients with mild AR (e.g., younger patients), signs of the VSD dominate the clinical picture, but as AR increases, the shunt decreases. Such patients characteristically have a to-and-fro murmur that may simulate the continuous murmur of PDA, but occasionally may be mistaken for that of isolated AR or combined AR and stenosis.

NATURAL HISTORY

Among all patients with VSD, the prevalence of aortic valve prolapse and AR is reported to be 4% to 9% and 2% to 6%, respectively. Prevalence is also related to type of VSD. The reported prevalence of aortic cusp prolapse in subarterial VSD exceeds 40%, with over half demonstrating progression of AR. Eroglu and colleagues reported a prevalence of aortic cusp prolapse of 12% and aortic regurgitation of 7% among patients with perimembranous VSD. Aortic cusp prolapse and AR are more frequently reported with VSD among Asian populations because of the greater prevalence of subarterial VSD in China and Japan.

Prevalence is related in part to age at which the population is studied. AR is rarely present at birth but develops during the first decade of life (after age 2 years), then gradually worsens, such that by the end of the second decade it is usually severe. This rate of progression is similar whether the VSD is subarterial or perimembranous. At repair, the AR is mild to moderate in about half of patients and severe in about half.

As regurgitation increases, VSD shunt flow often decreases from occlusion of the VSD by the prolapsed aortic cusp. If the defect remains open through adolescence, about 10% of patients develop aortic valve prolapse or AR.

Secondary effects of AR on the LV are at least as marked as those of rheumatic AR and may be more severe because of additional volume load from the VSD. Rp is seldom if ever elevated, presumably because functionally the VSD is usually not large. Risk of infective endocarditis is high.

Aneurysms of the sinuses of Valsalva also may develop as part of the natural history of patients with doubly committed subarterial VSD or perimembranous VSD with outlet extension. This is a slower process than development of AR, and Momma and colleagues did not observe sinus of Valsalva aneurysms before age 10 years in patients with perimembranous VSDs. Most often the aneurysm is observed during the third decade, when it may be present in 10% of patients whose VSDs of these types are still open.

TECHNIQUE OF OPERATION

In patients in whom AR is trivial or absent, only the VSD is repaired. When AR is moderate or severe and often when it is mild, the aortic valve is repaired. The aortic valve is usually replaced in adults, and this is done only when AR is moderate or severe.

TEE is performed after induction of anesthesia and before incision for a final analysis of the aortic valve and VSD. For myocardial protection, operation is performed on CPB with cold cardioplegia. A transverse aortotomy is made. Dimensions of the aortic root are measured at the ventriculoaortic junction (“anulus”) and sinutubular junction. These dimensions are compared with normal valves adjusted for size of the patient (see “Dimensions of Normal Cardiac and Great Artery Pathways” in Chapter 1). The aortic valve is examined to assess feasibility of repair rather than replacement. If the cusp edge is retracted and thickened or the valve bicuspid, repair is usually not possible.

One or more leaflets may be repaired by the Trusler method of plication. This procedure is carried out at the commissure adjacent to the prolapsed cusp (usually the right or noncoronary cusp). A 5-0 or 6-0 polypropylene suture is placed through the fibrous lacunae at the midpoint of each cusp. Cusps can then be assessed for elongation and attenuation. Cusp plication is performed at the elongated free edges of the aortic valve cusps. A 5-0 or 6-0 PTFE suture is woven between the right and noncoronary cusps to adjust the excessive length of the prolapsed cusp to the adjacent aortic wall. Repair may be reinforced by pledgets (pericardial or felt) or a small cap of polyester secured as a pledget over both affected cusps adjacent to the commissure. Hisatomi and colleagues proposed pledget stitch aortoplasty to make
An entirely different technique has been successfully used by Carpentier, Chauvaud, and colleagues. Its basic feature is triangular excision and reconstruction of the prolapsing cusp. Combined with this is an anuloplasty of the left ventriculoaortic junction. They also recommend that the VSD be repaired through the aortic root, using a glutaraldehyde-treated pericardial patch.

Yacoub and colleagues have proposed another alternative repair (Fig. 35-38) that addresses the basic morphologic defect more completely. All anatomic components of the aortic cusps protrude for even greater aortic cusp coaptation. The stitch at the center of the valve is removed after VSD repair.

Approach to the VSD is appropriate to the location of the defect and may be transaortic if the defect is accessible. Any infundibular stenosis is relieved by excising trabecular muscle bands between the infundibular septum and free wall of the RV and, when necessary, by mobilizing and excising parietal and septal extensions of the infundibular septum and portions of the moderator bands.

Figure 35-37 Repair of prolapsed aortic valve cusp by Trusler technique in patients with ventricular septal defect and aortic valve regurgitation. A, Transverse aortotomy is made at a level just downstream from commissural attachments of aortic valve. B, A stitch of 5-0 or 6-0 polypropylene is placed through midpoint of each cusp. Traction on this stitch allows identification of redundant or elongated free edges of a cusp, as shown here in the case of right coronary cusp near its commissure with noncoronary cusp. C, A 5-0 or 6-0 polytetrafluoroethylene suture is used to “reef up” redundant and attenuated portions of aortic valve. Double row of reefing stitches is used to bring ends of suture to outside of aorta at commissures. Pledget is added to strengthen repair.
defect are corrected by a simple transaortic repair. A transverse aortotomy is made (Fig. 35-38, A). Extent of dilatation of the right coronary sinus and exact definition of the thin area of sinus resulting from discontinuity between aortic valve “anulus” and media of aorta are accurately defined. A series of pledget-reinforced mattress sutures are placed through the crest of the ventricular septum slightly on the RV side to avoid injuring the conduction system. Sutures are passed through the “anulus” of the aortic valve and then used to plicate the thin portion of the sinus of Valsalva and continued until strong aortic tissue supported by aortic media is reached. Tying of sutures results in closing the VSD, elevating the right coronary anulus and cusp, and reducing the size of the right coronary sinus and RV outflow tract bulge (Fig. 35-38, B). Repair of the defect is possible in all cases regardless of VSD size, which is usually slitlike, because there are always redundant tissues in the septum and aortic sinus in the vertical plane. Plication of redundant tissues toward the media of the

Figure 35-38 Repair of aortic valve in syndrome of ventricular septal defect (VSD) and aortic valve regurgitation by Yacoub technique. A, Aortic valve and VSD are approached through a transverse aortotomy. Morphologic defect causing lack of coaptation of aortic cusps is considered to be discontinuity between aortic media and “anulus” of aortic valve, resulting in lack of support to “anulus” and sinus of Valsalva, with downward and outward displacement of “anulus” into right ventricle. VSD is closed by plication suture, which elevates crest of septum to aortic media and plicates unsupported sinus of Valsalva. A series of interrupted mattress stitches using 4-0 braided polyester suture with pericardial pledgets are placed from crest of ventricular septum slightly toward its right ventricular aspect. Stitches are passed through “anulus” of aortic valve and reeved through unsupported sinus of Valsalva to strong tissue of aortic media. B, Stitches are tied down (knots inside aortic sinus), elevating ventricular crest to aortic valve “anulus” to close VSD as well as displacing “anulus” and aortic valve cusp centrally to achieve greater aortic cusp coaptation, restoring valve competence. (Modified from Yacoub and colleagues.)
aortic sinus elevates the aortic valve cusp and anulus, displacing them centrally toward the aortic lumen. This results in increased aortic valve coaptation and restored aortic valve competence. This operation can be applied to patients with doubly committed subarterial VSDs with AR and thus may apply to the Asian population, in whom these types of defects are common.

If the valve requires replacement, the RV (or pulmonary trunk) should be opened before valve insertion, the VSD repaired, the RV closed, and then the aortic valve replaced. This sequence is advised because occasionally it may be necessary to place sutures from the prosthetic valve ring across the upper margin of the VSD patch where it extends between the base of the right and noncoronary cusps (in the region normally occupied by the membranous septum). Sutures in this area should be securely buttressed with pledgets. Although a freehand allograft has been used successfully for valve replacement under such circumstances, degree of distortion of the aortic sinuses often makes accurate placement difficult. Allograft aortic root replacement or aortic valve replacement with a pulmonary autograft (Ross procedure) is probably a better choice (see “Autograft Pulmonary Valve” under Technique of Operation in Chapter 12).

When there is also a true thin-walled aneurysm of the sinus of Valsalva at the base of the right aortic cusp and a VSD, repair is more difficult because the sinus must also be repaired. If the aortic valve requires excision and replacement, excision should include the base of the cusp and the thinned area of the sinus wall, which becomes continuous with the VSD and is incorporated into its closure. Again, under such circumstances, the prosthetic valve suture line will cross the polyester patch. Aortic root replacement may be a simpler solution. When the valve is suitable for plication, the base of the cusp is preserved and sutured back to the patch.

**RESULTS**

**Survival**

Only 1 of 76 patients operated on by the UAB and GLH groups died in hospital (1.3%; CL 0.2%-4.4%); at last follow-up, no late deaths had occurred, an experience similar to that of Okita and colleagues over an 18-year follow-up and Yacoub and colleagues over 24 years with a mean follow-up of 8.4 years. Thus, in the current era, risk of operation should approach 1%.

**Heart Block**

Heart block rarely occurs, even though operation is in the region of the conduction system. In Yacoub and colleagues’ series of 38 patients, there were no cases of conduction abnormality, and ECG remained normal.

**Relief of Aortic Regurgitation**

When AR is mild, VSD closure alone usually prevents progression of regurgitation. When AR is moderate before repair, about two thirds of patients have no or trivial AR after repair using the Trusler technique. Satisfactory late outcomes have also been reported with techniques described by Carpenterie and Yacoub. Infrequently, AR is severe preoperatively, and chances of a good result decrease in this setting.

Okita and colleagues have determined perimembranous VSD (rather than VSDs in the RV outlet) to be a risk factor for important residual AR, possibly because factors other than cusp prolapse are partly responsible for preoperative AR when the VSD is perimembranous. Bicuspid aortic valves are less satisfactorily repaired than tricuspid ones.

Older age at operation also contributes to presence of important AR after repair.

**Freedom from Aortic Valve Replacement**

Some patients will probably require aortic valve replacement in later life, although freedom from aortic valve reoperation using the Trusler technique was 89% at 8 years in the UAB group’s series; parametrically predicted freedom at 20 years was 81% (Fig. 35-39). Elgamal and colleagues confirmed these data, reporting 15-year freedom from reoperation of 81% ± 19% after Trusler repair of the aortic valve. Adequacy of repair at operation was the most important determinant of long-term results. Yacoub and colleagues reported 5 valve replacements among 38 patients 8 to 11 years after operation.

Data from Maehera and colleagues. Data from 36 patients operated on from 1967 to 1987. Three patients who had aortic valve replacement at the original operation after failure of Trusler repair and two other patients who had missing values for postoperative aortic regurgitation are not included. These two patients received late postoperative aortic valve replacement.

---
and parametric estimation of freedom from aortic valve reoperation (one second repair, two valve replacements) after repair of ventricular septal defect and aortic regurgitation in 38 patients. (From Maehara and colleagues.)

INDICATIONS FOR OPERATION

When the murmur of AR first develops in a child with a VSD, the VSD should be promptly repaired while the AR is still mild. If cusp prolapse without AR is demonstrated by 2D echocardiography or on the aortogram in association with any perimembranous VSD, early repair is also indicated. Even if cusp prolapse has not occurred, doubly committed subarterial and moderate or large perimembranous VSDs with outlet extension should be closed before the patient is about 3 years of age to prevent cusp prolapse. Patients having doubly committed subarterial VSD should have prompt operation regardless of age if any aortic valve deformity or regurgitation is detected; anatomic and hemodynamic features of the VSD contribute greatly to development of aortic valve cusp deformity and subsequent AR. When AR is moderate or severe and cusp prolapse is noted on the 2D echocardiogram or aortogram, operation should be undertaken promptly. Operation certainly should be done before the patient reaches age 10, because reconstruction of the valve is usually possible when operation is done during the first decade of life; thus, valve replacement is prevented or at least postponed. This fact is confirmed by the UAB experience, in which the average age of patients requiring replacement was 20 years, compared with 12 years for the remainder of the group.

When 2D echocardiography shows bicuspid aortic valve, or when the aortogram shows minimal enlargement of the sinuses and no cusp prolapse in the presence of severe AR, a bicuspid valve is probably present and valve replacement may be required. Operation should therefore be postponed until symptoms develop or LV enlargement indicates need for operation.

When operation is delayed until adult life, aortic valve replacement is usually required.

SPECIAL SITUATIONS AND CONTROVERSIES

Some surgeons prefer to visualize and repair VSDs through an aortotomy. This practice can produce good results, but if the VSD is perimembranous rather than in the RV outflow tract, possibility of permanent damage to the bundle of His may be increased by this essentially LV approach to repair. Repair through the pulmonary trunk or RV is recommended for subarterial and anterior muscular defects, and through the right atrium or RV for perimembranous defects.

Section III Straddling and Overriding Tricuspid (or Mitral) Valve

A straddling and overriding tricuspid valve sometimes coexists with an otherwise isolated VSD, usually one that extends posteriorly to the crux. Straddling and overriding of an AV valve may also coexist with a VSD that is simply part of a congenital cardiac anomaly (e.g., transposition of the great arteries, congenitally corrected transposition of the great arteries, univentricular AV connection). The subject is considered in its entirety in this chapter, with reference to other chapters.

Straddling and overriding of an AV valve always occur in relation to a VSD close to the valve. When straddling or overriding of an AV valve is mild, surgical considerations are usually related primarily to associated anomalies. When straddling or overriding is severe, or when there is associated hypoplasia of the ventricle to which the AV valve is appropriately (see following text) connected, surgical considerations are usually based primarily on straddling and overriding and severity of any coexisting ventricular hypoplasia.

Hypoplasia of the ventricle guarded by the straddling or overriding valve (termed the appropriate ventricle) usually coexists. Generally, the more severe the overriding, the greater the ventricular hypoplasia. Occasionally, a straddling or overriding AV valve has leaflets that differ from normal in number and morphology. Overriding and straddling AV valves may occasionally produce subpulmonary or subaortic obstruction.

DEFINITION

An AV valve is considered to be straddling when part of the tension apparatus of the valve crosses the VSD and the crest of the interventricular septum to attach to the septum or a papillary muscle in the opposite (inappropriate) ventricle. The tension apparatus is thus attached within both ventricles, and blood passing through the valve is directed into both ventricles. An AV valve is considered to be overriding when the AV junction to which the AV valve leaflets attach is connected to both ventricles. AV valve straddling and overriding usually occur in combination, and occasionally both AV valves are involved with these anomalies in the same heart.

HISTORICAL NOTE

Lambert in 1951 and Van Praagh and colleagues in 1964 appeared to be aware of AV valve straddling and overriding, although they were not explicit about it. In 1966, Mehrizi and colleagues referred to overriding and straddling of the right AV valve onto the RV in hearts with double inlet left
ventricle (DILV) and the LV lying posteriorly and to the left.\textsuperscript{518} Subsequently, de la Cruz and Miller in 1968 and Lev and colleagues in 1969 referred to this occurrence in hearts with various types of “single ventricle” (generally double inlet ventricles).\textsuperscript{3,11}

Rastelli and colleagues reported “straddling right atrioventricular valves” in hearts with a large VSD, but the right AV valve in their cases appears to have been both overriding and straddling.\textsuperscript{83} These investigators identified malalignment of atrial and ventricular septa as the characteristic of hearts with overriding AV valves, along with cleft leaflets often present and juxta-crucial position of the VSD. Libeithson, one of whose coauthors was Lev, clearly distinguished between overriding and straddling AV valves in hearts with double inlet ventricles in 1971, although those terms were not used or defined.\textsuperscript{112} Again, in the context of double inlet ventricles, Tandon and colleagues discussed “straddling AV valves.”\textsuperscript{112} Thereafter, ease of diagnosis provided by 2D echocardiography rapidly led to broader recognition and improved understanding of these AV valve abnormalities.\textsuperscript{1,12,28}

Surgical management of straddling and overriding AV valves was first reported in 1979, independently by Pacifico and by Tabry and their colleagues.\textsuperscript{21,21,21} Surgical possibilities, rapidly expanding knowledge of morphology of congenital heart disease, and increased use of 2D echocardiography resulted in clear perception of the morphology and implications of these AV valve anomalies.

Clarifying terminology used in this section was evolved by Milo and Ho and their colleagues in studies of straddling and overriding AV valves.\textsuperscript{117,110} Milo and colleagues described disposition of the conduction system in hearts with overriding AV valves.\textsuperscript{110} and Anderson and colleagues formulated the basis for categorizing these hearts as well as those with univentricular AV connections (“single ventricle”).\textsuperscript{111}

**MORPHOLOGY**

**Morphologic Syndromes**

When atria are in usual (solitus) situs, ventricular topology is right-handed, and AV and ventriculoarterial (VA) connections are concordant (see “Terminology and Classification of Heart Disease” in Chapter 1), the right AV valve sometimes overrides or straddles. This anomaly is associated with a posteriorly placed (juxta-crucial) VSD in the inlet portion of the ventricular septum when viewed from the RV aspect. The interventricular septum does not attach to the crux cordis in this situation. The overriding tricuspid valve is associated with malalignment of the atrial and interventricular septa. The RV is usually somewhat hypoplastic.

When there is atrial situs solitus, ventricular right-handedness (D-loop), AV concordant connection, and discordant VA connection (complete transposition of the great arteries), the left AV valve may be overriding, in this case over a VSD in the anterior portion of the ventricular septum.

When there is atrial situs solitus, ventricular right-handedness, AV concordant connection, and DORV (one of the most common situations in which overriding and straddling of an AV valve occur\textsuperscript{58}), the right AV valve may be overriding and is usually straddling in hearts with a VSD that is juxta-aortic, and usually also perimembranous and juxta-crucial. When the VSD is juxta-pulmonary and somewhat anterior (Taussig-Bing heart), the left AV valve may be straddling and overriding a VSD that does not extend to the crux cordis.\textsuperscript{519}

When there is atrial situs solitus, left-handed ventricular topology (L-loop), AV discordant connection, and VA discordant connection (congenitally corrected transposition of the great arteries), the right AV valve (which generally in this setting has two leaflets) may override an anteriorly situated VSD. The intraventricular septum does reach the crux cordis. When overriding of the right AV valve in this setting is more than 50%, there is double inlet right ventricle (DIRV) with the RV lying to the left and more or less posterior, and an anterior, right-sided, and often hypoplastic and rudimentary (incomplete) LV. In hearts with congenitally corrected transposition of the great arteries, the left-sided AV valve may override a posteriorly placed VSD; in these hearts, the intraventricular septum does not reach the crux cordis. When overriding is more than 50%, the condition is DILV with left-sided and anteriorly placed hypoplastic and rudimentary (incomplete) RV, the most common type of double inlet ventricle. A special group of cases with AV discordant connection, usually with DORV, involves a VSD that is juxta-crucial and in which one or both AV valves are overriding and straddling. Ventricles in this setting are usually in an over-and-under position, and circulations appear to crisscross within the heart.

Similar patterns may occur with atrial situs inversus and with atrial situs ambiguous.

**Conduction System**

Knowledge of location of the AV node and bundle of His is required for satisfactory surgical treatment of cardiac malformations. When the AV valve is overriding or straddling a VSD that does not reach the crux cordis, the conduction system is usually unaffected by the overriding valve.\textsuperscript{112} Thus, the AV node is in its usual location in the AV septum when the ventricular topology is right-handed and the AV connection concordant. When the ventricular topology is left-handed and the AV connection discordant, the conduction system generally arises from an anomalous anterolateral node, and this is unaffected by the overriding valve.

When in hearts with AV concordant connection the AV valve (in this case the tricuspid valve) overrides a VSD that is juxta-crucial (such defects may be perimembranous as well), the AV node is situated anomalously.\textsuperscript{112} It lies at the point inferiorly at which the ventricular septum attatches to the anulus (or circumference) of the right AV valve.\textsuperscript{110}

When the VSD is juxta-crucial and the AV connection discordant, the left AV valve overrides and the AV node occupies an anterolateral position near the right AV valve anulus, as is usual in hearts with AV discordant connection.

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

Straddling and overriding of an AV valve are uncommon, occurring as an added anomaly in about 3% of patients with congenital heart disease. They seem to be more prevalent in hearts with AV discordant connection than in those with AV concordant connections (Table 35-5). Among hearts with AV discordant connections, straddling and overriding of an AV valve occur most often in hearts with DORV and in those with complete transposition of the great arteries.
Straddling and overriding AV valves are usually competent and have no features that permit their identification by history, physical examination, chest radiograph, or ECG. Echocardiography is the technique by which they are generally diagnosed, although overriding can often be diagnosed or inferred from the angiogram.

### TECHNIQUE OF OPERATION

When an AV valve is only overriding, repair of the associated VSD or other cardiac anomalies can usually be done in essentially the normal manner, except for some deviation of the patch to accommodate the overriding. Straddling presents a more severe surgical challenge, particularly when it is moderate or severe in degree and when the inappropriate ventricle into which the straddling cords enter is not the one the surgeon is working in which. For these reasons, the Fontan operation (see Section IV of Chapter 41) is often the most appropriate option when severe straddling or overriding is present.

*Data from 35 patients operated on at UAB from 1967 to 1985. Total deaths include hospital deaths and those in follow-up period.
*Several cords from mitral valve straddled to insert on right ventricular side of septum near ventricular septal defect.
*One patient also had right atrioventricular valve atresia.

Key: AV, Atrioventricular; CTGA, corrected transposition of the great arteries; DORV, double outlet right ventricle; LAVV, left atrioventricular valve; PS, pulmonary stenosis; RAVV, right atrioventricular valve; TF, tetralogy of Fallot; TGA, transposition of the great arteries; VSD, ventricular septal defect.

#### Section of Straddling Cords

Rarely, a single straddling cord can be sectioned to permit repair of a VSD or an intraventricular tunnel repair, without rendering the AV valve regurgitant. This technique can probably be used only when straddling is mild.

#### Slotting of Repair Patch

Rarely, straddling cords can fit into a slot or cut made in the patch used to close the VSD or make an intraventricular tunnel. The slot is then closed by sutures. This technique is applicable only to mild or possibly moderate straddling involving just a few cords, and it probably results in loss of free motion of the cords.

#### Reattachment of Sectioned Tensor Apparatus

When straddling is mild or moderate, and when the straddling tensor apparatus attaches to only one papillary muscle or area of the muscular interventricular septum in the inappropriate ventricle, and when that muscle has no other cord attachments, the muscle may be sectioned at its base. Then, along with its straddling cords, the muscle is brought back into the appropriate ventricle. The VSD is closed with a patch, or if indicated, an intraventricular tunnel repair is performed. Finally, the muscle to which the straddling cords connect is reattached to the patch or tunnel.

This technique is used infrequently and is applicable only when surgery is being performed from within the appropriate ventricle, approached either through its atrium or a ventriculotomy. Probability of dehiscence of a reattached papillary muscle or tendinous cord has not been determined.

#### Minor Septation

The patch used to close a VSD or create an intraventricular tunnel may be deviated around the papillary muscle and septal attachments of a straddling AV valve so that they lie within the appropriate ventricle after repair (Figs. 35-40 and 35-41). This approach is most easily performed when straddling is into the ventricle the surgeon is working in, through its atrium or a ventriculotomy. This is usually the ventricle ejecting into the pulmonary trunk: the right-sided RV in DORV with concordant AV connection, or the right-sided LV in hearts with discordant AV connection. In some cases, however, the technique of minor septation can be applied when straddling is into the ventricle ejecting into the aorta (see Fig. 35-40).

#### Replacement of Straddling Atrioventricular Valve

When the straddling AV valve is regurgitant (a relatively unusual situation), operation usually includes valve replacement. In some cases, this approach may be used simply because of complexity and severity of the straddling. The valve replacement device may face onto the patch used for repair of the VSD or creation of an intraventricular tunnel, because of the malalignment of the atrial and ventricular septa. This possibility emphasizes the value of a low-profile device in this setting, and even with such a device, some functional impairment may result.
Particular care and thoughtfulness are required when straddling or overriding occurs in the setting of ventricular L-loop, when valve replacement appears to be indicated. This situation, along with the sometimes associated complete heart block, may compromise long-term outlook sufficiently that a Fontan operation is preferable to a two-ventricle repair (see Chapter 41).

**Fontan Operation**

The Fontan operation is also the only method that can be used when moderate or severe hypoplasia of a ventricle is associated with straddling and overriding AV valves. Current information concerning early and intermediate-term results of this operation encourages its wider use when AV
Figure 35-41 Intraventricular tunnel repair incorporating a minor septation for straddling and overriding left atrioventricular (AV) tricuspid valve in a patient with congenitally corrected transposition of the great arteries and about 40% overriding of aorta onto right-sided left ventricle. A, Vertical left (right-sided) ventriculotomy is shown, but an approach through right atrium is preferred. Straddling and overriding left AV (tricuspid) valve is shown, as well as ventricular septal defect and aortic overriding. B, Repair patch creates an intraventricular tunnel conducting systemic arterial blood flow from left-sided right ventricle to aorta and keeping entire left AV valve apparatus on appropriate side of patch. (From Pacifico and colleagues.)

valve straddling or overriding is moderate or severe (see Chapter 41).

Cardiac Transplantation
Cardiac transplantation is reserved for patients with straddling and overriding AV valves in whom a severe secondary cardiomyopathy has developed (see Section II in Chapter 21).

RESULTS
Early and intermediate-term (5 to 15 years) survival after surgery in patients with straddling and overriding AV valves is determined primarily by the cardiac defect with which the AV valve anomaly is associated. However, survival is somewhat less satisfactory than that in general after repair of the primary cardiac defect. Exceptions are patients in whom the Fontan operation or cardiac transplantation is performed;
survival after these operations is unrelated to the cardiac anomaly for which the operation was done and is not lessened by presence of a straddling or overriding AV valve.

Heart block has occurred more frequently than usual after repair of hearts with concordant AV connection and overriding AV valves associated with a VSD extending to the crux cordis and in patients with discordant AV connection. Because position of the AV node and conduction system in such hearts is now known, heart block should now occur less frequently.

INDICATIONS FOR OPERATION

*Indications* for operation in patients with overriding and straddling AV valves lie with the coexisting anomalies rather than with the AV valve anomaly.

*Strategy* of operation is greatly influenced by the AV valve anomaly, and whenever possible that strategy should be decided in early life. If straddling is mild, the strategy can probably be that for the coexisting anomaly in general, and the AV valve anomaly can be managed by the technique of minor septation or an even lesser procedure.

When straddling is severe, these techniques seem likely to be associated with a relatively high early risk. Valve replacement in this setting carries more than the usual early and intermediate risks and improbables. A Fontan operation probably is associated with better early and late results than these procedures and is the only type of procedure that can be considered when the patient has important ventricular hypoplasia. Therefore, diagnosis of AV valve straddling or overriding should be made in early infancy. If the patient has cyanosis from reduced pulmonary blood flow, a PTFE interposition systemic-pulmonary arterial shunt or a bidirectional cavopulmonary anastomosis should be performed (see Chapters 38 and 41). If there is a large left-to-right shunt, pulmonary trunk banding should be performed in early life. In either case, the Fontan operation is then performed in patients aged 1 to 2 years, before ventricular hypertrophy becomes marked (see Chapter 41).

36 Congenital Sinus of Valsalva Aneurysm and Aortico–Left Ventricular Tunnel

Section I: Unruptured and Ruptured Sinus of Valsalva Aneurysms

DEFINITION

Congenital sinus of Valsalva aneurysms are thin-walled saccular or tubular outpouchings usually located in the right sinus or adjacent half of the noncoronary sinus. They generally have an intracardiac course but may protrude into the pericardial space. They may rupture into the right (or rarely the left) heart chambers to form an aortocardioc fistula, or into the pericardial cavity. Associated congenital cardiac anomalies are common.

HISTORICAL NOTE

The syndrome of acute rupture of a congenital sinus of Valsalva aneurysm was apparently first described by Hope in 1839. A year later, Thurman published the first important paper on the subject. He discussed Hope’s case and added five of his own, none of which had ruptured. Eighty years later, Abbott reviewed the clinical features of acute rupture from eight previous cases and reported another case. At that time, and even as late as 1937, most ruptured and unruptured sinus of Valsalva aneurysms were considered syphilitic. Smith stated in 1914 that “the lesion, which is usually syphilitic, is not so rare as to be altogether devoid of clinical interest, but the diagnosis, perforating or otherwise, presents almost insurmountable difficulties.” Jones and Langley reviewed congenital and acquired aneurysms in 1949. They accepted 25 cases as being of congenital origin and elucidated most of the important features of the condition. In 1951, Venning may have been the first to diagnose acute rupture during life, although Oram and East claimed this distinction in 1955, as did Brown and colleagues. In Oram and East’s patients, cardiac catheterization confirmed the presence of a left-to-right shunt, although angiography was not performed. The earliest report of using aortography to diagnose an unruptured aneurysm was that of Falholt and Thomsen in 1953. The first successful surgical repairs of sinus of Valsalva aneurysms were performed in 1956 at the Mayo Clinic and the University of Minnesota, using cardiopulmonary bypass (CPB). Spencer, Blake, and Bahnson and Morris and colleagues also reported early successful cases. In 1957, both Morrow and colleagues and Bigelow and Barnes successfully closed a ruptured congenital sinus of Valsalva aneurysm using mild hypothermia with inflow stasis, but this...

Section II: Aortico–Left Ventricular Tunnel

DEFINITION

Congenital sinus of Valsalva and Aortico–Left Ventricular Tunnel
Precise location of this basic congenital abnormality, which may be accompanied by an adjacent separation of the ventricular septum from the aorta to form a VSD, tends to be different in Asians and non-Asians. In Asians, the basic abnormality is located leftward and toward the commissural area between the right and left coronary cusps, so compared with non-Asians, rupture occurs more often into the right ventricle than right atrium (94% vs. 77%, \( P[\chi^2] = .0001 \)). The coexisting VSD in Asian patients is usually leftward and juxta-arterial, whereas in non-Asians it is usually rightward and only juxta-aortic (see Chapter 35 for definitions). The leftward tendency in Asians is also manifested by fewer aneurysms of the more rightward noncoronary sinus than in non-Asians (11% vs. 32%, \( P < .0001 \)). Left sinus of Valsalva aneurysms are uncommon in both Asians (2%) and non-Asians (5%) (\( P[\chi^2] \) for difference = .11).\(^{55}\)

**Aquired** sinus of Valsalva aneurysms caused by syphilis,\(^{54}\) atherosclerosis,\(^{52}\) endocarditis,\(^{51}\) Behçet disease,\(^{54,51}\) or penetrating injuries\(^{55}\) are usually readily distinguishable from congenital forms. They are more diffuse, involving more of the sinus or multiple sinuses and often the ascending aorta, and therefore project into the pericardium outside the heart. A congenital aneurysm is frequently diagnosed by exclusion of other etiologies as well as by presence of associated congenital cardiac defects. Difficulties arise in establishing a diagnosis of mycotic aneurysms,\(^{11,52}\) because endocarditis complicates about 5% to 10% of congenital aneurysms.\(^{51}\) Similarly, difficulty exists in diagnosing the presence of medionecrosis (cystic medial degeneration), because it and Marfan syndrome are both present in some patients with congenital sinus of Valsalva aneurysms.\(^{53,52}\)

**Rupture**

In some patients, the aneurysm gradually develops a localized windsock, which ultimately ruptures into an adjacent low-pressure cardiac chamber (Fig. 36-3). The thin-walled, ruptured aneurysm characteristically has an intracardiac fistulous portion and a nipplelike projection into the cardiac chamber, with one or more points of rupture at its apex (Fig. 36-4). Rarely it projects outside the aortic root or heart. When the aneurysm coexists with a VSD, the windsock usually projects into the right ventricle through a thinned area of myocardium just downstream from the VSD; the aneurysm is separated from the VSD by the hinge line of the aortic valve cusp, at the septal portion of the left ventriculooaortic junction (Fig. 36-5; see also Fig. 36-2, C).

About one fourth of patients have no windsock or other suggestion of aneurysm formation, but rather have a direct fistulous communication between the aortic sinus and the heart.\(^{11,53}\) This defect has been recognized in a few patients at or soon after birth.\(^{54,53,52,53}\) Windsock deformity is typical in lesions originating from the right sinus and communicating with the right ventricle; a direct fistula is typical in those from the noncoronary sinus to the right atrium.\(^{57,53}\) and an extra-cardiac aneurysm is typical \(^{53,52,53,51,516}\) in the rare cases of left sinus origin.\(^{53}\)

Although the prevalence of aneurysms of the sinus of Valsalva in various locations is different among Asians and non-Asians, in both groups the **sinus of origin** is the main determinant of the direction of protrusion and rupture of the aneurysm, and thus of the chamber into which it ruptures (Fig. 36-6). Also in both populations, but with differing
Figure 36-2 Unruptured right sinus of Valsalva aneurysm. **A,** Viewed from the aorta, aneurysm has a well-defined origin, or neck, presenting as an almost circular ostium in the base of the sinus of Valsalva just above the hinge line of the aortic cusp. **B,** Viewed from right ventricle, aneurysm protrudes into right ventricular outflow tract just below pulmonary valve. **C,** Anatomic depiction of a specimen with coexisting juxta-aortic ventricular septal defect (VSD) in right ventricular outlet portion of ventricular septum. The narrow band of aortic wall and septum separating aneurysm from VSD is located behind the aneurysm. Figure 36-3 Cineangiograms in right anterior oblique projection of a right sinus of Valsalva aneurysm ruptured into right ventricle in systole (**A**) and diastole (**B**). Noncoronary and left coronary sinuses and cusps are normal. Right coronary sinus is enlarged, and there is an aneurysm (windsock) protruding into right ventricular infundibulum. Arrows indicate contrast medium shunting through holes in aneurysm and filling right ventricular infundibulum in diastole and pulmonary trunk in systole (when the aneurysm almost prolapses through the pulmonary valve). There is no aortic regurgitation, but the ruptured aneurysm is associated with a large conoventricular juxta-aortic ventricular septal defect. Key: **A,** Aneurysm; **L,** left coronary sinus; **N,** noncoronary sinus; **PT,** pulmonary trunk; **R,** right coronary sinus; **RV,** right ventricular infundibulum.
prevalence, aneurysms of the right aortic sinus of Valsalva are most common.\textsuperscript{5,6,8,13,25,51,63} The aneurysm may arise from the leftward portion of this sinus, with the windsock projecting into the adjacent right ventricular outflow tract just below the pulmonary valve, termed type I by Sakakibara and Konno.\textsuperscript{51} It may also originate more centrally and project through the substance of the outlet portion of the right ventricular aspect of the ventricular septum (Fig. 36-7), or from the rightward portion of the sinus, entering the right ventricle beneath the parietal band (parietal extension of the nutrient aortic sinus).
Figure 36-8  Cineangiogram in right anterior oblique projection (diastole) of a large aneurysmal connection of noncoronary sinus (N) to right atrium (RA). Contrast flow (arrows) was observed to enter RA close to tricuspid anulus (dashed line) before passing through tricuspid valve to right ventricle (RV). Right (R) and left (L) coronary sinuses appear normal. There is no aortic regurgitation and no ventricular septal defect. At operation a 15-mm-long windsock aneurysm was projecting into the right atrium adjacent to anteroseptal commissure of tricuspid valve.

infundibular septum) in the region of the membranous septum. Rarely the aneurysm may project into the pulmonary trunk.510

Aneurysms from the noncoronary sinus usually originate from its anterior portion and project into the right atrium (Fig. 36-8), but in rare cases they project and rupture into the right ventricle. Rarely, rupture can occur simultaneously into the right ventricle and right atrium or into the muscular ventricular septum.511 Aneurysms arising from the posterior portion of the noncoronary sinus may rupture into the pericardium.59,72,108 Another rare occurrence is a right sinus or noncoronary sinus aneurysm that ruptures into the left ventricle.74,91,92,94 Rarity of rupture into the left ventricle may be related to the relatively thick wall and high pressure in that chamber. Aneurysms arising from the left coronary sinus may rupture into the left atrium, left ventricle, or rarely the pulmonary trunk or pericardium.113,116

Sinus of Valsalva aneurysms rupturing into areas adjacent to the tricuspid valve are also adjacent to the atrioventricular (AV) node and His bundle and may be a cause of heart block, bundle branch block, and ventricular fibrillation.5,519,71,92

Table 36-1 shows the overall distribution of the various sites of rupture, based on analysis by Chu and colleagues of 361 cases in the literature, including 57 from their own institution.58

### Associated Cardiac Anomalies

#### Ventricular Septal Defect

A VSD is the most common coexisting cardiac anomaly and may arise from the same congenital anomaly that produced the aneurysm. VSDs occur in 30% to 50% of patients,5,54,59,101,104,107,112,113,116 but prevalence is higher when the aneurysm arises from the right sinus.54,59 When the aneurysm arises from the left third of the right aortic sinus, the VSD is **juxta-arterial**, with its upper margin formed by the confluent aortic and pulmonary valves. When the aneurysm arises from the central third of the right sinus, the VSD may be **juxta-aortic** or may lie within the muscle of the outlet portion of the septum. When the aneurysm arises from the right third of the right sinus (or rarely, the anterior portion of the noncoronary sinus),2,52 the VSD is usually **conoventricular** and may be **perimembranous** as well (see Chapter 35 for definitions). Rarely, a conoventricular VSD occurs in association with an aneurysm arising from the central or leftward third of the right sinus. Sakakibara and Konno considered this a coincidental association between two independent malformations rather than a combined developmental anomaly.52

#### Aortic Valve Abnormalities and Aortic Regurgitation

Aortic valve abnormalities and AR are common in patients with sinus of Valsalva aneurysms.5,54,59,101 When a VSD is present, AR usually results from a prolapsed aortic cusp, similar to the finding in the syndrome of VSD and AR (see Section II of Chapter 35). When a VSD is not present, AR usually arises from other aortic valve abnormalities, including a bicuspid valve.

As in VSD and AR, when prolapse of the aortic cusp into a VSD is the cause, severity of AR progressively worsens.2 If the fibrous hinge line remains intact at the base of a prolapsed cusp, a sinus of Valsalva aneurysm projects toward the ventricle superior to the hinge line, and the cusp projects through the VSD inferior to it. When the hinge line does not retain its integrity, however, as in long-standing cases, both structures form a single sac.51,52,2,116 Taguchi and colleagues noted that prolonged AR produces a fixed fibrous deformity of the prolapsed cusp.71

The frequency of aortic cusp prolapse in sinus of Valsalva aneurysms was undoubtedly underestimated in earlier reports, particularly when no aortograms or echocardiograms were obtained and the aorta was not opened at operation. Aortic cusp prolapse is also less common if only ruptured sinus aneurysm is considered. Thus, in the series of Taguchi and colleagues, which included unruptured cases, AR (although usually mild) was present in 75% of patients,71 whereas in the

Data from Chu and colleagues.55
series of Okada and colleagues from Japan, which included only ruptured cases, the prevalence was 17%.  

A complicating problem is the difficulty of determining what constitutes a true (unruptured) sinus aneurysm with combined VSD and AR. Aneurysmal enlargement of the aortic sinus is common in this setting, and the distinction from unruptured sinus aneurysm is difficult to delineate by aortography and even at operation or autopsy. However, 7 (15%) of 48 surgical patients with VSD and AR operated on at GLH from 1960 to 1982 had a distinct but unruptured sinus of Valsalva aneurysm.

**Pulmonary Stenosis**

Important pulmonary stenosis is uncommon in patients with congenital sinus of Valsalva aneurysms, but small gradients are common. The stenosis may be mild but is usually caused by either a projection of the windsock in front of the infundibular septum or a developmental anomaly of the right ventricular outflow tract similar to that present in tetralogy of Fallot and VSD-AR syndrome.

**Other Anomalies**

Infrequently, other congenital cardiac anomalies coexist with sinus of Valsalva aneurysms, including aortic coarctation, patent ductus arteriosus, atrial septal defect, subaortic stenosis, and tetralogy of Fallot.

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

Unruptured congenital sinus of Valsalva aneurysms are usually silent lesions; their diagnosis depends on echocardiograms or aortograms usually obtained to demonstrate associated symptomatic lesions such as VSD or AR. Diagnosis can be made incidentally during echocardiography or coronary angiography. Rarely, unruptured aneurysms produce tricuspid valve dysfunction or right ventricular outflow obstruction, bringing the patient to medical attention. These aneurysms may also produce severe myocardial ischemia by compressing the right or left main coronary artery.

Embolization from unruptured sinus of Valsalva aneurysms and complete heart block have also been reported. Embolization from unruptured sinus of Valsalva aneurysms and complete heart block have also been reported.

Presence of this anomaly should be considered in men, who represent 80% of patients with sinus of Valsalva aneurysms.

Acute symptoms occur in about 35% of patients with rupture of the aneurysm. In 45% of patients, surprisingly, rupture is associated only with gradual onset of effort dyspnea, and in 20%, no symptoms develop. Acute symptoms consist of sudden breathlessness and pain. The pain is usually precordial and may also be epigastric, probably because of acute hepatic congestion. Precordial pain may mimic myocardial infarction, although radiation of the pain beyond the substernal area is unusual. In a few patients, death occurs within days of rupture from right-sided heart failure, but most patients improve during the latent period, which may last for weeks, months, or years. This improvement may occur without specific medical therapy. The latent period is usually followed by recurrence of dyspnea and signs of right-sided heart failure. Characteristic features at this final stage are aortic and tricuspid regurgitation, an unusual combination.

The infrequency of severe symptoms at rupture may be due to the initially small size of the rupture in many patients. Studies by Sawyers and colleagues in dogs indicate that symptoms are severe when the fistula is greater than 5 mm in diameter. However, in humans, Taguchi and colleagues found little correlation between size of the fistulous opening at operation and a history of acute symptoms. Acute symptoms at rupture may occur less often with a VSD and more often with severe AR.

Acute symptomatic ruptures may be precipitated by heavy exertion, but they also occur after serious automobile accidents and at cardiac catheterization. Rarely, an episode of infective endocarditis may be the precipitating factor. Marfan syndrome may also predispose the aneurysm to rupture.

Rupture is heralded not only by pain and dyspnea but also by a characteristic murmur that is loud, harsh, superficial, and accompanied by a coarse thrill. The murmur is usually continuous with either systolic or diastolic accentuation, but it may be to and fro, similar to that present in the VSD-AR syndrome. In the past, this murmur has been mistaken for that of patent ductus arteriosus, but it is maximal at a lower site, usually the left second, third, or fourth intercostal space. With rupture into the sinus portion of the right ventricle or right atrium, the murmur tends to be maximal at a low level over the sternum or to the right of the lower sternum.

Rarely the murmur is systolic only, possibly because the communication is small. Alternatively, the murmur may be confined to diastole in those few cases when rupture occurs into the high-pressure left ventricle or when right ventricular pressure is at systemic level, as in the neonate.

When the murmur is continuous, its timing and accentuation are a function of several factors including degree of associated AR, degree of aortic systolic murmur, functional size of the VSD, and size of the fistula. Morehead and Greenwood assessed the various causes of murmurs that were believed to be continuous and associated with signs of rapid aortic runoff in their adult patients and found that ruptured sinus aneurysm (8 cases) was the second most common cause after patent ductus arteriosus (33 cases), followed by VSD and AR (3 cases), aortopulmonary window (3 cases), coronary arteriovenous fistula (1 case), and pulmonary arteriovenous fistula (1 case).

Other physical signs of ruptured aneurysm include widened aortic pulse pressure, suggesting mild to severe AR. An elevated jugular venous pressure with a prominent v wave, suggesting tricuspid regurgitation, may be caused by direct entrance of a fistula into the right atrium, but in most cases this sign is absent until onset of right-sided heart failure, when liver enlargement and pulsation also occur.

The chest radiograph does not show enlargement of the aortic root. Plethora may be present, although the left-to-right shunt through both the fistula and any associated VSD is usually small. The electrocardiogram shows either left ventricular or biventricular hypertrophy. Right bundle branch block may occur and may be more common in aneurysms with an intracardiac course close to the AV node and bundle of His. Complete heart block can also occur.

Although the diagnosis is virtually certain on clinical grounds in patients with acute symptoms and sudden appearance of a continuous murmur, two-dimensional Doppler color flow echocardiography is used for verification (Fig. 36-9). Cardiac catheterization and angiography are generally performed to study the site of origin and termination of the fistula and the presence of associated anomalies, particularly VSD, AR, and pulmonary stenosis (see Figs. 36-2, 36-4, 36-7, and 36-8). The true size of the VSD cannot be
Although death after intracardiac rupture of a sinus of Valsalva aneurysm is usually from heart failure, infective endocarditis complicates heart failure in about 10% of patients and may itself be a cause of death.

When a VSD coexists with the aneurysm, the aortic valve is usually at least mildly regurgitant. The natural history then becomes similar to that of VSD and AR (see Section II of Chapter 35). The AR becomes progressively more severe, as does prolapse of the right aortic cusp and aneurysmal sac. This process gradually reduces the size of the VSD until even an anatomically large defect becomes functionally small. Pulmonary arterial hypertension and increased pulmonary vascular resistance therefore are rare. By the time most patients with this combination of anomalies reach age 15 to 20 years, a fixed fibrous deformity of the prolapsed cusp has developed.

**TECHNIQUE OF OPERATION**

The many types and variations of ruptured and unruptured sinus of Valsalva aneurysms, as well as the rarity of some, make detailed description of repair of each impractical. Instead, this section details repair of three of the most common varieties; from these, the techniques of repair for most other aneurysms can be deduced. For example, an aneurysm of the right sinus of Valsalva, without VSD, that has ruptured into the right ventricle is repaired much the same as described for this type of aneurysm that has ruptured into the right atrium, but substituting “ventricle” for “atrium.” Some rare and difficult types may be most simply repaired through an aortic approach, closing the origin of the aneurysm from the sinus with a patch.

Unruptured sinus of Valsalva aneurysms are probably best repaired by excision or, occasionally, by exclusion of the aneurysm and reconstruction by the identical method used for a similar but ruptured aneurysm.

Ruptured Right Sinus of Valsalva Aneurysm, with Ventricular Septal Defect

Repair of a ruptured aneurysm at the midportion of the right sinus of Valsalva with coexisting juxta-aortic VSD is described first because the surgical principles are more easily appreciated in this setting. If the aneurysm is in the rightward portion of the right sinus, the VSD is probably conoventricular (perimembranous) and would be approached through the right atrium, often with detachment of the anterior and septal leaflets of the tricuspid valve. If the aneurysm is in the leftward portion of the right sinus of Valsalva, the associated VSD in the infundibular septum would be juxta-arterial, and the approach would be through the right ventricle or pulmonary trunk. In either case, operation is usually facilitated by a combined aortic and right ventricular, pulmonary trunk, or right atrial approach.

Initial preparations follow the usual routine (see Section III of Chapter 2). After median sternotomy, the pericardium is opened and complete external evaluation of the heart is made. The protruding nipple of the ruptured aneurysm may be palpated through the free wall of the right ventricle. It is important to note that no external evidence of the aneurysm itself is usually seen, and the aortic root appears to be normal on inspection. Intracardiac transesophageal echocardiography (TEE) is useful for defining the location of the aneurysm.
and the cardiac chamber into which it has ruptured (see Fig. 36-9), and for assessing completeness of the fistula and VSD repair and severity of AR before and after repair.

CPB is established after ascending aorta and direct caval cannulation, and body temperature is reduced. The aorta is clamped promptly, caval tapes are placed and secured, the right atrium is opened through a short oblique incision, and a sump suction catheter is placed across the foramen ovale. In most cases the aortic valve is at least mildly regurgitant. The aortic root is opened transversely (Fig. 36-10, A), and cold cardioplegic solution is infused directly into the left and right coronary ostia or retrogradely through the coronary sinus, which is cannulated directly through the opened right atrium (see Chapter 3).

Exposure is obtained by placing stay sutures on the edges of the aortotomy. The orifice of the aneurysm is visualized, and elevating the right aortic cusp reveals the underlying VSD. No attempt is made to determine the feasibility of

Figure 36-10  Repair of ruptured sinus of Valsalva aneurysm into right ventricle, with ventricular septal defect (VSD). A, Initial incision is a transverse aortotomy. The orifice of the aneurysm in the right sinus is visualized. The right ventricle is opened through a transverse incision. Care must be taken to ensure that the aortic incision does not extend into right coronary artery. B, Windsock of ruptured aneurysm is seen overlying VSD. The thinned-out portion of the windsock containing the perforation is excised, taking care not to damage the hinge line of the right aortic valve cusp.
C, Hinge line is now visible between orifice of the aneurysm and VSD. D, Repair is performed using one patch and inserting it through right ventriculotomy. The patch is first sutured to inferior rim of VSD, incorporating septal leaflet of tricuspid valve and avoiding conduction system, using a continuous polypropylene suture. E, Midportion of patch is sutured to hinge line of right aortic cusp using interrupted polypropylene mattress sutures. This step is accomplished before remainder of patch is sewn into place. F, Superior aspect of patch is sewn into place over orifice of the aneurysm in the aortic sinus, completing the repair.
repairing the VSD through the aortic root; it may be difficult through the aortotomy to distinguish between a conoventricular VSD adjacent to the His bundle and a juxta-aortic VSD in the right ventricular outflow tract that does not border the His bundle. Any redundancy or tendency of the right coronary cusp to prolapse is noted, but its repair is deferred.

The right ventricle is opened through a transverse or vertical incision, depending on distribution of the branches of the right coronary artery. Alternatively, an approach is made through the pulmonary trunk. The anatomy is visualized (Fig. 36-10, B). The thinned-out windsock, often containing one or more perforations, is resected, creating a large defect in the right sinus of Valsalva. This defect is downstream (cephalad) from the VSD and separated from it by the hinge line of the right aortic cusp (Fig. 36-10, C). Most of the excised windsock is devoid of aortic media (see Fig. 36-1). A polyester or pericardial patch is sewn into place to close the VSD and the defect in the sinus of Valsalva, and the area of the hinge line of the right aortic cusp, which has been isolated by the resection, is sutured to the patch at an appropriate level (Fig. 36-10, D-F).

After closing the ventriculotomy (or pulmonary trunk) with polypropylene suture placed as a continuous stitch, the interior of the aortic root is again exposed through the aortotomy. When AR coexists and the patient is young with pathology limited to prolapse, all or part of a Trusler repair of the aortic valve is then performed (see Chapter 35, Figs. 35-37 and 35-38). In older patients with AR or when the aortic valve defect is more extensive, valve replacement is necessary (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 12). Either before or after closing the aortic root, the controlled, initially hyperkalemic reperfusion is begun if indicated (see Chapter 3), the sump suction catheter is removed, and the foramen ovale and then the right atrium are closed. The remainder of the operation is completed in the usual manner (see Section III of Chapter 2). Alternatively, when it is certain that the VSD is not conoventricular, the entire repair can be performed through the aortic root. Attachment of the base of the right coronary cusp to the patch is more conveniently accomplished from this exposure than from the right ventricular approach.

Ruptured Sinus of Valsalva Aneurysm into Right Atrium, without Ventricular Septal Defect

When the sinus of Valsalva aneurysm, usually from the non-coronary sinus but occasionally from the right coronary sinus, ruptures into the right atrium, the approach may be through both aorta and right atrium. If AR and VSD can be securely excluded, the approach may be from the right atrium or aorta alone. Intraoperative TEE facilitates this assessment.

In either situation, CPB is established using direct caval cannulation, an aortic root cannula is inserted, and the aorta is clamped (see Section III of Chapter 2). After placing and securing caval tapes, the right atrium is opened obliquely and a sump suction catheter inserted across the foramen ovale. A clamp can be placed across the windsock, or it can be occluded with a finger. Infusion of cardioplegic solution into the aortic root is begun. If the aortic valve is not completely competent, the root infusion is stopped, a transverse aortotomy is made, and cardioplegic solution is infused directly into the coronary ostia (see “Perfusion of Individual Coronary Arteries” in Chapter 3). Alternatively, cardioplegic solution is administered retrogradely through the coronary sinus, which is cannulated directly (see “Technique of Retrograde Infusion” in Chapter 3).

A coexisting VSD is always sought because it may be overlooked during preoperative evaluation if it is plugged by a prolapsing aneurysm or valve cusp. The windsock is then excised, remembering the precise location of the hinge line of the valve cusp. When the windsock is narrow and the bordering edges of the sinus are of good quality, direct closure of the defect is safe. Usually, however, closure is made with a polyester or pericardial patch.

The remainder of the operation is completed in the usual manner (see Section III of Chapter 2).

Unruptured Sinus of Valsalva Aneurysm

Most unruptured sinus of Valsalva aneurysms can be repaired through the ascending aorta. CPB is established using a single cannula in the right atrium (see Section III of Chapter 2). A venting catheter is placed into the left atrium through the right superior pulmonary vein. A catheter is placed into the ascending aorta for delivery of cardioplegic solution; alternatively, a cannula can be placed into the coronary sinus for delivery of cardioplegic solution retrogradely. The ascending aorta is occluded and cardioplegic solution administered. The aorta is opened transversely and the site of origin of the aneurysm identified (Fig. 36-11, A-B). The orifice of the aneurysm is closed with a polyester or pericardial patch, avoiding injury to the aortic cusp and ostium of the coronary artery (Fig. 36-11, C). If the aneurysm is large with associated AR, valve replacement, aortic root replacement with a composite valve-graft or aortic allograft, or a valve-sparing procedure may be necessary.

SPECIAL FEATURES OF POSTOPERATIVE CARE

The usual care is given to patients after repair of sinus of Valsalva aneurysm (see Chapter 5).

RESULTS

Survival

Most patients survive the early period after operation. Hospital mortality has not exceeded 5% in the largest reported series. 

A long-term results are excellent, particularly when aortic valve replacement is not required. Abe and Komatsu reported 86% survival at 25 years in 31 surgical patients. All patients who died late after operation had undergone aortic valve replacement. In the report by van Son and colleagues of the entire Mayo Clinic experience, survival of 31 patients was 95% at 20 years. The single late death resulted from endocarditis 9 years after a subsequent aortic valve replacement.

Risk Factors for Premature Late Death

Severe AR accompanied by marked left ventricle enlargement is a risk factor for premature death in the late postoperative period. Aortic valve replacement appears to be a risk factor
Figure 36-11  Repair of unruptured sinus of Valsalva aneurysm. A, Aneurysm is approached through a transverse aortotomy. B, Orifice of aneurysm in right coronary sinus is identified, noting its proximity to the right coronary artery (RCA) and hinge point of the aortic cusp. C, Orifice is closed with a polyester or pericardial patch using a continuous 5-0 or 6-0 polypropylene suture.

for late death, as does dehiscence of an aortic valve prosthesis.

Functional Status
Most surviving patients are asymptomatic. Abe and Komatsu found that 22 (86%) of 26 surviving patients were in New York Heart Association (NYHA) functional class I, and the other four were in class II. Similar results were observed in the Mayo Clinic series; 25 of 28 known surviving patients were in NYHA class I (89%), and the other three were in class II. Persistent or worsening AR accounted for most of the functional disability after operation.

Complications
Direct closure of the ruptured aneurysm, with or without repair of a coexisting VSD, has resulted in a 20% to 30% prevalence of reoperation for recurrence of the fistula. Other groups have experienced a lower prevalence of reoperations. When the defect left by excision of the ruptured aneurysm is repaired with a patch, reoperation is rare. Heart block occurs in 2% to 3% of patients postoperatively, occasionally late postoperatively. This complication is not surprising given the proximity of the His bundle and its branches to the area of repair.

INDICATIONS FOR OPERATION
When congenital sinus of Valsalva aneurysm ruptures or is associated with VSD or with VSD and AR, prompt operation is advisable.

Unruptured sinus of Valsalva aneurysms that are (1) producing hemodynamic derangements and (2) enlarging should be repaired. Small and moderate-sized unruptured aneurysms probably should not be repaired surgically, at least with the present state of knowledge about the natural history of these lesions, although this issue is controversial.
SPECIAL SITUATIONS AND CONTROVERSIES

Transcatheter Closure of Ruptured Sinus of Valsalva Aneurysm

With improved cardiac imaging and advances in percutaneous interventional therapy, percutaneous closure of ruptured sinus of Valsalva aneurysms represents a therapeutic alternative. Percutaneous closure of a congenital ruptured sinus of Valsalva aneurysm was first described by Cullen and colleagues in 1994.57 Arora and colleagues employed percutaneous closure devices (Rashkind umbrella device, Amplatzer occluder) in eight patients with ruptured sinuses of Valsalva aneurysms.44 One patient required surgical repair because of hemolysis, and one died of progressive cardiac failure. The remaining six patients were asymptomatic from 2 to 96 months following repair. Chang and colleagues subsequently reported successful treatment of four patients using the Amplatzer duct occluder in three and a Gianturco coil in one.43 One patient had a small residual shunt.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Patients with an aortico–LV tunnel usually have severe AR into the LV. They present with heart failure and marked cardiomegaly as well as symptoms and signs of severe AR.1,2,52 Diagnosis can usually be made with two-dimensional echocardiography and Doppler color flow imaging (Fig. 36-12).82,83,84,85,86 Cardiac catheterization and angiography are usually performed to exclude uncommon associated cardiac anomalies.

NATURAL HISTORY

In view of the rarity of the condition, the natural history of patients with aortico–LV tunnel can be outlined only in general terms. Age at presentation and severity of symptoms are related to cross-sectional area of the tunnel and severity of AR. Some patients present as neonates with cardiomegaly and severe heart failure; others who have a smaller tunnel present in childhood without symptoms.107,109 Patients rarely present beyond the second decade of life. When symptoms are present, marked LV enlargement has already occurred, and the natural history thereafter is that of severe AR (see Chapter 12). When symptoms are present in infancy and surgical repair is not accomplished, death usually occurs within a few months.

TECHNIQUE OF OPERATION

Repair is performed using CPB, and a single venous cannula may be used in most cases. In neonates and small infants, hypothermic circulatory arrest may be advantageous. The aorta must be clamped soon after cooling the patient with CPB to prevent LV distention from rapid aortic runoff. Cardioplegic solution must be infused directly into the coronary ostia or retrogradely via the coronary sinus (see “Perfusion of Individual Coronary Arteries” and “Technique of Retrograde Infusion” in Chapter 3).

A transverse aortotomy is made just downstream from the external bulge in the region of the right sinus of Valsalva. The ostium of the right coronary artery is identified and protected. Care is taken to avoid damaging the aortic cusps while visualizing the opening of the tunnel into the LV cavity through the aortic valve. If possible, both ends of the tunnel should be closed. The ventricular end is closed by sutures, usually pledgeted, or with a polyester or pericardial patch.107,108,109 The aortic end of the tunnel is closed by suturing a pericardial patch into place; direct suture closure distorts the sinus and may aggravate the tendency to develop AR postoperatively.109 If necessary, the ostium of the right coronary artery is excised before placing the patch and is reimplanted.107

The aortotomy is closed, and the remainder of the operation is completed in the usual manner. Particular care is taken to avoid LV distention from residual AR, because the heart is recovering from the period of global myocardial ischemia.

Section II  Aortico–Left Ventricular Tunnel

DEFINITION

Aortico–left ventricular (LV) tunnel, or communication, is a short abnormal pathway that begins in an aneurysmal dilatation of the aortic root and upper portion of the right sinus of Valsalva (rarely the left), just to the left of the orifice of the right coronary artery. The defect then passes through the upper end of the ventricular septum to open into the LV cavity.

HISTORICAL NOTE

Aortico–LV tunnel, a rare congenital cardiac anomaly, was first described by Levy and colleagues in 1963.11

MORPHOLOGY

In its most characteristic form, the aortic orifice of the aortico–LV tunnel is anterior and just downstream from the commissural level of the aortic valve and separated from the right sinus of Valsalva by a prominent transverse supra-valsar ridge.58,59,60,11,12,13 The anomaly is visible externally, and the extracardiac bulge can often be seen on the chest radiograph. The tunnel passes directly downward, alongside the aortic valve and through the junction between the aorta and ventricular septum, to communicate with the LV. The tunnel may displace the outlet portion of the ventricular septum into the right ventricle and produce important subpulmonary stenosis.17 A VSD may coexist.82 Rarely the tunnel may communicate with the infundibulum of the right ventricle rather than the left.

In one patient the orifice of the right coronary artery was shown to arise from the extracardiac portion of the tunnel.55 This finding, coupled with demonstration of elastic fibers in the extracardiac portion of some tunnels, suggests that some may actually be examples of coronary artery fistulae. However, most observers believe this anomaly is related to a congenital weakness in the region of the right sinus of Valsalva. In several patients the ostium and proximal portion of the right coronary artery were absent.515

A transverse aortotomy is made just downstream from the external bulge in the region of the right sinus of Valsalva. The ostium of the right coronary artery is identified and protected. Care is taken to avoid damaging the aortic cusps while visualizing the opening of the tunnel into the LV cavity through the aortic valve. If possible, both ends of the tunnel should be closed. The ventricular end is closed by sutures, usually pledgeted, or with a polyester or pericardial patch.107,108,109 The aortic end of the tunnel is closed by suturing a pericardial patch into place; direct suture closure distorts the sinus and may aggravate the tendency to develop AR postoperatively.109 If necessary, the ostium of the right coronary artery is excised before placing the patch and is reimplanted.107

The aortotomy is closed, and the remainder of the operation is completed in the usual manner. Particular care is taken to avoid LV distention from residual AR, because the heart is recovering from the period of global myocardial ischemia.
SPECIAL FEATURES OF POSTOPERATIVE CARE

The usual care is given to patients after the repair (see Chapter 5).

RESULTS

Risk of hospital death has been 5% to 20%. Most patients have at least mild AR after the operation, and in about half of these the regurgitation becomes severe enough to require later aortic valve replacement. The reason for postoperative AR is poorly understood, although in some patients it appears to be due to anuloaortic ectasia. Patients who do not require aortic valve replacement have excellent functional status.

INDICATIONS FOR OPERATION

Diagnosis of aortico–LV tunnel is an indication for operation. Surgery should be performed as early in life as possible to minimize damage to the LV from chronic volume overload imposed by AR.

### Patent Ductus Arteriosus

**Definition**

Patent ductus arteriosus (PDA) is abnormal persistence of a patent lumen in the fetal ductus arteriosus, which usually connects the upper descending thoracic aorta with the proximal portion of the left pulmonary artery (LPA). When the aortic arch is right-sided, the ductus usually connects to the proximal right pulmonary artery. The ductus may at times connect to the adjacent subclavian or brachiocephalic artery rather than to the upper descending thoracic aorta.

This chapter is primarily concerned with isolated PDA. PDA associated with other anomalies is discussed briefly here and in more detail in other chapters (Coarctation of the Aorta and Interrupted Aortic Arch, Chapter 48; Ventricular Septal Defect, Chapter 35; and Ventricular Septal Defect with Pulmonary Stenosis or Atresia, Chapter 38).

### Historical Note

The ductus arteriosus apparently was first described by Galen (born AD 129). It was rediscovered by Botallo in the 16th century, although some attribute the description of its postnatal closure to Acierno and Harvey. In 1888, Munro demonstrated in an infant cadaver the feasibility of dissecting and ligating a PDA. In 1900, Gibson described the characteristic continuous murmur of this anomaly. However, it was not until 1937 that Strieder in Boston attempted to close a PDA surgically in a patient with fulminating infective endarteritis; the patient died on the fourth postoperative day with gastric distention and aspiration of vomitus.

Cardiac surgery received a great impetus on August 26, 1938, when Gross successfully ligated the PDA of a 7-year-old girl at Boston Children’s Hospital. Subsequently, he

### Definitions

- Patent ductus arteriosus (PDA) is abnormal persistence of a patent lumen in the fetal ductus arteriosus, which usually connects the upper descending thoracic aorta with the proximal portion of the left pulmonary artery (LPA). When the aortic arch is right-sided, the ductus usually connects to the proximal right pulmonary artery. The ductus may at times connect to the adjacent subclavian or brachiocephalic artery rather than to the upper descending thoracic aorta.

- This chapter is primarily concerned with isolated PDA. PDA associated with other anomalies is discussed briefly here and in more detail in other chapters (Coarctation of the Aorta and Interrupted Aortic Arch, Chapter 48; Ventricular Septal Defect, Chapter 35; and Ventricular Septal Defect with Pulmonary Stenosis or Atresia, Chapter 38).
The ductus arteriosus is completely closed by 8 weeks of age in 88% of infants with a normal cardiovascular system. When the process is delayed, the term *prolonged patency* of the ductus arteriosus is appropriate; when the process ultimately fails, *persistent patency* of the ductus arteriosus is the appropriate term. Ductus closure or patency is mediated by release of vasoactive substances (acetylcholine, bradykinin, endogenous catecholamines, and probably others), by variations in pH, but chiefly by oxygen tension and prostaglandins (PGF₂α, PGE₂, and prostacyclin PGL₂). Oxygen tension and prostaglandins act in opposite directions, with an increasing PO₂ constricting the ductus and prostaglandins relaxing it; the potency of each varies at different gestational ages. Thus, the ductus is considerably more sensitive to PO₂ in the mature fetus and to prostaglandins (specifically, PGE₂) in the immature fetus. The complex interplay of these factors is the reason prolonged patency of the ductus is more common in premature than term infants, particularly when there is associated respiratory distress syndrome (see *Special Situations and Controversies* later in this chapter). *Intermittent patency* of the ductus arteriosus has been documented, particularly when the ductus is long and narrow.

**Position and Absence**

At birth, usually in subjects with other cardiac anomalies, the ductus may be unilateral, bilateral, or (rarely) completely absent. It is absent in 35% of autopsy specimens with tetralogy of Fallot with pulmonary stenosis, in 40% of those with tetralogy of Fallot with pulmonary atresia, in almost all patients with tetralogy of Fallot and absent pulmonary valve (see Chapter 38), and in truncus arteriosus (see Chapter 43). It is rarely absent in patients with pulmonary atresia and intact ventricular septum (4%) (see Chapter 40) or in those with pulmonary atresia and other complex anomalies (15%).

**Isolated Patent Ductus Arteriosus**

The usual isolated PDA connects to the upper descending thoracic aorta 2 to 10 mm beyond the aortic origin of the left subclavian artery (Fig. 37-1). From the aorta, it passes centrally toward the origin of the LPA from the pulmonary trunk, either directly or angling superiority and hugging the undersurface of the distal aortic arch. When, as in the normally developing heart, the ductus delivers approximately 55% of the combined ventricular output into the descending aorta, the ductus meets the aorta at a proximal acute angle (<40 degrees) and a distal obtuse angle (110 to 160 degrees, mean 134 degrees) (Table 37-1; see also Fig. 37-1).

The PDA is generally 5 to 10 mm in length (in autopsy specimens, 2.5–8 mm), with a wide aortic orifice (4–12 mm) and a considerably narrower pulmonary orifice, and it is restrictive to flow. The PDA may be longer or shorter than this and may have a wide pulmonary as well as aortic orifice.

**Patent Ductus Arteriosus as a Coexisting Anomaly**

When other cardiac anomalies are present, orientation of the ductus to the aortic arch varies, as does the flow pattern in fetal life. When there is pulmonary atresia and the pulmonary circulation is ductus dependent, with ductal flow in utero occurring from the aorta to the pulmonary artery, the ductus becomes a downwardly directed branch of the distal aortic arch. The proximal angle is much less acute and often...
Figure 37-1 Specimen of isolated patent ductus arteriosus (D) in an infant. Ductus passes from junction of pulmonary trunk (PT) and left pulmonary artery (LPA) in an inferior and lateral direction to join descending aorta (Ao). Angle between superior border of ductus (asterisk) and aorta (proximal angle) is acute, and that between the lower border and aorta (arrow) (distal angle) is obtuse. Uncommonly, in the presence of a left aortic arch, the ductus may arise from an aortic diverticulum (thought to represent persistence of the most distal portion of the right fourth branchial arch) that projects from the medial aspect of the left arch just distal to the origin of the left subclavian artery.\textsuperscript{G9} In rare cases in which the ductus is bilateral, the right-sided PDA connects the right pulmonary artery to the brachiocephalic artery. In the presence of a right aortic arch, a left-sided ductus is still more common than a right-sided ductus. When there is mirror-image branching of the right arch, the left PDA arises from the distal brachiocephalic (or proximal left
subclavian) artery (see Chapter 38). Much less commonly, the right PDA persists in mirror image to the normal, passing from the right arch beyond the right subclavian artery to the right pulmonary artery origin. A PDA (or ligamentum arteriosum) arising from an aortic diverticulum or from an aberrant left subclavian artery is one form of vascular ring (see Chapter 51).

Histology

Histology of a persistent PDA is different from that of simple prolonged patency of the ductus. It is also different from that of the adjoining great arteries. A persistent PDA has a relatively thick intima with an unfragmented elastic lamina separating it from the media, an additional and pronounced wavy unfragmented subendothelial elastic lamina, and variable mucoid material in the media where there is an intricate helicoid spiral muscular arrangement. The media contains variable amounts of elastic material that may form conspicuous lamellae, making the ductus wall resemble the wall of the aorta (aortification).

Aneurysms of Ductus Arteriosus

Aneurysms of the ductus arteriosus, which are rare lesions, appear to be of two types. One is the spontaneous infantile ductal aneurysm, which is present at birth or develops shortly thereafter. The other develops in childhood or adult life.

Presence of the first type may not be detected until autopsy after death from other causes. The aneurysm involves the entire length of the ductus arteriosus and is usually associated with occlusion of the pulmonary artery and a relatively narrow but patent aortic end. It generally contains thrombus and is occasionally a site of infection and embolism. Rarely, it may be a true dissecting aneurysm of the ductal wall. This rare lesion manifests most often in newborns with a history of respiratory difficulties. It produces a tumor-like shadow of variable size that projects beyond the mediastinum adjacent to the aortic knob in the posteroanterior chest radiograph. The aneurysm usually regresses spontaneously within weeks or months, presumably as a result of complete thrombosis and organization, but progressive enlargement or onset of hoarseness from recurrent laryngeal nerve involvement is an indication for surgical exploration and excision. Less marked dilatation of the ductus can be seen on the plain chest radiograph as a fusiform shadow between 6 and 18 hours after birth, disappearing by 24 to 48 hours of age. It has been called the ductus bump.

The second type of ductal aneurysm is thought to be unrelated to the infantile form. The ductus may be patent at both ends, but usually the pulmonary artery end is closed. There is a tendency for progressive enlargement, and death may occur from rupture.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Symptoms and signs of a PDA are the consequence of left-to-right shunting, with the magnitude of the shunt dependent upon size of the communication and relationship between systemic and pulmonary vascular resistances. In this regard, it is similar to other types of high-pressure shunts, which include those across the ventricular septum and others from the aorta.

Large Patent Ductus Arteriosus

Aortic and pulmonary artery pressures are essentially equal when the PDA is large, and the magnitude and direction of shunting are dependent on changes in pulmonary vascular resistance, because systemic vascular resistance remains fairly constant after birth. As neonatal pulmonary vascular resistance decreases, left-to-right shunting increases and severe heart failure develops within a month or so of birth. There is tachypnea, tachycardia, sweating, irritability, poor feeding, and slow weight gain. Pulmonary edema and pneumonia or less severe, and recurrent respiratory infection may occur.

On examination, there is an overactive precordium, sometimes with a systolic thrill, and evidence of cardiac enlargement with a thumping left ventricular apical impulse. The pulse is jerky or frankly collapsing, and the pulse pressure is correspondingly wide. These features become more obvious when heart failure is medically controlled. On auscultation, there is a systolic murmur maximal in the pulmonary area, with late systolic accentuation and minimal spillover into diastole. Occasionally the murmur is continuous, but sometimes with severe heart failure, no murmur is heard. The first and second heart sounds are accentuated, and there is a third sound at the apex or a prominent mid-diastolic mitral flow murmur. The liver enlarges and jugular venous pressure rises; frequently, rales are heard in the lung bases.

The electrocardiogram (ECG) shows left ventricular enlargement with deep Q and tall R waves in the left ventricular leads. There may be evidence of right ventricular hypertrophy with upright T waves in the right precordial leads and evidence of left atrial enlargement with widened P waves. The chest radiograph shows marked cardiomegaly and plethora with or without interstitial or alveolar pulmonary edema. The pulmonary trunk is enlarged, as is the ascending aorta. The echocardiogram shows left atrial enlargement. The ductus may be visualized with two-dimensional echocardiography.

In some infants with a large PDA, heart failure may be less marked, presumably because pulmonary vascular resistance does not fall to the usual level. Histologic changes of pulmonary vascular disease may develop within the first few months of life. These changes may occur in infants in whom heart failure is controlled medically and the ductus is not closed by intervention. These patients become asymptomatic, and the left-to-right shunt diminishes. The murmur becomes purely systolic, the pulmonary component of the second heart sound is markedly accentuated, the apical mid-diastolic murmur disappears, and the pulse loses its jerky quality. Right ventricular hypertrophy becomes dominant in the ECG, the heart becomes smaller on the chest radiograph, and pulmonary plethora disappears. Cyanosis develops as pulmonary vascular resistance increases above systemic vascular resistance (Eisenmenger syndrome), typically earlier than with ventricular septal defect (see Chapter 35). Differential cyanosis may be noted, with blueness of the feet and sometimes the left hand, but not of the face or right hand.

Moderate-Sized Patent Ductus Arteriosus

Left-to-right shunt in moderate-sized PDA is regulated by size of the ductus arteriosus. In this setting, pulmonary artery
pressure is only moderately elevated. As neonatal pulmonary vascular resistance declines, the shunt increases and heart failure may occur. By the second or third month of life, however, compensatory left ventricular hypertrophy is usually associated with clinical improvement and stabilization of symptoms. Physical development may be somewhat retarded, and breathlessness and fatigue may occur, but many patients with moderate-sized PDA remain essentially asymptomatic until the second decade of life or later.

On examination, the pulse is jerky, the precordium is mildly overactive, and the left ventricle is palpable at the apex in association with some cardiac enlargement. The classic continuous murmur is usually heard by age 2 to 3 months, although it varies in intensity. The murmur is generally loud and often masks the heart sounds. It is maximal over the pulmonary artery and radiates upward beneath the mid-third of the clavicle. As described by Gibson in 1900, “it begins after the commencement of the first sound—it persists through the second sound and dies away gradually during the long pause. The murmur is rough and thrilling. It begins softly and increases in intensity so as to reach its acme at or immediately after the occurrence of the second sound, and from that point gradually wanes until its termination.”

Subnormal physical growth is common; Krovetz and Warden found body weight below the third percentile in 26% of 515 surgically proven cases. The ECG may be relatively normal during infancy, but some degree of left ventricular hypertrophy develops in older children. The chest radiograph shows moderate cardiac enlargement and plethora and a prominent ascending aorta (in contrast to findings in patients with a large ventricular or atrial septal defect). In adults, the PDA may be calcified. It is rare for pulmonary vascular resistance to increase, and Eisenmenger syndrome does not develop.

Small Patent Ductus Arteriosus

Left-to-right shunt is small in early life, and pulmonary vascular resistance decreases rapidly to normal after birth.

Left ventricular failure does not occur, and symptoms are absent in infancy and childhood. They may appear later in life, but usually attention is drawn to the condition by a murmur detected on physical examination. Physical development is normal unless there is maternal rubella. The pulse is normal and the precordium is not overactive. By age 2 to 3 months, a short systolic murmur is usually replaced by one that spills over into diastole, or it may be continuous in the second left intercostal space but less intense, and with less radiation than when the ductus is moderate in size. The continuous murmur varies greatly in intensity between patients and sometimes is detectable only when the patient is sitting or standing upright. The ECG and chest radiograph are normal or nearly so.

Special Investigations

Most children and young adults with a PDA and a continuous murmur that is maximal in the second left intercostal space do not need preoperative invasive studies unless other defects are suspected; such studies may be necessary for diagnosis in atypical cases. Instead, two-dimensional echocardiography is usually performed and will image the ductus arteriosus. It has identified so-called silent ductus (a PDA without auscultatory findings). Managing patients with isolated silent ductus remains controversial, although endarteritis has been reported and may be an indication for closure. Cardiac catheterization and angiography are indicated if the echocardiogram suggests elevated pulmonary vascular resistance or associated cardiac anomalies.

NATURAL HISTORY

Isolated PDA in term infants occurs in approximately 1 in 2000 live births and accounts for 5% to 10% of all types of congenital heart disease. It is twice as common in females and may occur in siblings, suggesting a genetic factor. It is particularly common when the mother contracts rubella during the first trimester of pregnancy and may then be associated with multiple peripheral pulmonary artery stenoses and renal artery stenosis.

Because of the early introduction of surgical treatment of PDA, which antedated methods for establishing the diagnosis, its natural history is not completely documented.

Spontaneous Closure

Campbell’s study concluded that spontaneous closure of isolated PDA occurs in 0.6% of patients per year and that this rate is fairly constant through the first 4 decades of life. If this is accepted, it means that in approximately 20% of patients, the PDA will have closed by age 40. His study involved only patients diagnosed beyond age 12 months and was based entirely on clinical findings, closure being assumed to have occurred when a typical murmur was no longer audible, regardless of size of the ductus or initial right-to-left shunt. Other experience suggests that the closure rate is much lower, and it is generally agreed that spontaneous closure is uncommon beyond age 3 to 5 months in full-term infants. Delayed closure of the ductus arteriosus in preterm infants is, however, common (see Special Situations and Controversies later in this chapter).

Pulmonary Vascular Disease

Prevalence and type of pulmonary vascular disease in patients with large PDA are similar to those in patients with large ventricular septal defect (see “Pulmonary Vascular Disease” under Morphology in Section I of Chapter 35).

Rupture

Rupture of both non-aneurysmal and aneurysmal PDA has been reported.

Death

Mortality with untreated PDA in infancy is high, and it has been estimated that, particularly in earlier eras, 30% of patients born with an isolated PDA died within the first year. Risk of death is highest in the first few months of life (see “Patent Ductus Arteriosus in Preterm Infants” under Special Situations and Controversies later in this chapter).

After infancy, the annual death rate of patients with untreated PDA decreases dramatically to approximately 0.5% per year. By the third decade, the death rate has increased to about 1% per year; by the fourth decade, 1.8% per year; and in subsequent decades, as high as 4% per year. As a
result, approximately 60% of patients with PDA die by age 45. Most of the deaths in older patients are related to development of intractable left ventricular failure secondary to long-standing volume overload.

Modes of Death

In infants with a large PDA, mode of death is usually heart failure. Recurrent respiratory infection terminating in pneumonia is a less common mode. In those with a large PDA who survive infancy, death is usually due to acute or chronic right heart failure secondary to development of severe pulmonary vascular disease by the second or third decade of life.

In patients with a moderate-sized PDA, mode of death from the third and fourth decades onward is heart failure. Excluding infants and deaths from pulmonary vascular disease, Campbell estimated that heart failure was the cause of death in 30% of patients.25

Infected endarteritis occurs mainly as a complication of small and moderate-sized PDA. It rarely occurs when the ductus is large. In the preantibiotic era, endarteritis was responsible for approximately 45% of deaths in patients with surgically untreated PDA. A2,C2,K2 After the advent of antibiotics, few patients died from this cause, although they remained subject to recurrent infection. In the current era, risk of infective endarteritis is extremely low.24

TECHNIQUE OF OPERATION

Closure of Patent Ductus Arteriosus

Unless the patient is an infant in severe heart failure or elderly, an intraaerial monitoring catheter is usually unnecessary. After the usual induction of anesthesia and preparations for operation (see Chapter 4), the patient is positioned on the right side (Fig. 37-3, A). A small roll or pillow is placed under the mid-chest. The patient is positioned near the surgeon’s side of the table, but not so much so that the first assistant across the table from the surgeon cannot see into the field well and work comfortably.

Posterolateral Thoracotomy

A curving skin incision is made, centered about 1 to 2 cm below the tip of the scapula. In infants and young children, the incision is really a lateral one, because only the latissimus dorsi and posterior part of the serratus anterior are divided. In older children, the incision is posterolateral, extending posterolaterally to overlie the lower 1 or 2 cm of the trapezius, which is also incised. In patients who are in the second decade of life or older, the incision extends from the anterior axillary line around the scapula and up midway between the spine and posterior scapular border over the lower 3 to 4 cm of the trapezius.

After incising the latissimus dorsi (and trapezius if indicated), the scapula is elevated with a retractor and the ribs are cut from the top down to the fifth rib. Identifying the appropriate rib or intercostal space requires an accurate point of reference. There are three possible points of reference (the second and third are often more reliable than the first):

- First rib: The surgeon passes his or her left hand under the serratus and identifies the first rib by palpation.
- Second rib: The serratus anterior attaches superiorly to the second rib. The surgeon identifies this attachment using upward traction on the scapular retractor, which makes the prominent posterior border of this muscle taut.
- Second intercostal space: This is usually appreciably wider than the third intercostal space.

Counting down from the reference point, the fifth rib is identified and scored. Only then are the posterior and midportions of the serratus anterior divided so that the muscle incision may be directly over the fifth rib. The fourth intercostal space may be opened with a knife or cautery or the chest may be entered through the superior part of the bed of the nonresected fifth rib. With the latter method, the periostecum over the rib is incised, and its superior portion is elevated from the front and back with a periosteal elevator.

After the incision in the rib cage is extended anteriorly and posteriorly, the rib retractor is placed with the ratched portion anteriorly (Fig. 37-3, B). The retractor is opened only partially at first, but as the operation proceeds, it is gradually opened further to obtain adequate exposure.

A retractor is gently placed on the lung, and a vertical incision is made in the mediastinal pleura over the proximal descending thoracic aorta (see Fig. 37-3, B).1 Traction sutures are placed on the anterior and posterior pleural flaps. The lung retractor is removed, moist gauze is placed over the lung, and the anterior pleural traction sutures are pulled taut and anchored to the retractor or drapes. The vein that traverses the aorta obliquely on its anterior surface is divided. The PDA is completely dissected from the surrounding tissue (Fig. 37-3, C-E). In small infants, particular care is taken to be certain that the structure identified as the PDA connects the aorta and pulmonary artery, and that it is not the LPA or distal aortic arch. As dissection proceeds, the left recurrent laryngeal nerve is not isolated, although it should be clearly visualized behind the aortic tissue over the LPA, just inferior and posterior to the PDA (see Fig. 37-3, C).

When the PDA is an uncomplicated one, either division or ligation may be performed. Both techniques, when done properly, ensure complete closure with low risk.

Division When division is elected and the patient is an infant or young child, one straight and two angled fine-toothed Potts ductus clamps are selected. In teenagers and adults, longer-handled vascular clamps are used. At this time, and particularly in older children and adults, the anesthesiologist reduces arterial blood pressure (see Chapter 4) and maintains it below baseline level until the clamps are removed.

The straight clamp is placed completely across the aortic end of the PDA, making sure that its tip does not grasp the recurrent laryngeal nerve or other soft tissue posterior to the ductus. The clamp is placed in the surgeon’s left hand and is gently pulled anteriorly. One angled ductus clamp is placed on the aortic side of the straight clamp and usually on the aorta contiguous with the PDA rather than on the ductus itself. The straight clamp is removed. With the clamp on the aortic origin of the PDA, which is held in the surgeon’s right hand, the other angled clamp is placed with the left hand on

Gross made an anterolateral thoracotomy incision, placed the pleural incision midway between the phrenic and vagus nerves, and retracted the vagus nerve posteriorly.211-214 Exposure is probably less optimal with this approach, although it may be appropriate in small patients and those with variations of situs such as mesocardia and dextrocardia.
the pulmonary end of the ductus. To avoid dislodgment from the clamp and retraction into the pericardial cavity, the clamp must grasp only the ductus and not any of the lappet of pericardium or other tissue. This clamp, like the one on the aortic end, is “squeezed” onto the pulmonary artery as much as possible when it is being placed to give added length to the ductus. The ductus is divided midway between these clamps by Potts scissors or a scalpel (Fig. 37-3, F).

The aortic end of the PDA is oversewn with two rows of 5-0 or 6-0 polypropylene suture placed as a whip stitch (Fig. 37-3, G). The pulmonary end is similarly closed. Although accurate suturing is of obvious importance, the key to a safe repair is separating the clamps widely enough so that a substantial cuff of ductus remains beyond them after the ductus is divided. This permits placing additional sutures for hemostasis.
After anterior surface of ductus has been freed far enough medially so that junction of PDA with left pulmonary artery is visible, superior and inferior surfaces are similarly dissected. Right-angled clamp is passed behind ductus. Clamp stretches areolar tissue behind ductus, which is then grasped with forceps and cut away. This maneuver is repeated several times and creates a space behind ductus. Clamps are placed at aortic and pulmonary ends of ductus (see text), and it is divided midway between them. Aortic end of ductus is oversewn with two rows of 5-0 or 6-0 polypropylene suture. Clamp on aortic end of ductus is generally kept in place following closure and provides traction to expose pulmonary end, which is then oversewn in a similar fashion. Clamps are then released.
The clamp on the pulmonary end of the divided ductus generally is removed first. The clamp on the aortic end is then removed, and a sponge is placed between the divided ends and held in place with pressure for several minutes. Unless the original placement of the clamps has been faulty or the suture closure is inadequate, the bleeding that occurs when the clamps are released usually stops within this period. If not, and if there is no major bleeding that would require replacing one or both clamps, a 5-0 polypropylene suture approximating the adventitia from both sides of the suture line usually controls the bleeding. A pledget of absorbable porcine gelatin sponge is left between the divided ends of the ductus to prevent the suture lines from rubbing against each other.

**Ligation** If the situation is uncomplicated and the PDA is pliable, it may be ligated rather than divided. The technique is basically that described by Blalock in 1946. The operation proceeds exactly as described for ductal division until the PDA is completely dissected. Using a double-armed 5-0 or 6-0 polypropylene suture, adventitial stitches are placed into the accessible superior, inferior, and anterior aspects of the aortic wall contiguous with the PDA (Fig. 37-4, A). One end of the suture is passed beneath the ductus, and the ends are held. A similar stitch is placed on the pulmonary end of the ductus (Fig. 37-4, B). The aortic stitch is pulled up and snugly tied, and then the suture at the pulmonary end is tied. This leaves a long length of ductus between the tied sutures. Finally, a transfixion ligation of 5-0 or 6-0 polypropylene is placed at the middle of the ductus, and the ends are passed in the opposite direction around the ductus and tied to complete the ligation (Figs. 37-4, C to F).

The mediastinal pleura is closed with interrupted sutures, leaving a small opening at each end. In the unlikely event that there is substantial bleeding from the suture lines after operation, this closure will contain it and may be lifesaving.

The rib retractor is removed, a small catheter is inserted into the posterior part of the pleural space through a stab wound in the sixth or seventh intercostal space at the midaxillary line, and suction of 15 to 25 cm water is placed on it. The ribs on either side of the incision are approximated with interrupted sutures. The muscles are individually sutured with a slowly absorbable synthetic material (polyglycolic acid), and the skin edges are approximated with a subcutaneous stitch. In infants, the chest tube may be removed in the immediate postoperative period. A 3- to 4-cm incision is made over the third intercostal space in the axilla. The serratus anterior is reflected inferiorly and laterally, and the pectoralis major is reflected anteriorly. A 3- to 4-cm incision is made over the third intercostal space in the axilla. The serratus anterior is reflected inferiorly and laterally, and the pectoralis major is reflected anteriorly.

**Transaxillary Muscle-Sparing Lateral Thoracotomy**

A 3- to 4-cm incision is made over the third intercostal space in the axilla. The serratus anterior is reflected inferiorly and laterally, and the pectoralis major is reflected anteriorly. The third intercostal space is entered and a rib retractor inserted. The lung is retracted anteriorly, and the pleura overlying the descending thoracic aorta is incised. The PDA is identified at its junction with the aorta, and the recurrent laryngeal nerve is identified and protected. The PDA is dissected circumferentially and is divided or ligated using the techniques just described. Alternatively, it may be occluded with a medium-sized surgical clip. The lung is inflated as the chest is closed.

Fluid and air can be aspirated as the chest wall is closed with interrupted pericostal sutures, making a chest tube unnecessary. The muscle and soft tissue layers are approximated with a slowly absorbable synthetic suture (polyglycolic acid), and the skin edges are approximated with a subcutaneous stitch. This technique is applicable to premature infants, neonates, older children, and adults.

**Closure of Patent Ductus Arteriosus in Association with Repair of Intracardiac Lesions**

Closure of a PDA may be required during operations to correct intracardiac anomalies that require the use of cardiopulmonary bypass (CPB). This occurs in two distinct clinical situations. When the PDA is an incidental finding and relatively small and restrictive, such as with a large ventricular septal defect, dissection of the ductus is usually performed after CPB has been established, because exposure of the adjacent aorta and pulmonary artery is facilitated when the heart is decompressed, and injury to the ductus or surrounding structures can be avoided. The technique for closure of the PDA under these circumstances is described in Technique of Operation in Chapter 35. In the second situation, as can occur in the neonate with transposition of the great arteries with intact ventricular septum, the ductus is large. It must be exposed and controlled before initiating CPB so that it can be ligated immediately after bypass is established.

**Closure of Patent Ductus Arteriosus in Older Adults**

When a PDA requires closure in older adults, the aortic end is often calcified and the ductus very short. A technique using CPB described by Goncalves-Estella and colleagues and later by O’Donovan and Beck is appropriate in this circumstance.

With the usual preparations (see Chapter 2), a median sternotomy is performed and the usual stay sutures and purse-string sutures placed. The aorta and pulmonary trunk are dissected apart. CPB is established with a single venous cannula, and cooling of the patient by the perfusate is begun. The head of the table is lowered to place the patient in a moderate Trendelenburg position. As the heart begins to slow from the cold perfusion, the ductus is obliterated by compressing the front wall of the LPA against it with the index finger. This is essential because otherwise ductal flow into the pulmonary artery will overdistend the pulmonary vascular bed and the right ventricle (this does not occur when the heart is ejecting adequately). When the nasopharyngeal temperature reaches 20°C to 22°C, the aorta is clamped and cold cardioplegic solution is infused into the aortic root or retrogradely into the coronary sinus (see “Technique of Retrograde Infusion” in Chapter 3). The perfusion temperature is stabilized at 20°C to 22°C, and flow is reduced to 0.5 L · min⁻¹ · m⁻². The finger is removed, the distal pulmonary trunk is opened anteriorly and longitudinally, and the incision is continued into the LPA opposite the ductus. (If external pressure on the LPA does not control ductal flow during CPB cooling, perfusion is temporarily reduced to a low level, and the pulmonary artery incision is made such that the finger can be placed directly over the ostium of the ductus to control flow from it into the LPA. CPB flow rate is then increased until cooling is completed.)

The intracardiac sucker is positioned within the LPA beyond the ductus to aspirate blood entering it. The ductal orifice is closed by placing and tying one or more pledgeted
Figure 37-4  Closure of patent ductus arteriosus by ligation. A, Dissection has been completed as shown in Fig. 37-3. Adventitial purse-string suture of 5-0 or 6-0 polypropylene is placed around aortic end of ductus. B, Similar purse-string suture is placed around pulmonary end of ductus. C, The two purse-string sutures are snugly tied. Transfixion suture is placed through ductus. One end is passed beneath ductus. D, Other end of suture is passed beneath ductus in opposite direction, and the two ends are tied on anterior surface. E, Cross-sectional diagram showing scheme for passing ends of suture. F, Transfixion suture has been tied, leaving a space between it and other sutures.

mattress sutures of 3-0 or 4-0 polypropylene. This is usually readily accomplished because the pulmonary artery end of the ductus is rarely calcified, and the pulmonary artery tissues are strong enough to hold sutures well. If the orifice of the pulmonary artery end of the PDA is too large or immobile for this technique, an impervious patch of bovine pericardium, woven polyester, or polytetrafluorethylene can be used to close it, sewing the patch in place with continuous 4-0 or 5-0 polypropylene suture. Flows are then restored, the table leveled, and rewarming of the patient with the perfusate begun. Any leak from the ductus closure site is secured with additional sutures. The pulmonary arteriotomy is closed with a running stitch of fine polypropylene.

With strong suction on a venting catheter or needle that has been placed in the aortic root, the aortic clamp is released. The remainder of the operation is completed in the usual fashion (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2).
Closure of Patent Ductus Arteriosus in Premature Infants

Perioperative management and technique of operation are different when surgical closure of the ductus is indicated in the premature infant, most of whom weigh approximately 1000 g and some as little as 400 g. Precise management of ventilation, fluid administration, and body temperature, as well as a precise surgical technique, are essential for success.

Operation is usually performed in the neonatal intensive care unit. This simplifies the logistics and, when properly organized, can provide outcomes as good as those obtained in a conventional operating room.10,12,14

If the procedure is to be performed in the operating room, the infant is intubated in the neonatal nursery, and proper position of the tube is verified by a chest radiograph. The patient, covered by a plastic wrap blanket and cloth cap, is transported to the operating room in a prewarmed (37°C) transport isolette. The room is prewarmed to approximately 30°C, and the patient is placed on the right side on an infant operating table with overhead servocontrolled radiant warmers set at 37°C.

After preparation and draping, a left lateral incision of approximately 2.5 cm is made, cutting or reflecting the latisimus dorsi and posterior aspect of the serratus anterior. The chest is entered through the third or fourth interspace, and a small rib retractor is put into place. With a narrow malleable retractor, the lung is held forward by the first assistant. The ductus is usually large but is variable in position. It may course superiorly as well as anteriorly from the aorta and be immediately adjacent to the distal aortic arch. In this location it can be easily mistaken for the arch. It may course directly anteriorly and be well inferior to the arch.

The friable vascular tissue makes the usual complete dissection of the ductus inadvisable.15,16,71,76 The mediastinal pleura is incised with fine scissors just superior to the aortic end of the ductus and then just inferior to it. The tissue plane is developed by gently spreading fine scissors. As the inferior tissue plane is developed, the back wall (or right side) of the ductus is seen; no attempt is made to pass an instrument around it. The ductus is temporarily and lightly occluded with a fine forceps, and a pulse oximeter on the foot confirms that it is the ductus, not aorta, and that the aortic arch is intact without interruption or coarctation. A medium-sized hemoclip on a holder is positioned well across the ductus at its aortic end; the tip of the clip must be beyond the ductus posteriorly. The adventitia of the aorta may be grasped and gently retracted toward the surgeon as the clip is placed. By closing the holder the ductus is closed.

A 12F catheter is brought out through a stab wound in the chest wall and placed on suction. Placing a chest tube is usually not necessary. The chest wall is closed with two pericostal sutures. The muscles are closed with a continuous fine absorbable suture (polyglycolic acid), and the closure is completed with a subcuticular stitch of fine absorbable sutures. When the procedure is performed in the operating room, the infant is transferred back to the neonatal intensive care unit in a prewarmed transfer isolette.

SPECIAL FEATURES OF POSTOPERATIVE CARE

Care after division or ligation of PDA is simple and follows the principles described in Chapter 5. The patient is usually extubated and the drainage catheter removed in the operating room or within a few hours of leaving it. When the transaxillary muscle-sparing technique is used, most patients can be discharged from the hospital within 24 hours.13,14 When the operation is done with CPB, care is also simple and usual (see Chapter 5).

RESULTS

Early (Hospital) Death

Within 10 years of Gross and Hubbard’s first successful case, hospital mortality for surgical closure of uncomplicated PDA had become very low. In 1951, Gross and Longino reported eight deaths (1.9%; CL 1%-3%) among their first 412 surgically treated cases.14 In 1955, Ash and Fischer reported no deaths (0%; CL 0%-6%) among 116 consecutive children (ages 4 months to 14 years) undergoing surgical closure.15 Other similar experiences reinforce the idea that the operation is safe and that hospital mortality approaches zero.16

Incremental Risk Factors for Early Death

No risk factors for early death can be consistently identified. Operation in infancy or childhood, associated congenital anomalies, pulmonary hypertension, and mild or moderate increase of pulmonary vascular resistance do not increase the risk of hospital death, nor does the surgical technique used. However, by considering the entire span of time since Gross first successfully closed a PDA in 1938, certain situations can be presumed to increase risk.

When pulmonary vascular disease is severe and the shunt is bidirectional or dominantly right to left, risk is high; 5 of 14 such patients (36%; CL 21%-53%) died in the hospital in the early Mayo Clinic experience.15 Death was due to hemorrhage during operation (from the pulmonary artery suture line, because pulmonary artery pressure after closure was higher than systemic arterial pressure and the pulmonary artery was large and thin walled), or it occurred suddenly some days later without any demonstrable cause.15 However, no distinction with regard to reactivity of the pulmonary vascular bed was made in these patients. Thus, it is likely that with preoperative provocative testing, a subgroup of patients could be identified that would have lower operative risk.

When pulmonary vascular disease is mild or moderate, and thus when a large left-to-right shunt is present, there is no increased risk. Even in the early era, 16 among 271 patients undergoing repair of PDA at the Mayo Clinic had severe pulmonary hypertension but only mild or moderate pulmonary vascular disease and a large left-to-right shunt, and there were no (0%; CL 0%-11%) early or late deaths.15

Older age minimally increases risk of surgical closure even in the absence of severe pulmonary vascular disease. This increase is principally from the technical problems posed by the friable and often calcified ductal wall in older patients, and the tendency of the long-standing volume overload of the left ventricle to predispose them to fatal arrhythmias. The mildly increased risk in the older age group is illustrated by the report of Black and Goldman in 1972, which described one death (2%; CL 0.2%-6%) in 53 adults (aged 14-55 years) undergoing surgical closure of a PDA. Death occurred at early reoperation for postoperative bleeding from a tear in the aorta.17 In recent years, the technical problems in older
patients have been eased by use of an open technique (see “Technique of Operation” earlier in this chapter).

Time-Related Survival

Life expectancy is normal after surgical closure of an uncomplicated PDA in infancy or childhood. When moderate or severe pulmonary vascular disease has developed preoperatively, late deaths may result from its progression, as is the case in children with ventricular septal defect (see “Pulmonary Hypertension” under Results in Section I of Chapter 35).

When the operation is performed in adults with advanced chronic heart failure, premature late death is at times unavoidable. This is because the cardiomyopathy secondary to longstanding left ventricular volume overload is irreversible in some patients, in a way entirely analogous to the situation in patients with long-standing aortic valve regurgitation (see “Left Ventricular Structure and Function” under Results in Chapter 12).

Symptomatic and Functional Status

Disappearance of the signs and symptoms of heart failure is dramatic after surgical closure of a large PDA. Ash and Fischer recount that the marked hepatomegaly and splenomegaly in a 3-year-old girl with cardiac cachexia and advanced heart failure were no longer detectable 3 hours after surgical closure of the ductus, and cardiac size on chest radiography had returned to near normal within 4 months. It has been presumed that when a large isolated PDA is closed in infancy, growth pattern becomes normal. However, growth retardation, particularly in regard to height, tends to persist, particularly when the operation is delayed beyond infancy or if the child has a rubella syndrome. The same may occur after repair of ventricular septal defect (see “Physical Development” under Results in Section I of Chapter 35).

Recurrence of Ductal Patency

Currently, prevalence of recurrent or persistent ductal patency approaches zero when division or appropriate ligation techniques are used. In an earlier era, it did occur. In 1965, Jones reported 12 patients (20%; CL 14%-26%) with recurrent or persistent ductal patency out of 61 patients who had ductal ligation with heavy tape. Later, it became less common; Panagopoulos and colleagues reported only four cases (0.4%; CL 0.2%-0.8%) among 936 patients undergoing ductal closure, mostly by ligation. Tripested and Efksind reported 20 among 639 traced cases (3.1%; CL 2.4%-4.0%).

False Aneurysm

False aneurysm is a rare complication of surgical ductal closure that usually occurs after ligation rather than division. Only rare cases of false aneurysm have been reported after ductal division, and these probably resulted from technical errors or infection. Development of a false aneurysm is an indication for urgent reoperation.

Left Vocal Cord Paralysis

Transient and occasionally permanent left vocal cord paralysis resulting from manipulation or injury of the left recurrent laryngeal nerve occurs in 1% to 4% of patients following division or ligation of a PDA. Prevalence is higher among infants with low birth weight.

Phrenic Nerve Paralysis

Phrenic nerve paralysis with elevation of the hemidiaphragm after PDA closure occurs in approximately 4% of patients. It usually occurs on the left side, usually in infants, and most frequently in preterm babies. It is not necessarily due to surgical damage to the phrenic nerve, because it may develop on the right side. It often regresses spontaneously but may persist for many months or indefinitely.

Chylothorax

Chylothorax is a rare complication of surgical ductal closure. Its management is discussed in Section II of Chapter 5.

INDICATIONS FOR OPERATION

Persistent PDA is an indication for closure, and the optimal age for operating is during the first year of life. Patients, either term or preterm, with prolonged PDA require closure in early life only when a large left-to-right shunt results in heart failure. In practice, this means that in term infants in the first month of life, PDA closure is indicated only when symptoms of heart failure are present. (For a discussion of the special situation in preterm infants, see “Patent Ductus Arteriosus in Preterm Infants” under Special Situations and Controversies later in this chapter.)

Beyond the first month of life, prophylactic closure of the PDA is indicated. In the absence of symptoms, operation may be delayed until about age 6 months. However, closure is indicated at any time before this when symptoms of heart failure or failure to thrive persist despite intense medical treatment. Older age is not a contraindication to closure of an isolated PDA in the absence of severe pulmonary vascular disease.

Severe pulmonary vascular disease is a contraindication to closure. The criteria of inoperability in this setting are the same as described for patients with ventricular septal defect (see Indications for Operation in Section I of Chapter 35). In the case of patients with PDA, the ductus may be temporarily occluded at operation; if pulmonary artery pressure does not decrease but remains severely elevated with no increase in aortic pressure, the shunt is not dominantly left to right. Closure of the ductus, therefore, will not reduce pulmonary artery pressure or left atrial pressure and therefore cannot trigger a favorable change in pulmonary vascular resistance. Repair is contraindicated in this situation. With preoperative provocative testing, abandoning closure in the operating room should be uncommon.

Until recently, indications for closure of PDA were indications for operative closure. This is probably still true in many institutions, but percutaneous closure must also be considered (see “Percutaneous [Catheter] Closure of Patent Ductus Arteriosus” under Special Situations and Controversies later in this chapter).
SPECIAL SITUATIONS AND CONTROVERSIES

Patent Ductus Arteriosus in Preterm Infants

Historical Note
In 1963, both Powell and de Cancq, independently, were apparently the first to close a PDA in a preterm infant by operation.13,37 Subsequent improvement in the cardiovascular status of preterm infants after surgical closure of a PDA has been clearly demonstrated.38,41

Clinical Features and Diagnostic Criteria
The preterm infant with a PDA may have a continuous murmur, and under these circumstances diagnosis is made with confidence.48,66 The shunt is considered large enough to be important if there is pulmonary plethora and cardiomegaly on the chest radiograph, if peripheral pulses are bounding, or if by echocardiography, the left atrial–aortic ratio is 1.5 or greater and Doppler color flow interrogation demonstrates a large left-to-right shunt.34

A systolic murmur is less specific for PDA, but the diagnosis is made clinically if the murmur is associated with a hyperactive precordium, increased pulse pressure, or positive chest radiograph or echocardiogram. A few preterm infants have these positive clinical and laboratory findings of PDA without a murmur.48,71

Natural History
A high proportion of preterm infants have prolonged patency of the ductus arteriosus after birth. The frequency increases with decreasing gestational age and decreasing birth weight.12 Sassi and colleagues reported the presence of a PDA (based on presence of a long sputum murmur) in 77% of premature infants with a gestational age of 28 to 30 weeks, 44% with a gestational age of 31 to 33 weeks, and 21% with a gestational age of 34 to 36 weeks.83 Birth weights of less than 1000 g, 1000 to 1500 g, and 1500 to 2000 g were associated with a PDA prevalence of 83%, 47%, and 27%, respectively. Frequency of hemodynamically important PDA is less, however: approximately 40% when the birth weight is less than 1000 g and 10% when it is less than 1750 g.26,42

A PDA has the same hemodynamic effects in preterm infants as in term infants, as evidenced by collapsing pulses and radiographic evidence of increased pulmonary blood flow, left atrial enlargement, and cardiomegaly. Furthermore, experimental studies in preterm lambs have shown that the left-to-right shunt through the open ductus is associated with reduced effective systemic blood flow and organ hypoperfusion.84 This has led to the hypothesis that necrotizing enterocolitis in preterm infants may be associated with a large PDA, which is supported by results of a randomized trial of ductal closure in preterm babies and by other studies.33,62

A strong correlation exists between patency of the ductus arteriosus and idiopathic respiratory distress syndrome, although these may not be causally related.31,82,77 There is also an association between fluid administration and ductal patency; thus, PDA is less frequent in neonatal units that restrict fluids in preterm infants.85

Technique of Operation
See Technique of Operation earlier in this chapter.

Special Features of Postoperative Care
Because surgical closure of a PDA is only one facet of care of a preterm infant, the patient is returned to the care of the neonatologist in the neonatal intensive care unit. The drainage catheter may be left until mechanical ventilation is no longer necessary, because pneumothorax occasionally develops in preterm infants maintained on a ventilator.

Early Results
Hospital mortality is approximately 10% to 20%.12,41,51,59,79 It is not related to the interval between birth and operation, but, as in other circumstances in preterm infants, it is probably related to birth weight and gestational age. Death may be from continuing respiratory distress, intracranial hemorrhage, necrotizing enterocolitis, or a diffuse coagulopathy, but it rarely occurs during the immediate perioperative period. In low-birth-weight preterm neonates, postoperative morbidity includes bronchopulmonary dysplasia, intraventricular hemorrhage, necrotizing enterocolitis, and retinopathy.93 There is no clear evidence that prevalence of intracranial hemorrhage is increased by surgical closure of the ductus.94 Whether ligation of the PDA is causally linked to these adverse outcomes remains to be determined.94

Cardiac status usually improves immediately, and left atrial size is promptly reduced.110 At least one randomized study indicates overall benefit of early surgical closure of a PDA in preterm infants weighing less than 1500 g and requiring mechanical ventilation.51 Another randomized study of infants weighing 1000 g or less and requiring supplemental oxygen demonstrated reduction (P = .001) in necrotizing enterocolitis among those treated by early ligation.53

Late Results
Among preterm infants requiring PDA closure, only half the hospital survivors are well 1 to 5 years later.110,124 About one third have bronchopulmonary dysplasia on chest radiograph, with variable clinical findings. About one sixth have more severe complications, such as retrolental fibroplasia, blindness, and cerebral palsy.110,124

Indications for Operation
Recent publications have questioned the efficacy of PDA closure in preterm infants, whether by surgery or by pharmacologic therapy.36,62 The analyses performed in these publications rely on review and meta-analysis of existing historical literature pertaining to management of PDA in premature infants. The retrospective nature of these analyses incorporates major assumptions and limits the veracity of the conclusions. The authors of these studies acknowledge that there currently are no randomized controlled prospective trials evaluating surgical closure, pharmacologic closure, and conservative medical management not aimed at closure, and that such studies are the only way to resolve this question definitively. Notwithstanding these opinions, the overwhelming consensus is that closure should be actively pursued in preterm infants with hemodynamically important PDA. Indications for operative closure of a PDA include respiratory distress (ventilator dependency and need for high FiO2 in the absence of important shunt) and demonstration of a large PDA (collapsing pulses, left atrial enlargement by echocardiography, and a large Qp/Qs by radionucleotide scanning). In many centers, closure is reserved for infants who do not respond to medical management, including a course of indomethacin or...
ibuprofen therapy, and for infants in whom pharmacologic therapy is contraindicated. Failure of indomethacin treatment may approach 40% to 50%, particularly in low-birth-weight infants (<800 g). Surgical ligation should be considered the primary form of treatment in small preterm infants who have persistent cardiopulmonary compromise after pharmacologic therapy or an increased risk for development of complications from this therapy.

Percutaneous (Catheter) Closure of Patent Ductus Arteriosus

Technical improvements and operator experience have made percutaneous closure of PDA an intervention of proven efficacy. Percutaneous closure is generally contraindicated in patients weighing less than 6 kg. Device closure was effective in 58 patients weighing 3.6 to 6.0 kg, but complication rates led these authors to conclude that surgical closure is first-line therapy. Two case reports document device closure in infants weighing 2.2 and 1.7 kg, but it is not recommended. In earlier years, approximately 65% of patients had complete ablation of the shunt with this technique. Currently, closure can be achieved in a high percentage of patients with umbrella or button coils or plugs. Effective occlusion (no or trivial residual shunt) can be accomplished in up to 94% of patients. Procedures are performed under local anesthesia and on an outpatient basis in many centers. Procedural mortality has been extremely low (1 of 1640 procedures [0.061%; CL 0.01%-0.21%] reviewed by Fortes and colleagues). In this group of patients, embolization of the closure device occurred in 80 patients (4.9%; CL 4.3%-5.5%) and was successfully retrieved in 70. Aortic or LPA narrowing not requiring intervention occurred in 32 patients (2.0%; CL 1.6%-2.4%), significant hemolysis in 12 (0.73%; CL 0.52%-1.0%), and inguinal pseudoaneurysm or loss of pulse in 18 (1.1%; CL 0.82%-1.4%). Overall occurrence of minor complications was 8.8%. Procedural failure did not occur when PDA size was smaller than 1.5 mm. Infective endarteritis occurred in one patient, but follow-up to date is limited and variable in the reviewed studies. It is thus impossible to estimate the true risk of infective endarteritis with these techniques.

The ultimate role of outpatient closure of a PDA will be determined by its costs compared with those of operative closure, reproducibility of the results obtained, prevalence of complete and permanent closure, and occurrence of late complications resulting from a device residing in the ductus arteriosus. Currently in patients with a PDA of large diameter or short length, surgical closure is advisable.

Thoracoscopic Closure of Patent Ductus Arteriosus

An alternative to percutaneous catheter closure of a PDA is thoracoscopic closure without thoracotomy. It is performed under general anesthesia using three or four incisions 3 to 7 mm in length in the left hemithorax. The surgical field is viewed on a video screen. Once the ductus is dissected from the surrounding tissue, one or more clips are applied to close it. The technique has been used in neonates, children of all ages, and adults. In the experience of Laborde and colleagues with 332 consecutive pediatric patients, mortality was zero (CL 0%-0.57%) and morbidity minimal. Three patients with persistent ductal patency required surgical closure. Subsequent series have confirmed the safety of the procedure, with no operative deaths. When compared with open operation, more complications, particularly recurrent laryngeal nerve injury, occurred with the thoracoscopic technique.

Section I  Tetralogy of Fallot with Pulmonary Stenosis

DEFINITION

Tetralogy of Fallot (TF) is a congenital cardiac malformation characterized by underdevelopment of the right ventricular (RV) infundibulum, with anterior and leftward displacement of the infundibular (conal, outlet) septum and its parietal extension. Displacement (malalignment) of the infundibular septum is associated with RV outflow (pulmonary) stenosis (in extreme forms, atresia) and a large ventricular septal defect (VSD). Typically, the VSD is subaortic in position, but it may be beneath both the aorta and pulmonary trunk (juxta-arterial VSD) when the infundibular septum is absent. The RV and left ventricle (LV) are of equal thickness, and their systolic pressures are usually the same. The atrioventricular connection is concordant, and the aorta is biventricular in origin, overriding onto the RV. The amount of override varies widely. Importantly, there is fibrous continuity between the aortic and mitral valves (i.e., there is no subaortic infundibulum). This aorto-mitral fibrous continuity is the distinguishing morphologic characteristic separating TF from double outlet right ventricle with subaortic VSD (see Chapter 53). This section considers only TF with pulmonary stenosis.

HISTORICAL NOTE

TF was first treated surgically by Blalock and Taussig in 1945, when they performed a palliative subclavian–pulmonary arterial shunt. Other types of systemic–pulmonary arterial shunts were introduced by Potts and colleagues in 1946, Waterston in 1962, Kliner in 1961, Davidson in 1955, Laks and Castaneda in 1975, and de Leval and colleagues in 1981, among others. Palliation by direct relief of pulmonary stenosis with a closed technique was introduced by Sellors and Brock in 1948. TF was first successfully repaired by Lillehei and colleagues at the University of Minnesota in 1954 using controlled cross-circulation with another person serving as oxygenator. The first successful repair of TF using a pump-oxygenator was done by Kirklin and colleagues in 1955. Waterston in 1962, Kliner in 1961, Davidson in 1955, Laks and Castaneda in 1975, and de Leval and colleagues in 1981, among others. Palliation by direct relief of pulmonary stenosis with a closed technique was introduced by Sellors and Brock in 1948.

TF with pulmonary stenosis encompasses a wide spectrum of morphologic subsets that vary primarily in details of RV outflow obstruction, VSD, and aortic overriding. All four major components of TF—RV outflow obstruction, VSD, overriding aorta, and RV hypertrophy—are linked embryologically. Van Praagh has advanced the concept of TF being the result of a “monology.” The concept is that a small-volume subpulmonary infundibulum is the basic anomaly, resulting in pulmonary outflow tract obstruction (stenosis or atresia). There is a VSD because the small-volume infundibulum cannot fill the space above the trabecula septomarginalis (septal band; TSM) and the ventricular septum. The infundibular septum is malaligned anterosuperiorly above the RV outflow tract floor—the infundibular septum—fails to expand in a rightward, posterior, and inferior direction, thereby helping to close the interventricular foramen. Failure of this normal morphogenetic movement of the infundibular septum results in aortic overriding. Because the infundibular septum is abnormally anterosuperiorly malaligned above the RV, so too is the aortic valve, which is attached to what should be the LV outflow tract surface of the infundibulum septum. RV hypertrophy is a secondary response to resulting RV overload.

Thus, Van Praagh posits that embryologically, TF is a conotruncal malformation in which conotruncal septation is complete, but the infundibular septum is displaced. This anterior displacement is responsible for all of the morphologic characteristics of TF: crowding of the RV outflow tract and obstruction, overriding of the aorta, malalignment VSD, and RV hypertrophy.

Anderson, in contrast, argues that the “monology” concept is an oversimplification. His studies suggest two morphologic abnormalities that he considers pathognomonic for the lesion. (1) There is anterocephalad deviation of the outlet septum, but for obstruction of the RV outflow tract to occur, there must additionally be (2) an associated malformation of the septoparietal trabeculations, the muscular bars that reinforce the parietal wall of the RV. The squeeze produced between the malaligned outlet septum and the abnormally arranged septoparietal trabeculations identify the morphologic entity of tetralogy of Fallot.
Right Ventricular Outflow Tract

Infundibulum

Infundibular stenosis associated with specific alterations in position of the infundibular septum is the hallmark of TF. Specifically, the septal (leftward) end of the infundibular septum is displaced anteriorly, inserting in front of the left anterior division of the TSM (septal band) (Fig. 38-1)\(^{A12,VS}\) rather than between its two divisions, as in the normal heart (see Chapter 1, Fig. 1-5). In addition, the parietal (rightward) end of the infundibular septum is rotated anteriorly and passes anteriorly and inferiorly to reach the free wall of the RV (Fig. 38-2), so that the infundibular septum and its parietal extension may come to lie almost in a sagittal rather than the usual coronal (frontal) plane. Parietal and septal ends of the infundibular septum give rise to prominent muscle bands that attach to the right and left sides of the anterior RV free wall.\(^{A12}\) The anterior free wall may show additional trabeculations or moderate thickening.

There is frequently a localized narrowing, the os infundibulum, which in 72% of cases lies in a transverse plane at the lower infundibular septal edge (see Fig. 38-2). This sitting means that when the infundibular septum is well developed, there is a large infundibular chamber (or “third ventricle”; see Fig. 38-2), which in older patients occasionally becomes aneurysmal. In older patients, however, the os infundibulum is surrounded by fibrosis, which, when the chamber is small or absent, may extend into the RV–pulmonary trunk junction (pulmonary “anulus”). Less commonly (about 15% of cases), the major stenotic zone at the lower infundibular septal edge lies almost in a coronal plane, extending inferiorly from the lower infundibular septal edge. This occurs when hypertrophied muscle bands at the parietal end of the infundibular septum pass more inferiorly to join the free wall nearer to the RV apex, while on the septal (medial or leftward) aspect, there are not only inferiorly directed additional trabeculae, but also often an undue prominence and hypertrophy of TSM. Under these circumstances the inferior boundary of the os infundibulum may be formed by a prominent superiorly displaced moderator band.\(^{A12}\) (When this type of low-lying infundibular stenosis is associated with a small or moderate-sized VSD, it is not termed TF; see Section V.) Both transverse and coronal plane stenoses are occasionally present.

When an infundibular chamber is present, its walls laterally and medially consist of numerous trabeculated spaces, some of which may form prominent blind recesses that do not lead directly to the valve “anulus,” and occasionally an accessory opening is present. Endocardial fibrosis is not seen during the first 6 to 9 months of life and is seldom marked before age 2 years.\(^{C23}\) Later, fibrosis seems to progress, which may lead to acquired infundibular atresia.

Generally, the infundibulum is somewhat longer, relative to total RV length, than it is in normal hearts.\(^{B3,H29}\) When the infundibular septum is short (hypoplastic), infundibular stenosis reaches the pulmonary valve “anulus” without an intervening chamber. When the infundibular septum is absent, the VSD is juxta-arterial (doubly committed), extending superiorly to reach the pulmonary valve; infundibular stenosis is absent, and the posterior aspect of the RV outflow tract is formed by the VSD (Fig. 38-3).\(^{B30}\) The pulmonary valve and sometimes its “anulus” are the main sites of the usually moderate stenosis in these hearts. However, once a VSD patch is in position, the hypertrophied RV walls and dextroposed aorta may combine with the patch to form severe subvalvular stenosis.

The infundibulum may be diffusely narrowed and hypoplastic. This is usually associated with severe cyanosis at birth or shortly thereafter. There is no localized os infundibulum (Fig. 38-4) nor increased trabeculations, nor important muscular hypertrophy. Nevertheless, stenosis is usually severe because narrowing occurs throughout the outflow tract (Fig. 38-5). Length of the stenosis in this morphologic variant is determined by length of the infundibular septum (see Fig. 38-4).

Pulmonary Valve

The pulmonary valve is stenotic to some degree in 75% of patients with TF. Approximately two thirds of stenotic valves are bicuspid (Table 38-1).\(^{B9,N21}\) A three-cusp configuration occurs more commonly in nonstenotic valves. Even when nonstenotic, valve area is usually smaller than that of the
Figure 38-2  Autopsy specimen of tetralogy of Fallot with low-lying infundibular stenosis. Death occurred without surgical correction at age 3 years. A, Isolated infundibular stenosis viewed from below through opened right ventricle. B, Stenosis viewed from above after removing anterior wall of large infundibular chamber and opening front of pulmonary trunk. Stenosis is localized at lower border of infundibular septum (os infundibulum). Note that lateral (parietal) end of the septum is deviated anteriorly into almost a sagittal plane. Posterosuperior angle of ventricular septal defect is well seen (arrow), as is its proximity to right aortic cusp. Infundibular chamber is dilated and thin walled in association with the low, transversely placed infundibular stenosis. Pulmonary valve is tricuspid and not stenotic. Key: Ao, aorta; IS, infundibular septum; Osinf, os infundibulum; PT, pulmonary trunk; PV, pulmonary valve; RAA, right atrial appendage; RC, right coronary cusp; RV, right ventricle; TV, tricuspid valve; VSD, ventricular septal defect.

Aortic valve, which is the reverse of normal. The difference in size of these two valves is partly because the pulmonary valve is small and partly because the aortic valve is larger than normal.

**Stenotic valve cusps** are usually thickened, frequently severely so, a feature that increases the amount of obstruction at the valve level (Fig. 38-6). In approximately 10% of cases, cusps are replaced by sessile nubbins of fibromyxomatous tissue that offer little obstruction. Such vestigial valves are usually associated with a stenotic pulmonary “anulus.” When the “anulus” is not severely narrowed and the valve is vesti
gial, severe pulmonary regurgitation results, a condition called **TF with absent pulmonary valve** (see Section III).

Pulmonary valve stenosis is usually caused by cusp tethering rather than by severe commissural fusion (see Table 38-1). The free edge of tethered cusps is considerably shorter than the diameter of the pulmonary trunk, so the valve cannot open adequately, and the pulmonary trunk is pulled inward at the point of commissural attachment. This produces a localized narrowing or corseting of the trunk at distal valve level. Thus, both the valve and trunk are tethered (see Fig. 38-6). In this situation the sinuses of Valsalva are frequently well formed, but entry into them between the cusp edge and pulmonary trunk wall is often also stenotic, resulting in slow filling of the sinuses with contrast medium on cineangiography. Cusps of a tethered valve may be fused for a short distance. Tethering is more common in a bicuspid valve, but can occur in a three-cusp valve.

Less commonly, the dominant morphology is thickened cusps associated with congenital commissural fusion, resulting in a concentric or eccentric stenotic orifice. An eccentric orifice can also result from a unicuspid configuration.
Figure 38-3  Autopsy specimen of tetralogy of Fallot with juxta-arterial ventricular septal defect (VSD). A, Viewed from opened right ventricle (RV) with incision carried across right cusp of aortic valve. B, Viewed after opening RV across pulmonary valve and trunk. Infundibular septum appears to be absent, and VSD is bounded superiorly by fused aortic and pulmonary valve “anuli.” Trabecula septomarginalis (septal band) and RV free wall are severely hypertrophied. There is marked narrowing of pulmonary “anulus” and trunk and thickening and tethering of the valve cusps. Key: Ao, Aorta; FW, right ventricular free wall; L, left coronary cusp; LA, left anterior division at septal band; LC, left coronary aortic cusp; NC, noncoronary aortic cusp; PT, pulmonary trunk; PV, pulmonary valve; RC, right coronary aortic cusp; RP, right posterior division of septal band; TSM, trabecula septomarginalis (septal band); TV, tricuspid valve.

Figure 38-4  Autopsy specimen of tetralogy of Fallot with diffuse right ventricular (RV) outflow hypoplasia (same specimen as in Fig. 38-1). View is through opened RV. Stenotic infundibulum (arrow) is relatively short with a well-formed anteriorly displaced infundibular septum. There is no os infundibulum, but rather diffuse outflow tract narrowing without increased trabeculation or free wall thickening. Ventricular septal defect is conoventricular and perimembranous. Key: IS, Infundibular septum; TV, tricuspid valve; VSD, ventricular septal defect.
PART VII  Congenital Heart Disease

1366

cases, it is variably obstructive. It is small and obstructive when there is diffuse infundibular hypoplasia, resulting in diffuse RV outflow hypoplasia.

Pulmonary Trunk

Like the pulmonary valve and “anulus,” the pulmonary trunk is nearly always smaller than normal, and smaller than the aorta. Reduction is most marked when there is diffuse RV outflow hypoplasia. Then, the pulmonary trunk is less than half the aortic diameter and is short (see Fig. 38-6), directed sharply posterior to its bifurcation. It is thus largely hidden from view at operation by the prominent aorta, which also displaces the origin of the trunk leftward and posteriorly.

When the pulmonary valve is markedly tethered, the pulmonary trunk is also tethered or corseted at its commissural attachments (see Fig. 38-6), and it may be very angulated or kinked at this point. This is the usual mechanism of supravalvar narrowing, and it is not associated with wall thickening. Rarely, however, there may be a discrete supravalvar narrowing beyond commissural level with diffuse wall thickening.

Pulmonary Trunk Bifurcation

The left pulmonary artery (LPA) is usually a direct continuation of the pulmonary trunk, with the right pulmonary artery (RPA) arising almost at right angles and close to it, but this pattern varies (Fig. 38-7). Uncommonly, the distal pulmonary trunk and origin of the RPA and LPA are moderately or severely narrowed (bifurcation stenosis), and in this situation the bifurcation may have a Y shape. A Y-shaped bifurcation is more common when the ductus arteriosus is absent (see “Aortic Arch and Ductus Arteriosus” later in this section).

Right Ventricular–Pulmonary Trunk Junction

The RV–pulmonary trunk junction is normally a muscular structure and, like the infundibulum, varies in diameter during the cardiac cycle. In TF, it is almost always smaller in diameter than the aortic “anulus” (the reverse of normal), and smaller than the normal junction. It is less likely to be stenotic when infundibular stenosis is low lying. The pulmonary “anulus” may become thick from fibrosis, which is usually an extension of endocardial thickening surrounding an intermediate- or high-level infundibular stenosis; in such cases, it is variably obstructive. It is small and obstructive when there is diffuse infundibular hypoplasia, resulting in diffuse RV outflow hypoplasia.

Right and Left Pulmonary Arteries

Anomalies of the RPA and LPA are common in TF with pulmonary atresia (see Section II) but uncommon in TF with pulmonary stenosis, although any of the anomalies present in pulmonary atresia may occur in patients with
Chapter 38 Ventricular Septal Defect with Pulmonary Stenosis or Atresia

Figure 38-6 Specimen of tetralogy of Fallot showing thickened stenotic pulmonary valve (PV), and right ventricular (RV) cineangiograms in the right anterior oblique projection showing same feature. A, Specimen showing stenotic PV viewed through opened pulmonary trunk (PT). There are two thickened nonfused cusps, but PT wall is drawn inward where commissures attach (tethering). B, Early systolic frame. PV stenosis is due to valve tethering. Cusps are thickened and form a dome in systole from their attachments to pulmonary “anulus” (small arrow). Supravalvar PT narrowing (large arrow) is localized to region between pulmonary sinuses and PT. C, Diastolic frame. Distal edges of thickened cusps remain approximated to narrowed PT wall, and the prominent sinuses may be slow to fill with contrast. Note shortness of PT. Key: A, Aortic valve; Ao, aorta; L, left pulmonary artery; R, right pulmonary artery; RAA, right atrial appendage. (From Calder and colleagues.)

pulmonary stenosis (Table 38-2). Fellows and colleagues found pulmonary artery anomalies in 30% of infants having TF with pulmonary stenosis presenting in the first year of life. In particular, proximal LPA stenosis or hypoplasia, or both, can occur when certain configurations of the ductus arteriosus are present (see “Aortic Arch and Ductus Arteriosus” later in this section).

Distal Pulmonary Arteries and Veins

Pulmonary arteries and veins beyond the hilar positions are about normal in size in most patients. Intraacinar arteries are smaller than normal, and their media are thinner. In addition, lung volume, alveolar size, and total alveolar number tend to be reduced.

Dimensions of Right Ventricular Outflow Tract and Pulmonary Arteries

Hypoplasia of the RV outflow tract and pulmonary arteries in patients having TF with pulmonary stenosis is most marked centrally in the RV infundibulum and pulmonary trunk. On average, the RPA and LPA and their branches are not abnormally small. This does not deny the occasional existence of severe narrowing at the origin of the LPA or RPA (see Fig. 38-7). Elzenga and colleagues found juxtaductal proximal
Figure 38-7  Cineangiograms after right ventricular injection showing stenoses at origins of pulmonary arteries in tetralogy of Fallot with pulmonary stenosis. A, Stenosis at origin of left pulmonary artery (LPA) in region of ductus arteriosus, which is closed at its aortic end. B, Stenosis at origin of LPA. This arrangement is unusual in that the LPA comes off at right angles. C, Bifurcation stenosis. Note that, as usual, the right pulmonary artery comes off at right angles to pulmonary trunk. D, Severe narrowing of distal pulmonary trunk. Note that first portion of LPA appears to be a continuation of pulmonary trunk.

stenoses of the LPA in 10% of patients having TF with pulmonary stenosis. There is great variability in these dimensions, however, making their careful pre-repair study important.

Convenient Morphologic Categories of Right Ventricular Outflow Obstruction

The nearly infinitely variable spectrum of RV outflow obstruction in TF can be conveniently categorized in a way that is surgically useful because it relates to difficulty in obtaining good relief of the pulmonary stenosis and therefore to surgical techniques and mortality (Box 38-1). This supplements earlier discussion of patterns of the infundibular portion of the obstruction. It might be inferred that transanular patching to relieve outflow tract obstruction would be more frequently required in those with “anulus” stenosis or diffuse hypoplasia, but a blanket rule is probably inappropriate.

Iatrogenic Pulmonary Arterial Problems

A transanular patch may later produce severe stenosis at the origin of the LPA or, less commonly, of the RPA.
Collateral Pulmonary Arterial Blood Flow

Patients virtually always have increased collateral pulmonary arterial blood flow, primarily from true bronchial arteries. Occasionally (less than 5% of patients), large aortopulmonary (AP) collateral arteries are present (see detailed discussion in “Alternative Sources of Pulmonary Blood Flow” in Section II).
septum (see Fig. 38-4). The septum may support part or most of the right aortic cusp, depending on the degree of aorta overriding the RV (see Fig. 38-1). Because of the anterior and leftward deviation of the parietal end (parietal extension) of the infundibular septum, the posterosuperior angle of the defect extends higher than that of the usual isolated conoventricular VSD (see Fig. 38-2, A) and can be more difficult to expose surgically, particularly if the parietal band is not fully mobilized (transected). When the infundibular septum is hypoplastic, the defect is larger and extends closer to the pulmonary valve; when the infundibular septum is absent, the VSD becomes juxtapulmonary (and juxta-arterial).

Posterosuperiorly, the VSD is bounded by muscle (the ventriculoinfundibular fold) adjacent to the rightward edge of the noncoronary aortic cusp (Fig. 38-8). This cusp may override considerably onto the RV (Fig. 38-9); then, the LV-aortic junction adjacent to the noncoronary cusp forms this boundary.

The posterior margin is variable. It is related to the base of the tricuspid anteroseptal leaflet commissure and to the right fibrous trigone (central fibrous body) at the nadir of the noncoronary aortic cusp. There is tricuspid-aortic-mitral fibrous continuity at this margin, and the membranous septum is absent—characteristics of a true perimembranous VSD. In some hearts the VSD extends inferiorly beneath the tricuspid septal leaflet more than usual, described as “inlet extension” of the VSD. When there is marked clockwise rotation of the overriding aortic root, the right trigone may form the posterosuperior angle of the defect, and the bundle of His (which perforates at this point) is exposed along the edge of the defect (Fig. 38-10). Occasionally the posterior margin may be formed by a remnant of fibrous tissue.

![Figure 38-8](image1)

**Figure 38-8** Specimen of tetralogy of Fallot demonstrating ventricular septal defect (VSD) and position of bundle of His. A narrow muscular bridge separates VSD from anterior tricuspid leaflet and tricuspid anulus. Right ventricle (RV) has been opened and the incision carried across infundibular septum and right coronary cusp (RC) out into the ascending aorta, as shown in Fig. 38-1. Narrow muscular bridge separating VSD from tricuspid valve is the continuity between right posterior division of trabecula septomarginalis and ventriculoinfundibular fold (VI). VI joins the undersurface of the parietal end of infundibular septum. Sutures can be passed safely into this ridge along dashed line (or, alternatively, in base of tricuspid leaflet), but the margin for error is small because the course of the bundle of His (dotted line) is not far removed. Note marked RV overriding of RC. Key: IS, Infundibular septum; NC, noncoronary cusp; RP, right posterior division of trabecula septomarginalis (septal band); RV, right ventricle; T, anterior tricuspid leaflet.

![Figure 38-9](image2)

**Figure 38-9** Specimen of tetralogy of Fallot with right ventricle and pulmonary trunk opened with an anterior incision and infundibular septum divided to expose ventricular septal defect. Accessory prominent muscular trabeculations are present in front of septal attachment of infundibular septum (arrows), contributing to stenosis. Pulmonary valve is bicuspid and tethered, with mild cusp thickening. Marked overriding of aorta is visible, involving rightward margin of noncoronary cusp. Key: Ao, Aorta; IS, infundibular septum; N, noncoronary cusp; PT, pulmonary trunk; PV, pulmonary valve; TSM, trabecula septomarginalis; TV, tricuspid valve; VSD, ventricular septal defect.
Chapter 38  Ventricular Septal Defect with Pulmonary Stenosis or Atresia

The inferior margin of the VSD is formed by the TSM as it cradles the VSD between its limbs. The papillary muscle of the conus (or corresponding chordae only) arises from the right posterior division of the TSM at the anteroinferior angle of the defect. Anomalous tricuspid chordal attachments to other margins of the defect are rare, in contrast to the situation in isolated perimembranous VSD.

The anterior margin of the VSD is formed by the leftward anterior division of the TSM as it becomes continuous with the inferior margin of the infundibular septum. When the TSM is poorly developed, the defect extends further anteriorly, and the VSD is described as having “anterior extension.”

When the infundibular septum is absent, the VSD is juxta-arterial and is described as having “outlet extension.” Posteriorly, this type of VSD is commonly separated from the tricuspid anulus by a 2- to 5-mm strip of muscle, but it may extend to the anulus. Aortic and pulmonary valve “anuli” are contiguous over about one third of their circumferences, being separated at this point by only a thin fibrous ridge where the infundibular septum would have been, if present (see Fig. 38-3). The two valves are often side by side, with the aorta more than usually dextroposed.

The inferior margin of the VSD is formed by the papillary muscle as it cradles the VSD between its limbs. The papillary muscle of the conus (or corresponding chordae only) arises from the right posterior division of the TSM at the anteroinferior angle of the defect. Anomalous tricuspid chordal attachments to other margins of the defect are rare, in contrast to the situation in isolated perimembranous VSD.

When the infundibular septum is absent, the VSD is juxta-arterial and is described as having “outlet extension.” Posteriorly, this type of VSD is commonly separated from the tricuspid anulus by a 2- to 5-mm strip of muscle, but it may extend to the anulus. Aortic and pulmonary valve “anuli” are contiguous over about one third of their circumferences, being separated at this point by only a thin fibrous ridge where the infundibular septum would have been, if present (see Fig. 38-3). The two valves are often side by side, with the aorta more than usually dextroposed.

TF with this type of VSD is morphologically similar to double outlet RV with a doubly committed (juxta-arterial) VSD (see Chapter 53), with the important distinction that in TF, fibrous continuity is maintained between the aortic valve and the central fibrous body, whereas in double outlet RV there is infundibular muscle beneath the aortic valve, and thus there is fibrous discontinuity between the aortic valve and central fibrous body.

In 3% to 15% of patients (see Table 38-2), one or more additional VSDs coexist with the typical juxta-arterial one (Fig. 38-12). Usually the additional VSD is muscular, and multiple muscular defects sometimes occur. It may also be in the inlet septum, either as an inlet septal VSD or a muscular defect (see “Inlet Septal Ventricular Septal Defect” under Morphology in Section I of Chapter 35).

Figure 38-10  Two specimens of tetralogy of Fallot with perimembranous ventricular septal defect (VSD), opened as in Fig. 38-8. There is tricuspid-aortic-mitral fibrous continuity at the posterior margin (leftward in the photograph) of the VSD. A, Right fibrous trigone at nadir of noncoronary aortic cusp has been perforated by a pin passed from right atrial side at point of penetration of bundle of His; bundle extends from this point forward and slightly leftward along margin of VSD (dotted line). White arrow points to this area. VSD patch suture line must pass into base of septal tricuspid leaflet (dashed line) and not along lower VSD margin. B, Position of right fibrous trigone when there is important clockwise rotation of aortic root and right ventricular overriding of noncoronary and right aortic cusps. Bundle position is shown by dotted line and position of VSD suture line (passing into base of anterior tricuspid leaflet) by dashed line. Key: IS, Infundibular septum; NC, noncoronary cusp; T, tricuspid valve.

Figure 38-11  In this heart with tetralogy of Fallot, posterior muscular bridge is bulky and entirely hides right trigone that lies several millimeters caudal and leftward of margin of ventricular septal defect. His bundle will not be damaged by sutures passed into ridge along dashed line. Key: IS, Infundibular septum; NC, noncoronary cusp; T, tricuspid valve.
By contrast, the bundle of His does not lie on the VSD margin when a muscle ridge is present (see Figs. 38-8 and 38-11) because the ridge projects superiorly above the right fibrous trigone; when the ridge is bulky, sutures can be safely placed into it.

Aorta

The aorta is biventricular in origin and more anteriorly placed than normal, often almost obscuring the smaller pulmonary trunk from view at operation. These changes are due to RV overriding, rotation, and enlargement of the aortic root. The proportion of aorta lying above the RV varies between 30% and 90%. Generally, about 50% of the aortic orifice is over the RV.

Aortic overriding is associated with a variable degree of clockwise rotation of the aortic root (as viewed from below). This rotation moves the base of the noncoronary cusp rightward and superiorly onto the posteroseptal margin of the VSD and away from the base of the anterior mitral leaflet so that in extreme cases, it may no longer be continuous with this structure. This cusp may then lie in part just beneath the extension of the infundibular septum. Rightward rotation of the left aortic cusp results in more of it becoming continuous with the anterior mitral leaflet. Simultaneously, the superiorly positioned right cusp moves to the left, and in extreme examples it may be just beneath the uppermost extension of the left anterior division of the trabecula septomarginalis at the anteroseptal VSD margin. An important point is that, despite the degree of aortic rotation, continuity of some portion of the aortic “anulus” and the anterior mitral leaflet is always maintained. As a result the VSD is always related to the aorta in TF. The VSD may also be related to the pulmonary valve when the infundibular septum is absent (see “Ventricular Septal Defect” in this section).

Degree of overriding and clockwise rotation of the aortic root relates to degree of underdevelopment of the RV outflow tract and to deviation (malalignment) of the infundibular septum. When these are minimal, as seen with isolated low-lying infundibular stenosis, the aorta is minimally affected; when there is diffuse RV outflow tract hypoplasia in association with a small, markedly deviated infundibular septum and posterior and leftward movement of the pulmonary trunk origin, the aorta is markedly rotated and dextroposed.

In patients with severe TF, the aortic root is larger than normal, even in infants. Occasionally in adults, it is greatly dilated. This may result in aortic valve regurgitation.

Aortic Arch and Ductus Arteriosus

The ductus arteriosus is absent in about 30% of patients born with TF. This does not mean a closed ductus (ligamentum arteriosum), but rather complete absence of any ductal structure. Absence of the ductus or ligamentum is about twice as common when there is a right, rather than left, aortic arch. The pulmonary artery bifurcation often takes on a Y-shaped configuration, also described as the “staghorn” or “seagull” configuration, in this setting. In the other 70% of patients in whom a ductal structure is present, it is patent at birth and closes over a normal time course unless pharmacologically maintained with PGE1 for therapeutic reasons (cyanosis). The configuration of the ductus can vary from normal (an extension of the pulmonary trunk, creating an arch that somewhat

Conduction System

The sinus and atrioventricular nodes are in their normal locations (see “Conduction System” in Chapter 1), and the bundle of His follows the same general course as in patients with isolated perimembranous VSDs (see “Location in Septum and Relationship to Conduction System” under Morphology in Section I of Chapter 35). Thus, the His bundle emerges through the right fibrous trigone at the base of the noncoronary cusp of the aortic valve and courses forward toward the papillary muscle of the conus along the inferior VSD margin or slightly to the left side of the defect edge. In hearts showing marked clockwise rotation of the aortic root with RV overriding, the right trigone (and along with it the penetrating portion of the His bundle) is carried more rightward and superiorly and directly onto VSD margins (see Fig. 38-10).
Chapter 38  Ventricular Septal Defect with Pulmonary Stenosis or Atresia

A left aortic arch is present in about 75% of patients. In these, arch branching pattern is usually normal.

A right aortic arch is present in about 25% of patients. In 90% of these, there is mirror-image branching of the arch. Should a patent ductus arteriosus be present, it usually arises from the brachiocephalic or proximal left subclavian artery and joins the LPA. Rarely, there may be a right-sided ductus arteriosus to the RPA, usually arising from the upper descending thoracic aorta. In about 10% of patients, there is an aberrant left subclavian artery, analogous to the aberrant right subclavian artery of dysphagia lusoria in left aortic arch (see “Right Aortic Arch with Aberrant Left Subclavian Artery” in Section I of Chapter 51). In right aortic arch with aberrant left subclavian artery, the subclavian artery may arise directly from the descending aorta or from an aortic diverticulum. Thus, a ductus arteriosus may arise from the aortic diverticulum and pass to the left behind the esophagus to join the LPA.

Rarely, the left subclavian artery is sequestered or isolated from its aortic arch origin, but remains connected to the LPA by a patent ductus arteriosus. Often in these circumstances, there is vertebral steal, and on angiography the subclavian artery fills with contrast from the vertebral artery.

Right Ventricle

External dimensions of the sinus (inflow) portion of the RV are larger than normal due to hypertrophy, so the interven- tricular groove is displaced leftward and the LV lies more posteriorly than usual (clockwise rotation of ventricles). The RV sinus may be clearly separated from the infundibulum during systole by a transverse depression representing the site of maximal infundibular stenosis inferior to an infundibular chamber. RV wall thickness equals that of the LV and is therefore never excessive unless the large VSD is made restrictive by a fibrous flap valve on its right side (see Section IV). Normal trabeculations are, however, bulky and prominent. RV end-diastolic volume may be reduced and ejection fraction mildly depressed, typically in older children without TF repair, possibly the result of chronic hypoxia. Rarely (1.5% of cases), the sinus portion of the RV and tricuspid valve are underdeveloped, and rarely this may be so severe (end-diastolic volume < 30 mL · m−2) as to contraindicate primary repair.

The physiologic contributors to LV size are complex. The small pulmonary and thus left atrial blood flow tend to result in a small left atrium and LV. However, the RV ejects blood into the LV as well as the aorta, and this tends to increase LV size. Mild or moderate degrees of LV hypoplasia may result from these physiologic factors, but true hypoplasia is of morphologic rather than functional origin. LV systolic function is normal at birth but may become mildly reduced in older patients who have not undergone repair, particularly in severely cyanotic patients, presumably because of chronic hypoxia.

\(^4\)UAB experience (1967 to July 1982).  
Key: LAD, left anterior descending coronary artery; RCA, right coronary artery.

Coronary Arteries
As in other cyanotic conditions, the coronary arteries become dilated and tortuous in children and adults. A large conal branch of the right coronary artery (RCA) usually courses obliquely across the free wall of the RV, and the presence of this vessel should be noted at the time of surgical repair.

The left anterior descending coronary artery (LAD) arises anomalously from the RCA in about 5% of patients (Table 38-3).\(^1\)\(^-\)\(^4\)\(^,\)\(^5\) The entire LAD may originate from the RCA and cross the anterior wall of the infundibulum a variable distance from the pulmonary valve, or only the distal part of the LAD may arise anomalously, in this case usually from the large conal branch of the RCA.

Rarely, the RCA originates from the left coronary artery, and equally uncommonly, there is anomalous origin of the left coronary artery from the pulmonary trunk (see Section II of Chapter 46).\(^4\)\(^4\)

Major Associated Cardiac Anomalies
Major associated cardiac anomalies are relatively uncommon (see Table 38-2). Patent ductus arteriosus, multiple VSDs, and complete atrioventricular septal defect\(^6\)\(^,\)\(^7\) are most often seen.

Rarely, the RPA\(^8\)\(^9\) or LPA\(^10\)\(^11\) arises anomalously from the ascending aorta\(^12\)\(^,\)\(^13\) (see Chapter 45). This complicates the pathophysiology and repair, because the lung supplied by the pulmonary artery arising from the aorta usually has overcirculation, and the other usually has restricted flow due to the intracardiac anatomy.

Infrequently, aortic valve regurgitation coexists. This may be from typical cusp prolapse in TF with subarterial VSD (see Section II in Chapter 35).\(^14\)\(^15\) A bicuspid aortic valve occurs rarely in TF and may result in aortic regurgitation.\(^16\)\(^,\)\(^17\) Occasionally, ill patients with TF in the second decade of life or older develop aortic regurgitation from endocarditis.\(^18\)\(^,\)\(^19\)\(^,\)\(^20\) Massive dilatation of the aortic root from anuloaortic ectasia may result in aortic valve regurgitation,\(^21\) particularly in patients with large natural or surgically created systemic–pulmonary arterial shunts (see “Anastomotic” under Morphology in Chapter 26).

Minor Associated Cardiac Anomalies
Most infants undergoing repair of TF have a patent foramen ovale (PFO); when all ages are considered, a true atrial septal defect is found at operation in about 10%. Other minor associated cardiac anomalies are listed in Table 38-3.

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

**Clinical Presentation**
The hallmark clinical sign of TF is cyanosis. The severity of cyanosis and its variability depend on the specific morphology of the RV outflow tract. Infants with diffuse RV outflow hypoplasia, severe infundibular plus valvar plus anular stenosis, or severe infundibular plus valvar stenosis (see Box 38-1) are deeply cyanotic from birth and do not develop heart failure. They are breathless on feeding or other exertion. Hypoxic spells are rare, the cyanosis being constant and gradually worsening. It is seldom lessened by propranolol.

This situation contrasts with that in infants having dominant infundibular stenosis, in which onset of cyanosis is delayed and hypoxic (cyanotic) spells due to infundibular spasm may occur. These spells are often prevented or lessened in frequency by propranolol. Characteristically, they become less frequent with age, presumably because stenosis becomes fixed as a result of acquired endocardial fibrosis and thickening.

In up to 10% of patients who require surgical relief in infancy, presentation is initially as a large VSD with pulmonary plethora and sometimes heart failure at age 2 to 3 months, followed by gradually increasing cyanosis, frequently with cyanotic spells, at about age 6 months. In this group, stenosis is purely infundibular.

A minority of patients are acyanotic at rest and only mildly cyanotic during exercise because pulmonary stenosis is mild and right-to-left shunting minimal. In some the shunt is predominately left to right. These individuals may remain acyanotic without spells and present at any age within the first or second decades of life with gradually increasing cyanosis and breathlessness as stenosis slowly increases in severity.

In patients with severe cyanosis and polycythemia, cerebral thrombosis may precipitate hemiplegia at any age (particularly in association with dehydration), or hemiplegia may follow paradoxical embolism or a brain abscess. The latter is heralded by fever, headache, and sometimes seizures. Massive hemoptysis may occur in older patients who are severely cyanotic, presumably from rupture of bronchial collateral vessels.

Cyanosis is always accompanied by effort dyspnea that is sometimes the dominant symptom, and as the child begins to walk (frequently much later than for a healthy child), cyanosis is often accompanied by squatting, which lessens its severity.\(^22\) There may be increased occurrence of respiratory infection, but not to the same extent as in patients with large isolated VSD; failure to thrive is also less striking.

**Physical Examination**
Cyanosis of variable degree is generally evident. Deeply cyanotic infants are often obese (in contrast to infants with isolated VSD). Severe symmetric clubbing of the fingers and toes is often present in children and adults, but not in infants.
Older patients may also have marked acne of the face and anterior chest. Jugular venous pressure is normal. The heart is not enlarged and is relatively quiet with an unimpressive RV lift. In those few patients with increased Qp, the lift may be more marked than usual.

A precordial systolic thrill is rare. There is a moderate-intensity middiastolic pulmonary (ejection) murmur maximal in the second and third left intercostal spaces that becomes less prominent or even disappears when the stenosis is severe. When there is still a reasonable blood flow in the presence of moderate pulmonary stenosis, the systolic murmur is well heard posteriorly and in the axilla. In the presence of important cyanosis and low Qp, the second heart sound is single, but in acyanotic patients it may be finely split with a low-intensity pulmonary component. Splitting is also present in moderately cyanotic patients with only a mildly reduced Qp when there are important pulmonary artery origin stenoses.

Signs of heart failure with venous pressure elevation and liver enlargement occur in patients with a systemic-to-pulmonary arterial shunt that is too large, or in a neonate on PGE1 to maintain ductal patency. Heart failure may also appear in untreated severely cyanotic adults in the fourth or fifth decade of life, presumably secondary to myocardial fibrosis or in association with systemic hypertension or aortic regurgitation.

Laboratory Studies

Neonates or young infants who have severe TF with pulmonary stenosis usually present with marked reduction of arterial oxygen pressure (\(\text{PaO}_2\)) and saturation (\(\text{SaO}_2\)) and sometimes with metabolic acidosis. Polycythemia is rarely present, and, in fact, such infants are often anemic.

In older infants and children, red blood cell count and hematocrit are usually elevated, and degree of elevation is correlated with degree of arterial desaturation and thus with severity of the pulmonary stenosis. In older patients, hematocrit may reach 90%.

Most cyanotic patients have depressed platelet count and prolongation of most coagulation tests.

Chest Radiography

Chest radiographs in children usually show the typical boot-shaped heart of TF. In neonates and young infants the heart may be strikingly small, with an absent pulmonary artery segment along the left upper cardiac border and oligemic lung fields. In older patients, there may be a prominence of the left upper cardiac border caused by a large infundibular chamber. Large AP collaterals may alter the pulmonary blood flow pattern in one or both lungs. Plethora of one lung and oligemia of the other suggest anomalous origin of a pulmonary artery from the ascending aorta (see Chapter 45).

If there is a right aortic arch, posterior indentation of the shadow of the barium-filled esophagus results from an aberrant left or right subclavian artery.

Rib notching of the upper ipsilateral ribs may develop in the presence of a long-standing classic Blalock-Taussig (B-T) shunt, secondary to development of a rich collateral blood flow to the arm. This situation is rarely encountered in the current era because the classic B-T shunt is not commonly performed. Presumably, the same pathophysiology could develop after a modified B-T shunt if the subclavian artery were severely stenotic or occluded. Rarely, collaterals from the pleura to the lung may be sufficiently large, especially after poudrage or pleural stripping procedures, to result in bilateral rib notching in the lower half of the thorax. Patients in the second or third decade of life may show progressive kyphoscoliosis.

Electrocardiography

Electrocardiography (ECG) shows moderate RV hypertrophy consistent with RV pressure that is equal to but not greater than systemic pressure (in contrast to flap valve VSD; see Section IV). Occasionally, there is minimal RV hypertrophy, and in these circumstances RV underdevelopment should be suspected, although it may not be present. Left precordial leads are characterized by absent Q waves and low-voltage R waves. Occasionally the frontal plane vectorcardiographic pattern characteristic of atroventricular septal defect is found in patients with typical TF.

Echocardiography

ECG is considered the definitive diagnostic procedure of choice in neonates and infants. The VSD, atrial septal status, aortic overriding, narrowing of the RV infundibulum, pulmonary valve, pulmonary trunk and bifurcation into the branch pulmonary arteries, and the ductus arteriosus, if present, can usually be seen with ECG (Fig. 38-14). Also, in experienced hands, two-dimensional (2D) echocardiography with Doppler color-flow interrogation has the same sensitivity and specificity for multiple VSDs in TF as does cineangiography. However, morphologic details of distal pulmonary artery branches as they approach the hilum may not be reliably visualized. Additional imaging is indicated when important abnormalities of the branch pulmonary arteries are identified, such as hypoplasia, discontinuity, or stenosis, and when abnormal arterial signals on Doppler interrogation are identified in the central and posterior mediastinum, suggestive of major AP collaterals.

Color Doppler imaging can also provide important physiologic information. Accurate estimates of the severity of obstruction across the RV outflow tract, as well as the site of obstruction (infundibular, valvar, supravalvar), can be obtained. Flow characteristics across the VSD and LV outflow tract can be used to confirm that pressures in the RV and LV are equal. Systolic function of the ventricles and competency of the inlet valves are also easily assessed, and flow patterns across the inlet valves in diastole can provide important information about ventricular diastolic function. In most cases the coronary artery pattern can be characterized, and anomalous patterns, such as the LAD arising from the RCA, can be identified.

Newer modalities of echocardiography, such as 3D echo, tissue Doppler, and strain rate imaging, hold further promise as noninvasive tools for improved morphologic and functional evaluation.\(^{32}\) Echocardiography can effectively diagnose TF in the fetus,\(^{35}\) and can be helpful in planning early surgical intervention and in parental counseling.\(^{327}\)

In patients who have undergone operation for TF, whether palliative procedures or definitive repair, and in unoperated TF patients presenting well beyond infancy, echocardiography is an important part of the diagnostic workup; however, it is not definitive. Characterizing pulmonary vascular...
resistance (Rp) and imaging the distal pulmonary arteries require cardiac catheterization.

Cardiac Catheterization and Angiography
Preoperative cardiac catheterization and angiography, although not routinely required when expertly interpreted echocardiography is available, precisely portray the hemodynamic state and morphology, particularly that of the distal pulmonary arteries. Peak pressure in the RV cavity (P_{RV}) is similar to that in the left (P_{LV}), and pulmonary artery pressure (P_{PA}) is below normal. A systolic pressure gradient is demonstrable at infundibular and valvar levels when both zones are stenotic, but rarely at a more peripheral site. When proximal stenoses are severe, however, it may be impossible to enter the pulmonary trunk with a catheter.

There is right-to-left shunting at ventricular level and low Qp, the severity of which reflect severity of stenosis. In acyanotic patients, there is minimal right-to-left shunting at rest or even a slight increase in Qp, but in most patients, right-to-left shunting occurs on exercise. In severely cyanotic patients, P_{PA} and Rp are not elevated preoperatively, even in the presence of important peripheral pulmonary artery stenosis or thrombosis, because of low Qp. P_{PA} may be elevated when there is a large Qp and an increase in Rp.

Biplane cineangiography demonstrates all the morphologic features of the malformation as well as morphology and dimensions of the RV–pulmonary trunk junction, pulmonary trunk, and RPA and LPA and their branches. Oblique and angled views are used. Configuration of the RV sinus and infundibulum and degree and morphology of the RV outflow tract obstruction are studied. Morphology of the pulmonary valve and any tethering or narrowing of the pulmonary trunk at the level of the commissural attachments of the valve or beyond are noted. Bifurcation of the pulmonary trunk and origins of the LPA and RPA are studied with particular care because the surgeon cannot accurately assess presence or severity of stenoses in this area during operation. The
diagnostic test and in patients after palliative surgery or reparative surgery. It can define the branch and peripheral pulmonary arteries accurately and has replaced conventional angiography for many clinical indications (Fig. 38-16). The chief advantage is that it requires only peripheral intravenous access for contrast injection, thereby removing the risk of catheter-induced complications. Furthermore, CT images are 3D and amenable to image postprocessing (Fig. 38-17), whereas images from conventional angiography are projectional and overlapping vessels can be difficult to interpret. Conventional angiography has better spatial resolution, and
selective branch injections may reveal flow dynamics in collateral branches better than CTA.

At the present time, when echocardiography is not sufficient to allay concerns about peripheral pulmonary artery abnormalities, CTA may be indicated to clarify the morphologic details. The decision to use conventional versus CTA is partly based on institutional expertise and preference; however, if hemodynamic information is required, or if major AP collaterals are suspected, catheterization is necessary.

In neonates and infants with suspected branch pulmonary artery abnormalities on echocardiography, in whom there is usually little concern about abnormal Rp, CTA is an excellent method for defining pulmonary artery stenoses and arborization abnormalities. In patients with systemic to pulmonary artery shunts, in whom concerns about Rp abnormalities are not present, CTA can define the morphologic details of the peripheral pulmonary arteries, systemic-pulmonary collateral vessels, and their pulmonary distributions. Cardiac-gated CTA can also reveal unanticipated coronary artery anomalies associated with TF (see Fig. 38-17). In postrepair TF patients with residual RV outflow tract abnormalities, CT can accurately characterize the morphology from the infundibulum to the peripheral pulmonary arteries and help detect native stenosis and conduit stenosis (Fig. 38-18) and aneurysm or pseudoaneurysm (Fig. 38-19).

**Magnetic Resonance Imaging**

Magnetic resonance imaging (MRI) is also used selectively in TF. Generally speaking, CTA has higher spatial resolution than MRI, and therefore CT is preferred when finely detailed peripheral pulmonary vascular morphologic information is required. MRI can accurately define the anatomy of the RV outflow tract and branch pulmonary arteries (Figs. 38-20 and 38-21). MRI has the advantage that it does not use ionization radiation and is a good choice in larger patients and when repeated studies are anticipated. In neonates and infants, preoperative echocardiography is usually adequate and MRI is rarely indicated.

The major indication for MRI is in postrepair TF patients with chronic pulmonary regurgitation. RV volume, pulmonary valve regurgitant fraction, coexisting pulmonary stenosis, and tricuspid valve regurgitant fraction can all be assessed quantitatively (Fig. 38-22). Serial examinations can accurately define trends in the values of these variables over time, and these trends can be helpful in determining the timing of reoperation. RV end-diastolic volume greater than 150 mL · m$^{-2}$ in children has been identified as a threshold above which the RV is likely not to normalize its volume even after placement of a pulmonary valve prosthesis.

When pacemakers or defibrillators are present, MRI is contraindicated. Under these conditions, CTA can be an excellent alternative.

**NATURAL HISTORY**

The natural history of patients having TF with pulmonary stenosis without major associated cardiac anomalies is variable and is determined primarily by severity of RV and pulmonary arterial outflow obstruction.
Symptoms and Survival

Twenty-five percent of surgically untreated infants die in the first year of life, but uncommonly in the first month (Fig. 38-23, A and B). These are the patients with the most severe obstruction to pulmonary blood flow. Forty percent are dead by age 3, 70% by age 10, and 95% by age 40. Instantaneous risk of death (hazard function) is greatest in the first year of life (Fig. 38-23, C). Risk then stays constant until about age 25, when it begins again to increase.

Hypoxic spells in the first few years of life are related to hyperactivity of the infundibulum. This and contraction of the infundibular septum and its parietal extension earlier in systole than in normal subjects produce variable and sometimes severe episodes of RV outflow tract obstruction and symptoms. Any sudden reduction of systemic vascular resistance also may precipitate a hypoxic spell.

About 25% of patients are acyanotic at birth and become cyanotic in the ensuing weeks, months, or years as pulmonary stenosis increases. Progression of arterial desaturation, cyanosis, and polycythemia is variable and is furthered not only by increasing pulmonary stenosis but also by widespread tendency to thrombosis of the smaller pulmonary arteries, with progressive reduction in Qp. As part of this same tendency, death may result from cerebral thromboses or abscesses.

In those few patients surviving into the fourth and fifth decades of life, death is commonly from chronic heart failure due to secondary cardiomyopathy that results from RV pressure overload and chronic hypoxia and polycythemia.

Pulmonary Artery Thromboses

In severely cyanotic and polycythemic patients, diffuse pulmonary arterial thrombosis can occur. This is initially visible only microscopically, but rarely it progresses to occlusion of a lobar pulmonary artery or even an entire RPA or LPA. Usually, Rp is not importantly increased by this process, but rarely the thrombosis is so widespread and severe as to be a

cause of immediate and sometimes fatal pulmonary hypertension and RV failure following repair.

Pulmonary Vascular Disease

Pulmonary vascular disease rarely develops in surgically untreated patients. It may develop following too large a systemic to pulmonary arterial shunt (see “Interim Results after Classic Shunting Operations” later in this section). When a surgical shunt appears to be the cause, it is possible that preexistent pulmonary arterial thrombosis has compounded the problem.

Genetic History

Offspring of a parent who has TF are more likely to have the anomaly than offspring of parents without congenital heart disease. It is estimated that about 0.1% of live births have TF under the latter circumstances and about 1.5% under the former.29

TECHNIQUE OF OPERATION

General Plan and Details of Repair Common to All Approaches

Surgical Evaluation

Outcome of repair of TF depends mainly on relief of pulmonary stenosis, whether infundibular, valvar, pulmonary arterial, or (as is usual) a combination of these. Therefore, the surgeon must come to the operating room with a clear mental image of the morphology as it has been displayed in the preoperative imaging studies, particularly as it relates to the RV and pulmonary arterial outflow obstruction.

After median sternotomy, external anatomy of the heart is studied, with particular attention to RV and pulmonary artery anatomy and configuration of coronary arteries crossing the RV. The preoperative imaging studies are mentally reviewed; these and observation of the heart determine the incision and details of repair.

Conceptual Approach to Surgery

The idealized goal of repair is to eliminate intracardiac shunting, reduce RV pressure and volume load to normal, and preserve normal myocardial function. This is accomplished by complete closure of the VSD (and atrial septal defect if present) and complete relief of the RV outflow tract obstruction while maintaining a competent pulmonary valve. This ideal is achieved in only a minority of patients, generally those with the most favorable RV outflow morphology, consisting of a normal or nearly normal pulmonary “anulus” and functioning pulmonary valve cusps (see discussion of variability of RV outflow tract morphology under Morphology in this section). In all other cases, the repair will fall short of ideal. Thus, in most cases, a number of important morphologically driven decisions must be made during repair, and these decisions will determine how closely the repair will approach the ideal. The decisions listed here (and discussed further in text that follows) often involve both technical and conceptual elements:

- Performing a transanular patch and determining width of the patch
- Preserving or sacrificing RCA branches
- Managing the RV outflow tract when an anomalous LAD is present
- Technically approaching abnormal pulmonary valve cusps, and preserving cusps when transanular patching is performed
- Managing atrial septal defects and PFOs
- Managing the tricuspid valve when septal leaflet function is compromised at VSD closure
- Dividing or resecting obstructing septal and parietal muscle bands in the RV outflow tract.

Approach

Surgical access to the VSD and RV outflow tract through a right atriotomy, supplemented by evaluating the pulmonary valve via a pulmonary arteriography in most cases, is advocated by some.123,111 This approach makes sense when a well-developed infundibulum is present; however, if there is diffuse hypoplasia of the RV outflow tract, and a full-length transanular patch is anticipated, this approach makes little sense. Additionally, if a small tricuspid valve is present, exposure through the right atrium may be difficult, especially in small infants, and more damage than good may result from traction on the myocardium and tricuspid valve. Nevertheless, initial approach through the pulmonary artery and right atrium is preferred in all situations by some.

Transanular Patch

The question of whether to use a transanular patch arises in many cases, and this decision is now known to have far-reaching implications for long-term outcome. Recent publications continue to emphasize the detrimental effects of large transanular incisions.822,1314 A transanular patch creates obligatory pulmonary regurgitation, and when this is long-standing and severe, important RV dysfunction will inevitably occur (see Results later in this section). Degree of narrowing of the “anulus” can be expressed quantitatively by a z value—that is, the number of standard deviations (usually smaller) from normal. When the z value has been determined from echocardiography, corrected and transformed cineangiographic measurements, or MRI or CTA to be larger than −3, the surgeon’s bias should be that a transanular patch is probably unnecessary (Fig. 38-24); when it is −3 or smaller, a patch is probably required. The surgeon’s bias should also be that even with a transanular patch, when the z value of the “anulus” is less than −7 (<10% of cases), postrepair ratio of peak pressure in the RV to that in the LV (P_{RV/LV}) may be I or higher, even with a properly placed transanular patch (Fig. 38-25). It can be inferred from the findings outlined in Fig. 38-24 that the extremely small pulmonary valve “anulus” may in some cases be associated with diffuse hypoplasia of the distal pulmonary arteries. Thus, when a very small “anulus” is noted, preoperative evaluation of the distal pulmonary vasculature and Rp should be undertaken. If distal hypoplasia, elevated Rp, or both are observed, a reparative operation should be avoided (at least temporarily) in favor of a shunt procedure. It must be emphasized that the z value is used only as a guideline. The pulmonary valve cusp configuration—number, thickness, and fusion—will influence the eventual gradient across the RV outflow tract after repair, and because of these variables, different gradients may result despite similar z values. Thus, the actual gradient should always be assessed after separation.
from cardiopulmonary bypass (CPB), at a minimum by intraoperative echocardiography, and preferably by direct pressure measurement.

**Right Coronary Artery Branches** As a general principle, visible-to-the-eye RV coronary artery branches should be preserved whenever possible. Occasionally visible branches must be transected to achieve acceptable RV outflow obstruction relief. Before transecting a branch, its course should be fully examined. Those that traverse the body of the RV, and even those smaller branches that supply muscle farther down on the RV infundibulum than the lower margin of the infundibular incision, should be preserved. When necessary, small transverse infundibular branches, with distal perfusion that stays above the lower margin of the infundibular incision, can be sacrificed.

**Anomalous Left Anterior Descending Coronary Artery** When an anomalous LAD arises from the RCA, modifying RV outflow tract management is often, but not always, necessary. Key factors are the exact course of the coronary artery and morphology of the infundibulum. In cases with a LAD that crosses high in the infundibulum near the valve anulus, and with low infundibular obstruction and a well-developed distal infundibular chamber, the obstruction can be addressed without endangering the coronary artery. On the other hand, when severe diffuse infundibular hypoplasia is present and the obstruction can be addressed only by placing a conduit from the RV to the pulmonary trunk, the RV-conduit anastomosis should be placed proximal to the coronary vessel. Occasionally the anomalous LAD is intramyocardial. This should be suspected when the left aortic sinus gives rise to an isolated circumflex coronary artery.

**Pulmonary Valve** The pulmonary valve cusps should be assessed carefully, especially when a transanular patch is necessary. There is a high likelihood of bicuspid valve when a transanular patch is needed (small anulus). Orientation of the two commissures may be directly anterior and posterior, directly left and right, or any position in between. With the exception of the direct lateral orientation, the transanular incision can be designed to cross the anulus precisely through the most anterior commissure, thereby preserving the function of both cusps. This maneuver minimizes the severity of pulmonary regurgitation that results from the transanular patching.

**Atrial Septal Communications** Managing the atrial septum can be essential to repair, particularly in neonates and infants. The combination of a transanular patch and high Rp can lead to postoperative RV failure. If the foramen ovale is patent under these conditions, it should be left patent. If the PFO has naturally closed, it can be reopened using a blunt instrument in most young infants. If a true atrial septal defect is present, it should be subtotally closed using a patch, leaving a small open flap that overlaps the edge of the limbus, to function like a PFO. The resulting cyanosis of atrial right to left shunting is well tolerated postoperatively, because chronic cyanosis is typically present preoperatively. In patients who do not receive a transanular patch, the atrial septum can typically be completely closed.

**Tricuspid Valve** Careful attention to the tricuspid valve during VSD closure is essential, particularly in small infants. Tethering of the septal leaflet and distortion of chordal structures during VSD closure is sometimes inevitable. Valve competency should be tested routinely after VSD closure. If regurgitation is present, tricuspid valve repair should be performed. Partial closure of the anterior septal leaflet commissure is effective in restoring tricuspid valve competency when septal leaflet tethering is present. A competent tricuspid valve is critical to achieving excellent outcome, especially if a transanular patch is used.

**Right Ventricular Muscle Bundles** Surgical myotomy or myectomy to manage obstructing septal, parietal, and free-wall muscle bundles in the infundibulum can have both short- and long-term implications for RV function. Despite its necessity, it remains one of the most destructive procedures in all of pediatric cardiac surgery. A minimalist approach is recommended in most cases. In neonates and infants, in whom fibrosis and excessive hypertrophy are not yet present, incision of obstructing septal and/or parietal bands without excision is all that is necessary. In many cases,
if these muscle bundles are not obstructive, patching of the longitudinal infundibular incision is all that is needed to relieve infundibular obstruction. In older patients, when important fibrosis, hypertrophy, or both are present, simple incision may not relieve the obstruction, and excision may be required.

Preparations for Cardiopulmonary Bypass
Before establishing CPB, the ascending aorta is dissected free from the pulmonary trunk so that when the aortic clamp is in position, the pulmonary trunk and RPA are undistorted. Unless it is clear from preoperative imaging studies that the pulmonary trunk bifurcation and central and hilar portions of the LPA and RPA are free of stenoses or diffuse hypoplasia, these too are mobilized. On the left side, this is aided by cutting the pericardium down to the LPA, dissecting away and preserving the left phrenic nerve. The ligamentum (or ductus) arteriosum, if present, is dissected, ligated, and divided. Division of the ligamentum (or ductus) will prevent tethering of the proximal LPA, which can cause late kinking and obstruction, especially when a transanular patch is used at repair. On the right side the aorta is retracted anterior and to the left, and the RPA is dissected completely away from it out to the superior vena cava and beneath it if necessary.

Any surgically created shunts are at least partially dissected before establishing CPB (see later sections on repair after various shunts).

Technical Details of Repair
Immediately after CPB is established, all surgically created shunts are ligated or divided, and the ductus (if present) ligated and divided if this has not been accomplished prior to establishing CPB. Thereafter, once the heart is arrested, the right ventriculotomy or right atriotomy is made and the internal anatomy further visualized and conceptualized. The plan is to:

- Dissect and resect the infundibular stenosis (recalling that this may be at several levels).
- Visualize the pulmonary valve and open it if necessary.
- Estimate dimensions of the outflow tract, valve, and anulus with a Hegar dilator, and decide whether a transanular patch is needed.
- Repair the VSD.
- Evaluate the atrial septum and make a decision about closing any defects or leaving a PFO.
- Evaluate residual RV outflow tract obstruction following separation from CPB.

Repair is similar whether an RV or right atrial approach is chosen and is represented in Figs. 38-26 through 38-29, which should be studied in parallel with this text to obtain the most complete understanding of the pathologic anatomy and its repair.

Infundibular Dissection In patients presenting for surgery beyond early infancy, considerable RV infundibular muscle hypertrophy and fibrosis are typical, requiring a number of maneuvers during the infundibular dissection. The parietal extension of the infundibular septum is dissected away from the RV free wall and ventriculoinfundibular fold and is divided transversely 5 mm or so to the right of the attachment of the right coronary cusp of the aortic valve to the undersurface of the infundibular septum. This increases diameter of the infundibulum at its rightward end and improves exposure of the VSD from the RV approach. Any obstructive trabeculae along the left side of the outflow tract are also incised and partially removed. The aim is to increase the circumference of the infundibulum by enlarging each lateral recess in front of the infundibular septum. An obstruction at a low level (coronal plane) is relieved by dividing anomalous trabeculae above the moderator band while protecting adjacent papillary muscles; the moderator band is divided only when necessary to relieve the obstruction. When an os infundibulum is present at the level of the inferior edge of the infundibular septum, the fibrous thickening all around the ostial orifice is excised, as is any fibrous obstruction extending upstream toward the pulmonary valve. If the infundibular resection is performed using an RV infundibular incision, the...
Figure 38-27  Repair of tetralogy of Fallot via right ventricular (RV) approach using vertical incision. **A,** Superiorly, incision stops short of pulmonary valve “anulus” and may vary according to presence and direction of a large conal branch of right coronary artery. **B,** RV incision is spread widely by retraction sutures. Parietal extension of infundibular septum is transected where it begins to fuse with RV free wall, dissected away from ventriculoinfundibular fold, and then amputated from infundibular septum. This uncovers the ventricular septal defect (VSD) and tricuspid valve. Ventriculoinfundibular fold remains unseen because it is overhung by the tricuspid valve anterior leaflet. **C,** Parietal extension has been mobilized (divided and partially amputated). Septal extension is likewise mobilized to maximize circumference of infundibular outflow tract.
Figure 38-27, cont’d  

D, Pledgeted mattress suture is placed from right atrial side through base of commissural tissue between septal and posterior tricuspid leaflets and through patch. A few more stitches are taken, working posteriorly between base of septal leaflet and patch, followed by stitches through ventriculoinfundibular fold and patch.  

E, Suturing is continued onto parietal extension and infundibular septum, visualizing and staying close to aortic valve leaflets to avoid leaving a hole between muscular bands. Suture is then held. With other arm of suture, a few stitches are taken, working anteriorly between septal tricuspid leaflet and patch, weaving beneath any chordae crossing the VSD. When this has taken the suture line about 5 mm inferior to edge of the VSD, stitches are taken in septum, well back from VSD edge.  

F, Repair of VSD is completed. Note that suture line is away from bundle of His and its branches, except where it crosses the right bundle branch anteroinferiorly. Crista supraventricularis is pulled downward by the patch, which helps increase infundibular outflow circumference. Key: LAD, Left anterior descending coronary artery; RBB, right bundle branch; RCA, right coronary artery; TSM, trabecula septomarginalis.
Figure 38-28  Anatomy of tetralogy of Fallot from perspective of right atrial approach, shown as if right atrial free wall and tricuspid valve were translucent. The striking difference from the right ventricular (RV) perspective (see Fig. 38-27) is apparent position of parietal extension. From right atrial perspective, the surgeon is looking beneath this, as parietal extension arches over the RV outflow tract. Ventriculoinfundibular fold is easily seen through tricuspid valve. Key: AV, Atrioventricular; IVC, inferior vena cava; SVC, superior vena cava; TV, tricuspid valve; VSD, ventricular septal defect.

Figure 38-29  Repair of tetralogy of Fallot, right atrial approach. A, A high right atrial incision made close to the atrioventricular groove aids exposure. Ventricular septal defect (VSD) is located beneath anteroseptal commissure, indicated by dashed line. B, VSD is closed before amputating parietal extension. A pledged double-armed suture is begun at the anteroinferior aspect of VSD about 5 mm away from rim to avoid conduction fibers.

Incision is closed with a patch of glutaraldehyde-treated autologous pericardium or other material (see “Decision and Technique for Transanular Patching” later in this section). Direct closure could narrow the outflow tract. When a transanular patch is needed, a glutaraldehyde-treated or untreated pericardial patch is inserted after extending the infundibular incision across the pulmonary “anulus.”

This type of anatomic dissection is not possible in the presence of diffuse RV outflow hypoplasia and is often not possible when there is combined infundibular, valvar, and anular stenosis. These structures are all hypoplastic, a situation frequently encountered in patients who have become importantly symptomatic, as neonates or infants, and patch graft enlargement is often all that can be accomplished. In any event, particularly in infants, resection or even transection of RV muscle bundles that are not obstructive must be avoided because this unnecessarily impairs RV function.

Pulmonary Valvotomy If pulmonary valvotomy is needed, a vertical incision is made in the pulmonary trunk, taking care to avoid damaging the valve commissures (Fig. 38-30). The
pulmonary arteriotomy is not made through a commissure between the cusps, because placing a patch in such an incision renders the valve regurgitant. Rarely can an adequate valvotomy be performed by simply dividing one or more sites of commissural fusion, because fusion is present in only 20% of stenotic valves and is almost always associated with important cusp thickening, particularly at the cusp free edge (see Morphology earlier in this section). After valvotomy, therefore, the surgeon may elect to excise the thickened cusp edge to relieve the stenosis, although some pulmonary valve regurgitation results. When there is cusp tethering only, the most common situation, the cusp edge may be cut from its attachment to the pulmonary artery wall over about 3 mm. This is done to one cusp at each commissure. Here, too, excising thickened cusp tissue may be required. Regurgitation from minor detachment of a cusp may be less than that from a transanular patch. If considerable cusp incision and detachment are required, regurgitation results; if there is also important residual narrowing, it is preferable to excise the cusps and place a transanular patch after completing the intraventricular part of the repair. If a transanular patch is not needed (see “Decision and Technique for Transanular Patching” later in this section), the pulmonary arteriotomy is closed, usually with a pericardial patch.

**VSD Closure** In children and adults, the VSD is closed with a filamentous polyester or polytetrafluoroethylene...
Figure 38-30  Repair of tetralogy of Fallot with separate infundibular and pulmonary arterial patches. **A,** Pulmonary trunk incision is shown extending to but not into pulmonary valve “anulus” (dashed line). Vertical ventriculotomy is also shown. **Inset,** Stenotic pulmonary valve seen through pulmonary arteriotomy. Fused commissures are incised with a knife to the pulmonary trunk wall. Fine tissue forceps steady the cusps on each side of commissure and provide even tension as incision is made. **B,** Unless pulmonary trunk is of normal width, which is uncommon, incision is closed with an oval pericardial or polytetrafluoroethylene patch. Patch is cut in the form shown, and its dimensions ensure that it is convex rather than flat.

(PTFE) patch; in neonates and infants, glutaraldehyde-treated pericardium works well. The patch is trimmed to be slightly larger than the VSD. Exposure may be obtained entirely with stay sutures; alternatively, the VSD is exposed through the right ventriculotomy by the assistant using two small curved retractors, one beneath both ends of the infundibular septum, which are pulled upward and apart. A third retractor is positioned in the lower margin of the ventriculotomy for gentle inferior traction. Sequencing of the suturing depends on whether the repair is from the right atrium or RV and is similar to that used for isolated VSD (see Figs. 38-26 through 38-29; see also Chapter 35 and Figs. 35-24 and 35-25). For example, through the RV it is usual to begin the continuous suture at the base of the tricuspid septal leaflet at the posterior-inferior aspect of the VSD. Via the right atrial approach, the suture is often begun anterior to the insertion of the medial papillary muscle (muscle of Lancisi).

**Decision and Technique for Transanular Patching** Preoperative imaging, usually by echocardiography and occasionally by cineangiography, is used to estimate the diameter of the pulmonary “anulus,” and this information is used to assess the likelihood of whether a transanular patch will be
necessary. In extreme cases (of both large and small “anuli”), this measurement can be highly predictive of whether or not a transanular patch will be needed. In many less extreme cases (z values between −2 and −4), intraoperative information will be used to decide when to place a transanular patch. The surgeon’s bias regarding transanular patching is that it generally should not be necessary when the pulmonary “anulus” z value is larger than −3 as measured on the preoperative echocardiogram or cineangiogram. This is based on the high probability under these circumstances that the postrepair $P_{RV/LV}$ will be less than about 0.7, and on the anticipated increased need for insertion of a pulmonary valve very late postoperatively when a transanular patch has been placed. Generally, a transanular patch should not be placed when the z value is larger than −3. Otherwise, the incision is carried across the “anulus,” the pulmonary valve excised, and the patch inserted.

When the patient has TF with subarterial VSD, the “Asian” variant of TF, the surgeon’s bias is that there is a three in four chance a transanular patch will be necessary. Reassessment after closing the VSD is accomplished by estimating the diameter of the “anulus” with a Hegar dilator that passes snugly but not tightly through it. This provides one more precise estimate in borderline situations. This diameter is transformed to a z value as described in Chapter 1, Appendix Fig. 1D-1; generally this finding is similar to that obtained from the cineangiogram (but slightly smaller when the body surface area of the patient is less than 0.7 m² and slightly larger in patients with a body surface area greater than about 0.7 m²). Generally, a transanular patch should not be placed when the z value is larger than −3. Otherwise, the incision is carried across the “anulus,” the pulmonary valve excised, and the patch inserted (Fig. 38-31). If the situation is borderline, the lesser risk lies with inserting a transanular patch.
essentially unchanged and be at the junction of the patch and distal pulmonary trunk. In some patients the distal pulmonary trunk is narrower than the anulus; in these cases the incision is extended into the LPA, which usually continues in the same general direction as the pulmonary trunk and is usually proportionally larger than the distal pulmonary trunk. If the origin of the LPA is proportionally no larger than the distal pulmonary trunk, the incision and patch reconstruction should be carried into the midportion of the LPA, which is nearly always wider than the origin. Care must be taken to not damage the left phrenic nerve or left superior pulmonary vein. In neonates with a patent ductus, especially if they are on PGE, it is difficult to assess the proximal LPA, and patching that extends beyond the ductus onto the distal LPA should be performed.

The transanular patch may be of glutaraldehyde-treated or untreated autologous pericardium, processed bovine pericardium, or cut from a cylinder of preclotted double-vessel woven polyester, collagen-impregnated knitted polyester, or PTFE. In neonates and young infants, autologous pericardium should be used exclusively. In older patients, collagen-impregnated polyester provides the benefit of precise sizing of the patch (an important consideration), and when properly trimmed, its convexity is ensured, as is a relatively “square cut” of its distal end (see Fig. 38-31, B). Glutaraldehyde-treated pericardium has significant advantages. When a polyester tube is used, one is selected whose diameter corresponds to a z value of 0 to +2. Too large a transanular patch increases postoperative pulmonary regurgitation.

When the time comes for inserting the patch and the distal end of the incision is on the pulmonary trunk, the polyester tube is stretched slightly and cut to the length of the incision, cutting both ends squarely (see Fig. 38-31). The corrugated (crimped) nature of the tube provides sufficient length that it is convex longitudinally; the curve makes it a convex “roof” transversely. The tube is then cut longitudinally so that about three fifths of the circumference remains as the roof. Only the corners are trimmed at the distal end, leaving it very broad, while the proximal (RV) end is tapered. It is then sewn into place with a continuous 5-0 polypropylene suture (see Fig. 38-31, B).

When the incision has been carried onto the LPA, a slightly different technique is used, in the belief that the result is more apt to be geometrically correct. For this, a rectangular piece of pericardium is cut about 1.5 times wider than the apparent diameter of the LPA and about 1.5 times longer than the incision in the LPA. It is sewn into place with continuous 6-0 polypropylene sutures placed slightly farther apart in the patch than in the wall of the LPA. A polyester tube is used for the remainder of the reconstruction (Fig. 38-33). Alternatively, glutaraldehyde-treated pericardium can be used for both the transanular patch and the extension onto the LPA. Its length can be determined by measuring length of the incision from the RV to the pulmonary artery, and its maximum width is determined visually by holding the edges of the incision open at valve level and judging the size of the roof required to create a new pulmonary “anulus” whose diameter is no larger than three fourths the diameter of the ascending aorta. Alternatively, in infants, an 8-, 9-, or 10-mm Hegar dilator can be placed through the divided “anulus” and the width of the patch required to complete the roof over it measured. Both ends are cut almost transversely to create a blunt patch, particularly distally, and the patch is positioned using continuous 6-0 or 7-0 polypropylene sutures commencing at the distal end of the incision. The suture is placed using a running over-and-over technique, placing the first two or three throws along each side before pulling the pericardial patch into position as the suture is tightened. Suturing is continued down each side to anulus level, then the remainder of the right ventriculotomy is closed by incorporating the pericardial patch into it with continuous sutures. Deep bites of muscle are taken down each side and at the angle.

A monocusp may be attached to the pericardial roofing patch. The cusp diameter is fashioned somewhat larger than the planned rooved RV outflow. It is cut more or less circular and sutured to the patch when the latter suturing from distally reaches the valve “anulus.”

### Assessing Postrepair Right Ventricular Outflow Tract Obstruction

#### Measuring Postrepair (Operating Room [OR]) \( P_{RV/LV} \)

In older infants and beyond, the \( P_{RV/LV} \) is helpful in assessing important residual RV outflow tract obstruction. After repair and separation from CPB, and preferably with the cannulae for CPB still in place, postrepair (OR) \( P_{RV/LV} \) is obtained. The peripheral systemic systolic blood pressure can be used to estimate the \( P_{LV} \). A polyvinyl catheter is placed through the right atrial wall and passed across the tricuspid valve into the RV to measure \( P_{RV} \).

If a transanular patch has not been placed and postrepair (OR) \( P_{RV/LV} \) is greater than 0.7, CPB should be reestablished and a transanular patch placed.

When a transanular patch has been placed and the ratio is greater than about 0.8, localizing the site of the gradient is vigorously pursued by pressure manometry or transesophageal echocardiography. If pressure gradient or localized obstruction is identified between the sinus portion of the RV
Figure 38-33  Repair of tetralogy of Fallot in neonates.  
A, A transanular right ventricular–pulmonary trunk incision is almost always used, keeping ventricular portion as cephalad as practicable.  B, Pulmonary valve is incised fully to arterial wall and, if grossly distorted, resected fully. Parietal and septal extensions of the trabecula septomarginalis are incised at their origins from the infundibular septum, but resection of muscle is kept to a minimum. Ventricular septal defect (VSD) is closed as for the right ventricular approach (see Fig. 38-27). Often, pericardium is used for VSD patch.  C, Transanular incision is closed with a polyester, polytetrafluoroethylene, or pericardial patch large enough to attain a mildly convex contour in all directions. Key: LPA, Left pulmonary artery; SVC, superior vena cava.
and distal end of the patch, CPB is reestablished and the situation corrected. If the operation has been properly performed (in which case the gradient is located at the distal end of the patch) and if the patch has been extended into a widened portion of the pulmonary trunk or LPA, little more can be done to relieve the obstruction.

If no correctable cause of the elevation of postrepair (OR) \( P_{RV/LV} \) is found, and if the elevation is not extreme and the patient’s condition is good, the patient should be sent to the intensive care unit (ICU) with continuous monitoring of RV pressure. There, over a few hours, postrepair (ICU) \( P_{RV/LV} \) may fall to reasonable levels (see Special Features of Postoperative Care later in this section). If the patient’s condition in the operating room is not good or if right atrial pressure is considerably elevated above left, then the situation is precarious, although uncommon, and requires action. CPB is reestablished, and a large hole is cut in the VSD patch, usually during a brief period of aortic clamping and through a right atriotomy.

**Measuring Postrepair (OR) Right Ventricular Outflow Tract Pressure Gradient** In neonates and young infants, compared with older patients, the \( P_{RV/LV} \) is less helpful for assessing important residual RV outflow tract obstruction. There are several reasons for this. First, the data used to develop and interpret the ratio are from older patients, so the ratio thresholds predicting poor outcomes have not been validated in neonates. Second, and most important, the physiology in neonates and young infants is substantially different from that in older patients. Especially in the operating room post-CPB, systemic vascular resistance can be quite low, yielding systemic systemic arterial pressure (and thus the \( P_{LV} \)) as low as 50 mmHg. Also, \( R_p \) tends to be higher, so typically the \( P_{RV} \) may be as high as 40 to 45 mmHg without RV outflow tract obstruction. As a result, the \( P_{RV/LV} \) may approach 1.0 without any residual RV outflow tract obstruction.

Nevertheless, assessment of residual obstruction, both when the pulmonary “anulus” is left intact and when a transannular patch is used, should be routinely performed. A polyvinyl catheter is placed in the RV as described in the previous section, to measure \( P_{RV} \). Another catheter is placed in the pulmonary trunk and can be manipulated into the RPA and LPA, to obtain \( P_{RPA}, P_{LPA} \), and \( P_{LPA} \). In a patient with an intact pulmonary valve “anulus,” a gradient of 20 mmHg or more at the valve is an indication for revision with a transannular patch. In a patient with a transannular patch, a gradient of similar magnitude is an indication for revision at the specific site of the residual obstruction.

**Management of Atrial Septum** During repair, a PFO (present in about two thirds of patients) should generally be closed in older infants and children. Rarely, a persistent atrial communication can be the source of paradoxical cerebral emboli late postoperatively. If a true atrial septal defect is not closed, there may be left-to-right shunting at atrial level. In neonates and infants, if a transannular patch is placed or if important pulmonary regurgitation is present, a PFO is left unclosed to allow decompression of any right atrial hypertension caused by acute RV failure. Some arterial desaturation may be present in the first few postoperative days, but it then disappears as the RV remodels to accommodate the physiology of a high-volume, low-pressure circulation, as opposed to the preoperative physiology of a low-volume, high-pressure circulation. In fact, evidence of arterial desaturation is essentially proof that important RV failure is present.

A PFO should be narrowed to a diameter of 3 to 4 mm. This is accomplished by suturing a portion of the free edge of the septum primum to the left side of the limbus (where it would naturally attach if spontaneous closure had occurred) using several 5-0 polypropylene mattress sutures (Fig. 38-34). This will preserve a functioning, but somewhat smaller, PFO. If the pulmonary valve is competent in neonates and infants after repair, important RV failure is unlikely, and the PFO can be closed at repair.

**Repair of Uncomplicated Tetralogy of Fallot with Pulmonary Stenosis via Right Ventricle**

After usual intraoperative preparations (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2), a median sternotomy is performed. Prompt control of major bleeding from collaterals is accomplished with electrocautery. The usual dissections are made (see “General Plan and Details of Repair Common to All Approaches” earlier in this section) and purse-string sutures and tapes placed. A polyester tube (see “Decision and Technique for Transanular Patching” earlier in this section) may be selected and pericardium may be removed and treated with glutaraldehyde.

CPB is established, and the patient’s core temperature is cooled to 24° to 32°C using direct or indirect vena caval cannulation (see “Preparation for Cardiopulmonary Bypass in Section III of Chapter 2”). The colder end of the spectrum...
should be considered in older, very cyanotic patients who may have developed substantial acquired systemic to pulmonary artery collaterals. Two venous cannulae are preferred; however, a single right atrial cannula can be used (see “One versus Two Venous Cannulae” under Special Situations and Controversies in Section III of Chapter 2). The cardioplegic catheter (or needle) is secured into the ascending aorta. An efficient system for venting the left heart is essential for precise repair of TF, because of the potential for high collateral flow return to the left atrium. The left atrial suction line may be inserted through the base of the right superior pulmonary vein through a purse-string suture and advanced across the mitral valve to vent the LV. The aorta is clamped and cold cardioplegic solution injected (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3). Efflux from the coronary sinus is aspirated and discarded or allowed to escape from the right atrium.

The RV is opened through a vertical (longitudinal) incision, sparing large conal and anterior branches of the RCA that cross the RV. If it is expected that the pulmonary valve will be adequate, the incision is made in the midportion of the RV infundibulum and extended nearly to, but not into, the pulmonary valve superiorly and just into the sinus portion of the RV (see Fig. 41-27, A).311 Two pledgeted stay sutures placed through each side of the incision are placed on traction for exposure (see Fig. 41-27, B). Alternatively, this can be achieved manually using a hand-held retractor.

Infundibular dissection is performed (see “General Plan and Details of Repair Common to All Approaches” earlier in this section and Figs. 38-26 and 38-27, A to C). The pulmonary valve is examined, and if it is stenotic, a valvotomy is performed through a pulmonary arteriotomy (see Fig. 38-30, A). Diameter of the valve anulus is estimated with Hegar dilators. If a transanular patch is considered necessary (see “Decision and Technique for Transanular Patching” earlier in this section), the infundibular incision is carried across the “anulus” before performing the infundibular dissection, paying attention to the position of the pulmonary valve commissures (see Fig. 38-31).

After the RV outflow tract is addressed, the VSD is closed using a patch (see Fig. 38-27, D to F). If the decision earlier in the operation has been not to use a transanular patch, measurements with Hegar dilators are repeated from the RV after VSD closure. If no further narrowing has resulted, the pulmonary arteriotomy and infundibular incision are closed with patches (see Fig. 38-30, B). Similarly, if a transanular incision has been used, it is closed with a patch of appropriate diameter (see “Decision and Technique for Transanular Patching” under Technical Details of Repair earlier in this section). The right atrium is opened and the atrial septum examined. If an atrial septal defect or PFO is present, it is managed as described in “Management of the Atrial Septum” under Technical Details of Repair earlier in this section). The right atriotomy is closed.

Rewarming and myocardial reperfusion (see Chapter 3) can be commenced at any point after VSD closure. Thus, by preference, the RV outflow tract patches can be placed and atrial septum addressed either with the aortic clamp in place or with rewarming and myocardial reperfusion initiated. Separation from CPB is performed in the usual way (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2).

Repair of Uncomplicated Tetralogy of Fallot with Pulmonary Stenosis via Right Atrium

This procedure is identical to repair through the RV up to the point that CPB is established. Aortic cannulation is standard. Bicaval venous cannulation is required. After commencing CPB, cooling is initiated. The left side is vented by placing a cannula through the right upper pulmonary vein across the mitral valve into the LV. Once the desired core temperature is achieved, the aorta is clamped and cardioplegia administered. The caval tapes are snugged, and a long right atriotomy is carried from the base of the appendage well inferiorly, a little anterior to the inferior vena cava cannula site. The right atrium, atrial septum, tricuspid valve, VSD, and RV outflow tract are examined (see Fig. 38-29, A).

With properly placed 6-0 polypropylene traction sutures on the septal and anterior leaflets of the tricuspid valve, edges of the VSD can usually be visualized, although with more difficulty in TF than in isolated VSD because of the leftward and anterior displacement of the infundibular septum and its parietal extension.312 Alternatively, manual retraction by the surgical assistant using delicate instruments can achieve similar, or superior, exposure. The pathway from sinus to outflow portion of the RV is examined. The obstructive nature of the prominent parietal extension of the infundibular septum (see Figs. 38-28 and 38-29, B) is particularly well appreciated from this approach, and the infundibular chamber, if present, is easily visualized. The pulmonary valve can usually also be well seen. The VSD is repaired by sewing into place a patch (autologous glutaraldehyde pericardium or polyester velour) with continuous polypropylene (Fig. 38-29, B to D). It is closed before mobilizing and resecting the parietal band (as illustrated in Fig. 38-29). Often this allows better visualization of the borders of the VSD and, importantly, defines the limit of parietal extension to be resected (see Fig. 38-29, B). The VSD patch protects the aortic valve and crista during subsequent relief of outflow stenosis. Care should be taken not to cut or loosen the continuous patch suture anteriorly when resecting the parietal band. If needed, several interrupted sutures should be placed on this portion of the rim of the VSD patch.

RV outflow tract obstruction is addressed following VSD closure. The parietal extension is deeply incised 2 to 4 mm beyond its origin (toward the free wall) from the infundibular septum and 4 to 5 mm above the aortic cusps, which are visualized as the cut is made (see Fig. 38-29, E). The parietal extension is then dissected away from the ventriculo-infundibular fold (inner curvature of the RV) and from the anterior free wall of the RV and excised. The free wall of the RV is palpated occasionally from outside during this dissection to avoid perforating it. Any hypertrophied and obstructive trabeculae along the left side of the outflow tract are incised and removed together with the fibrous margins of the infundibulum. The infundibular chamber and areas just proximal to the pulmonary valve are examined to determine (in concert with the preoperative imaging studies) whether they need to be widened by an infundibular patch. Generally speaking, if this is the case, the atrial approach should not have been

---

1In about 5% of patients, aortic dextroposition is sufficiently severe that the cephalad (superior) borders of the VSD cannot be seen except with extreme traction on the tricuspid valve. In these cases, rather than using such strong traction, the right atrial approach is aborted and the RV approach used.
considered. This is because in TF, the VSD is always easier to expose and close through a ventriculotomy than through an atriotomy. Thus, if a ventriculotomy (infundibulotomy) is required because of a narrow infundibulum, the VSD should be closed through the infundibular incision. It makes little sense to close the VSD through the right atrium if an infundibular incision is required. The pulmonary valve is examined and the diameter of the “anulus” is estimated by passing a Hegar dilator antegrade across the RV outflow tract.

If a pulmonary valvotomy is needed, it is usually done through a vertical incision in the pulmonary trunk (see Fig. 38-30). After valvotomy, RV outflow diameter is again estimated by sizing the pulmonary valve orifice with Hegar dilators. The pulmonary arteriotomy is closed, usually with a pericardial patch. Management of an atrial septal defect or PFO and the remainder of the operation proceed as described for repair through the RV.

Repair of Tetralogy of Fallot in Infancy

A median sternotomy is performed and the heart exposed. A subtotal thymectomy is performed, paying careful attention to the phrenic nerve. If the echocardiogram or cineangiogram indicates that a transanular patch is required, and in borderline cases, the front of the pericardium is removed from where it joins the diaphragm to its most superior reflection from the aorta. This secures a piece of pericardium at least 6 cm long and 3 cm wide, tapering at both ends. The pericardium is stretched with its epicardial surface downward onto moist gauze or cardboard and is set aside for later use. Dissection of the pulmonary trunk, RPA, LPA, and ductus arteriosus or ligamentum arteriosum is easily and rapidly achieved.

CPB is established using aortic cannulation and, preferably, bicaval cannulation; however, single venous cannulation of the right atrium can be used. Standard continuous CPB with cooling to 28° to 32°C and cardioplegic cardiac arrest is preferred. The left heart is vented in standard fashion through the right upper pulmonary vein. Alternatively, hypothermic circulatory arrest can be used and is preferred by some. The ductus arteriosus, if present, is doubly ligated using two 5-0 polypropylene sutures and divided. The suture used to ligate the pulmonary artery end of the ductus should be placed precisely, at least 3 mm distal to the pulmonary artery origin of the ductus, to avoid constriction of the LPA branch or obstruction of the LPA lumen by extrusion of bulky ducal tissue. If a ligamentum is present, it should also be ligated and divided to avoid tethering of the LPA origin, which can cause late kinking and LPA obstruction, especially if pulmonary regurgitation and RV outflow tract dilatation develop. When imaging studies indicate that a transanular patch is not required and when dissection of the pulmonary trunk confirms that it is of adequate diameter, a vertical incision is made into the RV (see Fig. 38-27). The infundibular stenosis is completely relieved. This often involves simple transection of the parietal and septal extensions of the TSM, rather than resection (similar to that shown in Fig. 38-33, B). The pulmonary valve is examined from below and any stenosis relieved in the manner already described. The VSD is closed through the infundibular incision (similar to that shown in Fig. 38-27).

The tricuspid valve is retracted and the atrial septum exposed, looking retrograde from the RV into the right atrium. If a PFO is present, it is often possible to close or modify it from this approach; if not, the right atrium is opened and the PFO is managed through this approach. Or, if there is a more extensive atrial septal defect, the right atrium is opened and the defect closed using a pericardial patch with continuous polypropylene suture. If it has to be reduced in size, it is managed as described in Fig. 38-34. The right atrium is closed. The ventriculotomy is then closed with a narrow patch, also using a continuous suture.

When a transanular patch is indicated, the incision is carried across the “anulus” and out along the pulmonary trunk almost to the origin of the LPA, and a transanular pericardial patch is placed after VSD closure (see Fig. 38-33, A). Should there be LPA origin stenosis, the incision passes beyond this to reach the normal-diameter LPA (Fig. 38-35). If a transanular patch is used in neonates and young infants, the PFO should always be left open.

Repair of Tetralogy of Fallot with Stenosis at Origin of Left Pulmonary Artery

In this situation, there is usually sufficient hypoplasia of the pulmonary anulus and trunk that a transanular patch is also required (see Morphology earlier in this section). Repair is usually accomplished in exactly the manner described for situations in which the incision for placing a transanular patch must be extended onto the LPA (see “Decision and Technique for Transanular Patching” earlier in this section and see Fig. 38-35). In those uncommon instances in which a transanular patch is not needed, an incision is made across the stenosis in the origin of the LPA. A rectangular patch of pericardium is trimmed and sewn into place as described.

When there is virtual or total occlusion of the LPA origin, patch graft enlargement is not satisfactory. Instead, after locating the patent portion of the LPA beyond the zone of occlusion by dissecting along the chord of tissue that still connects it to the pulmonary trunk bifurcation, the patent LPA is opened longitudinally on its anterior surface for a short distance. The opened end is then sutured to the adjacent leftward edge of the pulmonary trunk with a running fine polypropylene suture to create a new posterior wall. The anterior wall is next created by a pericardial patch positioned as for reconstruction of a zone of stenosis (see earlier text). When the LPA is totally disconnected from the pulmonary trunk or is too small for this reconstruction, repair entails locating the LPA close to or adjacent to the lung hilum (usually by intrapleural dissection) and disconnecting it from any vessel, usually the ductus arteriosus, that supplies it. It is then usually possible to anastomose the LPA end to side to the leftward edge of the distal pulmonary trunk (mobilizing the trunk completely so that it will swing more easily to the left). If the LPA is narrowed proximally, however, a technique similar to that described earlier is employed.

Repair of Tetralogy of Fallot with Stenosis at Origin of Right Pulmonary Artery

This situation occurs uncommonly without associated LPA stenosis. In contrast to the LPA, the RPA is usually not an extension of the pulmonary trunk but comes off its side at a right angle. This makes the simple type of repair used for origin stenosis of the LPA less satisfactory, although it can be used when stenosis is not too severe.
Chapter 38 Ventricular Septal Defect with Pulmonary Stenosis or Atresia

Operation proceeds as usual until the VSD has been repaired. Then a small longitudinal incision is made in the pulmonary trunk to visualize the RPA orifice (Fig. 38-36, A). The origin of the RPA is excised from the pulmonary trunk. Lateral incisions are made to enlarge the orifice in the side of the pulmonary trunk (Fig. 38-36, B). The RPA is incised from its narrow orifice back into its wide portion. A rectangular piece of pericardium is trimmed and sewn to the RPA to make a markedly enlarged proximal RPA (Fig. 38-36, C). The proximal end of the reconstructed RPA is then sutured to the enlarged orifice in the side of the pulmonary trunk using continuous 6-0 or 7-0 polypropylene sutures, while taking care to avoid any purse-string effect (Fig. 38-36, D). Alternatively, the posterior edge of the opened RPA is sutured to the back wall of the opened pulmonary trunk; the rectangular piece of pericardium is then sewn to the remaining opening to widen it further.

Transection of the ascending aorta to improve exposure is rarely necessary.

Repair of Tetralogy of Fallot with Bifurcation Stenosis of Pulmonary Trunk

This condition requires appropriate reconstruction based on proper understanding of the morphology, although few papers discuss details of this repair. Both the LPA and RPA ostia are usually stenosed to a similar degree and over a short distance (<15 mm), and the distal pulmonary trunk is often similarly narrowed. The pulmonary trunk may be short, making the bifurcation proximal and more Y-shaped than usual.

In patients 5 years of age or older, the optimal procedure may be to replace the pulmonary valve, trunk, bifurcation, and proximal RPA and LPA with a pulmonary allograft (Fig. 38-37). It is a less desirable operation in infants, however, because the allograft will almost certainly be outgrown and require earlier replacement than when used in older children. However, this procedure has the greatest probability of providing a good hemodynamic result in this complex situation.
Alternatively, and especially in infants, repair rather than replacement is indicated (Fig. 38-38). Complete mobilization of the aorta, pulmonary trunk, RPA, and LPA is required, preferably before CPB. The vertical ventriculotomy is carried across the anulus into the pulmonary trunk and extended to the bifurcation. A second incision is made on the anterior aspect of the branch pulmonary arteries, extending from the normal diameter of the distal LPA, across the stenotic region of the LPA, onto the RPA, and extending across the stenotic region of the RPA to the distal normal-diameter RPA. Thus, the two incisions described create a T shape. Autologous pericardial tissue or allograft pulmonary artery tissue is used to patch-augment the pulmonary trunk and branch pulmonary arteries. Two patches are used, the first to patch the branch pulmonary arteries (Fig. 38-38, A) and the second as the transanular patch, which extends distally to the first patch (Fig. 38-38, B).

Repair of Tetralogy of Fallot with Anomalous Origin of Left Anterior Descending Coronary Artery from Right Coronary Artery

In hearts in which there is a large coronary artery crossing the RV outflow tract close to the pulmonary “anulus” (usually an anomalously arising LAD from the RCA, but sometimes the entire left coronary artery coming from the RCA), relief of pulmonary stenosis must neither divide nor compromise flow through this vessel. Because such a vessel is occasionally

Figure 38-36 One type of repair of stenosis at origin of right pulmonary artery (RPA). Initially, a small incision is made in pulmonary trunk through which stenotic orifice of RPA can be viewed from within. A, Ascending aorta has been mobilized to expose origin of RPA. Proposed incision for disconnecting RPA from pulmonary trunk is shown. B, RPA has been disconnected from pulmonary trunk. Resulting orifice in RPA can be enlarged as shown, but enlargement by incision is preferable. An incision is made down anterior aspect of RPA. C, RPA is enlarged with a pericardial patch. D, Enlarged RPA is reattached to enlarged aperture in pulmonary trunk. (At times, it may be easier to suture posterior wall of RPA to posterior aspect of pulmonary trunk orifice before making pericardial enlargement of RPA.) Key: LPA, Left pulmonary artery; SVC, superior vena cava.
Figure 38-37 Repair of severe pulmonary trunk and bifurcation stenosis using a pulmonary valve allograft and its bifurcation. A, Dissection must be complete. For this, entire ascending aorta is completely freed from its posterior connections and from pulmonary trunk and its bifurcation. B, Superior vena cava is completely mobilized and right and left pulmonary arteries (RPA and LPA) dissected at least to the point where the first branch is visualized; that is, beyond the immediately prebranching level. C, Ascending aorta may be divided, but often the procedure can be performed without this step. Distal anastomoses are made first, taking care to transect the LPA and RPA beyond the narrow areas and to leave some redundancy in allograft bifurcation. D, Completion of the proximal anastomosis, often with a polyester (or pericardial) hood as shown. If transected, aorta is brought together end to end. Importantly, however, if aorta is enlarged and compresses the underlying allograft bifurcation or RPA, a short segment of polyester or polytetrafluoroethylene tube should be interposed between the two ends of the aorta. Key: SVC, Superior vena cava.
This technique may be used by choice, instead of the patch technique, when the infundibulum requires mild or moderate augmentation; it is the only option when marked augmentation is needed.

If the left coronary artery is damaged by the right ventriculotomy, the left internal thoracic artery can be taken down (see “Internal Thoracic Artery” under Technique of Operation in Chapter 7) and anastomosed to the distal left coronary artery. Alternatively, the coronary can be primarily repaired. This procedure can be life saving.

Repair of Tetralogy of Fallot after Blalock-Taussig Shunt or Polytetrafluoroethylene Interposition Shunt

Systemic-to-pulmonary artery shunts will have been created either through a thoracotomy (left or right) or a median sternotomy, and will consist of either a native systemic artery–pulmonary artery anastomosis (classic B-T shunt), or an interposition PTFE graft between the systemic and pulmonary artery. In the modern era, PTFE shunts are used much more commonly than classic B-T shunts, and a median sternotomy approach has commonly been used. However, variation in preferred shunt technique still exists, and older patients may be encountered with shunts placed using techniques rarely used today.

In many centers, median sternotomy has replaced lateral thoracotomy for primary systemic–pulmonary arterial shunts in neonates. Generally, a PTFE tube graft is used, connecting the brachiocephalic artery or brachiocephalic-subclavian junction to a pulmonary artery. In patients with a left aortic arch, the shunt is placed on the right side; with a right arch, it is on the left. At complete repair, access to the shunt is much better than that for all other types of shunts, with the graft positioned intrapericardially and centrally. Right-sided shunts are positioned medial to the superior vena cava and apposed to the lateral aspect of the ascending aorta, and on the left, just leftward of the ascending aorta. The shunt can be dissected prior to institution of CPB in most cases, the only exception being deeply cyanotic patients with a very small shunt. Interruption of the shunt is accomplished as CPB is initiated by placing appropriately sized hemostasis clips securely across the tube graft at the systemic and pulmonary ends. The graft is divided.

Median sternotomy in an older patient with TF and a classic B-T shunt is usually accompanied by profuse bleeding from arteries in front of and behind the sternum that have developed as part of the collateralization that follows subclavian artery ligation. While this bleeding is being controlled, rapid volume replacement should not be made with banked blood. This is because this low-calcium-content and low-pH blood passes directly across the VSD into the aorta and coronary arteries. If this cold, unmodified banked blood is infused rapidly, the heart may slow and even develop asystole. Warmed calcium-enriched blood may be used.

Left thoracotomy has often been used for shunt placement in neonates or small infants with a left aortic arch. Typically, a left PTFE tube graft has been used between the left subclavian artery and LPA. In part this was motivated by the ease with which it can be closed during repair. After sternotomy is performed, hemostasis secured, and sternal retractor inserted, and when the patient’s condition is good, initial dissection is made. Because the graft lies deeply in the left chest, the approach is not beneath the thymus gland but over it, directly into the left pleural space. The few adhesions between the mediastinal pleura and lung are divided with the electrocautery. The PTFE tube graft is somewhat rigid and easily palpated. A small incision is made directly over it and carried down to it. At times a plane of dissection between the graft wall and surrounding tissue is easily established; if so, this dissection is carried out. Otherwise, the pericardium is opened and CPB established. The lungs are collapsed, and a plane of dissection is easily established around the graft. The shunt is clipped at each end and divided. Remainder of the operation is carried out as usual.

When a classic right B-T shunt is present in a patient with a left aortic arch, the pericardium is opened, and as the assistant elevates and retracts the ascending aorta to the left, the RPA is visualized coming from beneath the aorta. The superior vena cava is dissected off it and gently retracted rightward (in a few cases, exposure of the subclavian artery may be easier with the superior vena cava retracted to the left). Possible distortions of the RPA by the shunt are known from preoperative imaging studies, and these are kept in mind as dissection proceeds. Course of the right subclavian artery coming down to the RPA usually can be suspected from observation and palpation of a continuous thrill. The entire circumference of the subclavian artery may be freed along a short length by sharp dissection well superior to the anastomosis, and two heavy ligatures placed loosely around it. The artery is then temporarily occluded, and if vessel identification has been correct, the continuous thrill disappears, systolic and diastolic systemic arterial pressures increase, and pulse

---

**Figure 38-38** Repair of left pulmonary artery (LPA) stenosis in tetralogy of Fallot using two-patch technique. A, Typical right ventricular (RV) outflow tract hypoplasia and LPA stenosis present at ductus arteriosus or ligamentum arteriosum. B, Separate RV outflow tract patches and LPA patches are placed using a running monofilament suturing technique. This technique is useful when the angle of take-off of the LPA makes a single patch difficult to position correctly. Key: PA, Pulmonary artery; RPA, right pulmonary artery.
pressure narrows. If these things do not occur, the RPA has been misidentified as the subclavian artery or the shunt is small. The heart is cannulated, CPB is begun, ligatures around the subclavian artery are tied, and the operation proceeds as usual. An alternative preferred method is closure with hemostasis clips, in which case temporary ligatures are not placed.

When a classic left B-T shunt is present in a patient with a left or right aortic arch, the subclavian artery is approached from outside the pericardium. For this, the upper left pericardial stay sutures are placed on strong traction to the patient’s right. Level of the LPA is noted before this maneuver; just cephalad (superior) to this level, the thymus gland and left phrenic nerve are dissected from the pericardium, sharply and over a limited area, because excessive dissection in this region can result in major bleeding that is difficult to control. A narrow retractor is slipped under the thymus, and the region of the subclavian artery is located by gentle palpation and sharp dissection beneath the thymus gland. The subclavian artery is dissected out as described for the right side, and the same tests are made for accuracy of identification. Operation then proceeds as described earlier.

If the left subclavian artery cannot be located by going over the thymus gland and phrenic nerve, an alternative method is used in patients with a right aortic arch. The brachiocephalic artery is identified beneath the brachiocephalic vein and traced distally to the point at which it bifurcates into left subclavian and left common carotid arteries. After identifying the left subclavian artery positively by the maneuvers described and by the fact that the anesthesiologist can feel the left common carotid (or left superficial temporal) pulse when the vessel is temporarily occluded, the operation proceeds as described.

**Repair of Tetralogy of Fallot after Waterston and Potts Shunts**

These shunts are of historical interest only; they are not used in current practice. In previous years, occasional older patients were seen for evaluation and repair who received the shunt many years before. Nearly all such patients have been repaired or have died; thus, it is rare to encounter such a patient currently. TF repair after Waterston or Potts can be performed using well-described techniques, including those in editions 1 through 3 of this book.

**Technique of Shunting Operations**

Fig. 38-39 is a composite illustration of various positions used for systemic–pulmonary arterial shunts for augmenting pulmonary blood flow. General anesthesia with endotracheal intubation and controlled ventilation is used. Monitoring with an intraarterial catheter placed in an artery that will not serve as the systemic source of the shunt is established. Reliable intravenous access is obtained, either centrally or peripherally. Continuous pulse oxymetry is utilized. Details of each type of shunt follow.

**Classic Right Blalock-Taussig Shunt**

This is the original shunt described; however, it is typically not the first choice in modern practice. This is because it has the disadvantages of both sacrificing direct circulation to the right arm and delivering unpredictable flow to the pulmonary arteries. The artery can vary in size initially and can dilate over time. It may have some advantage in extremely small infants.

With the patient in left lateral decubitus position, a right lateral thoracic incision is made (Fig. 38-40, A, inset). The thorax is entered through either the top of the bed of the nonresected fourth rib or the third interspace. A rib spreader is positioned and gradually opened (see Fig. 38-40, A).

The first step in dissection is to securely identify the right superior pulmonary vein as it courses obliquely downward (medially and inferiorly) toward the heart to pierce the pericardium posterior to the phrenic nerve. The vein partially overlies the RPA; however, the RPA, in contrast to the vein, follows a straight course medially. With the lung retracted toward the surgeon, the periarterial sheath over the RPA is incised. Usually the superior branch of the RPA is first freed, in the process of which the main RPA (lying in a slightly different plane of dissection) can be easily overlooked. To find it, the superior surface of the right superior pulmonary vein is cleared, and it and the superior vena cava are elevated (Fig. 38-40, A). Dissection is carried centrally until the proximal RPA is identified as a single vessel, proximal to its first branch. With lateral traction on a loop of heavy suture placed around it, the RPA is dissected in the periarterial tissue plane...
as far centrally as possible. The loop is then removed so that the RPA does not inadvertently become obstructed during the next phase of the operation.

The lung is packed off and retracted inferiorly. An incision is made in the mediastinal pleura over the azygos vein and carried superiorly to the top of the chest, parallel and posterior to the phrenic nerve. The azygos vein is divided between ligatures, and the soft tissue and right paratracheal lymph nodes are divided to provide a free pathway for the turned-down right subclavian artery. Any small veins overlying it are ligated and divided. Vagus and recurrent laryngeal nerves are identified, and the periarterial plane over the right subclavian artery is incised. By grasping only the adventitia of the often delicate subclavian artery, dissection is carried distally in the periarterial plane until the origins of internal thoracic and vertebral arteries are identified. These vessels are divided between ligatures, taking care that the proximal ligature is placed 1 to 2 mm away from the subclavian artery (Fig. 38-40, B). Anomalies in branching of the subclavian artery are frequent. The vagus nerve is gently retracted laterally, and
Chapter 38  Ventricular Septal Defect with Pulmonary Stenosis or Atresia

Figure 38-40, cont’d  C, Subclavian artery has been divided and appropriate occluding devices placed on RPA. Incision in RPA is made on its very superior aspect. D, Anastomosis is made using interrupted or continuous 7-0 polypropylene sutures, starting posteriorly from within vessels. Inset shows completion of anastomosis. Key: SVC, Superior vena cava.

the periarterial plane over the subclavian artery medially is opened and dissected. The subclavian artery is divided between ligatures placed beyond the first two large branches, and a right-angled clamp is passed beneath the vagus nerve from its medial aspect superior to the recurrent laryngeal nerve (Fig. 38-40, C). The subclavian artery beyond the ligature is grasped with the clamp and pulled out from under the vagus nerve. Holding the artery beyond the ligature, dissection is carried centrally in the periarterial plane until the distal portion of the brachiocephalic artery and nearly the entire right common carotid artery are liberated. As dissection proceeds, a small artery is occasionally found arising from the origin of the subclavian from the brachiocephalic artery; this must be ligated and divided. The only thing limiting the turned-down length of the subclavian artery is the common carotid artery. Any obstructing bands in the paratracheal soft tissue are divided so that there is nothing in the pathway of the relocated right subclavian artery.

A light, straight arterial clamp with a handle long enough to allow easy holding by the first assistant is placed across the subclavian artery about 8 mm proximal to the point of final transection. The artery is cut squarely across, just proximal to its first branch. (Rarely the first branch comes off very proximally and the subclavian artery is unusually large beyond it. In such instances, the artery can be transected beyond this branch.) Double-looped elastic ligatures are placed around the upper branch and distal main RPA, snugged, and weighted laterally with heavy Kocher clamps. An appropriate-sized Baumgartner clamp is placed across the very proximal RPA, with the surgeon passing a right-angled clamp beneath the artery for lateral retraction as the first assistant tightens the clamp. A longitudinal incision is made in the very superior surface of the RPA (so that when the occluding devices are removed, there will be no torsion of the RPA).

Anastomosis is made with continuous or interrupted double-armed 7-0 polypropylene or polyester sutures, the continuous suture placed from within the respective arteries posteriorly (Fig. 38-40, D). The first assistant holds the two clamps such that the vessels are in perfect apposition and without tension during the anastomosis. Before placing the last few sutures, the lumina are examined and any tiny thrombi or debris irrigated away. After completing the anastomosis,
in rather rapid succession the two doubly looped elastic ligatures are cut and removed, the clamp on the subclavian artery removed, and the proximal RPA clamp removed. Packing is placed lightly around the anastomosis, any unusual bleeding is controlled digitally, the lung is partially reexpanded, and 5 minutes are allowed to pass. During this time, a palpable continuous thrill should be present in the RPA. When the packs are removed, the field is usually dry. Rarely, an additional adventitial suture is needed.

A small chest catheter is brought out from the posterior gutter through about the seventh intercostal space and attached to gentle suction. The chest wall is closed and the lungs are well inflated before the ribs are brought together with absorbable suture. The wound is closed in layers with continuous fine polyglycolic acid sutures, and the skin approximated with a continuous subcuticular suture.

**Interposition Shunt between Left Subclavian and Left Pulmonary Artery**

This is a commonly performed procedure. It can be performed classically through a left thoracotomy or through a median sternotomy. The procedure performed through a thoracotomy is described.

Thoracotomy is as described for the classic B-T shunt, except on the left side. The LPA is identified and dissected out. The mediastinal pleura is opened over the left subclavian artery and contiguous portion of the aortic arch, and the periarterial sheath over these structures is opened. The subclavian artery is not mobilized.

The diameter of the graft is chosen based on the patient’s weight and other factors. In normal-sized neonates or in the case of a very small LPA, a 3.5- or 4-mm PTFE tube graft is used, despite a possible small reduction in patency (see “Size” under Special Situations and Controversies, Systemic–Pulmonary Arterial Shunt, in Section II of Chapter 41 for discussion of criteria for selecting size of the PTFE tube graft). Before any occluding devices are placed, the proper length of the tube graft is determined. For this, the lung is partially inflated to bring the LPA into its usual position. When the anastomosis is completed, the graft should lie without tension and without redundancy (and thus potential kinking) between the proximal half of the subclavian artery and the superior surface of the LPA. The end of the graft that will be anastomosed to the subclavian artery is beveled (Fig. 38-41), the graft is placed in a temporary position, and the other end is cut square at the point that will make the length to the LPA correct.

A delicate side-biting clamp is placed deeply on the subclavian artery so that its handle lies inferiorly and the clamp occludes the artery both proximally and distally. A longitudinal incision is made in the excluded portion of the delicate subclavian artery, and an adventitial stay suture is placed on the anterior lip. The proximal anastomosis is made with a continuous 6-0 or 7-0 polypropylene suture. The clamp on the subclavian artery is not loosened or removed at this time (see variation in detail under “Systemic–Pulmonary Arterial Shunt” under Technique of Operation in Section II of Chapter 41). Elastic ligatures are looped twice around the upper branch and main LPA and snugged, and heavy Kocher clamps are placed on each for lateral traction. A C-shaped clamp is placed very proximally on the LPA, taking care not to compromise the ductus arteriosus. A longitudinal incision is made in the superior surface of the LPA, making this a little shorter than half the circumference of the PTFE tube graft. The distal anastomosis is made with continuous 6-0 or 7-0 polypropylene suture.

In quick succession, the doubly looped ligatures are cut and removed, the clamp on the subclavian artery is opened and carefully removed from the field, and the LPA clamp is opened and removed. A light pack is placed about each anastomosis, with light digital pressure if needed. A continuous thrill should be present in the LPA. Other evidences of patency include registration of an immediate increase in oxygen saturation (pulse oximeter) and an immediate increase in systolic and diastolic blood pressure when the shunt is briefly occluded with forceps. Five minutes are allowed to pass.

Remainder of the procedure is completed as described for the classic B-T shunt.

The interposition operation as an isolated procedure in patients with left aortic arch can be performed through a right thoracotomy. The PTFE tube graft is anastomosed proximally to the junction of the right subclavian and brachiocephalic arteries, which is in the cupola of the chest. This operation is more difficult than that on the left side. In comparison with the classic B-T anastomosis, the PTFE interposition shunt is a more reliable resistor and is easier to close later.

**Right-Sided Interposition Shunt Through Median Sternotomy**

The preferred systemic–pulmonary arterial shunt in neonates with left aortic arch is a right PTFE interposition shunt performed through a median sternotomy (Fig. 38-42, A). After sternotomy, most of the thymus gland is removed. The pericardium is opened in its superior portion and stay sutures applied. The posterior pericardium is opened over the RPA between the ascending aorta and superior vena cava. A small, fine side-biting (C-shaped) clamp is used to isolate the junction between the brachiocephalic and right subclavian arteries. A longitudinal incision is made, and the end of a beveled 3.5- or 4-mm PTFE tube is anastomosed to the incision (Fig. 38-42, B). A small, fine side-biting clamp is placed on the RPA as it is elevated with fine forceps; the clamp isolates the full width of the RPA. The other end of the PTFE tube graft is anastomosed to this opening (Fig. 38-42, C). Continuous 6-0 or 7-0 polypropylene on a cutting needle is used for both anastomoses. The clamps are removed sequentially, the RPA clamp first. After hemostasis is secured, the pericardium is loosely closed. The remainder of the sternotomy is closed in the usual manner. Although this technique has been used primarily in neonates, it is applicable to infants.

In patients with a right aortic arch, a left-sided PTFE interposition shunt from the left subclavian–brachiocephalic junction to the LPA is preferred. Details of the technique are the same as described for the right-sided shunt.

**Classic Left Blalock-Taussig Shunt (in Patients with Right Aortic Arch)**

Left thoracotomy incision and dissection of the LPA are as described in the preceding text. The left subclavian artery is dissected in the cupula of the chest, and maneuvers for freeing it, bringing it beneath the vagus nerve, and preparing it for anastomosis are those described for the right side (see Fig. 38-40). Occluding devices are placed, the anastomosis performed in the manner already described, and the operation
completed as described. This procedure has the same disadvantages as the right classic B-T shunt.

**Right-Sided Interposition Shunt (in Patients with Right Aortic Arch)**

This procedure in patients with right aortic arch proceeds exactly as the procedure on the left side in patients with left aortic arch (see Fig. 38-41).

**SPECIAL FEATURES OF POSTOPERATIVE CARE**

**Repair**

Management is by the general measures described in Chapter 5. Patients with TF have a particular tendency to increase their interstitial, pleural, and peritoneal fluids early postoperatively. Like other deeply cyanotic individuals, they probably have abnormal systemic and pulmonary capillary membranes, and this may make them particularly sensitive to the damaging effects of CPB (see “Response Variables” in Section II of Chapter 2). Therefore, particular care is taken lest loss of intravascular plasma to extravascular spaces produces undesirable hemoconcentration early postoperatively, and attention is given to the possible development of pleural and peritoneal fluid collections. If these develop, they should be aspirated.

Evaluation is complicated by the fact that in patients convalescing normally after repair of TF, with warm feet and good pedal pulses, arterial blood pressure tends to be as much as 10% lower than that in patients who are acyanotic.
Figure 38-42 Right-sided interposition shunt performed through median sternotomy using a 3.5-, 4-, or 5-mm thin-walled polytetrafluoroethylene (PTFE) tube graft. A, Aorta and superior vena cava are mobilized enough to expose right pulmonary artery (RPA). Brachiocephalic vein is elevated and right subclavian, right carotid, and brachiocephalic arteries are mobilized. Proposed incisions (indicated by dashed lines) are at cephalad aspect of RPA and junction of brachiocephalic and subclavian arteries. B, PTFE tube graft is cut on a bias and sutured to brachiocephalic–subclavian artery junction using continuous 6-0 or 7-0 polypropylene suture, beginning the anastomotic suture from within PTFE tube graft and systemic arteries. C, Shunt is completed after transecting PTFE tube graft squarely and using a suture technique similar to that for the systemic arterial anastomosis. Although not shown, subclavian artery clamp remains in place until RPA anastomosis is completed. Key: SVC, Superior vena cava.

Preoperatively, cardiac index is usually normal for this stage of convalescence, and tendency to hypotension is related to relatively low systemic vascular resistance. In the presence of other signs of normal convalescence, treatment of arterial blood pressure is not indicated.

The hemodynamic state is assessed continuously and management constantly reviewed to be certain of its appropriateness. Measurement of cardiac output is helpful, along with other determinants of adequacy of cardiovascular subsystem function (see “Cardiovascular Subsystem” in Section I of Chapter 5). An important right-to-left or left-to-right shunt must be identified, either by the indicator dilution method (see “Risk Factors for Low Cardiac Output” under Cardiovascular Subsystem in Section I of Chapter 5) or by 2D echocardiography with Doppler color flow interrogation. This is particularly important in neonates and infants, in whom the foramen ovale may have been left open for early postoperative decompression of the right atrium. Arterial desaturation is then the rule in the early hours after operation, and demonstrating right-to-left shunting at atrial level by echocardiography using color Doppler reassures that desaturation is not from pulmonary dysfunction (Fig. 38-43). Desaturation from right-to-left shunting usually decreases within 48 hours as RV function improves.

In the absence of shunting, values of left (PLA) and right (PRA) atrial pressures provide considerable insight into the relative function of the two ventricles. After repair of TF, these are usually similar, but one may be 2 to 4 mmHg higher than the other. Rarely, PLA is 5 to 10 mmHg higher than PRA. When this occurs, a residual left-to-right shunt at ventricular or great artery level must be sought and, if found, promptly closed by reoperation. Even relatively small postoperative residual left-to-right shunts may not be well tolerated in repaired TF patients. An important reason for this is that preoperative physiology in TF is that of a volume-underloaded heart, rather than the volume-overloaded preoperative physiology of lesions that tolerate postoperative small residual left-to-right shunts quite well, such as VSDs, atrioventricular septal defects, or truncus arteriosus. If no shunt is found, elevated PLA indicates LV hypoplasia or severe impairment of
LV systolic or diastolic function, and an inotropic agent and afterload reduction are indicated.

Rarely, PRA is 5 to 10 mmHg higher than PLA, indicating important volume or pressure overload of the RV or severe impairment of RV function. This situation is precarious and requires intense treatment, especially when postrepair \( \frac{P_{RV/LV}}{P_{LV}} \) is greater than about 0.7 (Fig. 38-44). If a transanular patch was not used, generally the patient should promptly be returned to the operating room and a patch placed. If a transanular patch is in place, as complete a repair as possible was obtained, and the patient’s condition is reasonably good on only modest catecholamine support (e.g., 5 \( \mu \)g · kg\(^{-1} \) · min\(^{-1} \) of dopamine or dobutamine), then delay for a few hours is reasonable. If no improvement occurs, and particularly if postrepair \( \frac{P_{RV/LV}}{P_{LV}} \) is 0.8 or greater, risk of death approaches 50% and intervention is indicated. In neonates and young infants, \( \frac{P_{RV/LV}}{P_{LV}} \) may not be as useful as in older patients. Anesthetized postoperative neonates may have low systemic vascular resistance and thus low systemic systolic blood pressure despite excellent cardiac output. In this setting, a relatively normal RV and pulmonary artery pressure may result in a \( \frac{P_{RV/LV}}{P_{LV}} \) as high as 0.8 or 0.9. Under these circumstances, the absolute \( P_{RV} \) should be carefully evaluated. Systolic \( P_{RV} \) over 50 mmHg should be investigated routinely, and that between 40 and 50 mmHg considered for investigation. Regardless of the patient’s age, investigation, when indicated, is the same. A right ventriculogram and determination of site of the gradient by cardiac catheterization is performed. If an appreciable gradient is found in the RV or at the pulmonary “anulus,” or a localized important uncorrected LPA or RPA origin or bifurcation stenosis is found, correction of these areas of residual stenosis at prompt reoperation is indicated.

However, if the original repair was complete, it is likely that none of these will be found. Instead, the gradient will be located at the distal transanular patch suture line. This circumstance is uncommon (1%-2% of patients), limited almost entirely to patients with severe hypoplasia of the “anulus” and pulmonary trunk. In that setting, and particularly without a distal widening (in the distal pulmonary trunk or LPA) into which the transanular patch can be extended, it may be impossible to make a geometrically proper patch.\(^{20,310}\) If evaluation reveals that hypoplasia or discrete stenosis is present in the branch pulmonary arteries with normal distal pulmonary arterial development, then further patch augmentation of the pulmonary arteries is indicated. If the pulmonary artery hypoplasia is diffuse, a large perforation is made in the VSD, preventing the \( P_{RV} \) from becoming suprasystemic, and augmenting systemic output from right-to-left shunting across the VSD.

Particular attention is paid to the possible need for reoperation for bleeding. Preoperative polycythemia and depletion of many clotting factors, extensive collateral circulation, and damaging effects of CPB often combine to produce a considerable bleeding tendency. Intense treatment, particularly with platelet-rich plasma, is indicated. The usual criteria for reoperation are followed (see “Bleeding” in Section II of Chapter 5), and prompt reoperation is advised as soon as they are violated. This practice was one factor contributing to the considerable reduction in risk of operation in the early 1960s. Currently, with careful intraoperative hemostasis and definitive repair at a young age, reoperation for bleeding is rarely necessary.

After the patient leaves the ICU, body weight is followed closely because transient fluid retention is common, particularly when a transanular patch has been used. Pharmacologic management of right-sided heart failure is indicated.

**Systemic–Pulmonary Arterial Shunting**

In neonates and young infants, careful intraoperative and postoperative monitoring and control of \( P_{\text{O}_2} \), pH, and

buffer base are required (see “Neonates and Infants” in Section II of Chapter 5). The usual intense postoperative care and protocols are applied (see Chapter 5). An intraarterial catheter is used to monitor blood pressure, paying careful attention to the systolic/diastolic difference and absolute diastolic pressure. The patient is returned to the ICU ventilated through an endotracheal tube. A chest radiograph is obtained immediately. Ventilation is controlled postoperatively for at least several hours and up to a full day, until stable hemodynamics and confirmation of balanced systemic-pulmonary blood flow is assured. A combination of $\text{SaO}_2$, diastolic blood pressure and pulse pressure, and various signs that reflect systemic cardiac output are used to estimate the systemic-pulmonary blood flow balance. Assuming normal hematocrit and pulmonary gas exchange, an $\text{SaO}_2$ of about 80% usually reflects well-balanced systemic and pulmonary blood flow. Diastolic blood pressure ideally should be above 30 mmHg. Major diversions from these levels usually indicate an imbalance of systemic-pulmonary blood flow. A repeat chest radiograph should be performed to confirm that a pulmonary parenchymal process, and thus gas exchange, is not responsible. If this is ruled out, intravascular volume, pharmacologic (inotropes), and ventilator manipulation should be initiated to restabilize the balance of flow.

Maintaining an adequate cardiac output and blood pressure is an important factor in assuring shunt patency in the vulnerable period of the first 48 hours after surgery. Some centers use a heparin drip as an additional measure. Additionally, or alternatively, aspirin at 10 mg · kg$^{-1}$ daily may be started and continued for the life of the shunt.

Infrequently, mild renal failure, and rarely, acute renal failure and anuria, develop after a simple shunting procedure. This is related to the renal pathology sometimes present in cyanotic patients with TF and to renal damage by radiopaque dye that may have been used for the cineangiogram a few hours or days before operation. Therefore, urine flow is carefully observed postoperatively.

A surgically created shunt must function. Therefore, auscultation is used to assess its patency during the entire postoperative hospitalization. If doubt develops concerning shunt function, immediate 2D echocardiography, cineangiographic study, or both are indicated. If it is poorly functioning, prompt reoperation is indicated. In older patients with large acquired systemic-to-pulmonary artery collaterals, a continuous murmur is present preoperatively, and therefore simple auscultation is not as useful early postoperatively. In this setting, if cyanosis has not improved, echocardiography and/or cineangiography is indicated.

**RESULTS**

**Survival**

**Early (Hospital) Death**

Although hospital mortality in a few series of heterogeneous groups of patients has been 1% or less, in most series it varies between 2% and 5% (see Section II of Chapter 5). TF repair in patients 90 days of age or younger at 32 centers participating in the Society of Thoracic Surgeons congenital heart database over a 3-year period from 2002 to 2005 was associated with a mortality of 6.1% (CL 3.6%-9.6%). In the same centers, mortality for shunt palliation was 8.3% (CL 5.4%-12%).

Because the early rapidly declining phase of hazard does not flatten out until 3 to 6 months after operation (Fig. 38-46), hospital or 30-day mortality underestimates the risk of death early after repair.

**Time-Related Survival and the Question of “Cure”**

In considering survival after surgical repair, it must be recalled that deaths occurring before repair are not represented. Thus, an institution that delays repair until some specified age may have a few patients who, whether shunted or not, die before repair, whereas an institution that has a policy of one-stage repair in all symptomatic patients, no matter how young, may have an apparently higher mortality while actually saving more lives. Vobecky of Toronto’s Hospital for Sick Children examined this issue in 270 TF patients younger than age 18 months. A few deaths occurred before palliation, between palliation and repair, and after repair (Table 38-4). Major noncardiac anomalies may preclude repair, and major associated malformations may increase operative risk at any age. At present, the data show nearly equal time-related survival for one-stage repair performed at any age and staged operation.

In one analysis, time-related survival after repair in heterogeneous groups of patients at 1 month and 1, 5, 10, and 20 years was about 94%, 92%, 91%, 90%, and 87%, respectively (Fig. 38-47). Patient-specific survivals and those of homogeneous groups of patients vary, with 10- and 20-year values as high as 97% in some circumstances (Fig. 38-48). In another analysis, overall time-related survival was 80% at 40 years. In that study, predicted 40-year survival for patients repaired in the latter part of the experience (operation performed in the year 1985) was 88%.

“Is the patient cured of TF?” This is a critical question that must be examined not only for the entire heterogeneous population of patients undergoing repair but also for specific patients, taking into account the strength and time-relatedness of their various risk factors. For operation to be curative, the hazard function for death after the early postoperative period (3-6 months) must be no greater than that for an age-sex-race-matched general population and have no late increase

*Fourteen deaths occurred before repair (5.9%; CL 4.3%-7.9%).

Figure 38-46  Hazard function for death after repair of tetralogy of Fallot (TF) with pulmonary stenosis from two different studies. In both, the rapidly declining early phase of hazard does not flatten appreciably until 3 to 6 months after repair. A, Hazard function from UAB study (1967 to May 1986; n = 814) with follow-up over 15 years. There is a constant phase of hazard extending for as long as patients were followed. B, Hazard function from combined Boston Children’s Hospital–UAB study (September 1984 to 1989; n = 176), which has no late constant phase.220 Thus, the hazard function at 5 years, and presumably for a considerable period beyond, is the same as that of a matched general population (barely visible as dash-dot-dash line). (From Kirklin and colleagues.220)

Figure 38-47  Survival after repair of tetralogy of Fallot with pulmonary stenosis in the two heterogeneous groups of patients whose hazard functions are depicted in Fig. 38-46. Each circle represents a death estimated by the Kaplan-Meier method. Vertical bars represent 70% confidence limits (CL) of these estimates. Solid line represents parametric estimate of survival, and dashed lines enclose its 70% CLs. Dash-dot-dash line represents survival of an age-sex-race–matched general population. A, Survival after repair in UAB study (1967 to May 1986; n = 814). B, Survival after repair in combined Boston Children’s Hospital–UAB study (September 1984 to 1989; n = 176). (From Kirklin and colleagues.220)
Hospital–UAB data set, most of whom underwent primary (one-stage) repair, is behaving as if the constant hazard phase will be closer to that of a matched general population when they have been followed long enough for this to be identified. The Boston-UAB long-term data suggest that a late rise in the hazard function will not occur within the first 20 to 30 postoperative years (see Fig. 38-46).69,K20

Thus, the inference is that time-related survival of most patients after repair of TF with pulmonary stenosis under proper circumstances is excellent, approaching that of the general population, but that the risk of death throughout life is slightly greater than that of the general population.

Modes of Death

Considering death with multiple subsystem failure to be basically death in subacute heart failure, only half the patients who died in hospital after repair in the combined Boston Children’s Hospital–UAB study died this way. Pulmonary failure, hypermetabolic state, and catastrophic surgical or early postoperative events account for the remainder, a higher percentage than after most kinds of cardiac surgery in adults.275 Pathologic basis of the pulmonary failure has been described by Harms and colleagues,116 who found in their autopsy studies that extensive alveolar and interstitial edema and hemorrhage are characteristic of the lungs of patients dying early after repair of TF. This process is probably caused by the damaging effects of CPB (see Chapter 2),116,K18 to which severely cyanotic and polycythemic patients seem particularly sensitive. Thus, further improvement in results of repair may demand not only improved myocardial management but also lessening of the damaging effects of CPB and improved technical efficiency in the operating room and ICU when repair is being done in very small patients.

Incremental Risk Factors for Death

Incremental risk factors for death early and late after repair have been identified from a number of studies. A typical analysis from a single institution, identifying early hazard phase and late hazard phase risks, is shown in Table 38-5. There are a number of difficulties in definitively identifying risk factors for early death. These difficulties are that some variables were available for one analysis and not for another, that the risk factors may be different if procedural as well as patient characteristics are considered, and that some simultaneously determined “independent” risk factors are highly correlated and thus may be surrogates for one another (see “Variable Selection” in Section IV of Chapter 6). One of the most important difficulties is that in the current era, early mortality is so low that identifying risk factors for that phase is not possible.

Young Age at Repair

Young age at repair2 has been identified as a risk factor for death early after repair.19,C19,C22,M12,P20,W16 There are, however, two important qualifications that accompany this observation. First, young age is not necessarily an immutable risk factor, because the age at which risk increases appreciably has been progressively reduced as experience and knowledge have grown. This improvement is illustrated by the UAB experience, in which risk of hospital death and predicted 20-year survival after repair in a 6-month-old infant improved considerably between 1967 and 1986 (Fig. 38-49). The

Data from Hickey and colleagues.774 Reliability represents the percentage reliability of the P value as determined by percentage of bootstrap resamples for which the variable is included in the parametric model (inclusion threshold P < .1). Key: RV-PT, Right ventricular-pulmonary trunk.
incremental risk of young age in general is currently unapparent until age is younger than 3 months, and in some circumstances younger than 1 month (Fig. 38-50). Second, studies examining young age as a risk factor for early death have the inherent bias that only symptomatic patients were repaired in the neonatal period or early infancy. Because symptoms correlate with less favorable morphology of the RV outflow tract in patients with TF, it follows that patients who underwent repair at a very early age uniformly had less favorable morphology. Thus, there were no patients who underwent very early repair in these series with favorable morphology (asymptomatic). Even with multivariable analysis, it is difficult to overcome this bias.

Reduction of the age at which risk is increased is due in part to increasing technical expertise in intracardiac surgery and early postoperative care in the very young. Further improvements in these areas may completely neutralize the increased risk of young age. Control of the damaging effects of CPB (see Chapter 2) and improvement in the function of the heart early postoperatively, brought about by more effective intraoperative myocardial management, will assist in this effort.

Older Age at Repair
Older age has been identified as a risk factor for death early and late after repair (see Table 38-5). Its effect on survival late after repair is probably truly immutable (Fig. 38-51). This is because the bases of the incremental risk of older age lie in the adverse, and to a considerable extent irreversible, effect of long-standing RV hypertension, cyanosis, and polycythemia on cardiac structure and function. It is in part to prevent these irreversible changes that repair is advisable early in life. A contraindication to early repair may be presence of an anomalous LAD from the RCA. Relative contraindications include complex pulmonary artery anatomy or very small pulmonary arteries. However, independent reports from Reddy, Stellin, Sousa-Uva, Starnes, and Groh and their colleagues document excellent results when early one-stage repair is applied routinely in neonates and infants.

Severity of Right Ventricle–Pulmonary Trunk Junction Hypoplasia
Severe hypoplasia of the RV–pulmonary trunk junction (“anulus”) has been identified as a risk factor for death, at least early after repair (see Fig. 38-50). This may be related in part to the need for a transanular patch when the hypoplasia is severe, and to the correlation between severity of anular hypoplasia and postrepair \( P_{RV/LV} \), even when a transanular patch is used and particularly when there is coexisting hypoplasia of the distal pulmonary trunk (see “Decision and Technique for Transanular Patching” earlier in this section). Thus, severity of anular hypoplasia, use of a transanular patch, and postrepair \( P_{RV/LV} \) are all surrogates for one another in a complex manner that is difficult to quantify (Fig. 38-52).

Small Size of Right and Left Pulmonary Arteries
Important localized or diffuse hypoplasia of the RPA and LPA is uncommon in patients having TF with pulmonary

Figure 38-49 Nomograms illustrating decreasing strength across year of operation of the incremental risk of young age on early and late survival after repair of tetralogy of Fallot with pulmonary stenosis. (Nomogram is specific solution of multivariable risk factor equation from Kirklin and colleagues. Values entered for other variables in equation are in Appendix 38A). A, Predicted 30-day mortality. B, Predicted 20-year survival, including early deaths.

Figure 38-50 Nomogram illustrating incremental risk of young age and of dimension of pulmonary “anulus” on early survival after repair of tetralogy of Fallot with pulmonary stenosis in recent era. Note that effect of young age is stronger and more evident in patients with a very small “anulus” (\( z \) value of –8) than in the others, reflecting the usual incremental effect of one risk factor on another. (From Kirklin and colleagues.)
Transanular patching was not a risk factor late postoperatively in earlier UAB and Mayo Clinic patients. However, the increased chance of needing later reoperation and its attendant risk suggest that in a sufficiently large and well-matched comparison, use of a transanular patch may have a late increased risk. The adverse effect of transanular patching, as noted in earlier studies, is well tolerated acutely and chronically out to about 20 years by the previously hypertrophied RV. However, the natural history of patients with isolated congenital pulmonary valvar regurgitation suggests that by about 40 years after repair, RV dysfunction will have developed in some and could lead to premature death.

**Postrepair \( P_{RV/LV} \)**

Important residual pulmonary stenosis after repair, expressed as postrepair \( P_{RV/LV} \), has been identified as a risk factor for premature death early and late after operation. This is true of postrepair (OR)
P_{RV/LV}, but the ratio as measured in the ICU about 24 hours after operation is a more powerful and precise predictor (see Fig. 38-44). The interaction of young age (or small patient size), small anulus, transanular patching, and postrepair P_{RV/LV} is apparent from these same studies.\textsuperscript{16,20} Although identified as a risk factor, postrepair P_{RV/LV} is inversely correlated with size of the pulmonary valve “anulus” and of the distal pulmonary trunk.

Previous Palliative Operations
A single previously performed classic shunting operation is not a risk factor for death after repair, but more than one palliative operation has been shown to be.\textsuperscript{16} When a pulmonary artery has been importantly distorted by a shunting operation, an unusual occurrence under proper circumstances, risks of repair are increased.

Multiple Ventricular Septal Defects
Multiple VSDs are present in only 1% to 3% of patients having TF with pulmonary stenosis, but they have been identified as a strong risk factor for death in the early hazard phase, as evident in Fig. 38-53.\textsuperscript{20}

Coexisting Related Cardiac Anomalies
Coexisting complete atrioventricular septal defect complicates repair of TF with pulmonary stenosis, and a composite review of outcomes from 50 individual studies reported over a 40-year period imply higher surgical mortality than for simple TF (Table 38-6).\textsuperscript{15} Although mortality improved in the 1990s compared with prior years, it has not improved further and remains substantial. Nevertheless, mortality varied from study to study in this review, with some reports showing only a small incremental risk.\textsuperscript{2}

In one study, Down syndrome, rather than the atrioventricular septal defect itself, appeared to be the incremental risk factor (Table 38-7).\textsuperscript{20}

Historically, large AP collateral arteries were risk factors for death early after repair of TF with pulmonary stenosis.

Data from Kirklin and colleagues.\textsuperscript{20}

Key: AV, Atrioventricular; CL, 70% confidence limits.

However, this may have been due to the greater frequency of important RPA and LPA hypoplasia in such patients, and of discontinuity between the pulmonary trunk and RPA or LPA.\textsuperscript{20} It is likely that early risk associated with AP collaterals has largely been neutralized, because current surgical mortality for patients with AP collateral arteries and TF with pulmonary atresia is now as low as 2%.\textsuperscript{56}

### Other Risk Factors
Although high hematocrit was frequently observed in an earlier era of delayed surgery, it is uncommon today; when seen, it may be a strong risk factor.\textsuperscript{11,17}

Graham and colleagues proposed that small LV end-diastolic volume (<55% of normal for age) is an important risk factor for early death after repair.\textsuperscript{26} Nomoto and colleagues also reported that small LV volume is a risk factor, with a demonstrable increase in risk when preoperative LV end-diastolic volume is less than about 65% of normal.\textsuperscript{10} Oberhansli and Friedli reported similar findings.\textsuperscript{91}

### Heart Block
Complete heart block is uncommon after repair. It occurred in 7 of 814 patients (0.9%; CL 0.5%-1.3%) from 1967 to May 1986 at UAB, and in 0.6% (CL 0.1%-1.9%) of patients from September 1984 to 1989.\textsuperscript{16,20} Right bundle branch block...
Figure 38-54  New York Heart Association (NYHA) functional class after repair of tetralogy of Fallot with pulmonary stenosis, according to interval between operation and last follow-up. Numbers in parentheses along horizontal axis represent number of patients available for functional class categorization at the odd-numbered interval below which number is positioned. Squares represent proportion of patients in functional class I at each interval; circles, those in class II; and triangles, those in class III. Solid line represents slope of solution of ordinal logistic (longitudinal) regression analysis, although the P value of .2 for the difference from zero slope indicates that change across time in the distribution of patients according to their NYHA functional class could be due to chance alone. (From Kirklin and colleagues.\textsuperscript{19})

Junctional Ectopic Tachycardia

Junctional ectopic tachycardia occurs infrequently after repair of TF. Survival depends on aggressive treatment in the ICU with moderate core cooling and amiodarone (see “Atrial Arrhythmias” in Section I of Chapter 5).\textsuperscript{39} Thereafter, there is probably little risk of complete heart block. Repair by way of the right atrial–pulmonary artery approach may carry a higher risk of junctional ectopic tachycardia; however, there are no firm data to support this.

Functional Status

About 98\% of patients are considered by themselves or their parents to be in New York Heart Association (NYHA) functional class I after repair.\textsuperscript{12,27} Most importantly, this proportion has not declined over time, at least to 20 years (Fig. 38-54).

Some asymptomatic patients have reduced exercise capacity,\textsuperscript{29,89} some have normal functioning capacity as judged by quantitative testing (Table 38-8), and some have the capacity of a trained athlete.\textsuperscript{89} Some patients with normal response to exercise testing have other abnormalities, such as limitation in chronotropic response to exercise.\textsuperscript{12}

Risk factors for impaired exercise tolerance have been identified, and these include older age at repair. Repair in the first 5 years of life results in a normal response to objective exercise testing.\textsuperscript{11,36,12} Patients averaging 12 years of age at operation have subnormal exercise capacity late postoperatively.\textsuperscript{11} Residual RV hypertension, expressed as P\textsubscript{RV}, P\textsubscript{RV/LV}, or RV-to–pulmonary artery gradient, adversely affects functional status late after complete repair.\textsuperscript{39,14,99} Wessel and colleagues suggest that in the absence of other problems, P\textsubscript{RV} greater than 50 mmHg (corresponding roughly to P\textsubscript{RV/LV} > 0.7) is likely to exert this effect (Table 38-9), although P\textsubscript{RV} greater than 70 mmHg may be a more realistic number (indeed, the relation is likely continuous but nonlinear).\textsuperscript{99} Pulmonary valve regurgitation after repair in reduced exercise capacity regardless of RV systolic pressure.\textsuperscript{14,12,12,33,77,99} Consistent with this is the tendency of patients with transanular patches to have larger cardiothoracic ratios and RV volumes\textsuperscript{82} late postoperatively. In patients who have undergone repair without insertion of a valve for TF with absent pulmonary valve (Section III),

Data from Wessel and colleagues.\textsuperscript{99} Key: P\textsubscript{RV}, Right ventricular pressure; SD, standard deviation. \textsuperscript{a}Exclusive of patients with residual ventricular septal defects.
When the pulmonary valve is regurgitant, RV systolic function and end-diastolic volume are less likely to be normal, and their abnormality correlates with amount of regurgitation. When a transanular patch has been used in the repair, ejection fraction is more likely to be low, and RV end-diastolic volume is increased, often severely so. 

Increased RV wall thickness and consequently decreased ventricular compliance may limit volume expansion and RV enlargement. Reduced compliance may also protect against detrimental effects of pulmonary regurgitation. 

When repair is made at a still older age, the functional result is clearly worse than when it is performed in infancy or early childhood.

Pulmonary regurgitation has its most evident effect on RV function. When a transanular patch has not been used and the pulmonary valve is competent, RV systolic function (ejection fraction) and end-diastolic volume may be normal late postoperatively. Furthermore, large residual or recurrent VSDs (Qp/Qs > 2) strongly predispose the patient to chronic heart failure late postoperatively. 

Maximal oxygen uptake during exercise is only 30% to 40% of normal in patients corrected at an average age of 19.5 years. When repair is made at a still older age, the functional result is clearly worse than when it is performed in infancy or early childhood.

Figure 38-55 Results of serial exercise testing (work capacity above, exercise duration below, expressed as percentage of predicted value for age) after repair of tetralogy of Fallot with absent pulmonary valve. Intracardiac repair was performed without a valve in this patient at age 8.45 years, and exercise and work capacity steadily decreased. An allograft pulmonary valve was inserted when the patient was 19 years old, with subsequent improvement in performance. Key: APV, Allograft pulmonary valve; Ex, Exercise; ICR, intracardiac repair; Pred, predicted; W, work. (From Ilbawi and colleagues.)

Pulmonary regurgitation has its most evident effect on RV function. When a transanular patch has not been used and the pulmonary valve is competent, RV systolic function (ejection fraction) and end-diastolic volume may be normal late postoperatively. However, even in this circumstance, RV ejection fraction may not increase normally with exercise (Fig. 38-56). 

Residual or recurrent VSDs decrease exercise capacity. Furthermore, large residual or recurrent VSDs (Qp/Qs > 2) strongly predispose the patient to chronic heart failure late postoperatively.

Maximal oxygen uptake during exercise is only 30% to 40% of normal in patients corrected at an average age of 19.5 years. When repair is made at a still older age, the functional result is clearly worse than when it is performed in infancy or early childhood.

Figure 38-56 Right ventricular and left ventricular systolic function at rest and during exercise after repair of tetralogy of Fallot. Mean value for each set of data is indicated by open circle. Key: LV, Left ventricular; NS, not significant; RV, right ventricular. (From Reduto and colleagues.)

Figure 38-57 Right ventricular end-diastolic volume late after repair of tetralogy of Fallot. Patients are separated into those with and without a transanular patch. Stippled area represents normal values. Key: RVEDV, Right ventricular end-diastolic volume. (From Graham and colleagues.)

When the pulmonary valve is regurgitant, RV systolic function and end-diastolic volume are less likely to be normal, and their abnormality correlates with amount of regurgitation. When a transanular patch has been used in the repair, ejection fraction is more likely to be low, and RV end-diastolic volume is increased, often severely so. However, it has been suggested that increased RV wall thickness and consequently decreased ventricular compliance may limit volume expansion and RV enlargement. Reduced compliance may also protect against detrimental effects of pulmonary regurgitation.
valve regurgitation. Decrease in ejection fraction is correlated with the increase in end-diastolic volume. Precise measurements of RV end-diastolic volume using MRI and CT imaging suggest that volume over 150 to 170 mL · m⁻² will result in failure of the RV to remodel even after placement of a competent pulmonary valve.

A resting systolic pressure up to 60 to 70 mmHg has little adverse effect on postrepair RV systolic and diastolic function. Higher systolic pressures produce dysfunction, but this is not well quantified.

Other potential determinants of postrepair RV function have not been correlated with it in a quantitative fashion.

**Right Ventricular Aneurysms**

RV aneurysms adversely affect RV function, but they are uncommon. True aneurysm is more common than false aneurysm and is presumably related to excessive thinning or devascularization of the RV free wall, or thinning and bulging of pericardium if it has been used as an infundibular or transanular patch. Most RV aneurysms develop within 6 months of operation, and true aneurysms stabilize and rarely progress. False aneurysm, in contrast, may progress rapidly and rupture.

**Residual Right Ventricular Outflow Obstruction**

Residual narrowing in the infundibulum at the RV–pulmonary trunk junction (with or without a transanular patch) or more distally can result in at least some residual RV outflow obstruction. Magnitude of obstruction is not evident at the end of operation, because both the gradient between the RV and distal pulmonary trunk and the postrepair \( P_{RV/LV} \) are usually somewhat less late postoperatively than when measured in the operating room (Fig. 38-58). Dimensions of the RV–pulmonary junction enlarge proportionally to growth of the child after repair, whether or not a transanular patch was used (Fig. 38-59). However, disproportionate growth (i.e., “catch-up” growth) of the “anulus” does not occur without a transanular patch, and it cannot be expected that an “anulus” that is relatively small preoperatively and intraoperatively will become normal sized late postoperatively (Table 38-10). In some cases when a transanular patch is used, the junction will enlarge far out of proportion to growth of the child. This is caused by the same mechanism proposed for RV aneurysm formation: stretching and thinning of the patch, native tissue, or both.

Progression of originally unimportant residual RV outflow tract obstruction to important obstruction occurs uncommonly. Stiffening, thickening, and eventually even calcification of pulmonary valve cusps may occur and produce increasing RV hypertension, whether they are left in an intact “anulus” or beneath a transanular path. Also, if mild to moderate infundibular obstruction is present immediately after surgery, progressive hypertrophy and fibrosis in the infundibulum may lead to an increase in obstruction. This usually becomes evident within a year of initial repair.

Important residual or recurrent RV outflow obstruction is an indication for reintervention if the obstruction is considered treatable. This is because of its adverse effect on RV function, particularly when considerable pulmonary regurgitation coexists.

*bBased on follow-up and analysis of 757 hospital survivors (UAB experience, 1967 to May 1986). |
| bObstruction was isolated and in the infundibulum in 4, at anulus in 1, at bifurcation of pulmonary trunk in 2, at origin of one or both pulmonary arteries in 2, and at multiple sites in 4. In one person each, it was associated with a small VSD, a right ventricular aneurysm, a small VSD and a right ventricular aneurysm, and severe tricuspid regurgitation. |
| cThrough a recanalized classic Blalock-Taussig shunt and residual VSD. |

Reoperation and Other Reinterventions for Right Ventricular Outflow Problems

Reoperations are infrequent in the first years after TF repair (Table 38-11), but by 30 years, half of all survivors require reoperation (Fig. 38-60).1,18 Risk of reoperation for RV outflow tract obstruction and pulmonary regurgitation both increase as time passes; however, the pattern is different. Most reoperations for obstruction occur early postoperatively, mostly in the first year, and then the rate slows but persists.1,16 The pattern of reoperation for pulmonary regurgitation varies depending on the study. In one study, the reoperation rate for pulmonary regurgitation was very low in the first years after repair and then increased substantially as time passed.1,16 In a report that covered operations performed between 1967 and 1986 that involved a transanular patch, Kirklin and colleagues reported freedom from reintervention for pulmonary regurgitation of 98% at 10 years and 88% at 20 years.1,16 In a recent (2009) study from Toronto, however, the hazard for pulmonary valve replacement was constant up to 4 decades after repair, at 0.8% per year.1,18 In an earlier (1997) study from Toronto, with follow-up extending to 36 years, only 1.2% of patients underwent reintervention for pulmonary regurgitation.1,18 Furthermore, the study by Kirklin and colleagues identifies use of a transanular patch as a risk factor for subsequent pulmonary valve replacement, but the Toronto study does not. Although Kirklin and colleagues identify transanular patching as a risk factor, few patients in whom a transanular patch was inserted have undergone reoperation unless their postrepair (OR) $P_{RV/LV}$ was greater than about 0.7 (Fig. 38-61). Many of these differences and inconsistencies among studies probably reflect the subjective nature of the decision-making process related to the timing of reintervention for pulmonary regurgitation.

These classic studies notwithstanding, compelling data now exist showing that late serious problems arise in patients with isolated free pulmonary regurgitation; that is, pulmonary...
regurgitation without associated residual elevated RV pressure or residual left-to-right shunting. Free pulmonary regurgitation results in dilatation of the RV, \( \text{RV} \) dilatation correlates with prolonged QRS duration on ECG, and prolonged QRS duration is associated with sudden death. Reoperation as a marker of residual RV outflow tract problems in many analyses presents some difficulties and limitations. There are no accepted, standardized physiologic criteria for reoperation. This is of particular concern when the problem is pulmonary regurgitation. The long-term follow-up studies cited above show varying, but generally low, rates of reoperation for pulmonary regurgitation, even with follow-up of several decades or more. It must be kept in mind, however, that these studies used criteria for reoperation that are both more subjective and less strict than those used today. Also these studies rarely involve patients who originally underwent neonatal or even infant repair. They utilized presence of symptoms, onset of arrhythmias, and progressive tricuspid regurgitation as criteria for reoperation. More recently, a prolonged QRS complex of greater than 180 msec, and RV diastolic volume greater than 150 to 160 mL·m\(^{-2}\) have been added. Several studies using MRI indicate that enlarged RVs above about 150 to 170 mL·m\(^{-2}\) do not remodel to normal volume after a competent pulmonary valve is placed, although substantial volume reduction is observed.

Inserting an allograft aortic or pulmonary valve, or a bioprosthetic valve, are the therapeutic options when intervention is required for pulmonary regurgitation, because they increase RV ejection fraction, decrease RV end-diastolic dimensions, and improve symptomatic status. Survival after pulmonary valve replacement is excellent, with reports of 94% at 20 years. Percutaneous transcatheter pulmonary valve placement is an alternative in selected cases.

Reoperation for residual pulmonary stenosis is uncommon, with 95% of patients being free from it for at least 20 years (Fig. 38-62). Although rate of reoperation is highest early after repair, there is a constant phase of hazard as well, lasting as long as patients have been followed. The higher the postrepair (OR) \( P_{RV/LV} \), the greater the probability of this type of reoperation, and the prevalence increases particularly steeply when the value is greater than about 0.7 (Fig. 38-63).

Early results for pulmonary valve replacement are good, even when additional procedures such as tricuspid valve repair or more complex RV outflow tract reconstruction are also performed. Thirty-day mortality of 2.6% (CL 1.2%-5.1%) has been reported, with 19% occurrence of postoperative arrhythmias, 13% respiratory complications, 13% renal complications, 13% reoperation during admission, and 3% myocardial infarction. Predictors of prolonged hospitalization include age greater than 45 years, number of previous sternotomies, and need for urgent operation.

Left Ventricular Function
LV systolic and diastolic function are variable late after operation. Risk factors for poor LV function include older age at repair, pre-repair status of LV (affected as it is by previous palliative operations), and residual or recurrent defects.

Patients undergoing repair during the first few years of life have normal or near-normal LV function not only at rest but also during stress. Patients who are older at the time of...
repair, often have depressed LV ejection fraction at rest that intensifies during stress. Less satisfactory function in patients undergoing repair at an older age may be due to myocardial damage from chronic preoperative hypoxia and to long-standing LV overload from systemic–pulmonary arterial shunts in most patients who are older at repair. Other potential causes of LV dysfunction include intrinsic aortic root pathology. Aortic root dilatation and reduced aortic elasticity have been linked to aortic regurgitation, and aortic regurgitation to reduced LV function.

The age range at repair within which late postoperative LV function at rest and during exercise can be expected to be normal is not clearly defined. Some studies indicate that it extends to only age 2 to 3 years, others suggest that it extends to as late as age 10 if shunting operations have not been necessary.

Pulmonary Function

Patients with an optimal hemodynamic result from repair of TF in infancy or early childhood (closed VSD, PrV < 50 mmHg, and no pulmonary valve regurgitation) have normal lung volumes and capacities late postoperatively. Conversely, patients with a less than optimal hemodynamic result and those operated on later in life have distinctly subnormal lung function. Postoperative pulmonary valve regurgitation has a particularly adverse effect on late postoperative lung volume and function.

Recurrent (Residual) Ventricular Septal Defects

Important recurrent or residual VSDs are uncommon, with reoperation being necessary in less than 1% of cases. Even small and hemodynamically unimportant leakage is infrequent. Routine left ventriculography done an average of 23 months postoperatively in 23 infants showed a tiny residual VSD in one (4%; CL 0.6%-14%). Others have reported small leakage in up to 10% of patients. When important shunts are present, they are usually from inaccurate repair or dehiscence at the posteroinferior angle of the VSD.

Sudden Death and Important Arrhythmic Events

There has been much discussion about the possibility of sudden or arrhythmic death late after repair of TF with pulmonary stenosis, but there is a lack of information about the circumstances under which this is likely to occur. These events are more likely to occur in patients not operated on in early life and are unlikely when patients are repaired in the first few years of life. Thus, probability of sudden death or an important arrhythmic event (defined as a clearly arrhythmic death, intractable ventricular tachycardia, or insertion of a pacemaker for bradycardia developing late postoperatively) within 20 years of repair has occurred in less than 1% of patients who were younger than age 5 years at operation (Fig. 38-64). When the patient underwent repair in adult life, probability was 5% to 10%. Castaneda and colleagues found no sudden deaths and no important ventricular electrical instability in long-term follow-up of patients undergoing repair in infancy. Others have reported similar experiences with the relation between age and prevalence of sudden death late postoperatively.

When repairs are incomplete, and particularly when this results in postoperative cardiomegaly, prevalence of ventricular arrhythmias and sudden death is higher. During long-term follow-up of the early Mayo Clinic patients, only 2% experienced sudden death; most had important cardiomegaly. Similar findings have been reported by others.

When there is important residual pulmonary stenosis, prevalence of late postoperative arrhythmic events may be somewhat higher, but the correlation is weak. Strong correlation has been demonstrated between pulmonary regurgitation and important ventricular arrhythmias late postoperatively. Prolongation of the ECG QRS complex, which develops with the RV dilatation associated with pulmonary regurgitation, is associated with sudden death.

Rarely, the right ventriculotomy scar may be arrhythmogenic. This should be considered as a possibility in patients with life-threatening ventricular arrhythmias only when cardiomegaly is absent and there is neither important pressure nor volume overload of the RV. Under these circumstances, electrophysiologic mapping is indicated. When the source of the arrhythmia can be localized to the right ventriculotomy scar, excising the scar and inserting a patch graft have been reported to be beneficial. Cryoablation techniques may also be effective in controlling arrhythmogenic foci localized to the ventriculotomy scar.

Infective Endocarditis

Infective endocarditis is rare after repair. No instances were observed with up to 10-year follow-up in two large studies. Interim Results after Classic Shunting Operations

Survival

Classic B-T and PTFE interposition shunts have a hospital mortality approaching zero and 1-month mortality of less than 1%. Other types of shunting operations have a higher hospital mortality; however, they
are rarely used in modern practice and are of historical interest only.\textsuperscript{\text{118}}

Probably the most important risk factor for early death after classic shunting procedures is pulmonary arterial problems.\textsuperscript{\text{113}} Young age adds an increment of risk to shunting operations, but a relatively small one (Fig. 38-65).

**Interim Events**

*Early (<30 days) nonfatal shunt closure* or narrowing occurs uncommonly (7%) in patients undergoing classic B-T or PTFE interposition shunt operations for TF.

*Early and intermediate-term shunt closure* or narrowing requiring reoperation occurs in 3% to 20% of heterogeneous groups of infants and children.\textsuperscript{\text{26,42,44,20,\text{113}}} Closure or important narrowing is considerably more common in neonates and young infants than in older patients (74% vs. 90% freedom at 2 years).\textsuperscript{\text{113}} However, closure may be less common in neonates and young infants when a PTFE interposition graft is used.\textsuperscript{\text{113}} Overall, shunt closure or narrowing results in unsatisfactory palliation within 3 years of shunting in about 40% of patients.\textsuperscript{\text{14}} This prevalence does not seem to differ among patients receiving a classic B-T shunt and those receiving a PTFE interposition graft.\textsuperscript{\text{14}} Use of aspirin seemingly does not increase long-term patency or reduce occurrence of localized shunt stenosis.\textsuperscript{\text{14}}

One manifestation of reduced blood flow in the arm on the side of a classic B-T shunt is that it becomes slightly shorter and smaller during the intermediate term after operation.\textsuperscript{\text{107}} Likewise, strength of the arm on the side of the shunt has been demonstrated to be less than normal, even though the patient is unaware of this.\textsuperscript{\text{73}} When blood flow reduction is more severe than usual, gangrene of the hand can occur, although rarely.

*Sudden death* without explanation or autopsy, and nonfatal brain abscess each occur in about 1% of cases.\textsuperscript{\text{116,22}} Improperly performed shunts of any kind result in a higher prevalence of unsatisfactory interim results, primarily because of iatrogenic pulmonary arterial problems.

Iatrogenic pulmonary arterial problems are reported to be uncommon after classic shunting or PTFE interposition

shunting operations in early series.\textsuperscript{\text{26,22}} However, in the present era, because shunts are performed more frequently in patients with small pulmonary arteries, especially neonates, angiographic evidence of pulmonary artery distortion is fairly common late postoperatively and must be dealt with at the time of repair.\textsuperscript{\text{118}} From a historical perspective, these problems are much less frequent and less severe than those that were seen with obsolete shunts, such as Waterston and Potts shunts.\textsuperscript{\text{111,11,5,13,17,13}}

The key beneficial interim results of shunting procedures are increased $Q_p$, with consequent reduction in cyanosis and polycythemia, and improved functional capacity. NYHA functional class is usually I or II after shunting. $Sao_2$ at rest is usually 80% to 90%, but it always decreases with exercise, at times to as low as 50%.\textsuperscript{\text{47,15}} These benefits are obtained at the expense of increased LV stroke volume, a stimulus to gradual development of LV dysfunction.

Another benefit of classic shunting procedures is the diffuse increase in size of the RPA and LPA.\textsuperscript{\text{22,19}} The response of the valve and pulmonary “anulus” to shunting procedures is unpredictable. Some studies suggest that enlargement of the “anulus” can occur as a result of a shunting procedure.\textsuperscript{\text{47,26,18}} Whereas others indicate that a stenotic valve can progress to atresia after shunting.\textsuperscript{\text{1,28}}

Important pulmonary vascular obstructive disease does not occur with use of PTFE shunts if size of the shunt is chosen appropriately. Historically, vascular disease did develop after other shunts, such as a classic B-T, Waterston, or Potts shunt, but rarely before 5 years had passed.\textsuperscript{\text{25,24}} Beyond this time, the proportion of patients who developed hypertensive pulmonary vascular disease increased with increasing shunt duration.\textsuperscript{\text{24,6,3,21,10}}

**INDICATIONS FOR OPERATION**

Diagnosis of TF is generally an indication for repair. Early repair is advisable because of the unfavorable natural history of the disease, particularly in the first year of life (see Fig. 38-23), advantages of repair before irreversible secondary myocardial and pulmonary changes occur, and low risks of repair in the current era. Yet the timing of repair remains controversial. When severe symptoms develop in the first 1 or 2 months of life, some favor one-stage repair, whereas others prefer an initial shunting operation followed within 12 months by repair.

When diagnosis is made in the neonatal period and the patient is, and remains, essentially asymptomatic or only mildly symptomatic, one-stage repair is typically deferred for a variable period. The ideal period of deferral, if any, is unclear and in current practice ranges from 2 to 24 months. A strong argument can be made that for institutions experienced in complex surgery in small infants, one-stage repair should be performed in the first 2 to 3 months.

Overall results with a two-stage protocol with an initial shunting operation for patients younger than about age 6 months and repair between age 6 and 24 months appear to be similar to those of one-stage repair, although such a protocol is not ideal.\textsuperscript{\text{20}} However, two-stage repair is probably prudent for institutions not well prepared for the intraoperative and early postoperative care required by neonates and small children undergoing intracardiac operations. It is also reasonable for surgeons who are not yet certain of their ability to achieve comparable results with one-stage

![Figure 38-65 Nomogram illustrating effect of age on hospital mortality after repair of tetralogy of Fallot with pulmonary atresia versus pulmonary stenosis in patients with previous classic shunts. (Nomogram is specific solution of multivariable risk factor equation in original publication. Values entered for other variables are also given in original publication.) (From Kirklin and colleagues.\textsuperscript{\text{25}})](image-url)
repair in neonates and infants younger than about age 6 months.

When the LAD arises from the RCA, repair can be accomplished with usual techniques unless a “full-length” transanular patch is required. When a transanular patch is needed, there are two alternatives. One is to perform a systemic-to-pulmonary artery shunt in small symptomatic neonates and infants, deferring repair with a valved conduit for several years. The other is to perform a one-stage repair using a small valved conduit.

Multiplicity of VSDs in very young patients increases the risk of repair. Closure of apical muscular defects can often be accomplished percutaneously (see “Percutaneous Closure of Ventricular Septal Defects” under Special Situations and Controversies in Chapter 35). Thus, an initial shunting operation may be prudent, with subsequent percutaneous closure of muscular VSDs, followed by repair.

SPECIAL SITUATIONS AND CONTROVERSIES

Timing and Type of Initial Surgery

There remains wide variability in the initial surgical approach to TF.4,12,26,72,74 It is becoming increasingly common to follow a protocol that involves only primary repair without use of palliative shunts; however, this approach is not universal4,12 and may not even be the most common. In an analysis of 196 patients undergoing surgery within the first 90 days of life from 32 centers participating in the Society of Thoracic Surgeons congenital heart database, 99 underwent primary repair and 97 shunt palliation.28

Even when primary repair is used exclusively, there is variability in timing of repair. In patients with important symptoms, repair is performed immediately regardless of age.4,44,56,65,72,81 In asymptomatic patients, however, practices vary, ranging from elective repair as early as 8 to 12 weeks of age4,44 up to about 1 year of age.81

Others prefer to perform a palliative shunt in symptomatic patients under a specific age, and primary repair above this age.4,12 The age threshold varies between 4 months and 1 year.

Currently, there is no conclusive evidence that any one of these protocols is superior.

Rationale for Use of Postrepair P_{RV/LV}

P_{RV/LV} is easily measured in the operating room after repair, so when pulmonary artery pressure is known to be low, it is a convenient way of assessing adequacy of relief of pulmonary stenosis. It has the disadvantage of being difficult to measure postoperatively, so in its place the ratio of peak P_{RV} to peak radial, femoral, or aortic pressure is generally used. P_{RV/LV} is neither better nor worse for assessing relief of pulmonary stenosis than is the theoretically more useful gradient between RV and pulmonary artery. Scanty data available concerning the relationship both of postrepair (OR) RV–pulmonary artery gradient to that of the next day or late postoperatively42,44,47 and of the gradient to late results are compatible with information and conclusions drawn from postrepair P_{RV/LV}.

Postrepair P_{RV/LV} is related to pulmonary arteriolar resistance, size of the RPA and LPA,28 presence and severity of localized or segmental stenoses or incomplete distributions of the pulmonary arteries, and residual pulmonary trunk or RV outflow obstructions. It is also related to flow through the RV outflow tract, which may be increased postoperatively by residual left-to-right shunting across the VSD and by pulmonary valve regurgitation, or decreased by right-to-left flow through a PFO.

Postrepair P_{RV/LV} should be interpreted with caution in neonates and small infants. Data correlating this ratio with medium and long-term outcome are based on patients repaired at an older age. Very young patients, especially those sedated and anesthetized perioperatively, may have low systemic vascular resistance and thus low systemic blood pressure. This may result in a P_{RV/LV} that is high, above 0.7, even though the absolute RV systolic pressure is only 30 to 40 mmHg.

Initial Palliative Operations

In most institutions, a PTFE interposition shunt between the brachiocephalic or subclavian artery and pulmonary artery via a median sternotomy is preferred in all age groups. The PTFE shunt, introduced by Gazzaniga and colleagues in 1976,63,64 is reliable even in young infants, with few late occlusions (see “Interim Results after Classic Shunting Operations” earlier in this section). This shunt has for the most part replaced the classic B-T shunt.

Although at one time the Waterston ascending aorta–RPA shunt was popular, most groups find it has higher mortality in infants,64,33 a considerably higher proportion of iatrogenic RPA problems, and a relatively high prevalence of late pulmonary hypertension because of excessive Qp.61 The same disadvantages pertain for the Potts descending aorta–LPA anastomosis.66 In addition, it is more difficult to perform than other shunts and more difficult to close later. These shunts are not performed in modern practice.

A central PTFE shunt between the ascending aorta and pulmonary trunk is another option. It has no proven advantage over a properly performed laterally placed PTFE interposition shunt; however, it will never result in branch pulmonary artery distortion. On the other hand, it may not allow as fine a regulation of pulmonary blood flow as the laterally placed interposition shunt.

Initial Palliation by β-Adrenergic Blockade

The possible advantage of β-adrenergic blockade with, for example, propranolol therapy for severe cyanosis and hypoxic spells in early infancy is that surgery may be deferred. Disadvantages are that propranolol does not always provide good palliation, and risk of repair may be higher in patients who are taking it.

Honey and colleagues showed in 1964 that β-adrenergic blockade usually alleviates paroxysmal hypoxic spells.27,30,31 When doses of about 2.5 mg · kg{}^{-1} · day{}^{-1} of propranolol are used, relief of the hypoxic spells for at least 3 months occurs in 80% of patients.33 However, Garson and colleagues found this regimen to be more effective in patients older than 1 year, when it could be considered unnecessary, and less successful in infants age 6 months or less.35 However, their conclusion was that the drug was effective in very young patients if the dose was adequate (2–6 mg · kg{}^{-1} · day{}^{-1} and serum propranolol levels about 100 ng · mL{}^{-1}).
Initial Palliation by Balloon Valvotomy

Percutaneous balloon dilation of the infundibulum and pulmonary valve, and percutaneous infundibular myectomy, have been reported to provide good relief of cyanosis and symptoms, with little risk, in some small patients. However, the reports are anecdotal, and risks and effectiveness of the procedure in safely deferring repair remain to be clearly defined. Because repair can be performed safely at any age, these procedures are most applicable when extenuating circumstances increase surgical risk.

Monocusp Valves Beneath Transanular Patches

Many informal reports suggest that constructing monocusp valves, usually made of pericardium, beneath a transanular patch, or use of cusp-bearing allograft patches, are of value. They usually support the idea that these valves are competent in the early postrepair period but generally become regurgitant later. Over the long term, they do not appear to result in less pulmonary regurgitation than does a simple transanular patch. Subsequent calcification of the cusp is potentially obstructive. Some enthusiastic formal reports have appeared, but evidence favoring their use is not persuasive.

Timing of Pulmonary Valve Replacement for Pulmonary Regurgitation Late after Repair

When this procedure should be performed to maximize effect and promote longevity of the RV remains unclear. Symptomatic deterioration of exercise ability, onset of clinical arrhythmia, or overt right heart failure from severe pulmonary regurgitation are unequivocal for pulmonary valve replacement. However, it is likely that these criteria represent a degree of hemodynamic deterioration that has progressed beyond the capacity for complete recovery (“reverse remodeling”) after intervention. Therrien and colleagues showed that using these criteria, pulmonary valve replacement failed to provide for satisfactory RV reverse remodeling, with many patients suffering continued RV dilatation and low ejection fraction. Also, QRS duration stabilized (it continued to increase in a control group with similar follow-up duration), but failed to decrease to a normal level as one would have hoped. It can be argued that patients would benefit more if valve replacement were performed before onset of symptoms. However, this approach presents an additional problem. Currently, indications for pulmonary valve replacement in asymptomatic patients are being developed. Degree of RV dilatation, RV ejection fraction, and volume of pulmonary regurgitation can all be measured with precision using MRI, for example, but the need for and timing of pulmonary valve replacement late after TF on the basis of such measurements remain to be firmly established. For example, pulmonary regurgitant fraction and RV diastolic dimensions (as assessed by MRI) were not independently associated with impaired clinical status in long-term survivors of TF repair. However, numerous MRI studies show that recovery of RV function following pulmonary valve replacement was less likely if RV end-diastolic dimension exceeded 150 to 170 mL · m⁻². Similar arguments can be made for asymptomatic patients with prolonged QRS duration on ECG.

Percutaneous Pulmonary Valve Implantation

Percutaneous pulmonary valve implantation is a new option for patients with dysfunctional RV to pulmonary trunk conduits in selected TF patients who meet specific physiologic and anatomic criteria. The device can be used in cases of both RV outflow tract obstruction and pulmonary regurgitation. As of 2008, more than 500 percutaneous valves have been placed worldwide. In Lurz and Bonhoeffer’s experience with 230 of these cases followed for a mean of 28 months, freedom from reoperation was 93% at 10 months and 70% at 70 months. Currently, technology has not been modified to allow implantation in native outflow tracts.

Section II Tetralogy of Fallot with Pulmonary Atresia

DEFINITION

The definition of tetralogy of Fallot with pulmonary stenosis applies to TF with pulmonary atresia, except that in the latter there is no luminal continuity between the RV and pulmonary trunk (or both the RPA and LPA). Atresia is usually congenital but may be acquired.

HISTORICAL NOTE

As noted in Section I, Lillehei and colleagues first successfully repaired TF, and their original paper included a patient with pulmonary atresia. Rastelli and Kirklin reported the first use of an RV–pulmonary trunk extracardiac conduit to repair this anomaly in 1965. Ross and Somerville first reported use of a valved conduit for this purpose in 1966, as did Weldon and colleagues soon thereafter. Enlarging very hypoplastic pulmonary arteries by increasing pulmonary artery pressure and flow using a conduit connecting the RV to pulmonary arteries or by a systemic–pulmonary arterial shunt was reported by McGoon and colleagues and Kirklin and colleagues in 1977.

The important role of large aortopulmonary (AP) collateral arteries in many patients having TF with pulmonary atresia appears to have been first addressed in a constructive manner by Macartney and colleagues. These investigators reported on the hemodynamic characteristics of these arteries in 1973 and again in 1974. They introduced the concept of a multifocal blood supply to the pulmonary circulation through both the central pulmonary arteries and large AP collateral arteries. In 1980, Haworth and Macartney described in detail the large AP collateral arteries supplying blood to some pulmonary arterial segments by end-to-end anastomosis, and to others by end-to-side anastomosis. By then, the UAB group had described, in 1978, the adverse effect of incomplete distribution (arborization) of the pulmonary arteries on survival after repair of TF with pulmonary atresia. In 1981, Haworth, Macartney, and colleagues introduced the concept of unifocalization of pulmonary arterial supply as a first step to repair in patients with multifocal supply and large AP collateral arteries. Subsequently the surgical results of these procedures have accumulated (see...
“Results after Staged Palliative Operations for Unifocalization” later in this section). Systematic one-stage complete repair in infancy, involving bilateral unifocalization and intracardiac repair via median sternotomy, was introduced by Reddy and Hanley in 1992 and reported in 1995. Percutaneous catheter dilatation of localized stenoses in the RPA and LPA was reported by Lock and colleagues in 1983 and closure of large AP collateral arteries using this technique was reported by Yamamoto and colleagues in 1979.

MORPHOLOGY AND MORPHOGENESIS

Tetralogy of Fallot with Congenital Pulmonary Atresia

General morphology of the heart in TF with pulmonary atresia is similar to that in TF with pulmonary stenosis. The most important differences are that in TF with pulmonary atresia:

- No blood passes from RV to lungs; consequently, all pulmonary blood flow arises from the ductus arteriosus, collateral vessels, or fistulae.
- Pulmonary arterial anomalies are common.
- Large AP collateral arteries are common.

Right Ventricular Outflow Tract

Atresia, when congenital, may be in the infundibular area or at the RV–pulmonary trunk junction (“anulus”).

Infundibular atresia is the most severe manifestation of RV outflow atresia in TF, occurring in about 70% of hearts. The RV infundibulum seems to be totally absent in such cases, or the infundibular septal elements may be present but nearly fused with the anterior RV free wall (Fig. 38-66). The VSD is usually large and extends nearly to the free wall of the RV anteriorly, as does the aortic valve. The RV in such hearts is usually massively hypertrophied.

When the atresia is at the RV–pulmonary trunk junction, the infundibulum is usually present, but the pathway is narrowed by marked hypertrophy of the infundibular structures (Fig. 38-67). Obstruction consists of a thick fibrous membrane (analog of the pulmonary valve) above the infundibulum. Length and width of the infundibulum is variable.

Pulmonary Trunk

The pulmonary trunk may be present and of reasonable size, but more commonly it is importantly hypoplastic (Fig. 38-68). Occasionally, it is represented by only a fibrous cord without a lumen. In about 5% of patients with duct-dependent pulmonary blood flow, it appears to be completely absent. In patients with collateral-dependent pulmonary blood flow, the pulmonary trunk as well as the central branch pulmonary arteries are absent in up to 23%.

No clear correlation has been developed between location and type of atresia and morphology of the pulmonary trunk. An unusual variation of pulmonary trunk morphology has been recognized with increasing frequency recently, especially in patients with arborization abnormalities of the pulmonary artery branches. In this variant the pulmonary trunk arises from the proximal coronary artery system. Origins from the left main, right, and circumflex coronaries have all been identified. The true prevalence of this variant is not known, because most cases have been reported in isolation or in small groups; however, when systematically sought in a population of patients with arborization abnormalities of the pulmonary artery branches, it has been found to occur in up to 10%.

Right and Left Pulmonary Arteries

Confluence of Right and Left Pulmonary Arteries About 20% to 30% of patients have nonconfluent RPAs and LPAs (discontinuity). This usually results from absence of the central portion of one or both of these arteries. Rarely, it is caused by atresia of at least the distal pulmonary trunk and origins of both pulmonary arteries. (Patients having TF with pulmonary stenosis rarely have discontinuity of the RPA and LPA.) Confluent RPA and LPA may be associated with either a patent or atretic pulmonary trunk.

Figure 38-66 Specimen of tetralogy of Fallot with congenital infundibular atresia. Infundibular septum is small and divisions of trabecula septomarginalis prominent. Ventricular septal defect is perimembranous but extends anteriorly and superiorly almost to anterior free wall of ventricle. The danger of inadvertently cutting into the aortic root when making the right ventriculotomy is evident. There is marked overriding of noncoronary aortic cusp. Key: FW, Anterior free wall; L, left coronary cusp of aortic valve; LA, left anterior division of trabecula septomarginalis; N, noncoronary cusp of aortic valve; R, right coronary cusp of aortic valve; RP, right posterior division of trabecula septomarginalis; TSM, trabecula septomarginalis; TV, tricuspid valve.
Stenoses of Origins of Pulmonary Arteries

Among patients with confluence of the RPA and LPA and normal distribution arborization of pulmonary arteries, about 10% have stenosis of the origin (central portion) of the RPA, and about 20% have stenosis of the LPA. The latter anomaly seems clearly related to extension onto the LPA of the process of ductal closure.

Distribution (Arborization) of Pulmonary Arteries

An important feature of the morphology of TF with pulmonary atresia is frequent failure of the pulmonary arteries to distribute to all 20 pulmonary vascular segments. In this regard, patients with relatively normal caliber confluent central portions of the RPA and LPA are very different from those with either hypoplastic confluent branches or non-confluent ones. Also, the presence or absence of a ductus arteriosus is an important factor determining arborization abnormalities. If a ductus arteriosus is present and the branch pulmonary arteries are confluent, arborization abnormalities and large AP collaterals are rarely if ever seen. If a ductus arteriosus is present and the branch pulmonary arteries are discontinuous, the branch pulmonary artery (usually the left) that receives flow from the ductus rarely if ever has arborization abnormalities, and that lung rarely if ever has large AP collaterals. In this setting, the opposite branch pulmonary artery (usually the right) is almost always hypoplastic and has arborization abnormalities or is completely absent, and the lung blood supply is solely from large AP collaterals.

In one series, distribution of the pulmonary arteries was complete to all 20 pulmonary arterial segments in slightly more than half (53%; CI 48%-58%) of the patients with confluent RPA and LPA, and normal distribution was associated with relatively normal caliber of the confluent LPA and RPA (Table 38-12). In contrast, more than 80% of those with nonconfluent RPA and LPA or confluent but hypoplastic pulmonary arteries had incomplete distribution of one or both arteries, and in slightly more than one third of this group less than 10 pulmonary vascular segments were in continuity with a central or proximal extrapericardial portion.
Stenoses of Pulmonary Arteries

Stenoses beyond the origins of the pulmonary arteries are identified in only a small percentage of cases. However, when these small pulmonary arteries are subjected to increased pressure and flow after a palliative or corrective operation, they may enlarge in some areas and not in others. Thus, localized areas of noncompliance in the pulmonary arterial walls may not present as stenoses until after a procedure that increases pulmonary blood flow.

Overall, stenoses are most common at the origin of the pulmonary artery on the side of the ductus arteriosus, when one is present. Such juxtaductal stenoses (pulmonary artery coarctations) were found in 65% of patients studied by Elzenga and colleagues.

Size of Pulmonary Arteries

The immediately prebranching portion of the RPA and LPA varies widely, from normal caliber in some patients to extremely small in others—as low as McGoon ratios of about 0.5, which corresponds to a Nakata index of about 20 and a z value of about −10. These dimensions are particularly small in the subset with nonconfluence (discontinuity) of the RPA and LPA. In a subset of patients, intrapericardial pulmonary arteries are completely absent. In the series of 462 cases of TF with pulmonary atresia and large AP collaterals reported by Malhotra and Hanley, among the 77% of patients who had centrally confluent native pulmonary arteries, mean diameter of the branches was 2 mm. In general, patients with TF with pulmonary atresia have considerably smaller RPA and LPA than those with TF with pulmonary stenosis; in the latter group, these dimensions are similar to those in normal individuals.

Abnormal Hilar Branching Patterns

Even when the pulmonary arteries distribute to all parts of the right and left lung, hilar branching patterns may be abnormal, particularly in patients with large AP collateral arteries.

Alternative Sources of Pulmonary Blood Flow

Large Aortopulmonary Collateral Arteries

The most dramatic route of collateral flow is through large AP collaterals of an ipsilateral pulmonary artery (see Table 38-12). Pulmonary arterial segments that are not connected to a central pulmonary artery usually receive large AP collateral arteries. As a general rule, there is an inverse correlation between the number of lung segments supplied by collaterals and those supplied by the native pulmonary arteries. Fig. 38-69 shows this relationship. In one large series of patients with pulmonary atresia and collateral-dependent pulmonary blood flow, 23% of all patients had no vascular distribution from native pulmonary arteries to the lungs, and 13% had complete vascular distribution from native pulmonary arteries to 18 lung segments (considered to be complete arborization in this study). The remaining 64% of patients had vascular distribution from both native pulmonary arteries and collaterals along the spectrum shown in Fig. 38-69. In contrast, most patients having TF with pulmonary stenosis have all 20 pulmonary arterial segments in continuity with a central or proximal extrapericardial portion of an ipsilateral pulmonary artery.

*Absence of one or both central pulmonary arteries.

Data from Shimazaki and colleagues. 

Stenoses of Pulmonary Arteries

Stenoses of the pulmonary arteries beyond their origins are identified in only a small percentage of cases. However, when these small pulmonary arteries are subjected to increased pressure and flow after a palliative or corrective operation, they may enlarge in some areas and not in others. Thus, localized areas of noncompliance in the pulmonary arterial walls may not present as stenoses until after a procedure that increases pulmonary blood flow.

Overall, stenoses are most common at the origin of the pulmonary artery on the side of the ductus arteriosus, when one is present. Such juxtaductal stenoses (pulmonary artery coarctations) were found in 65% of patients studied by Elzenga and colleagues.

Size of Pulmonary Arteries

The immediately prebranching portion of the RPA and LPA varies widely, from normal caliber in some patients to extremely small in others—as low as McGoon ratios of about 0.5, which corresponds to a Nakata index of about 20 and a z value of about −10. These dimensions are particularly small in the subset with nonconfluence (discontinuity) of the RPA and LPA. In a subset of patients, intrapericardial pulmonary arteries are completely absent. In the series of 462 cases of TF with pulmonary atresia and large AP collaterals reported by Malhotra and Hanley, among the 77% of patients who had centrally confluent native pulmonary arteries, mean diameter of the branches was 2 mm. In general, patients with TF with pulmonary atresia have considerably smaller RPA and LPA than those with TF with pulmonary stenosis; in the latter group, these dimensions are similar to those in normal individuals.

Abnormal Hilar Branching Patterns

Even when the pulmonary arteries distribute to all parts of the right and left lung, hilar branching patterns may be abnormal, particularly in patients with large AP collateral arteries.

Alternative Sources of Pulmonary Blood Flow

Large Aortopulmonary Collateral Arteries

The most dramatic route of collateral flow is through large AP collateral arteries of an ipsilateral pulmonary artery (see Table 38-12). Pulmonary arterial segments that are not connected to a central pulmonary artery usually receive large AP collateral arteries. As a general rule, there is an inverse correlation between the number of lung segments supplied by collaterals and those supplied by the native pulmonary arteries. Fig. 38-69 shows this relationship. In one large series of patients with pulmonary atresia and collateral-dependent pulmonary blood flow, 23% of all patients had no vascular distribution from native pulmonary arteries to the lungs, and 13% had complete vascular distribution from native pulmonary arteries to 18 lung segments (considered to be complete arborization in this study). The remaining 64% of patients had vascular distribution from both native pulmonary arteries and collaterals along the spectrum shown in Fig. 38-69. In contrast, most patients having TF with pulmonary stenosis have all 20 pulmonary arterial segments in continuity with a central or proximal extrapericardial portion of an ipsilateral pulmonary artery.

### Table 38-12

| Confluence or Nonconfluence of Central Pulmonary Arteries and Number of Pulmonary Artery Segments Centrally Connected in Patients with Tetralogy of Fallot with Pulmonary Atresia |
|---------------------------------|---------------------|------------------------|
| No. of Pulmonary Artery Segments | Confluent (n = 132) | Nonconfluent* (n = 28) |
|                                 | No. of Patients | %                     | No. of Patients | %                     |
| 20                              | 62       | 47                    | 5               | 18                    |
| 19                              | 8        | 6                     | 2               | 7                     |
| 18                              | 8        | 6                     | 2               | 7                     |
| 17                              | 13       | 10                    | 0               | 0                     |
| 16                              | 6        | 5                     | 0               | 0                     |
| 15                              | 8        | 6                     | 0               | 0                     |
| 14                              | 6        | 5                     | 1               | 4                     |
| 13                              | 6        | 5                     | 0               | 0                     |
| 12                              | 5        | 4                     | 0               | 0                     |
| 11                              | 4        | 3                     | 0               | 0                     |
| 10                              | 2        | 2                     | 8               | 29                    |
| 9                               | 2        | 4                     | 1               | 4                     |
| 8                               | 0        | 0                     | 0               | 0                     |
| 7                               | 0        | 0                     | 2               | 7                     |
| 6                               | 1        | 1                     | 0               | 0                     |
| 5                               | 0        | 0                     | 1               | 4                     |
| 4                               | 1        | 1                     | 0               | 0                     |

*Absence of one or both central pulmonary arteries.

Data from Shimazaki and colleagues.

**Figure 38-69** Spectrum of lung perfusion in pulmonary atresia with ventricular septal defect. This is a hypothetical relation between number of pulmonary segments perfused by native pulmonary arteries (PAs) and those perfused by major aortopulmonary collateral arteries (MAPCAs).
arteries, which are present in about 60% of patients having TF with pulmonary atresia (Fig. 38-70). In this context, “large” implies embryologic rather than acquired origin of the collaterals, the latter typically resulting in smaller, more numerous collateral vessels. Large collaterals occur rarely in TF with pulmonary stenosis. AP collateral arteries are large discrete arteries, typically from one to six in number but sometimes more, most commonly originating from the upper or mid-descending thoracic aorta. The most common origins after the mid-descending thoracic aorta are the aortic arch and the low thoracic aorta. Occasionally a collateral originates from the intraabdominal aorta. Regardless of origin, collaterals generally pursue a somewhat serpiginous course, occasionally passing through the esophageal wall, and most commonly terminate by joining an interlobar or intralobar pulmonary artery that arborizes normally within a pulmonary lobe or segment.

AP collateral arteries arise from the aorta (or other source) either as elastic vessels with a wide lumen or as muscular arteries with stenotic areas. In either event, beyond their origins they resemble muscular systemic arteries. Areas of intimal proliferation (intimal pads) are frequent and result in stenoses. Extensive areas of these are prominent at branching points and at the junction of AP collateral arteries with pulmonary arteries. This process eventually results in stenoses in about 60% of collateral arteries.

In most patients, stenoses are sufficient in number to prevent pulmonary overcirculation; when this is not the case, pulmonary overcirculation is present early in life, and pulmonary vascular disease develops in patients surviving past infancy. Even in the absence of clinical signs and symptoms of overcirculation, however, an unobstructed collateral may cause pulmonary vascular disease in the area of lung it supplies. Thus, both regional and localized overcirculation can occur.

Although stenoses in some cases are primarily related to structural abnormalities in the collateral vessel wall, in others they are acquired, the result of abnormal postnatal flow patterns. Severe stenoses have been documented angiographically in patients as young as age 3 to 4 months in vessels that showed normal caliber at neonatal angiography. Stenoses can evolve variably and unpredictably.

An AP collateral artery that joins end to end with an intrapulmonary artery changes in histologic appearance as it becomes a pulmonary artery and changes its positional relation to the bronchi. Thus, peripherally, its histologic appearance and position become typical for “true” pulmonary arteries. In this situation, the distal pulmonary arterial
branches may be abnormally small\textsuperscript{11} and fewer in number than in normal individuals.

In about 50% of patients with large AP collateral arteries, the collateral enters end to side into a complex manifold in the hilum of the lung. This manifold usually includes the hilar portion of the pulmonary artery, and from this manifold interlobar and intralobar pulmonary arteries distribute distally, and central pulmonary arteries may fill retrogradely.\textsuperscript{52} The lung segments in this situation are said to have dual supply from the collateral and the true pulmonary artery. In other cases, the collateral distribution distally into the lung does not communicate with the central pulmonary artery system. In this situation, the involved lung segments are said to have isolated supply from the collateral only.

Less commonly, an AP collateral artery may connect end to side to a central pulmonary artery. Rarely, a single AP collateral artery on each side connects end to end with the hilar portion of the ipsilateral pulmonary artery.\textsuperscript{11,14,30} It is this last form that gave origin to the erroneous appellation “truncus type IV.”

AP collateral arteries are usually associated with abnormal branching patterns and incomplete distribution of the hilar portion of the pulmonary arteries. There may be associated single or multiple, localized or segmental, pulmonary arterial stenoses or diffuse hypoplasia.\textsuperscript{11,14,30}

**Paramediastinal Collateral Arteries** These are no different from AP collaterals, with the exception that their systemic origin is from a vessel other than the aorta. A large right or left paramediastinal collateral artery occasionally arises from the right or left subclavian artery, most often on the side opposite that of the aortic arch. It may connect end to side to the right or left central or hilar pulmonary artery, or it may distribute end to end to the intrapulmonary arteries of the upper lobe. It may be difficult to distinguish such a collateral from an unusually positioned and tortuous patent ductus arteriosus if the collateral is the sole vascular supply to one lung.

**Bronchial Collateral Arteries** Systemic vessels that originate from the mid-descending thoracic aorta and follow the course of the trachea and major bronchi before communicating with the lung parenchyma are often designated as bronchial collateral arteries. These vessels are often adherent to the airways and give off numerous small branches that supply the walls of the airways. They tend to be thin walled and tortuous, but may be large and carry a large amount of collateral flow. Collaterals that fit this description can be found in some but not all patients with TF and pulmonary atresia. They may also occur in the same patients who have more typical AP collaterals.

Increased use of various collateral arteries in surgical reconstruction has stimulated their careful pathologic evaluation. The picture is complex. It is becoming increasingly clear that the distinction between bronchial collaterals and other AP collaterals, and between intraparenchymal and extraparenchymal vessels, is simplistic; rather, the course and structure of those vessels that carry these labels is highly variable and unpredictable. Thus, these distinct labels may not apply to many vessels.\textsuperscript{18} This observation corresponds with embryologic evidence that AP collateral artery formation occurs over extended periods during development.\textsuperscript{11,13}

**Other Collaterals** Small collateral channels may pass from coronary arteries to the bronchial arteries.\textsuperscript{11} Relatively large communications between the proximal right or left coronary artery and the central pulmonary artery confluence occur in up to 10% of cases.\textsuperscript{11} In rare cases a fistula between the RCA and pulmonary trunk may be the sole large collateral source of pulmonary blood flow.\textsuperscript{238} Even more rarely, an AP window may serve this function (see Chapter 44).\textsuperscript{110}

**Acquired Collaterals** These vessels are stimulated or promoted by several factors, primarily cyanosis and adhesions from previous surgery or procedures. They typically arise from intercostal, internal thoracic, and smaller mediastinal and diaphragmatic arteries and are almost always multiple (dozens or even hundreds), small, and tortuous. Thus, they are almost impossible to control or eliminate using either surgical techniques or interventional coil occlusion. This collateral circulation may be so well developed as to make even the most careful mobilization of the lung hazardous. Such situations are not encountered in infants who are not chronically cyanotic and who have not undergone previous surgical procedures.

**Ductus Arteriosus**

In the absence of AP collaterals, pulmonary circulation at birth is dependent on ductal flow to the site of pulmonary artery confluence. This represents about 40% of these patients. Ductus orientation and position are usually abnormal—a downwardly directed branch coming from beneath the left aortic arch.\textsuperscript{15} It is also longer and more tortuous than is otherwise the case (Fig. 38–71) and is often narrowed at its pulmonary end. In the setting of left aortic arch, a right-sided patent ductus arteriosus is rare. When present, it comes off the right subclavian or brachiocephalic artery, or if associated with an aberrant right subclavian artery, it may come from an aortic diverticulum and pass to the right behind the esophagus.

When the pulmonary arteries are confluent, presence of large (embryologic rather than acquired) AP collaterals almost always means that there will not be a ductus arteriosus. When the pulmonary arteries are not confluent, a ductus arteriosus may or may not be present (see “Distribution [Arborization] of Pulmonary Arteries” earlier in this section).

**Morphogenesis**

A feature that distinguishes patients having TF with pulmonary atresia from those with pulmonary stenosis is the association of pulmonary atresia with chromosome 22q11 deletion. This association is particularly high in those with pulmonary artery arborization abnormalities and large AP collaterals.\textsuperscript{11,17,117,119,116} This deletion is associated with clinical evidence of DiGeorge syndrome, or velocardiofacial syndrome, in approximately 90% of cases. In those cases, careful consideration must be given to the typical immunologic, calcium metabolism, and neurodevelopmental abnormalities that may be part of this syndrome.

**Tetralogy of Fallot with Acquired Pulmonary Atresia**

Pulmonary atresia may develop spontaneously after birth in patients born with TF with pulmonary stenosis, or may be stimulated by a palliative operation.\textsuperscript{11,114} Acquired atresia is usually valvar, but may develop in the immediately subvalvar region or in the os infundibulum. This type of TF has the morphologic characteristics of TF with pulmonary stenosis.
CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

When the patient has TF with congenital pulmonary atresia and no AP or other large collateral arteries, cyanosis is usually evident during the first few days of life, becoming extreme as the ductus narrows and closes. This rapid progression is modified when there are large collaterals supplying the pulmonary bed, when the ductus stays open, or when an operation is performed.

Infants with pulmonary atresia and large AP collateral arteries present at birth with varying degrees of cyanosis. In approximately 80%, cyanosis is mild to moderate and hemodynamics are stable. In about 10%, presentation is with heart failure, which usually peaks at age 4 to 6 weeks as neonatal Rp decreases and Qp becomes large; cyanosis is mild. In about 10%, cyanosis is severe at birth, occasionally to the degree that hemodynamic instability develops. Regardless of presentation at birth, without intervention there is a general trend for cyanosis to worsen as collateral stenosis and pulmonary vascular disease develop. Both processes may occur in the same patient within different collateral areas.

Primary and secondary airway problems have been recognized with increasing frequency. The reasons are many, including upper airway extrinsic compression from a large aorta or collateral vessel to small airway hyperresponsiveness. Children who first present at an older age are usually symptomatic, cyanotic, and polycythemic no matter what the source of collateral blood flow, because it has become inadequate by that time.

Physical examination discloses findings similar to those of patients who have TF with pulmonary stenosis. In pulmonary atresia, however, a systolic murmur is usually absent. There is frequently a continuous murmur from large AP collateral arteries, a patent ductus arteriosus, or a coronary–pulmonary artery fistula. The murmur is maximal over the site of the collateral at its point of stenosis and may therefore be heard to the left or right of the sternum or posteriorly.

Clinical presentation, examination, and special studies are similar to those described for TF with pulmonary stenosis, with some important distinctions.

Echocardiography

Echocardiography is diagnostic for all cases of TF with pulmonary atresia, but it is definitive only if confluent normal-caliber branch pulmonary arteries connected to a patent ductus arteriosus can be identified.
Catheterization and Angiography

Cardiac catheterization and angiography should be performed at birth in all patients with an echocardiographic diagnosis of TF with pulmonary atresia and non–duct-dependent pulmonary blood flow. The origin, course, and distribution of every collateral should be clearly identified. Characterization of the collateral blood supply to a given lung segment should be further assessed to determine whether the collateral vessel provides the sole blood supply or is part of dual or multiple sources of blood flow coming from other collaterals or from the central or “true” pulmonary arteries. Further assessment is performed to identify whether any of the sources of blood supply come from a ductus arteriosus or the coronary artery system. Central and peripheral stenoses are identified both external to and within the lung parenchyma. Finally, specific effort should be made to fully characterize the central true pulmonary arteries using collateral and pulmonary wedge injections. Only after this level of definition is achieved can an appropriate surgical management plan be formulated.

Although clinical status of the patient and specifics of the management plan may influence the need for repeat study at any time, in almost all cases, repeat cardiac catheterization and detailed angiography are required in a matter of months. The reason may be to reevaluate an infant at age 3 to 4 months immediately before a one-stage unifocalization and intracardiac repair, because collaterals can change dramatically in the first few months of life, or it may be to assess the results of a previous palliative procedure performed in the neonatal period. Clinical stability (i.e., a thriving infant with SaO2 of 80% ± 5%) is not an indication to postpone cardiac catheterization. Such infants are likely to have important maldistribution of pulmonary blood flow despite their clinical stability, putting some lung segments at risk of developing pulmonary vascular disease due to overcirculation, and other segments at risk of being lost due to collateral occlusion.

In patients with ductus-dependent pulmonary blood flow with normally developed confluent pulmonary arteries, early repeat catheterization is typically not necessary, whether the initial neonatal procedure was one-stage repair or shunt placement. Although cardiac catheterization and standard angiography are absolute necessities in the workup of TF with pulmonary atresia and complex pulmonary arteries, newer imaging modalities such as 3D CTA or MRI currently provide an adjunctive role and may eventually take on increasing diagnostic importance in defining the complex morphology of abnormal pulmonary arteries and AP collaterals. Echocardiography is important in defining the intracardiac morphology, but has a subordinate role in the arterial assessment.

Computed Tomographic Angiography

This modality is being used increasingly in the neonatal period for TF with pulmonary atresia and large AP collaterals (Fig. 38-72). CTA in the neonatal period may prevent need for invasive catheterization if the CT demonstrates that a particular patient does not fall within one of several specific morphologic subgroups requiring neonatal surgery. The examples shown in Fig. 38-72 represent two specific subgroups that require neonatal surgery, according to the Stanford Management Protocol for TF with pulmonary atresia and aortopulmonary collaterals (Fig. 38-73). Because neonatal surgery is required in these subgroups, preoperative catheterization with detailed angiography of the collaterals is indicated. Catheterization can be deferred until the preoperative evaluation, typically at 3 to 4 months of life, in the majority (75%) of patients who make up the other morphologic subgroups. Thus, CT can serve as the definitive neonatal study in patients who will not require a neonatal operation. It should be emphasized that catheterization with angiography is strictly indicated if immediate surgery is anticipated.

Natural History

The natural history of patients with TF and congenital pulmonary atresia cannot be described simply, in part because of the great variability of morphology. This is reflected in the more complex hazard function for death compared with that for TF and pulmonary stenosis (see Fig. 38-23, C). It consists of a short-lasting early hazard phase, considerably more acute than for TF with pulmonary stenosis, that merges with a constant hazard phase (exponentially decreasing survival) that lasts to about age 50, followed by an increasing late hazard (with wide confidence limits). Unfortunately, morphologic characteristics of the anomaly corresponding to early death were not available to Bertranou and colleagues for their study of natural history, nor is it certain that reported groups of patients were an unselected sample of all patients born with this condition. This is particularly unfortunate in this condition, because it is likely that morphologic and physiologic characteristics influence survival.

Nevertheless, knowledge of the pathophysiology of the anomaly suggests that the shape of the natural history hazard function (see Fig. 38-23, C) may result from a mixture of different morphologic and physiologic subgroups that have been conveniently formed because of their surgical significance.

- **Confluent and normally distributing RPA and LPA and patent ductus arteriosus.** In this group, the only source of pulmonary blood flow is a patent ductus arteriosus, and the RPA and LPA are confluent, usually minimally hypoplastic, and distribute to all 20 pulmonary arterial segments.
- **Confluent, nonconfluent, or absent RPA and LPA with AP collaterals.**

The branch pulmonary arteries vary from confluent and almost normal size to confluent and severely hypoplastic, to nonconfluent, to completely absent. If they are not confluent, a ductus will connect to a normally arborizing (usually left) branch pulmonary artery, and the opposite branch pulmonary artery will be absent, with the lung solely supplied by AP collaterals. To add to the complexity, the degree of hypoplasia of the branch pulmonary arteries (as judged by their luminal diameter) does not necessarily correlate with the degree of arborization. Arborization of the pulmonary arteries, if present and confluent, may be to the majority of the lung segments or to a minority of lung segments. Segments not supplied by the pulmonary arteries are supplied by AP collaterals. There is an inverse relationship between the distribution of the pulmonary arteries and the distribution of the AP collaterals.
Computed tomographic angiography (CTA) of patients with pulmonary atresia with ventricular septal defect and large collateral arteries, illustrating the Stanford University management protocol. **A1 and A2**, Two CTA images of a 1-week-old girl with very small centrally confluent native pulmonary arteries and large collaterals (MAPCAs). Images show a small right and left native right pulmonary arteries (RPA, LPA) and two major aortopulmonary collateral arteries (MAPCA2, MAPCA3) arising from the mid-thoracic descending aorta. Collaterals are connected peripherally to native pulmonary arteries. RML PA identifies right middle lobe branch of the RPA. LUL PA and LLL PA identify left upper and left lower branches of LPA. An additional very small collateral was present in this patient, but is not visualized in these images. According to the Stanford management protocol, this patient is identified as requiring neonatal surgery because of the normally arborizing and centrally confluent native pulmonary arteries, with all "dual-supply" collaterals. A neonatal preoperative cardiac catheterization with detailed angiography of the collaterals is required. **B**, Coronal cut of a volume-rendered image of airways and aorta in a 1-week old girl with large collaterals to right lung. There is a right-sided aortic arch. Peripheral LPA is connected to aorta through a patent ductus arteriosus originating from left brachiocephalic artery. According to the Stanford management protocol, this patient would require neonatal surgery because of the presence of the unilateral ductus. A preoperative neonatal catheterization would be required to define the details of the right lung collateral distribution. Key: *Ao*, Aortic arch; *LLL*, left lower lobe branch; *LPA*, left pulmonary artery; *LUL*, left upper lobe branch; *MAPCA*, major aortopulmonary collateral artery; *PA*, pulmonary artery; *PDA*, patent ductus arteriosus; *RML*, right middle lobe branch; *RPA*, right pulmonary artery.
Physiologically. Cyanosis is always present, and symptoms may develop, depending on the number, size, and behavior of collateral vessels, but not as quickly nor as severely as in the group described in the preceding paragraph. Symptoms early in life are related either to severe cyanosis or to severe pulmonary overcirculation. Over time, a gradual increase in cyanosis is typical because of collateral stenosis with reduced pulmonary blood flow, Eisenmenger-like physiology in unobstructed collaterals, or both. Without interventional therapy, 10% of this group may die within the first few years of life, half by age 3 to 5 years, and 90% by age 10.

Pulmonary Arterial Disease

Patients with pulmonary atresia and AP collateral arteries probably differ from other patients with TF with respect to pulmonary arterial disease. The phrase pulmonary arterial disease rather than “pulmonary vascular disease” is used because of uncertainty regarding how much the increased pulmonary vascular resistance is due to hypoplasia and

**Figure 38-73** Treatment protocol for patients with tetralogy of Fallot and pulmonary atresia with major aortopulmonary collateral arteries. Key: AP, Aortopulmonary; MAPCAs, major aortopulmonary collateral arteries; PA, pulmonary artery; TF, tetralogy of Fallot.
stenoses of the distal pulmonary arteries themselves and of the distal portions of the AP collateral arteries, versus how much is due to microvascular hypertensive pulmonary vascular disease.\textsuperscript{58} Without question, both mechanisms occur.

Pulmonary arterial disease tends to develop in those pulmonary arterial segments that are centrally connected. It progresses at a considerably accelerated rate, and perhaps even in fetal life or in the first few months after birth, in segments whose only or major source of pulmonary blood flow is large AP collateral arteries.\textsuperscript{512} Patients who survive without correction into the second and third decades of life often develop massive and sometimes fatal hemoptysis related to these large AP collaterals.\textsuperscript{58}

\section*{TECHNIQUE OF OPERATION}

\subsection*{Repair of Tetralogy of Fallot with Acquired Pulmonary Atresia}

Occasionally, and particularly in patients with pulmonary atresia that has developed after a shunting procedure, atresia is at the level of the infundibulum. The operation described for TF with pulmonary stenosis can then be done (see Technique of Operation in Section I), often without a transanular patch. When acquired atresia is at the pulmonary “anulus” and the pulmonary trunk is present (which it usually is), a transanular patch repair can be used, as described next under “Repair of Tetralogy of Fallot with Pulmonary Atresia and Confluent and Normally Distributing Right and Left Pulmonary Arteries and Patent Ductus Arteriosus.” In about 90\% of patients with TF and acquired pulmonary atresia, these straightforward repairs are feasible.

\subsection*{Repair of Tetralogy of Fallot with Pulmonary Atresia and Confluent and Normally Distributing Right and Left Pulmonary Arteries and Patent Ductus Arteriosus}

This operation is generally performed in neonates and young infants in whom atresia is usually at the pulmonary “anulus” and the pulmonary trunk and confluence of the RPA and LPA are generally patent and of reasonable size. Occasionally, it is performed in older infants and in children who have been palliated by a shunting operation early in life. Operation proceeds much as described under Technique of Operation in Section I for TF with pulmonary stenosis with respect to CPB management, myocardial protection, and many technical details (see “Decision and Technique for Transanular Patching” and “Repair of Uncomplicated Tetralogy of Fallot with Pulmonary Stenosis via the Right Ventricle” under Technique of Operation for details of most aspects of the procedure except for those described in text that follows). There are, however, several important differences. The ductus arteriosus is always present and large and may be tortuous. There are, however, several important differences. The ductus arteriosus is always present and large and may be tortuous. It is dissected, and ligatures placed around it, prior to establishing CPB. It is then immediately ligated and divided as CPB is initiated (see “Closure of Associated Patent Ductus Arteriosus” under Technique of Operation in Section I of Chapter 35).

The VSD is always closed through a longitudinal incision in the RV infundibulum, never through the right atrial approach. The incision, RV muscle resection, and VSD closure are performed as described for TF with pulmonary stenosis under Technique of Operation in Section I.

There are several options for managing the RV-to-pulmonary trunk reconstruction. Preferably, a valved conduit is used to connect the RV to the pulmonary trunk. This is performed as described later in “Establishing Right Ventricle–to–Pulmonary Artery Continuity” under Repair of Tetrology of Fallot with Pulmonary Atresia and Large Aortopulmonary Collaterals. Alternatively, it may be possible in some cases to make a single vertical incision in the RV infundibulum and extend it through the atresia to an appropriate point distally on the pulmonary trunk. This is appropriate when the atretic area is very short. Sufficient tissue must be present posteriorly at the site of the atresia so that growth of the area can proceed satisfactorily. The transanular patch must be appropriately contoured at the atretic area to accomplish satisfactory widening. The patch is roughly diamond shaped, with the widest portion applied to the atretic area. Great care is taken to avoid damage to the left anterior descending coronary artery (LAD) and right coronary artery by the patch suture line. Severe pulmonary regurgitation will be present immediately when this technique is used.

Management of the atrial septum will vary. If a valved conduit is used to reconstruct the RV outflow tract, closure of the atrial septal defect or PFO, if present, is performed. If a transanular patch is used, especially in neonates and young infants, a PFO is left open using the same criteria as given in “Managing the Atrial Septum” under Technique of Operation in Section I.

\subsection*{Repair of Tetralogy of Fallot with Pulmonary Atresia and Confluent, Nonconfluent, or Absent Right and Left Pulmonary Arteries and Aortopulmonary Collaterals}

Vascular supply of blood to the lungs in this condition represents, arguably, the most variable and complex “lesion,” both morphologically and physiologically, in congenital heart disease. As such, no single operative approach is applicable to all patients. That said, recent techniques have been developed, supported by midterm follow-up data, demonstrating that a majority of patients with TF with pulmonary atresia and large AP collaterals can be managed with one-stage repair in early infancy, involving left and right lung unifocalization, VSD closure, and RV outflow tract reconstruction.\textsuperscript{1,2,9,16,31,33,38,39,48,67}

This approach can be applied to patients having relatively large confluent true pulmonary arteries, minor or moderate arborization abnormalities, severely hypoplastic confluent true pulmonary arteries with major arborization abnormalities and dominant collaterals, or completely absent intrapericardial true pulmonary arteries and collaterals only.

There are specific subpopulations, both morphologic and physiologic, in which the one-stage approach is contraindicated; these are discussed under “Alternatives to One-Stage Unifocalization and Intracardiac Repair” under Special Situations and Controversies later in this section. It should also be emphasized that individual surgeons selectively use one-stage repair based on morphologic details and their own experience.\textsuperscript{5,7,18,38,51,21,27,26,53,96}

\subsection*{One-Stage Unifocalization and Intracardiac Repair}

In the text that follows, various components of the operation are described, including preliminary procedures leading up to it. These components include:
Assessing intrapericardial true pulmonary artery system
Identifying and assessing collateral system
Managing sources of pulmonary blood flow on CPB
Completing unifocalization
Assessing adequacy of unifocalization
Performing intracardiac repair
Establishing RV-to–pulmonary arterial continuity
Assessing complete repair

This procedure is typically performed in infants at approximately 3 to 4 months of age. Occasionally it is performed in neonates or in younger infants whose condition is unstable because of either profound cyanosis or severe pulmonary overcirculation, or in whom there are nonconfluent central pulmonary arteries and a ductus arteriosus providing blood flow to one of the lungs, with collateral supply to the contralateral lung. Exposure is through median sternotomy. The skin incision is extended from the suprasternal notch to well below the xiphoid to provide adequate exposure for the extensive dissection that is necessary. If a thymus gland is present, it is subtotally removed, leaving a small remnant of thymic lobes above the brachiocephalic vein. The pericardium is opened anteriorly with a longitudinal incision; a piece of anterior pericardium may be removed and treated in glutaraldehyde for later use in the operation.

**Assessing True Pulmonary Artery System** The first task is to assess the intrapericardial true pulmonary artery system. Commonly there are confluent and very hypoplastic central pulmonary arteries with a small pulmonary trunk segment that ends blindly at the level of an atretic pulmonary valve (Fig. 38-74). The pulmonary trunk and branch pulmonary arteries are dissected over their entire course beginning centrally and moving to the periphery, clearly identifying major branches of the RPA and LPA as they enter the lung parenchyma.

**Identifying and Assessing Collateral System** The next task is to identify and assess the collateral system. This requires a clear mental image of it based on careful study of the preoperative angiograms. The technical maneuvers used in this part of the procedure are variable and depend on the number and positions of the large collaterals. This may take several hours to accomplish. Each large collateral artery is identified at its systemic source and dissected over its entire length to the point where it enters the lung parenchyma. The specific approach to each collateral depends on its point of origin. The most common site of origin is the upper descending aorta with the collaterals coursing anteriorly through the posterior mediastinum into the middle mediastinum and then into the lung hilum (see Fig. 38-74). It is best to approach these collaterals through direct mediastinal dissection rather than by entering the pleural space. With the ascending aorta retracted anteriorly and to the left and the superior vena cava retracted to the right (see Fig. 38-74), the posterior pericardial reflection is opened in the midline within the space bordered above by the tracheal bifurcation and below by the dome of the left atrium. If confluent central pulmonary arteries are present, it may be necessary to work around them as the posterior dissection proceeds. Once the posterior pericardium is opened and the soft tissue of the posterior mediastinum is entered, collateral vessels are easily identified. Further posterior dissection exposes the esophagus and descending aorta, allowing access to the origin of collaterals that arise from this aortic position (see Fig. 38-74).

Occasionally, large collateral arteries arise lower on the descending aorta or from the major head and neck vessels. Those arising from head and neck arteries can be accessed directly by dissecting the artery of origin and then exposing the collateral along its length until it enters lung parenchyma. Collaterals originating from the lower thoracic aorta and occasionally intraabdominally are best exposed by opening the appropriate pleural space anterior to the phrenic nerve and gently retracting the lung out of the pleural space to expose the descending aorta and collateral origin. These lower collaterals may enter the hilum of the lung directly or travel in the inferior pulmonary ligament before entering the lung parenchyma. It is not uncommon for collateral vessels to pass through the muscle of the esophagus before entering the lung tissue.

**Managing Sources of Pulmonary Blood Flow on Cardio pulmonary Bypass** Once the true pulmonary artery system and all collateral vessels have been identified and fully dissected, cannulation sutures are placed in preparation for CPB. Aortic and bivacal cannulation are standard (see Section III of Chapter 2). After full heparinization and aortic and bivacal venous cannulation, CPB is initiated. All collateral vessels (or remaining collaterals, if some are ligated prior to initiation of CPB) are rapidly ligated at their aortic or systemic vessel origin using appropriately sized permanent metal clips. Patients with TF generally have a large intracardiac return during repair because of acquired collateral flow to the pulmonary arteries; those with pulmonary atresia, and especially those with the large AP collateral arteries, may have a particularly large intracardiac return requiring special consideration. Thus, an important goal in patients who will be placed on CPB is to have control of as much pulmonary blood flow as possible. The surgeon should be aware of all sources of pulmonary flow. This is accomplished by detailed review of the preoperative cardiac catheterization and angiographic data. Possible sources include the ductus arteriosus, surgically created systemic–pulmonary arterial shunts, large AP collateral arteries, and acquired AP collaterals. Before commencing CPB, all sources should be surgically identified and dissected to the degree that instantaneous control can be achieved. This is most easily accomplished with the ductus or with surgically created shunts. Although more difficult, it is also necessary to dissect the origin of all large AP collaterals as described in the preceding text. Acquired collaterals, usually smaller in size but more numerous and diffuse, pose the greatest challenge. They usually arise from the internal thoracic artery, intercostal arteries, bronchial arteries, or other unnamed mediastinal vessels. If previous surgery has been performed, acquired collaterals may form at sites of pleural fusion. Some, and sometimes many, acquired collaterals can be coil occluded by an interventional cardiologist at preoperative catheterization. The surgeon should attempt to control remaining acquired collaterals during the operation before placing the patient on CPB (still, it is not unusual for intracardiac return to increase once CPB is established).

CPB is established with the perfusate at about 34°C and with ionized calcium at a normal level so that ventricular fibrillation does not occur before proper preparations are made for managing intracardiac return. After aortic and bicaval cannulation is accomplished, CPB is slowly established with the heart continuing to beat vigorously. A left
ventricular vent of appropriate size (10F for patients weighing 4.0 kg or less; 13F for patients weighing 4 to 10 kg; adult size for patients weighing more than 10 kg) is placed via a purse-string suture into the right upper pulmonary vein, and the vent tip is passed across the mitral valve into the LV. At this point, full CPB and vigorous venting are established, and immediately, all sources of pulmonary blood flow, previously identified and dissected at their systemic origin, are permanently closed using metal clips. If appropriate pre-CPB dissection has been accomplished, all major sources, including complex situations with up to eight large AP collaterals, can be controlled in 30 to 90 seconds. Commonly, especially in patients with baseline SaO2 greater than 80%, a substantial portion of the multiple sources can be closed before initiation of CPB, with this process limited only by decrease in SaO2. It is not unusual, particularly if the patient is in early infancy and has not undergone prior palliation, for these maneuvers to reduce intracardiac return to normal levels.

In older children who have been chronically cyanotic or palliated, acquired collateral vessels from the systemic to the pulmonary circulation have often developed. In these cases, control of the embryologic large AP collaterals may still leave substantial cardiac return through the acquired collaterals. Then, a larger LV vent and higher perfusion flow rates may...
be needed to account for the abnormally high runoff. Once CPB is established, perfusion temperature is gradually reduced, aiming for a core body temperature of 25°C.

In addition to these precautions against damage from large intracardiac return, cerebral perfusion can be further maintained at an adequate level by blood gas control despite rapid aortic runoff. Arterial PCO₂ is maintained at 45 mmHg or greater to maximize cerebral blood flow.

Completing Unifocalization The next task is to complete the unifocalization process. This again depends on number and positions of the collateral arteries and status of the central pulmonary artery system. Depending on number and complexity of collaterals, this aspect of the procedure may take several hours. It is performed without an aortic clamp so that the myocardium is well perfused in an empty beating state. Most collateral arteries can be connected directly to the central pulmonary artery system by working within the central mediastinal space previously dissected. Most commonly, long side-to-side anastomoses between the collaterals and true pulmonary arteries, extending from a midline position all the way to the periphery where the arteries enter the lung parenchyma, are performed using 7-0 absorbable monofilament suture (Fig. 38-75). Occasionally, collateral arteries arising from head and neck vessels or from much lower on the descending thoracic aorta can be connected in end-to-side fashion to the central system. Collateral arteries are usually connected to the superior-posterior, directly posterior, or inferior-posterior circumferential aspect of the central pulmonary artery system, leaving its anterior aspect untouched. Typically, collateral vessels that are candidates for unifocalization will not reach the true pulmonary artery easily if the collateral artery is rerouted over the hilum of the lung, and this technique is avoided.

Once all collateral vessels have been unifocalized, it is often beneficial to incise the remaining anterior aspect of the central true pulmonary arteries from left hilum to right hilum, and then patch them with a segment of cryopreserved allograft pulmonary artery. In this fashion, a completely unifocalized pulmonary artery system with newly reconstructed branch pulmonary arteries that are of normal or even supranormal diameter can be achieved, with no areas of circumferential pulmonary artery patch throughout the system.

With rare exceptions (i.e., small remote collaterals with single lung segment distribution or less), all isolated supply collaterals should be unifocalized because failure to do so will eliminate lung segments from the central pulmonary artery circulation after repair. In many cases, dual-supply collaterals (those that communicate with the true pulmonary arteries) should also be unifocalized. Even though a dual-supply collateral will distribute to the same distal vascular bed as that portion of the true pulmonary artery with which it communicates, the value of unifocalizing such a collateral is that it can be used to augment the diameter of the small true pulmonary artery. If the true pulmonary arteries are of adequate size, a dual-supply collateral need not be unifocalized and can be simply ligated at its origin.

If there is complete absence of true pulmonary arteries within the pericardium, collateral vessels from the right and left lungs can be easily connected to one another across the midline within the dissected central mediastinal space. Most frequently, on each side, all ipsilateral collateral vessels are first connected to one another with long side-to-side anastomoses, with the anastomoses beginning at the transected systemic end of the collaterals and extending to the lung parenchyma. Then the left side is connected to the right, achieving complete unifocalization and left-right confluence. Occasionally the older child or young adult will present as a good candidate for unifocalization. In this case more liberal use of circumferential synthetic material (no growth potential) is acceptable (Fig. 38-76). This should be avoided if possible in the growing infant and child.

Assessing Adequacy of Unifocalization Once unifocalization is complete, an assessment must be made regarding whether the pulmonary artery system will have adequately low resistance to allow intracardiac repair with subsequent low RV and pulmonary artery pressure. Following intracardiac repair, peak RV pressure should be less than 60% of peak systemic arterial pressure. Experienced surgeons can often predict this by size of the true pulmonary arteries and collateral arteries and adequacy of the unifocalization. In such cases, proceeding directly to intracardiac repair is indicated. In other circumstances, typically those in which neither the true pulmonary artery system nor the collateral system is sufficiently large to ensure low pulmonary arterial resistance, or in which unifocalization was difficult and a question remains regarding adequacy of anastomoses or positioning of the unifocalized vessels, it is most prudent to assess pulmonary arterial resistance objectively before deciding whether to move ahead with intracardiac repair.

Objective assessment can be made using an intraoperative blood flow study. The perfusionist primes a separate circuit, which draws blood from the venous reservoir and perfuses a cannula that is placed into the central portion of the newly unifocalized pulmonary artery system. Based on body surface area, controlled perfusion into the pulmonary artery circuit is then performed in incremental steps beginning at 20% of baseline indexed cardiac output and increasing in increments of 20% up to 100% indexed cardiac output. At each increment, after a steady state is achieved, pressure is measured using a small catheter placed into the pulmonary artery system and connected to a pressure transducer. During the assessment, careful attention is paid to the left atrial appendage. If the heart is not beating vigorously because of hypothermia or hypocalcemia, or if it is arrested with cardioplegia or is fibrillating, the left atrium and LV can be quickly overdistended by pulmonary venous return. To counter this, the LV vent is placed on vigorous suction and the vent pop-off valve is completely occluded. Even then, careful attention should be paid to the left atrial appendage to be sure that the vent system is not overwhelmed by pulmonary blood flow at higher incremental flows.

If mean PPA remains less than 25 mmHg at full indexed cardiac output in a 3- to 4-month-old infant, intracardiac repair can proceed. These values have been shown to predict accurately that P_{IV/LS} will be less than 0.5 following intracardiac repair in both controlled laboratory studies and in the clinical situation. In older children, a mean PPA of 25 to 30 mmHg at full indexed cardiac output usually indicates ability to move ahead with intracardiac repair. If pressures increase to more than these threshold values at any incremental step in the pulmonary blood flow study, then the test is terminated and intracardiac repair is not performed. In this case, a central aorta to pulmonary artery shunt is performed from the left side of the ascending aorta to the central portion of the unifocalized pulmonary artery system using standard
Figure 38-75  One-stage complete unifocalization and intracardiac repair via median sternotomy for tetralogy of Fallot with pulmonary atresia and large aortopulmonary collateral arteries. Median sternotomy preliminary dissection of true pulmonary arteries and collaterals, and cardiopulmonary bypass (CPB) details are described in the text, in Section III of Chapter 2, and in Fig. 38-74. Once CPB is established, previously dissected collateral vessels are immediately ligated at their systemic origin. This preserves entire length of each collateral so that this tissue can be used in the reconstruction that results in complete unifocalization. For clarity, heart, ascending aorta, and trachea have been eliminated in this figure. A, Hypoplastic centrally confluent true pulmonary arteries are present. Hypoplastic left pulmonary artery (LPA) distributes to left upper lobe and hypoplastic right pulmonary artery (RPA) distributes to lateral aspect of right lower lobe. Three large collateral arteries are present. One arises from right carotid artery and takes a tortuous course (dashed lines) to provide blood flow to medial aspect of right lower lobe (APC2). Two other collaterals arise from typical upper descending thoracic aortic position. One courses to right upper and middle lobes (APC3) and the second to left lower lobe (APC1). The surgeon should be acutely aware, based on careful preoperative evaluation of the angiograms, of all stenotic areas within each collateral artery. Stenotic areas must be eliminated (dashed lines on APC2) if they are proximal within the collateral, or addressed surgically with either patching or some other form of augmentation if they are more distal. B, All three collateral arteries have been ligated and divided at their systemic origins. Hypoplastic pulmonary trunk has been transected just distal to atretic pulmonary valve. Unifocalization sites (dashed lines) have been chosen on the true pulmonary arteries in accordance with positions and lengths of collateral arteries to be unifocalized. In this case the two short dashed lines on the true pulmonary artery represent sites of implantation of the left and right mid-thoracic collateral vessels (APC1 and APC3). These incisions on the true pulmonary arteries are placed directly posterior. APC1 has been incised over part of its length to allow a side-to-side anastomosis over left hilum. Dashed line on APC3 identifies intended incision that will allow a side-to-side anastomosis with the true RPA. Tortuous APC2 has been mobilized, and the dashed line along its length indicates proposed incision that will allow performing an extensive side-to-side anastomosis onto the true pulmonary arteries beginning in the left hilum and extending all the way to the right hilum. The long incision on the true pulmonary artery, represented by the dashed line, is positioned on the superior-posterior aspect of the true pulmonary arteries.
The three collateral vessels have been connected to the true pulmonary artery system as shown using running 7-0 absorbable monofilament sutures. Exquisite attention to detail and a three-dimensional vision of the result are required to avoid kinking, overstretching, and twisting of the delicate vessels. In this particular case, large tortuous collateral APC2 provides a large degree of “raw material” to augment the central pulmonary artery system adequately. In the absence of such abundant raw material, a less extensive anastomosis of the collateral to the true pulmonary artery would be performed, similar to the other two collateral anastomoses in this example, and the central pulmonary artery system would be augmented centrally from hilum to hilum with a patch of pulmonary arterial allograft tissue. At this point in the operation the decision is made whether to perform an intraoperative pulmonary blood flow study as an aid in designing the remainder of the operation. In this case operation is completed by ventricular septal defect (VSD) closure and right ventricular outflow tract conduit (see text for other options). The small opening at transected pulmonary trunk is enlarged to the left and right sides in order to perform distal anastomosis of valved allograft conduit into newly reconstructed central pulmonary artery system. This aspect of the procedure and remaining VSD closure and proximal conduit to right ventricular anastomosis is performed in standard fashion for tetralogy with pulmonary atresia without large aortopulmonary collateral arteries. Key: APC, Aortopulmonary collateral artery; Desc Ao, descending thoracic aorta; PT, pulmonary trunk.
Intracardiac Repair

If pulmonary arterial resistance is acceptable, intracardiac repair commences. The aorta is clamped and cardioplegic solution introduced into the aortic root in the usual manner (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3). After adequate cardiac

Figure 38-76 Alternative unifocalization repair of tetralogy of Fallot (TF) with pulmonary atresia and large aortopulmonary collateral arteries with absent true pulmonary arteries. In most cases when true pulmonary arteries are completely absent, central confluence between left- and right-sided collaterals is provided by creating direct continuity between collateral arteries from each side, working within the dissected space in central mediastinum, as described in Fig. 38-75. This is especially important in infants and young children, who require growth potential of living tissue. Occasionally a patient will present at an older age with stenotic but open collaterals with well-developed distal vasculature, as shown in this case. Under these conditions, native tissue-to-tissue anastomoses are not critical because growth potential is not required. For clarity, the heart and ascending aorta are eliminated from this figure. A, Four collateral vessels are shown arising from the upper mid-thoracic aorta. They have been exposed according to the dissection process described in the text and in Fig. 38-75. There is one large collateral vessel supplying the entire left lung; it is stenotic at its origin. Three separate collateral vessels, all stenotic at their origins and in their proximal segments, supply the right lung—one each to the right upper, right middle, and right lower lobes. B, All collaterals have been ligated and divided at their aortic origins. A polytetrafluoroethylene (PTFE) conduit of appropriate diameter is used to connect left and right sides. The large left-sided collateral is connected end to end to the PTFE tube graft, and the three right-sided collaterals are unifocalized either directly or with a separate smaller PTFE tube, after resecting proximal stenotic segments. C, Conduit placement and ventricular septal defect closure are performed as for typical TF with pulmonary atresia without large aortopulmonary collateral arteries. Key: Desc Ao, Descending thoracic aorta.

techniques for creating systemic–pulmonary arterial shunts (see “Techniques of Shunting Operations” in Section 1). Size of the shunt is based on body size and on total pulmonary arterial resistance as assessed from the pulmonary blood flow study just completed. If resistance is particularly high, then a slightly larger shunt may be needed.
arrest is achieved, superior and inferior caval tapes are tightened around the venous cannulae to isolate systemic venous return. A longitudinal incision is made in the infundibulum of the RV and the ventricular cavity is entered. Hypertrophied muscle is removed from the septal and parietal bands and infundibular free wall. This adequately exposes the VSD, which is then closed with either a glutaraldehyde-treated autologous pericardial patch or a woven polyester patch. Depending on the surgeon’s preference, either a running nonabsorbable monofilament suture or interrupted pledgeted mattress sutures are used for attaching the patch to the borders of the VSD. All the same considerations are addressed in this situation as in VSD closure in more typical TF (see Technique of Operation in Section 1).

A small right atriotomy is made and status of the atrial septum examined. If a competent but patent foramen ovale is present, it is usually left as is. A secundum atrial septal defect is typically closed either primarily or, if needed, with a pericardial or polyester patch attached with running nonabsorbable monofilament suture. If the atrial septum is intact, it is left in this state. If appropriate decisions have been made with respect to Rp, presence of a competent RV to pulmonary artery valve conduit usually allows for adequate RV function early postoperatively, minimizing the potential benefits of an open atrial septum (as described in the text that follows). The right atrial incision is then closed in standard fashion and the aortic clamp removed, allowing reperfusion of the myocardium.

At this point, RV-to-pulmonary artery reconstruction is undertaken. With adequate unifocalization and central pulmonary artery augmentation as described earlier, the conduit procedure is the same as used in the more straightforward case with duct-dependent TF, pulmonary atresia, and normally arborizing confluent central pulmonary arteries.

Establishing Right Ventricle-to-Pulmonary Artery Continuity Valved polyester conduits were used in the early era of this type of surgery; today, allograft conduits, either aortic valve with ascending aorta, or pulmonary valve with pulmonary trunk, with or without the bifurcation, are preferred. The allograft pulmonary valved conduit with its bifurcation is often the optimal replacement device. When a bifurcated graft is not required, there is no secure evidence that the pulmonary or aortic valve allograft has an advantage over the other; however, the thinner wall of the pulmonary allograft may have more tendency to become aneurysmal if pulmonary artery pressure becomes importantly elevated.

During the early stages of the procedure, the allograft valved conduit is selected, thawed, and rinsed. In neonates and infants, depending on their size, a 10- to 18-mm-diameter valve can be used; in children older than age 5, a 22- to 25-mm-diameter valve can be used. These sizes should not be flow limiting.

Two somewhat different techniques of allograft insertion are used. In one (preferable), the proximal end of the allograft is sunk into the RV outflow tract and a piece of pericardium, allograft arterial wall, or polyester is used as a roof over the ventriculotomy (Fig. 38-77). The distal end of the allograft is attached to the newly reconstructed transverse central pulmonary artery system before making the proximal anastomosis of the allograft conduit directly onto the right ventriculotomy site. This method has the advantages of minimal use of foreign material on which a thick neointima may develop, and freedom from sternal compression. However, care must be taken that the allograft valve anulus retains its proper circular geometry and that the opening from RV into allograft is large.

In the second method, a woven polyester tube 2 to 5 mm larger than the diameter of the allograft valve anulus is sutured to the proximal end of the allograft. Before insertion, the proximal polyester end is cut in a severely beveled fashion so that it serves primarily as a roof on the ventriculotomy incision, with only a few millimeters of fully circular polyester conduit just proximal to the allograft. With care, the conduit can be kept completely away from the sternum. This technique has the advantage that the perfectly circular geometry of the allograft valve is well maintained and that with it all types of RV and pulmonary trunk morphology can be managed. It has the disadvantage of a very short 2- to 3-mm cylinder of polyester in the proximal end of the conduit.

There are situations in which one or the other method is mandated, depending on RV morphology and availability of the pulmonary trunk, but more often selection is one of preference.

Using either technique, the proximal end of the allograft is cut transversely about 5 mm below the nadir of the valve cusps, leaving the muscular remnant at least 4 mm thick (thicker than when the valve is used for aortic valve replacement). The conduit is not trimmed distally until the nature of the pulmonary artery confluence is established following completed unifocalization and central pulmonary artery augmentation and the distance between this and the right ventriculotomy is measured.

With the first method (see Fig. 38-77, A), a limited longitudinal incision is made in the superior RV wall where the pulmonary trunk would normally arise. Care is taken in extending the incision distally so that the anterior margin of the VSD and right coronary cusp of the aortic valve are not damaged. The RV opening is also enlarged proximally, and any thick trabeculations from the free wall, particularly inferiorly, are excised. The VSD is repaired in a fashion similar to that described for TF with pulmonary stenosis (see Fig. 38-27). The distal end of the allograft conduit is cut so that it is the correct shape and the conduit is the correct length. It must not be too long, or it may kink and possibly compress either branch of the pulmonary artery. The reconstructed or augmented pulmonary artery confluence is opened with an incision extending out along the RPA and LPA. The opening is made long enough to match exactly the diameter of the allograft. The distal anastomosis is made with continuous 5-0 or 6-0 polypropylene suture (Fig. 38-77, B). The proximal conduit anastomosis is made by commencing the suturing posteriorly where the allograft is apposed to the superior margin of the ventriculotomy and any remnant of infundibular septum. A 4-0 polypropylene suture is used, and often both the RV wall and superior edge of the VSD patch are picked up in the suture line to make it particularly secure posteriorly. The suture line is continued from the midline along both sides around about half the circumference of the conduit, and the sutures are held. A patch of pericardium, polyester, or allograft arterial wall is cut to an approximate semilunar shape and sutured into place to complete the anterior half of the anastomosis (Fig. 38-77, C). Its straight superior edge is anastomosed to the muscular portion of the graft as the first step, and its curved inferior edge is attached to the edges of the right ventriculotomy. Good bites of muscle are taken all around and care is used to avoid...
Figure 38-77  Right ventricular outflow tract conduit placement for tetralogy of Fallot (TF) with pulmonary atresia. Much of the surgical technique for repair of TF with pulmonary atresia is similar to that for TF with pulmonary stenosis (e.g., cardiopulmonary bypass [CPB], myocardial management, and intracardiac management of ventricular septal defect [VSD] and atrial septum). Management of these two malformations, however, deviates at several important points. Specific management of the pulmonary arteries depends on the form of pulmonary atresia. For duct-dependent atresia, ligation and division of ductus arteriosus is performed at commencement of CPB. For more complex forms of TF with pulmonary atresia and large aortopulmonary (AP) collateral arteries, complex reconstruction of the pulmonary vasculature is often required (see Figs. 38-74 to 38-76). Although in TF with pulmonary stenosis the VSD closure may be managed through a right atrial incision working through the tricuspid valve orifice, in TF with pulmonary atresia the VSD is always closed through an infundibular incision in the right ventricle (RV).

In the various parts of this figure (and in Fig. 38-78), pulmonary artery anatomy is that of normally arborizing, normal diameter, confluent branch pulmonary arteries with patent ductus arteriosus. However, RV outflow tract conduit placement is the same for more complex TF with pulmonary atresia in which the pulmonary artery system has been reconstructed through unifocalization. A, Ductus arteriosus has been ligated, taking care to avoid narrowing the left branch pulmonary artery. Dashed line on the distal pulmonary trunk shows site of transection in preparation for distal anastomosis of valved conduit to it. Opening in pulmonary trunk may need to be extended with incisions along left and right pulmonary arteries to accommodate circumference of the conduit. A longitudinal infundibular incision has been made and VSD closed with a patch and running suture technique. Note in this case that VSD has an inlet component. Hypertrophic muscle of the RV infundibulum and VSD closure are handled in a manner similar to that in TF with pulmonary stenosis. B, Ductus arteriosus has been divided. A pulmonary allograft valved conduit is shown with the distal anastomosis performed end to end, allograft to pulmonary trunk. A running suture technique using fine monofilament suture is used. Proximal aspect of conduit is then attached to RV. Conduit is placed into ventriculotomy with the suture line attaching its proximal end to the infundibular septum within the ventricular incision. Although not shown in this figure, commonly the proximal suture line incorporates the upper aspect of VSD patch, which is also attached to the anteriorly displaced edge of the infundibular septum. C, Posterior suture line of proximal conduit anastomosis is completed as it transitions onto free edge of infundibular incision. Proximal component of the reconstruction is completed using a roughly hemi-oval patch made of polyester, polytetrafluoroethylene, or glutaraldehyde-treated autologous pericardium. Straight edge of patch is sewn around remaining anterior aspect of proximal conduit, and curved edge is sewn around ventriculotomy site to complete the reconstruction. All sutures lines are running nonabsorbable monofilament suture.
damaging the valve cusps of the graft or the LAD. The conduit arises from the RV in nearly the same position as a normal pulmonary artery and passes superiorly and posteriorly directly to the pulmonary artery bifurcation. It is in little danger of being compressed by the sternum.

In the second method, a longitudinal incision is made in the downstream portion of the RV (Fig. 38-78, A). If a rudimentary infundibular septum and parietal extension are present, these are dissected away from the RV free wall. The VSD is repaired as described in “Ventricular Septal Defect Closure” under Technique of Operation for TF with pulmonary stenosis in Section I, and preparations are made for inserting the conduit. The conduit, once in position, should be directed toward the patient’s left shoulder as it comes off the right ventriculotomy (it need not be oriented parallel to the ventriculotomy) and then curve gently back to the right to approach the pulmonary trunk with just a little redundancy and in an undistorted fashion. This is accomplished by cutting the distal end of the allograft exactly transversely (not obliquely). The proximal end of the conduit is cut obliquely so that the tubular part of the proximal polyester extension is only a few millimeters long and the rest is merely a hood (Fig. 38-78, B). The distal and proximal anastomoses are made using a running polypropylene suture (Fig. 38-78, C).

Completing the Procedure After reconstruction is completed, rewarming and separation from CPB is the same as for TF with pulmonary stenosis, as described in Section I (see also “Completing Cardiopulmonary Bypass” in Section III of Chapter 2).

Assessing Complete Repair Immediately after discontinuing CPB, postrepair (OR) $P_{RV/LV}$ is measured (see “Measuring Postrepair [OR] $P_{RV/LV}$” under Technique of Operation in Section I). A polyvinyl catheter is introduced into the right atrium and advanced into the RV. The level of postrepair (OR or ICU) $P_{RV/LV}$ that is acceptable in this situation is arguable. Thus, repair is left if the $P_{RV/LV}$ is less than about 0.7 and the patient is clinically stable. Although the probability of early death is low for a $P_{RV/LV}$ up to 0.9 (Fig. 38-79), important RV dysfunction occurs at midterm follow-up at these higher RV pressures. If the $P_{RV/LV}$ is greater than 0.7, or if cardiac output is compromised at levels between 0.5 and 0.7, the VSD patch is taken down and the conduit removed, and a central aortic-to–pulmonary artery shunt is placed. This situation, however, should be encountered rarely if the intraoperative blood flow study is used appropriately.

SPECIAL FEATURES OF POSTOPERATIVE CARE

Postoperative care is similar to that described for TF with pulmonary stenosis (see Section I). When the patient has come from the operating room with a complete repair, including closure of the VSD, and postrepair (ICU) $P_{RV/LV}$ (or some surrogate for it) is consistently less than about 0.7 and the patient is hemodynamically stable, further intervention is seldom needed. However, if the ratio approaches that level, there is a considerable probability of death (see Fig. 38-79), and either the cause of the residual obstruction must be removed or ameliorated or the VSD patch perforated. If the patient’s original morphology was pulmonary atresia with confluent pulmonary arteries and a ductus arteriosus, the $P_{RV/LV}$ will rarely reach this value unless the RV-to-pulmonary trunk reconstruction (usually conduit) is technically inadequate, resulting in obstruction. Immediate revision of the conduit is indicated.

If the patient’s original morphology involved AP collaterals that were unifocalized, the situation is more complex. Use of the intraoperative flow study will minimize the number of cases that result in an elevated $P_{RV/LV}$. However, should the situation arise, and the elevated pressure is proven not to be due to obstruction in the conduit but rather to elevated resistance in the pulmonary vascular bed, surgical revision is indicated. Cardiac catheterization should be performed to identify the precise cause of the elevated pressure. If surgically reparable obstruction is found in the reconstructed pulmonary arteries, revision aimed at relieving the obstruction is indicated. If there is no surgically correctable obstruction, the cause of the elevated pressure is elevated resistance in the pulmonary microvascular bed. In this case, if the $P_{RV/LV}$ is above 1.0, VSD perforation is performed; if the $P_{RV/LV}$ is between 0.7 and 1.0, VSD patch removal, conduit takedown, and placement of a systemic-to–pulmonary artery shunt is performed.

Occasionally, pulmonary hypertension is caused by reactivity in the microvascular bed rather than by proximal or fixed distal obstruction. This is more likely if the PPA and PVR had been low earlier postoperatively. Increased ventilatory support, sedation, and a trial of inhaled nitric oxide are typical maneuvers that are both diagnostic and therapeutic.

Postoperative airway difficulties are more common in TF with pulmonary atresia than in TF with pulmonary stenosis, especially if complex unifocalization was performed. Large airway problems caused by external compression by the aorta, unifocalized collaterals, or conduits can occur. $M^{17}$ Unmasking of subclinical, or exacerbation of clinically important, preoperative tracheobronchial malacia can also occur. Phrenic nerve injury is an important concern when extensive dissection has been performed. Small airway reactivity also appears to be more common than in TF with pulmonary stenosis, possibly related to an intrinsic predisposition, but also almost certainly related to direct trauma, autonomic nerve disruption, or airway blood supply disruption. $^{R4}$ Careful and aggressive pulmonary toilet is an important component of treatment, both intraoperatively after CPB and in the ICU. Tracheobronchial suctioning and lavage, and even bronchoscopy, may be needed to keep airways free of both clear and bloody secretions.

A problem particular to certain unifocalization cases is lung reperfusion injury. This is most likely to occur in cases that preoperatively have severely underperfused segments of lung. The acute increase in flow and pressure into these vascular beds can result in important lung parenchymal edema, increased airway secretions, and pleural effusion. The process typically reaches a peak in severity 24 to 48 hours after surgery and resolves gradually over the following 3 to 5 days. The diagnosis is made by chest radiogram findings of pulmonary edema and consolidation, with evidence of intrapulmonary shunting (hypoxemia) in the appropriate clinical setting and with no evidence of infection. The treatment is largely expectant, with mechanical ventilator support until there is clinical evidence that the process has peaked and is resolving.

If the PLA is considerably higher than the PPA (see “Risk Factors for Low Cardiac Output” in Section I of Chapter 5), a left-to-right shunt may be present at some level. Unless
Figure 38-78  Alternative method for right ventricular (RV) outflow tract valved conduit placement in tetralogy of Fallot with pulmonary atresia. General operative management is similar to that described in Fig. 38-77. Using this method, a circumferential polyester conduit is attached to proximal end of allograft valved conduit to facilitate ventricle-to-conduit anastomosis. A, Dashed lines indicate incisions to be made on central pulmonary artery and on RV infundibulum. B, Inset shows polyester conduit being connected to proximal end of allograft valved conduit with a running monofilament suture. In main figure, distal anastomosis between allograft conduit and incision in pulmonary trunk is performed, leaving atretic pulmonary trunk intact. Proximal polyester extension of allograft is tailored with a sharp bevel to accommodate its connection to the RV. C, Beveled free edge of polyester conduit is connected to ventriculotomy to complete operation. As seen here, there may be only several millimeters of length to circumferential component of polyester extension of the conduit, which mostly serves as a proximal hood, similar to freestanding patch used for hood in technique shown in Fig. 38-77. Key: PTFE, Polytetrafluoroethylene.
the patient is convalescing well, an echocardiographic and cineangiographic search is made for sites of shunting that can be closed percutaneously or surgically.

RESULTS

After Repair

Early (Hospital) Death

Overall hospital mortality after repair in a heterogeneous population varies between less than 3% and up to 20%, depending on era, patient characteristics, and institution.

Most recent studies report hospital mortality of less than 5% for a heterogeneous population and less than 3% when patients undergoing extensive unifocalization procedures are excluded. When examining clinical series dealing only with complete repair involving unifocalization, hospital mortality historically has generally been less than 10% as experience with surgical management of this difficult group of patients has accumulated, the typical pattern of improved hospital mortality has emerged. Large series indicate that over the last 5 to 10 years, hospital mortality can be as low as 2% (as compared to 5% for a heterogeneous population) and less than 3% when patients undergoing extensive unifocalization procedures are excluded.

Incremental Risk Factors for Death

Variables relating to morphology of the pulmonary arterial circulation have traditionally been considered the strongest risk factors for death after repair, presumably accounting for most of the historical differences in outcome between these patients and those having TF with pulmonary stenosis. Available data for patients who do not require unifocalization, as well as for those who do, suggest that at least in the medium term, these variables can be and are being neutralized.

Pulmonary Artery Abnormalities

Size of central and proximal extracardiac right and left pulmonary arteries, congenitally nonconfluent right and left pulmonary arteries, and number of large AP collateral arteries have been identified as risk factors for death after repair, presumably accounting for most of the historical differences in outcome between these patients and those having TF with pulmonary stenosis. Available data for patients who do not require unifocalization, as well as for those who do, suggest that at least in the medium term, these variables can be and are being neutralized.

Modes of Death

Most early postoperative deaths are attributable to acute cardiac failure, although some are due to acute or subacute pulmonary failure and a few to hypoxia or hemorrhage. In the large series of patients undergoing one-stage unifocalization and repair by Hanley and colleagues, acute hepatic failure was an important cause of death in the early years of the experience, accounting for much of the early 10% mortality; however, in the most recent decade, this cause has been virtually eliminated, with overall early mortality improving to approximately 2%. Most late postoperative deaths are due to chronic heart failure, although an appreciable number are sudden. These latter may be arrhythmic deaths. Unifocalized patients may experience fatal hemothysis.

Incremental Risk Factors for Death

Variables relating to morphology of the pulmonary arterial circulation have traditionally been considered the strongest risk factors for death after repair, presumably accounting for most of the historical differences in outcome between these patients and those having TF with pulmonary stenosis. Available data for patients who do not require unifocalization, as well as for those who do, suggest that at least in the medium term, these variables can be and are being neutralized.

Pulmonary Artery Abnormalities

Size of central and proximal extracardiac right and left pulmonary arteries, congenitally nonconfluent right and left pulmonary arteries, and number of large AP collateral arteries have been identified as risk factors for death after repair, presumably accounting for most of the historical differences in outcome between these patients and those having TF with pulmonary stenosis. Available data for patients who do not require unifocalization, as well as for those who do, suggest that at least in the medium term, these variables can be and are being neutralized.
the latter identified in early studies is probably a surrogate for that of increased Rp. Early and aggressive complete unifocalization of all collateral vessels and patch augmentation of centrally hypoplastic pulmonary arteries have eliminated the association between higher Rp and native pulmonary arterial arborization abnormalities.\textsuperscript{54,86,87}

**Age (Size)** Age older than about 5 to 8 years is a risk factor for death, primarily late after repair.\textsuperscript{5,17} The incremental risk of young age, once important, has largely been neutralized. This is evident in more recent experiences from institutions in which one-stage repair is typically performed in neonates and young infants.\textsuperscript{16,1,20,84,86,74}

**Postrepair \(\text{P}_{\text{RV/LV}}\)** Higher postrepair \(\text{P}_{\text{RV/LV}}\) is a risk factor for death after repair, probably an immutable one (see Fig. 38-79).\textsuperscript{5} This factor is the final common expression, which includes the influences of intrinsic Rp, degree of arborization of the pulmonary arteries (which includes completeness of unifocalization), size of the large pulmonary arteries, and precision with which any reconstruction or unifocalization has been accomplished.

**Duration of Cardiopulmonary Bypass** Duration of CPB was identified as a risk factor for death in early studies, particularly in the early period after repair.\textsuperscript{1,5,17,24} Duration of CPB may carry risks related to CPB’s intrinsic damaging effects, but it may also be a surrogate for technical complications during surgery. More recently, duration of CPB has not been associated with increased risk of early death in the large series of one-stage unifocalization and repair cases reported by Hanley and colleagues.\textsuperscript{36} Prolonged duration of CPB is a necessity in these patients in order to complete the unifocalization process, and thus does not represent difficulties or complications during surgery. Also, in more recent years, a reduction of the damaging effects of CPB has almost certainly been achieved.

**Heart Block**

Heart block is rare after repair, just as it is after repair of TF with pulmonary stenosis.

**Functional Status**

Most patients who survive repair have a good functional status (Table 38-13). Importantly, a tendency to declining functional status across time exists, but this may be attributable to chance alone (Fig. 38-81). Few objective studies of exercise performance have been reported.

Data from Kirklin and colleagues.\textsuperscript{524}

**Pulmonary Artery Pressure and Resistance**

As with other postoperative outcome events, information about P\(\text{PA}\) and Rp is limited. RV pressure can in no way substitute for P\(\text{PA}\) and Rp, because almost all patients have a pressure gradient between the RV and pulmonary arteries after repair. Shimazaki and colleagues found that 75% of patients had a gradient of at least 20 mmHg late after repair, and 10% had one of 60 mmHg.\textsuperscript{512} When patients undergoing repair in infancy or the neonatal period are considered, gradients progress inevitably over time, and at midterm follow-up essentially all patients will have important gradients.

Early data suggested that about 50% of a heterogeneous group of patients will have elevated P\(\text{PA}\) and Rp late after repair, with elevated Rp correlating highly and inversely with extent of native pulmonary artery arborization.\textsuperscript{512} More recent data from patients undergoing surgical management plans that include early and complete correction of pulmonary artery arborization abnormalities demonstrate low P\(\text{PA}\) and Rp, both early and at midterm follow-up and regardless of degree of original arborization,\textsuperscript{84,86} indicating that this correlation is not immutable (Table 38-14). At midterm follow-up, \(\text{P}_{\text{RV/LV}}\) was similar to the perioperative value, indicating that the unifocalized vascular bed grows over time.\textsuperscript{36}

**Reintervention**

Reoperations other than those on valved conduits and on peripheral pulmonary arteries in patients undergoing unifocalization are rare. Reintervention is infrequently needed to repair a residual or recurrent VSD or to close an overlooked large AP collateral artery (both in 3% of patients).\textsuperscript{24} Progressing dilatation of the aortic root and development of aortic valve regurgitation has required aortic valve replacement in 1% of patients.\textsuperscript{24} For patients undergoing early aggressive unifocalization, reoperation on the peripheral pulmonary
arterial vasculature for persistent or recurrent obstruction is less than 15% at 5-year follow-up. The most common reoperation is replacement of an obstructed xenograft or allograft valved conduit. Among a heterogeneous group of patients receiving these conduits for a variety of conditions, but most commonly for TF with pulmonary atresia, freedom from reoperation for conduit obstruction was 99%, 95%, 59%, and 11% at 3.5, 5, 10, and 15 years, respectively. Among very young patients receiving 12-mm porcine valve xenografts in a polyester conduit, 3.5-, 5-, and 10-year freedom from replacement was 60%, 35%, and 9%, respectively, related in part to rapid growth of the patient. Time-related freedom from reoperation on allograft aortic and pulmonary valved conduits larger than about 21 mm is not yet known with a high degree of certainty. Currently, for properly preserved allograft aortic conduits, this appears to be about 95% at 5 years, falling to about 90% at 10 years and 60% at 20 years (Fig. 38-82, A). The hazard function for reoperation has a steadily rising single phase (Fig. 38-82, B), suggesting that all such conduits may ultimately require replacement. Small patients require small allograft valved conduits, and the very small conduits required in neonates and infants clearly have a shorter reoperation-free interval than do larger conduits that can be used in children (Fig. 38-83). Despite these general trends, individual patient reoperation-free intervals can be quite variable, with some neonates having intervals up to a decade.

Prevalence and rate of reoperation for conduit obstruction are considerably greater when an allograft valved conduit is extended with a polyester cylinder than when it is not. It is not known whether this applies to proximal or distal extensions, or to both. A proximal polyester gusset in the RV does not seem to have this effect. Use of the valved bovine jugular vein conduit for RV to pulmonary artery reconstruction has received mixed reports. One individual institution report showed a high degree of midterm obstruction, whereas an eight-institution multi-institutional study, as well as individual institutional studies, showed midterm results that compare favorably with those of valved allografts.

After Palliative Operations for Increasing Pulmonary Blood Flow

**Effect on Size of Pulmonary Arteries**

Important enlargement of at least some portions of the pulmonary arteries can be obtained by increasing pulmonary flow. The ratio improved when the periods between years 1992 through 1997 and 1999-2005 were compared. The ratio in patients younger than 1 year, the most common operation was repair of truncus arteriosus; in older patients, it was repair of tetralogy of Fallot with pulmonary atresia. Key: $P_{RV/LV}$ Ratio of right-to-left ventricular pressures.

blood flow and pressure. This observation has influenced a number of institutions to follow management plans in patients with small pulmonary arteries that include staging procedures to achieve increased flow and pressure into both the pulmonary arteries and collateral vessels. Various ways of achieving this have been described, including placing PTFE systemic–pulmonary arterial shunts, directly connecting central pulmonary arteries to the ascending aorta, placing RV–pulmonary trunk conduits or patches, and constructing shunts into individual or partially unifocalized collateral vessels. Although vessel growth clearly results from these procedures, it is difficult to document how frequently they lead to intracardiac repair with acceptable PRV and PPA. Reports suggest that approximately 20% of anastomoses performed in the palliative setting will occlude, and about half the patients undergoing staged palliative procedures will eventually undergo intracardiac repair. A substantial portion of these patients will have unacceptably high PPA.

Also well established is the fact that enlargement is not always diffuse, and there may remain areas of stenosis, presumably because pulmonary arterial walls are not uniformly compliant. Reasons for the noncompliance are not completely clear. Intrinsic abnormalities within the vessel wall and persistently abnormal blood flow patterns related to the palliative procedure may both play a role. These areas can be approached by percutaneous balloon dilatation or stenting, or by reoperation. An immediate favorable response can be achieved in more than 80% of cases; however, later stenosis and occlusion are common.

Likewise, the degree of enlargement that can be obtained in individual patients cannot be accurately predicted. However, it is correlated with the magnitude of increase in the Qp and PPA that can be brought about by the palliative procedure. When the central pulmonary arteries are small, palliative RV–pulmonary trunk and systemic–pulmonary arterial shunts can provide maximal stimulus for pulmonary arterial enlargement. There is no reason to believe that this growth is any greater than that occurring in the pulmonary arteries and unifocalized collaterals following reparative surgery. Although there are no definitive data, there is a suggestion that focal areas of stenosis may be reduced in the setting of the normal pulmonary blood flow patterns that attend reparative, as opposed to palliative, operations.

**Survival**

Early mortality (1-month) for palliative operations, as reported in the mid-1980s, was 17%, with most of the deaths occurring in very small (young) infants with severe hypoplasia of the pulmonary arteries or other kinds of pulmonary arterial anomalies (Fig. 38-84). It is likely that mortality would be lower in a more contemporary series, considering recent improvements in perioperative care. Recent reports from institutions that emphasize palliative procedures for TF support this. Survival for at least 12 years has been good (75%) in patients receiving a systemic–pulmonary arterial shunt and no further procedures (see Fig. 38-84). These patients were deemed unsuitable for repair in the era of 1967 to 1983. There is no way, it seems, to compare in a risk-adjusted manner this survival with that had these same patients undergone one-stage repair or received no treatment. Most of the deaths occurred within the first 3 postoperative months.

**Figure 38-84** Time-related survival in patients having tetralogy of Fallot (TF) with pulmonary atresia who underwent no interventional therapy (n = 22) and who underwent only a systemic–pulmonary arterial shunt with no further intervention (n = 49). (Analysis is based on cross-sectional follow-up of 244 patients having TF with pulmonary atresia seen at UAB between 1967 and July 1983; follow-up was in mid-1986.) A, Survival. Depiction is as in Fig. 38-47. B, Hazard function for death.

**Modes of Death**

Death early after operation is usually due to acute cardiac failure, whereas late postoperatively it is usually from hypoxia.

**Functional Status**

There is little information on functional status; however, because all palliated patients have a completely mixed circulation, function is reduced in this population.

**Results of No Interventional Therapy**

**Historical Perspective**

Because there has been increasing recognition over the past 20 years that surgical or other interventional therapy is beneficial to patients with all forms of TF with pulmonary atresia, unselected patient cohorts receiving no intervention no longer exist.

**Survival**

Survival for at least 12 years in 22 patients receiving no interventional treatment was 75%, with most of the deaths occurring within a year of presentation (see Fig. 38-84). These were patients considered unsuitable for complete repair and

---

**PART VII Congenital Heart Disease**

---

**Survival**

Early mortality (1-month) for palliative operations, as reported in the mid-1980s, was 17%, with most of the deaths occurring in very small (young) infants with severe hypoplasia of the pulmonary arteries or other kinds of pulmonary arterial anomalies (Fig. 38-84). It is likely that mortality would be lower in a more contemporary series, considering recent improvements in perioperative care. Recent reports from institutions that emphasize palliative procedures for TF support this. Survival for at least 12 years has been good (75%) in patients receiving a systemic–pulmonary arterial shunt and no further procedures (see Fig. 38-84). These patients were deemed unsuitable for repair in the era of 1967 to 1983. There is no way, it seems, to compare in a risk-adjusted manner this survival with that had these same patients undergone one-stage repair or received no treatment. Most of the deaths occurred within the first 3 postoperative months.
too well oxygenated to require a systemic–pulmonary arterial shunt when they presented between 1967 and 1983. Most were older children who had fewer than 10 pulmonary arterial segments in continuity with central or hilar RPA or LPA. Again, there is no way to make a risk-adjusted comparison of their survival with that of patients who received interventional therapy. It is, however, almost a certainty that this patient group is highly selected and does not represent the newborn population with this malformation.

**Modes of Death**
Among the four patients who died within the follow-up period, one died of hypoxia and one of massive pulmonary hemorrhage. Mode of death was unknown in the other two.

**Functional Status**
Functional status of living patients was unknown, except in four. Two of these considered themselves to be fully active (NYHA class I), whereas one each was in NYHA classes II and III.

**After Staged Palliative Operations for Unifocalization**
Results of unifocalization operations, performed as a preliminary step before complete repair in patients who have TF with pulmonary atresia and considerably incomplete distribution of the RPA and LPA, are not yet clear (see Special Situations and Controversies later in this section). Some reports refer only to a few patients; others contain information that is insufficient for assessing results. The best estimate based on available reports is that as many as half, but often less, actually undergo repair. Of those who do, a substantial percentage, even a majority, will have $P_{RV/LV} > 0.67$.18,M23,P21,S3,W6,Y1

One exemplary report from the Hospital for Sick Children at Great Ormond Street, London,530 states that among 26 infants and children undergoing staged unifocalization operations of various types through a lateral thoracotomy, most commonly with interposition of prosthetic tubes, 4 (15%; CL 8%-26%) died in hospital postoperatively. Eleven of 20 patients restudied had 10 or fewer pulmonary artery segments connected to central pulmonary arteries before the unifocalization procedure, whereas at restudy 9 were in this state (Fig. 38-85). Patency of the unifocalizing anastomoses varied between 5% and 100%, depending on the type of procedure. Seven (27%; CL 17%-39%) of the original group of 26 patients either underwent complete repair or were suitable for it.

A large experience has also been reported from the Mayo Clinic.521 Among 38 patients undergoing unifocalization, hospital mortality was 5% (CL 2%-12%), similar to that at Great Ormond Street. Sixty-one percent (CL 51%-70%) underwent complete repair, a higher prevalence than at Great Ormond Street; however, there is insufficient information to determine whether patient groups were comparable. Among the 23 patients undergoing complete repair, 21 (91%; CL 81%-97%) survived; these represent 55% (CL 46%-65%) of the original group, a higher prevalence than at Great Ormond Street. Of the 23 patients undergoing repair, 13% had postrepair (OR) $P_{RV/LV} > 0.85$, and the mean value was 0.63.

Fifty-eight patients with TF and pulmonary atresia were reported from the Royal Children’s Hospital in Melbourne, Australia, 34 of whom had unifocalization procedures. It is difficult to determine the outcome in these 34 separately from that of the entire group. However, among the 58 patients, 27 (47%; CL 39%-54%) either died after preliminary procedures or were ultimately considered unsuitable for repair. Results were good among the 30 patients who underwent repair, with one early death and three late deaths. In 2 of the 30 patients, late VSD patch fenestration was required because of $P_{RV/LV} > 1$. Among 27 survivors who had undergone postoperative hemodynamic study, 5 (29%; CL 17%-45%) had postrepair $P_{RV/LV} < 0.7$ to 0.9.18

Thirty-four similar patients were reported from the Heart Institute of Japan at the Tokyo Women’s Medical Colleges.53 Twenty-two had incomplete distribution of one or both pulmonary arteries. Among 16 of the 34 patients who underwent final repair, postrepair $P_{RV/LV}$ ranged between 0.86 and 1.00, with a mean of 0.71. In four other patients, a perforated VSD patch was used because severe elevation of postrepair $P_{RV/LV}$ was predicted if complete repair was done. Clearly, some patients are correctable after a staged unifocalization operation and successfully undergo complete repair. For those whose repair is not successful, many factors may come into play, including natural attrition of healthy lung segments that occurs over time due to either vessel occlusion or pulmonary vascular obstructive disease, iatrogenic loss of lung segments directly related to palliative surgery, inability to create vascular continuity between lung segments due to scarring from prior palliative operations, and general cardiovascular complications related to chronic mixed circulation. Risk-adjusted, time-related probabilities of death and of importantly elevated postrepair $P_{RV/LV}$ are not yet available. As a general observation, however, the number of patients who achieve complete repair, and in particular who achieve complete repair with a $P_{RV/LV} < 0.5$, when the routine approach is initial palliation, appears to be substantially less than when the routine approach is early one-stage unifocalization and intracardiac repair.

![Figure 38-85](image)

Figure 38-85 Number of pulmonary arterial segments connected centrally before and after unifocalization in 20 patients. $P < .01$ for difference in means (vertical bar represents one standard deviation).
Key: CPA, Central pulmonary arteries; Preop, preoperative. (From Sullivan and colleagues.139)
INDICATIONS FOR OPERATION

Proper indications for operation, and their sequencing in the various subsets of patients who have TF with congenital pulmonary atresia, cannot be identified with certainty. This is not surprising, because the necessary patient-specific (risk-adjusted) comparisons of outcomes after no interventional treatment vs. the various types and combinations of procedures are not yet available. Therefore, indications can only be discussed in general terms for the major groups.

Confluent and Normally Distributing Right and Left Pulmonary Arteries and Patent Ductus Arteriosus

The highly unfavorable natural history of newborns in this subset, coupled with the fact that up to 95% survive complete repair in early life and 75% of those undergoing repair are alive and in good health for at least 10 years, indicates that complete repair as early in life as possible should be undertaken, almost always meaning neonatal repair. It must be emphasized, however, that equal outcomes appear to be achievable with neonatal shunting followed by later repair.

In those patients first seen after the neonatal period and usually living because of an AP anastomosis of some type, repair as soon as possible is likewise advisable.

Confluent, Nonconfluent, or Absent Pulmonary Arteries and Aortopulmonary Collaterals

Although the natural history is much more variable in this morphologic group, rarely do patients reach adult life in a healthy state if left untreated. Based on early surgical outcomes before 1990, it has been argued by some that surgical intervention is not indicated unless the individual is very symptomatic. More recent surgical results following both staged unifocalization and one-stage unifocalization and intracardiac repair demonstrate that repair with low PRV and PPA can be achieved in a high percentage of patients whether symptomatic or not. Although long-term outcome using these newer techniques is not yet known, the combination of low operative mortality and resultant low PRV suggests that outcomes over the long term are likely, in many cases, to be comparable with those achieved in the more favorable morphologic subset of patients with TF with pulmonary atresia and ductus-dependent, confluent, normally distributing pulmonary arteries. The most important principles in achieving results comparable with this more favorable group are incorporating blood supply from all lung segments into the central pulmonary artery system and achieving this in a timely manner such that the microvasculature in each lung segment remains undamaged.

SPECIAL SITUATIONS AND CONTROVERSIES

Alternatives to One-Stage Unifocalization and Intracardiac Repair

Situations may arise in the setting of large AP collaterals and true pulmonary artery arteriography abnormalities in which one-stage unifocalization and intracardiac repair is not indicated. One of these is described earlier in which one-stage unifocalization through a midline sternotomy is accomplished, but Rp is proven to be elevated, intracardiac repair is aborted, and unifocalized pulmonary arteries are connected to the systemic circulation by a shunt. It has been demonstrated that approximately 80% to 90% of patients with large AP collaterals can achieve complete bilateral unifocalization through a midline sternotomy in one procedure in early infancy, and of these, approximately two thirds can undergo intracardiac repair at the same time. Of the one third of patients who undergo complete unifocalization, but in whom Rp is too high to permit immediate intracardiac repair, most achieve repair within 2 years.

There are various reasons why midline complete unifocalization is contraindicated in approximately 10% to 20% of patients with major AP collaterals. The most important is a lack of pulmonary vascular “raw materials.” *Raw materials* are defined as the combination of true pulmonary arteries and major AP collaterals taken together. If both the true pulmonary artery system and AP collateral system are severely underdeveloped, an alternative approach should be considered. In the setting of poorly developed collaterals and absent true pulmonary arteries, a lateral thoracotomy with single lung unifocalization connected to an AP shunt may be the procedure of choice. This would be followed by a similar procedure on the contralateral lung at a future time. At a third procedure, a median sternotomy approach would be used to achieve vascular confluence between the left and right lungs, with later intracardiac repair and takedown of the previously placed shunts. Many techniques, using native tissue as well as prosthetic material, have been described to accomplish this type of reconstruction. In other situations the true central pulmonary arteries are present, confluent, but extremely hypoplastic in the mediastinum; however, they arborize to all or almost all of the lung segments, and communicate to the collateral system extensively within the lung parenchyma. In this situation, there are few if any isolated segments of lung that are supplied by only collateral flow. In this setting, creation in the neonatal or early infancy period of a central native tissue anastomosis between the ascending aorta and blind end of the pulmonary trunk can be performed to promote growth of the central system with communication to most lung segments. Following an interim period of central pulmonary artery growth, a second procedure with ligation of the dual-supply collateral sources at their systemic origin, and subsequent intracardiac repair and placement of an RV-to-pulmonary trunk conduit, can be accomplished. It should be emphasized that there is wide variability among experienced surgeons in the approach to TF with pulmonary atresia and large AP collaterals. Experienced surgical teams may prefer one of the alternative surgical approaches described earlier as their procedure of choice.

One common approach is to perform an initial procedure that provides increased blood flow and pressure into the confluent hypoplastic central artery system whenever there exists confluent central pulmonary arteries. This can be accomplished through many techniques—for example, by creating the central systemic–pulmonary tissue-to-tissue connection described earlier. Another approach is to create an RV-to-pulmonary trunk conduit using various tissue or synthetic prostheses, leaving the VSD open. A third approach is to create a prosthetic systemic–pulmonary arterial shunt to the pulmonary trunk or one of its branches.

There are several major concerns about all of these approaches when they are used unselectively as first-line
management, especially when the central pulmonary arteries have limited arborization. First, they leave collateral flow untouched, allowing for time for detrimental changes to occur in the lung vasculature supplied by collaterals, either in the form of overcirculation with development of pulmonary vascular obstructive changes or in the form of stenosis and occlusion leading to loss of lung segments. These negative effects inevitably lead to reduction in healthy lung cross-sectional area, increasing Rp. Another concern is that any surgical procedure is followed by scarring and adhesions, markedly reducing the surgeon’s ability to manipulate, reroute, and unifocalize collaterals at subsequent operations. A final concern is that following any shunt or conduit procedure, no matter how small the shunt or conduit is, the flow and pressure transmitted into the distal vasculature of the true pulmonary arteries are likely to be pathologically elevated when there is a very limited distal bed in association with reduced arborization.

Regardless of the specific surgical approach, most programs with substantial experience with this lesion believe that unifocalization of large collaterals is an important component of overall management; however, this view is not universally acknowledged.

**Percutaneous Balloon Dilatation of Stenoses of Right and Left Pulmonary Arteries**

Lock and colleagues first demonstrated the feasibility of this procedure. Intimal disruption with tearing of the media is one mechanism of dilatation, with the tears being subsequently filled in by scar tissue. In a multi-institutional study of a heterogeneous group of 156 patients, the largest subset of which had some form of pulmonary atresia, systolic pressure gradient across the stenosis was reduced only 10 to 14 mmHg, on average. A single-institution analysis of results in 135 patients indicated that about 60% of the procedures were satisfactory, defining this as a decrease of 20% or more of the peak pressure ratio between RV and aorta. Risk of death or other major complication was 1% to 3%. Patient age had no correlation with outcome. Effectiveness may be increased in the future by use of expandable stents.

Effectiveness of balloon dilatation can also be assessed by its effect on normalizing the flow distribution in the lungs as measured by nuclear lung perfusion scan, even if Ptv is not reduced. Following complete repair, normalization of homogenous flow to the lungs can be promoted by balloon dilatation of lobar and segmental stenoses within the unifocalized pulmonary artery system.

**Percutaneous Closure of Large Aortopulmonary Collateral Arteries**

Yamamoto first demonstrated the feasibility of this procedure in 1979 and Szarnicki and colleagues accomplished it by embolizing a Gianturco wire coil device in 1981. Subsequently, a number of studies have demonstrated the effectiveness and safety of percutaneous closure of large AP collateral arteries as long as proper precautions are taken. When wire coil uniformly coated with thrombogenic polyester strands is used, occlusion by thrombosis usually occurs within about 10 minutes. Other devices for promoting thrombosis have been used, including bucrylate adhesive and detachable silicone balloons. With wire coil and proper techniques, complete occlusion is achieved in about 70% of instances and subtotal occlusion in another 25%.

A large AP collateral artery should never be closed surgically or percutaneously when it connects end to end to distal pulmonary arteries, and thus is the sole or major source of blood flow to one or more pulmonary segments. Even when blood supply to a pulmonary segment occurs from dual sources, occlusion of the collateral source may not be indicated. For example, if upon review of detailed angiograms, it is determined that the collateral tissue can be used productively in surgical unifocalization, it should not be occluded prematurely. In this case, the collateral should be left open at catheterization and then ligated and divided during surgery, with its tissue used in the unifocalization and pulmonary artery augmentation process. When it is determined that tissue from a dual-supply collateral is not needed in surgical reconstruction and coil occlusion is being considered, it is prudent to occlude the vessel temporarily to be certain that its presence is not necessary for maintaining reasonable SaO2.

---

**Section III  Tetralogy of Fallot with Absent Pulmonary Valve**

**DEFINITION**

Tetralogy of Fallot with absent pulmonary valve is a subset of TF in which the pathologic and clinical states are determined largely by the vestigial, severely hypoplastic, nonfunctioning pulmonary valve cusps at the RV–pulmonary trunk junction.

**HISTORICAL NOTE**

The first apparent description was by Royer and Wilson in 1908. A second example was not reported until Kurtz and colleagues described their case in 1927.

**MORPHOLOGY**

The pulmonary valve cusps are myxomatous nubbins of valvar tissue at the RV–pulmonary trunk junction. They are so severely hypoplastic that they are both nonfunctioning and only minimally stenotic. The pulmonary “anulus” is markedly narrow.

The VSD is large and similar to that in TF with pulmonary stenosis. The typical associated malalignment of the outlet septum contributes to infundibular narrowing. In addition, and perhaps related to the large flow, the RV outflow tract is often dilated and elongated. The sinus portion of the RV is hypertrophied and its volume large.

The pulmonary trunk and central portions of the right pulmonary artery and left pulmonary artery are often aneuysmally dilated at birth. This dilatation may extend into the hilar portions of these arteries, particularly the right, which then produces tracheobronchial compression. This often results in either hyperexpansion from air trapping or collapse of lobes or even an entire lung.
Beyond their hilar portions, pulmonary arteries are usually of normal size. Rarely are distal branches hypoplastic or hilar branching pattern abnormal.\textsuperscript{23} However, segmental distribution of the RPA and LPA is abnormal. Instead of single segmental arteries, tufts of arteries entwine and compress the interpulmonary bronchi in some patients. This pathology, when present, may in part account for symptoms of severe pulmonary dysfunction seen in some neonates and young infants.\textsuperscript{1,4}

There is controversy regarding the histopathology of the dilated pulmonary arteries in this syndrome. Arensman and colleagues report a normal pulmonary arterial wall in five of six children, with one child having a reduction in the amount of elastic tissue.\textsuperscript{5,19} Osman and colleagues have reported similar findings,\textsuperscript{8,10} but histopathologic abnormalities have been reported by others.\textsuperscript{11,25,9,9,11,19} Whatever the histology, physiologic studies indicate a marked decrease in RPA compliance in sick small babies.\textsuperscript{11,19}

Cause of massive dilatation of the pulmonary arteries in utero is unclear, but when there is severe pulmonary regurgitation and a large VSD, absence of ductal flow between the pulmonary trunk and aorta seems to be essential to intrauterine survival.\textsuperscript{26} Thus, a ductus arteriosus (or ligamentum) is almost always absent at autopsy\textsuperscript{22,25} unless the ductus connects to a pulmonary artery isolated from the pulmonary trunk. Thus, a likely cause of intrauterine dilatation of the pulmonary arteries is hemodynamic. The combination of a severely regurgitant valve in association with limited distal runoff from the pulmonary arteries from a combination of absence of a ductus and normally elevated intrauterine pulmonary vascular resistance (Rp) results in an exaggerated pulse pressure in the central pulmonary arteries.

There may be origin of the RPA or LPA from the ascending aorta,\textsuperscript{3} or a pulmonary artery (usually the left) may originate from a patent ductus arteriosus.\textsuperscript{26} When a pulmonary artery arises from a ductus, it is not aneurysmatically dilated, consistent with the hemodynamic explanation mentioned earlier.

### CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

TF with absent pulmonary valve generally results in both severe pulmonary regurgitation and a somewhat increased pulmonary blood flow (Qp). Narrowing at the pulmonary “anulus” in combination with the large VSD results in low PPA and similar peak pressures in both ventricles.\textsuperscript{11} Part of the pressure gradient between the RV and pulmonary trunk is related to large Qp (the \(Qp/Qs\) [ratio of Qp to systemic blood flow, \(Qs\)] is generally 1.5 to 2.0); part is related to mild “anular” and infundibular narrowing.

When pulmonary regurgitation is severe, \(Qp\) increased, and pulmonary arteries dilated and compressing the tracheobronchial tree, presentation may be in early infancy, often in the first weeks of life, with heart failure and severe intractable tracheobronchitis and respiratory distress responding poorly to routine medical measures. In the most severe cases, presentation may be immediate at birth, with the neonate \textit{in extremis} from an inability to breathe due to bronchial compression. Cyanosis is absent unless hypoxia develops from pulmonary complications. There is marked failure to thrive, and there may be low cardiac output, acidemia, and death.

In other cases, especially, but not always, when pulmonary regurgitation is less severe (in association with slightly more pulmonary stenosis, a near-normal \(Qp\), and less marked aneurysmal dilatation of the pulmonary arteries), presentation is later in life and less severe, usually confined to recurrent respiratory infections or mild heart failure. Notably, however, severity of the major morphologic and physiologic changes (size of the aneurysmal central pulmonary arteries and degree of pulmonary regurgitation) does not always predict severity of presentation. The important variable in critical neonatal presentation seems to be the inability of the airways to resist compression.

### Physical Examination

Severely affected infants are in considerable respiratory distress, with tachypnea, substernal retraction, and wheeze with rales and rhonchi audible throughout both lung fields. The heart is overactive and its rate rapid, pulse is of low volume, and there is obvious cardiomegaly, hepatomegaly, and raised venous pressure. There may be a precordial bulge. The infant is frail, cachectic, and febrile. On auscultation a to-and-fro murmur is audible along the left sternal edge, with the diastolic component often the more prominent. The second heart sound is single, and there may be an apical gallop.

### Chest Radiography

Chest radiography is distinctive, showing from birth marked supracardiac mediastinal widening caused by aneurysmal dilatation of central and hilar pulmonary arteries, usually equal on both sides although sometimes asymmetric, with relatively oligemic lung fields. Segmental or lobar atelectasis is common, and sometimes an entire lung is collapsed. Atelectatic portions of the lung may be overinflated (Fig. 38-86). Atelectasis is

\begin{figure}

Volume rendering from a computed tomographic
angiography image of a 5-year-old boy born with tetralogy of Fallot with absent pulmonary valve. The pulmonary trunk (PT), right pulmo-

nary artery (R), and left pulmonary artery (L) are markedly enlarged compared with the aorta (Ao).

Figure 38-87

associated with mediastinal shift, and in cases with partial or complete lung collapse, with acquired dextrocardia. \(^{228}\) In severe cases, there is considerable cardiomegaly. The left atrium may be pushed downward \(^{62}\) and the carina splayed with compression of lower trachea and both main bronchi.

Other Studies

The ECG is typical for patients with TF. In patients who are asymptomatic or mildly symptomatic and do not require neonatal surgery, 2D echocardiography is diagnostic and definitive. In unstable neonates and infants, further studies are indicated once the patient is resuscitated and stabilized. Currently, CTA provides the most information, characterizing the pulmonary artery and airway abnormalities and their interrelationships (Fig. 38-87). In some institutions cardiac catheterization is also performed, or is performed as an alternative to CT.

NATURAL HISTORY

TF with absent pulmonary valve is present in about 5% of patients born with a large VSD and pulmonary stenosis. A high percentage (perhaps 50%) die in the first year of life if untreated, and most in the first few months of life, from respiratory distress caused by the massively dilated RPA and LPA compressing the tracheobronchial tree. \(^{219,3,34,91}\) Such critically ill infants also have heart failure associated with a left-to-right shunt, and the RV is markedly enlarged and systolic function reduced. \(^{191}\)

Patients who survive infancy, however, generally do well for 5 to 20 years, because RV outflow obstruction is only moderate and cyanosis mild or absent. \(^{59}\) They tend to become symptomatic ultimately and die of intractable RV failure as a result of its chronic pressure and volume overload.

TECHNIQUE OF OPERATION

When operation is delayed to age 3 to 5 years or older, the usual procedure is repair of the VSD and orthotopic insertion of an allograft aortic or pulmonary valve conduit (see “Establishing Right Ventricle–to–Pulmonary Artery Continuity” under Technique of Operation in Section II; see also Fig. 38-77). An end-to-end anastomosis is usually made between the distal end of the conduit and the divided pulmonary trunk. Usually no “roofing” of the right ventriculotomy is required, because the large infundibulum permits direct approximation.

In critically ill neonates and infants, a number of palliative operations have been used, but the corrective repair just described is preferred. In addition, however, elliptical strips of arterial wall are removed from the anterior and posterior aspects of the RPA, LPA, and pulmonary trunk bifurcation; the resultant defects are closed with a continuous suture before inserting the allograft valve cylinder. \(^{221,30,31,85}\) This takes pressure off the underlying tracheobronchial tree. Waterston \(^{65}\) and Godart and colleagues \(^{221}\) report good results in infants using extensive pulmonary arterioplasty, closure of the VSD, infundibular resection, and placement of a transanular patch; a valved conduit is not used. Often the large pulmonary trunk can be transected, shortened, and moved ventrally and caudally to roof the infundibulum and relieve pressure from the tracheal bifurcation. Nevertheless, in unstable neonates and infants, it can be anticipated that residual airway problems will almost certainly persist following repair, even when aggressive reduction pulmonary arterioplasty is performed; therefore, normalizing the hemodynamics as much as possible by using a valved conduit is strongly recommended.

An alternative surgical approach for patients with airway compression involves translocating the pulmonary arteries anterior to the aorta \(^{310}\) in addition to VSD closure, conduit placement, and reduction pulmonary arterioplasty.

SPECIAL FEATURES OF POSTOPERATIVE CARE

When operation is performed electively in a patient age 3 to 5 years or older, care is the same as that usually given to patients after intracardiac surgery.

When operation has been performed urgently in neonates, infants, or young children, severe respiratory distress has usually been present and the patient receiving intensive treatment. This treatment (see Indications for Operation later in this section) is intensified in the postoperative period and then slowly withdrawn as the patient’s condition improves.

RESULTS

Survival

Early (Hospital) Death

Historically, absent pulmonary valve syndrome has been associated with a high probability of hospital death after repair in young infants. \(^{219,55,214,216}\) In the current era emphasizing pul-
monary arterioplasty, Waterston and colleagues \(^{65}\) report 16%
mortality (CL 7%-29%) in infants, and Godart and colleagues\textsuperscript{\textcircled{52}} 20% mortality (CL 6%-41%) in infants and 3.7% (CL 0.5%-12%) in children older than 1 year. Mortality in infants is related in part to their poor preoperative condition and severe respiratory problems. When operation is undertaken beyond the first year of life, respiratory problems have usually resolved or not been present, and hospital mortality is low.

\textit{Time-Related Survival}

This, and the incremental risk factors for premature death, as well as other outcome events, are similar to those in other patients with TF whose repair includes insertion of an allograft valved conduit.

**INDICATIONS FOR OPERATION**

Help is urgently needed for small babies with this morphologic variant who present with severe respiratory distress. Some have unrelated congenital hypertrophic lobar emphysema, and a few have severe hypoplasia of the RPA and LPA; in either event, salvage may be impossible. In others an intense medical program is begun as soon as the condition is recognized. It includes managing the baby while continuously in a prone position on a hinged board placed in head-up position with maximal ventilator support.\textsuperscript{\textcircled{549}} This allows the pulmonary arteries to fall forward and away from the bronchi, particularly the RPA.\textsuperscript{\textcircled{549}} In the most severe cases, even this maneuver may be ineffective, and emergency sternotomy in the ICU may be required.\textsuperscript{\textcircled{5117}}

Most often, critically ill babies with this condition remain seriously ill even if ventilation is stabilized, and operation is required.

In patients with this morphology who require no special care in early life, repair is advised electively at 3 to 5 years of age.

Although various procedures have been recommended from time to time, that described under Technique of Operation is considered indicated. This is because alternative palliative procedures\textsuperscript{\textcircled{537,517,699}} have not resulted in improved long-term outcomes.

**Section IV  Tetralogy of Fallot with Flap Valve Ventricular Septal Defect**

**DEFINITION**

Tetralogy of Fallot with flap valve VSD is a subset of TF characterized by a thick fibrous flap hinged on the right side of a large VSD that narrows the interventricular communication and thereby limits right-to-left shunting.

**MORPHOLOGY**

The VSD is typical for TF. Its inferior margin either reaches the tricuspid anulus or is separated from it by a ridge of muscle (see “Ventricular Septal Defect” under Morphology in Section I). A fibrous flap is attached posteriorly to the aortic margin of the VSD, and its inferior margin may or may not be fused with the base and superior margin of the anterior tricuspid leaflet. Elsewhere, the flap is unattached, and it rarely plays any part in tricuspid valve function (Fig. 38-88). It can hinge freely toward the right, but its thickness and bulk prevent movement through the VSD into the LV. Therefore, in the presence of severe pulmonary stenosis and raised RV pressure, it virtually occludes the defect.\textsuperscript{\textcircled{N7}}

Pulmonary stenosis is typical of TF, but the infundibular component is made more evident by the severe degree of RV hypertrophy that involves chiefly the sinus portion of the ventricle because of high ventricular pressure. Thus, there may be a localized high-, intermediate-, or low-level infundibular stenosis, or the narrowing may be diffuse, and the valve may or may not be stenotic. Congenital pulmonary atresia is occasionally present and pulmonary artery branch origin stenosis may occur.

This subset of TF is one of a group of conditions in which there is an accessory fibrous flap or pouch or excrescence arising in the region of the atrioventricular valve apparatus and sometimes from the leaflets themselves.\textsuperscript{\textcircled{C14,88,31}} They have sometimes been called, usually erroneously, “aneurysms of the membranous septum.”\textsuperscript{\textcircled{N99}} Such anomalies associated with the tricuspid valve may prolapse into the RV outflow tract and pulmonary valve and cause severe pulmonary stenosis\textsuperscript{\textcircled{226,99,97}} a phenomenon that may occur in the absence of a VSD.\textsuperscript{\textcircled{356}} A mobile mass of fibrous tissue related to the tricuspid valve may prolapse through a VSD and produce LV outflow tract obstruction.\textsuperscript{\textcircled{M4,95,96}} This type of subaortic stenosis is easily corrected by operation.\textsuperscript{\textcircled{M38}} When transposition of the great arteries and VSD coexist, prolapse of accessory tricuspid valve tissue through the VSD results again in LV outflow tract obstruction, which is then subpulmonary (see Chapter 52).\textsuperscript{\textcircled{H32,R18}} In cases with congenitally corrected transposition of the great arteries (see Chapter 55), accessory valvar tissues of the right-sided, morphologically left atrioventricular valve may coexist; in this situation, the tendency is for the accessory tissue to prolapse in ball-valve fashion into the morphologically LV outflow tract, producing subpulmonary stenosis.\textsuperscript{\textcircled{L12}}

This may occur with or without an associated VSD. Such prolapsing accessory tissue is uncommon, but appears to be more often associated with the systemic venous rather than the pulmonary venous (systemic) atrioventricular valve. Maclean and colleagues\textsuperscript{\textcircled{M5}} and Levy and colleagues\textsuperscript{\textcircled{L12}} each report such a case in which subaortic obstruction resulted. Such a phenomenon may rarely coexist with TF.\textsuperscript{\textcircled{Y3}}

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

Right-to-left shunting through the restricted VSD may be large enough to produce important cyanosis; usually it is not, so when the atrial septum is also intact, the patient is acyanotic or only mildly cyanotic despite severe pulmonary stenosis. When pulmonary stenosis is severe, the virtually intact ventricular septum results in severe RV hypertrophy on ECG (in contrast to the moderate RV hypertrophy typical of TF), near-normal splitting of the second heart sound (because Qp and PPA are maintained at a near-normal level), and a prominent a wave in the jugular venous pulse. Presentation is similar to that of pulmonary stenosis with intact ventricular septum (see Chapter 37). These features and the larger cardiac silhouette on chest radiograph than in classic TF make the diagnosis likely. Echocardiography defines the
intracardiac morphologic details and provides important information for estimating the degree of obstruction in the RV outflow tract and across the VSD. Cardiac catheterization is indicated only if there is a need to define pulmonary hemodynamics or morphology of the distal pulmonary arteries.

TECHNIQUE OF OPERATION

Intracardiac repair is similar to that for TF with pulmonary stenosis. However, severe RV hypertrophy makes relief of pulmonary stenosis more difficult and may also limit exposure of the VSD. Usually, wide excision of muscle is required. The fibrous flap is identified and excised unless it is atypical and part of the AV valve mechanism, which is rare. Then, its herniation into the VSD is simply reduced and the VSD repaired in the usual way. It may be necessary to attach the herniated portion to the tricuspid valve to prevent it from obstructing the RV outflow tract.

RESULTS

Hospital mortality after repair has, in the past, been relatively high. Four (24%; CL 12%-39%) of 17 patients in the GLH and UAB experiences died in hospital after repair (Table 38-15). One UAB death occurred in association with anomalous origin of the left main coronary artery from the pulmonary trunk and one GLH death in association with pulmonary atresia and a large fistulous communication between the left coronary artery and RV. Severe RV hypertrophy appears to be the primary incremental risk factor, and improved myocardial management may neutralize it. Late results in hospital survivors have been good.

INDICATIONS FOR OPERATION

Palliative shunting operations are inappropriate because they do not relieve the progressive RV pressure overload. Similarly, blind (or open) pulmonary valvotomy could result in excessive shunting from left to right through the VSD. One-stage repair is the proper treatment and is advisable when diagnosis is made.

Section V  Double-Chamber Right Ventricle (Low-Lying Infundibular Pulmonary Stenosis with or without Ventricular Septal Defect)

DEFINITION

Low-lying infundibular pulmonary stenosis, so-called double-chamber RV, is a type of intraventricular stenosis that clearly separates the sinus (inflow) portion of the RV...
from a typically, but not always, large and thin-walled infundibulum. It is usually but not always associated with a small or moderate-sized and occasionally large VSD, which is usually juxtatricuspid in position, but it may have a narrow bar of muscle between it and the valve anulus. Also included in this section are similar cases with an intact ventricular septum, because they may be considered part of this overall spectrum. In many cases with intact ventricular septum, a VSD was present earlier in life, with spontaneous closure occurring because of the same process of hypertrophy and fibrosis that contributes to the RV obstruction.

Low-lying infundibular pulmonary stenosis may coexist with otherwise typical TF (see Section I). Low-lying infundibular pulmonary stenosis may also coexist with double outlet RV (see Chapter 53).

HISTORICAL NOTE

Like many cardiac anomalies, low-lying infundibular pulmonary stenosis was encountered by cardiac surgeons during the mid- and late 1950s, before the malformation was well recognized by morphologists as a discrete entity. However, case 1 in the 1933 report by Eakin and Abbott and cases 1 and 3 in the 1959 report by Blount and colleagues were examples of the entity, and Grant and colleagues clearly discussed this malformation in their 1961 publication. However, credit for the first description of the entity is generally given to Tsifutis and colleagues, who published their paper in the same year.

MORPHOLOGY

The important morphologic characteristics relate to the infundibulum, the ventricular septum, and the LV outflow tract. There can be substantial variation in all three areas.

The classic morphologic finding is the large thin-walled infundibular chamber, which gives rise to the appellation “two-chambered RV.” The pulmonary valve and “anulus” are normal sized or large, as is the pulmonary trunk, and the right and left pulmonary arteries are virtually always large and free of stenoses or distributional anomalies. In some variations the infundibular chamber is not large. There is infundibular hypoplasia, and the anomalous muscle bundles arise from the infundibular septum a little more distally (downstream).

The stenosis is formed by accessory bulky muscle bundles concentrated at the junction of the sinus portion of the RV and infundibulum. In the most florid form, there is a bulky trabeculated muscular shelf lying almost in a coronal plane that separates a large, thin-walled infundibular chamber from a hypertrophied, thick-walled sinus portion containing the tricuspid valve apparatus and VSD. The shelf is often formed by medial and lateral anomalous muscle bundles that join the anterior free wall about halfway between ventricular apex and base. However, the shelf may be, in part, hypertrophied septoparietal bands. The stenotic ostium is usually centrally located, and in older patients it is surrounded by a bulky fibrous collar that further increases stenosis. There may be more than one ostium. This obstructing muscular diaphragm inserts so far inferiorly on the free wall that it lies nearly in a coronal plane, which predisposes the ventricular incision to be in the infundibular chamber. The muscular band on the right side usually seems to be the parietal extension of the infundibular septum.

The VSD is usually small or moderate in size, although it may be large or it may have closed, identified only by a fibrous dimple. It is usually perimembranous and juxtatricuspid and is overhung by thick tricuspid chordae, but it may have a bar of muscle at its posterior margin rather than abutting the tricuspid anulus. Importantly, the VSD, regardless of its size, does not demonstrate the characteristics of the VSD in the various forms of TF. Specifically, the infundibular septum is not anteriorly malaligned.

In about 5% of cases, important and otherwise typical subaortic stenosis (see Section II of Chapter 47) coexists with low-lying infundibular pulmonary stenosis. Why this relatively large proportion exists is unknown. A unifying theory, yet to be fully characterized, is the tendency for many of these
patients to produce exuberant endocardial fibrosis that importantly contributes to the RV obstruction, closes or narrows the VSD, and extends across the VSD into the LV outflow tract, causing the subaortic stenosis (personal observation, Frank Hanley).

Other morphologic variations rarely exist. These include combined infundibular and valvar pulmonary stenosis with membranous or muscular VSD, or isolated valvar pulmonary stenosis with membranous or muscular VSD. It is likely that these cases represent coincidental occurrence of unrelated defects.

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

Patients usually present with mild cyanosis in the midpoint of the first decade of life, but they may present in the second decade or even in adult life. Increasingly, patients are diagnosed earlier in life, usually between 1 and 3 years of age, with clear evidence of mid-cavity RV obstruction. On examination the most striking feature is the loud systolic murmur, often grade 6 (heard with the stethoscope off the chest wall). Chest radiography is not specific, but the pulmonary trunk shadow along the upper left cardiac border is usually prominent.

Diagnosis is made by 2D echocardiography, which defines the typical mid-cavity RV obstruction, the VSD, if present, and the subaortic obstruction, if present (Figs. 38-89 and 38-90).

**NATURAL HISTORY**

Natural history can only be surmised. Because in some cases only a dimple remains in the perimembranous area at operation, the VSD presumably has a tendency to close spontaneously. Because few patients with this entity present in infancy, it is not surprising that the stenosis has been demonstrated to increase gradually in severity as the child grows.\(^\text{C25,D5,F11,H8,H9}\)

The progression can lead to complete infundibular atresia.\(^\text{P10}\)

Cyanosis is also presumed to be an acquired event. If a VSD is present, it will shunt left to right early in life before the RV obstruction progresses; no cyanosis will be present. If the VSD remains open and the RV obstruction progresses such that the VSD shunts right to left, cyanosis will develop.

**TECHNIQUE OF OPERATION**

Preparations for CPB, median sternotomy, and placement of stay sutures and purse-string sutures are as usual (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2). Examination of the heart may confirm presence of a characteristically large, thin-walled infundibular chamber, but this is not always evident externally. Usually a marginal branch of the right coronary artery courses over the underlying infundibular stenosis and should be preserved if the ventriculotomy approach to repair is used.

CPB is established, employing direct caval cannulation or caval cannulation via the right atrium (see Fig. 2-22 in Chapter 2). The left side is vented using a catheter placed through the right upper pulmonary vein. Mild hypothermia is typically used. The aortic root infusion catheter is inserted, the aorta clamped, and cold cardioplegia given (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3).

When the infundibulum is large and thin walled, repair can be through a transverse low infundibular incision or a right atrial incision.\(^\text{P10,P9}\)

With the infundibular incision the view is interesting and unique, because the interior of the smooth thin-walled infundibulum is exposed, and in its depth inferiorly is seen the ostium of the low-lying infundibular stenosis. A moment of carelessness could lead to misidentifying it as the VSD,\(^\text{C23,L21}\) but further examination confirms it as the infundibulum because the tricuspid valve apparatus, lying entirely in the sinus portion of the RV, cannot be visualized.

Incision is made in the obstructing muscle mass anteriorly and to the left, which allows visualization of the interior of the sinus portion (proximal chamber) of the RV, tricuspid apparatus, and VSD. The part of the obstructing muscle mass that arches up and to the right from the infundibular septum (probably the parietal extension of the infundibular septum)
is dissected and largely resected. Before resecting the left side of the obstructive muscular collar, which is usually in part moderator band, location of the tricuspid papillary muscles is visualized, and they are protected as the left-sided heavy muscular band is dissected and largely amputated. There is then a wide exposure of the sinus portion of the RV and VSD. Although the VSD is typically small, it is repaired with a patch, just as for other VSDs in this area. If the VSD is small and overhung by thick chordae, a completely interrupted suture technique is preferable. The ventriculotomy is closed either primarily or with a narrow patch. The remainder of the procedure is completed as usual.

From the right atrial approach (Fig. 38-91, A), the obstructing muscle is located at its insertion anteriorly at the region of the moderator band. The anterior papillary muscle of the tricuspid valve is retracted. Relief of the muscular narrowing is accomplished much as for the atrial approach to classic TF, but exposure is easier because the obstruction is less anteriorly placed and more proximal in the RV. After muscle resection, the VSD, if present, is closed with a patch in a fashion similar to patch closure for isolated VSD by way of the right atrium (Fig. 38-91, B) (see Technique of Operation in Section I of Chapter 35). The right atriotomy is closed directly, and remainder of the procedure is completed as usual.

When the infundibular chamber is more hypoplastic, a vertical ventriculotomy and infundibular patching should probably be used routinely.

When associated subaortic obstruction is present, it should be addressed. If the patient has a large VSD, the fibrous tissue causing the obstruction in the LV outflow tract can often be visualized through the VSD and resected before closing the VSD. When the VSD is small or absent, the subaortic obstruction is addressed by way of an aortotomy, in a similar fashion to isolated subaortic membrane (see Chapter 47).

The morphology is so well suited to repair that usually no gradient is present after repair, nor are murmurs present postoperatively.

**SPECIAL FEATURES OF POSTOPERATIVE CARE**

Postoperative care is as usual (see Chapter 5).

**RESULTS**

**Early (Hospital) Death**

Hospital mortality after repair should approach zero.\textsuperscript{1,5}

**Time-Related Survival**

Long-term results are excellent, with no late deaths and all patients asymptomatic.\textsuperscript{1,16,75} In the University of Michigan experience, among 20 patients followed for at least 20 years, 85% were in NYHA functional class I and only one (5%) had hemodynamically important impairment of cardiac function.\textsuperscript{63} Similarly, in the study by Telagh and colleagues,\textsuperscript{75} there was no functional or hemodynamic impairment at follow-up extending to 11 years.

**INDICATIONS FOR OPERATION**

Diagnosis of the malformation is an indication for elective repair.
Chapter 38 Ventricular Septal Defect with Pulmonary Stenosis or Atresia

A few patients with infundibular pulmonary stenosis, with or without a VSD, do not meet the criteria for diagnosis of TF or low-lying infundibular stenosis. These are included in this section.

Some of these malformations may be similar in origin to low-lying infundibular pulmonary stenosis, except that there is infundibular hypoplasia and the anomalous muscle bundles arise from the infundibular septum a little more distally (downstream). Other examples in this subset probably represent instances in which the only discernible malformation at birth is a large VSD. With time, however, the parietal extension of the infundibular septum hypertrophies out of proportion to the rest of the right ventricle, and in some cases the VSD narrows or closes.\textsuperscript{525} Finally, occasionally valvar and infundibular stenosis may both coexist along with a VSD, in the absence of the typical morphology of TF.

Diagnosis, natural history, and techniques of repair are similar to those for low-lying infundibular pulmonary stenosis, except that a vertical ventriculotomy and infundibular patching should probably be used routinely. It is important to recognize the infundibular stenosis at time of repair of the VSD, because otherwise it can persist or worsen and reoperation may be required for relief.\textsuperscript{D19,M11}

Figure 38-91 Low-lying infundibular pulmonary stenosis. A, Inset Usual high right atriotomy is made as for right atrial approach to repair tetralogy of Fallot (TF). Anomalous muscle band arises from moderator band and is downstream from ventricular septal defect (VSD). Proposed incisions for resecting obstructing anomalous bands are shown (dashed lines). B, After relief of the obstruction, VSD is closed in same manner as for TF. Key: RAA, Right atrial appendage; SVC, superior vena cava.
Indications for operation are the same as for low-lying infundibular pulmonary stenosis.

Surprisingly, isolated valvar pulmonary stenosis with VSD is only rarely reported in the literature. It does exist but is not common (and may well be underreported), and may merely represent chance coexistence of these two malformations. The combination is an indication for elective operation by the techniques described earlier.

### Values of Variables Used in Nomograms

#### Values in Fig. 38-49

Specific values entered into the multivariable equation were hematocrit 50%, no more than one previous palliative operation, no Potts anastomosis, no previous direct approach to RV outlet obstruction, no multiple VSDs, no dextrocardia, no absence of unbranched hilar portion of one pulmonary artery, average prevalence of transanular patch placement (31%), and postrepair (OR) $P_{RV/LV}$ of 0.55. For age 6 months, 12 months, 24 months, and 48 months, body surface area was entered as $0.345 \, m^2$, $0.4125 \, m^2$, $0.5025 \, m^2$, and $0.630 \, m^2$, respectively.

#### Values in Fig. 38-51

Specific values entered into the multivariable equation were hematocrit 50%, no more than one previous palliative operation, no Potts anastomosis, no previous direct approach to RV outlet obstruction, no multiple VSDs, no dextrocardia, no absence of unbranched hilar portion of one pulmonary artery, date of operation 1988, and postrepair (OR) $P_{RV/LV}$ of 0.6.

#### Values in Fig. 38-53

Specific values entered into the multivariable equation were age 6 months at repair and postrepair (ICU) $P_{RV/LV}$ of 0.45.

### Relation of Body Surface Area to Age

#### Figure 38B-1

Nomogram of equation relating body surface area to age in patients with tetralogy of Fallot. Equation is based on data from 1533 patients with tetralogy of Fallot and pulmonary stenosis or atresia (UAB experience). They ranged in age from 1 day to 57 years, and in body surface area from 0.12 to 2.3 $m^2$. The equation is as follows:

$$
\ln(BSA) = 4.504 + 27.82 \cdot a^3 - 45.51 \cdot a^4 + 26.39 \cdot a^5 - 5.238 \cdot a^6
$$

where $a = \ln[\ln(age+9)]$, age is in months, $\ln$ is the natural logarithm (double logarithmic transformation), and $\ln[BSA(m^2)]$ is the natural logarithm of body surface area.

DEFINITION

Pulmonary stenosis and intact ventricular septum is a form of right ventricular outflow tract obstruction in which the stenosis can be valvar, infundibular, or both. Isolated infundibular stenosis is unusual. This chapter concerns primarily valvar pulmonary stenosis, with or without infundibular stenosis. When neonates present with the most severe form of this defect, the term neonatal critical pulmonary stenosis is used. When patients present beyond the neonatal period or in early infancy, the term pulmonary stenosis is used.

HISTORICAL NOTE

In 1913, as described by Dumont, Doyen first attempted to surgically relieve pulmonary stenosis in a 20-year-old woman who, in retrospect, is thought to have had infundibular obstruction. Thirty-five years later, in December 1948, Sellors performed a successful closed transventricular instrumental pulmonary valvotomy, closely following Doyen’s technique. Brock performed three successful closed valvotomies in early 1948. These patients probably all had tetralogy of Fallot. Blalock and Kieffer applied this procedure to patients with pulmonary stenosis and intact ventricular septum soon thereafter, reporting 19 patients and two hospital deaths. Swan and colleagues surgically corrected pulmonary stenosis and intact ventricular septum by an open technique in about 1953, approaching the valve through a pulmonary arteriotomy during circulatory arrest, with the patient rendered moderately hypothermic by surface cooling. Other techniques evolved.

Kirklin’s experiences with closed valvotomy at Mayo Clinic led to an appreciation of the importance of acquired infundibular obstruction caused by hypertrophy, and the need for a pump-oxygenator system that would allow relief by open operation. When cardiopulmonary bypass (CPB) became available in 1955, most surgeons began to use it to support patients during open valvotomy.

Surgical treatment of pulmonary stenosis was challenged in 1982 when Kan and colleagues reported successful percutaneous balloon valvuloplasty. This method of therapy is now applied to patients of all ages, and is, with the important exception of the morphologic variant called pulmonary valvar dysplasia, the initial procedure of choice.

AGE CONSIDERATIONS

Symptoms, signs, and treatment of valvar pulmonary stenosis in the neonate presenting in severe distress during the first few days of life have long been recognized as different from those of patients presenting later in life. Interrelationships exist between neonatal valvar pulmonary stenosis and intact ventricular septum and pulmonary atresia and intact ventricular septum. Now that percutaneous techniques are used for therapy, different groups of physicians, as a rule, care for valvar pulmonary stenosis in patients presenting for treatment for the first time as adults and those presenting in early childhood. For all these reasons, this subject seems best approached according to age categories.

Section I Critical Valvar Pulmonary Stenosis in Neonates

MORPHOLOGY

Pulmonary Valve

The pulmonary valve is commonly a uniform fibrous cone with a circular, central, and stenotic orifice and two or three ridges on its pulmonary arterial side. These ridges radiate from the central orifice to the periphery and outline two or three cusps that correspond to pulmonary sinuses of Valsalva, which are usually well formed. The valvar diaphragm is considerably thinner than normal cusp tissue, particularly around the ostium, but it is mobile. Thickening is produced by an increase in myxomatous tissue. Obstruction may be due to thickened, shortened, and rigid cusp tissue with little or no commissural fusion, known as pulmonary valvar dysplasia. This was described in 1969 by Koretzky, Edwards, and colleagues and further characterized by Stamm, Anderson, and colleagues. The right ventricular–pulmonary trunk junction (anulus) may be narrowed and the pulmonary trunk wall pulled inward or tethered at the site of commissural cusp attachment. The valve is often bicuspid. Although this condition may cause critical pulmonary stenosis in neonates, stenosis is typically moderate, a finding that is characteristic of Noonan syndrome.

Pulmonary Arteries

Although it has been reported that in about 50% of neonates with critical pulmonary stenosis, right and left pulmonary arteries appear to be moderately or severely hypoplastic.

Figure 39-1 Specimen from a neonate with congenital valvar pulmonary stenosis and intact ventricular septum viewed through open, dilated pulmonary trunk. Fibrous cone with its central, very stenotic orifice; well-formed sinuses of Valsalva; and potential three-cusp valve structure are typical. Moderate right ventricular hypoplasia coexists (see Fig. 39-3).
Rarely, the right ventricular (RV) cavity is severely reduced in size. More commonly, mild or moderate reduction is present (Fig. 39-2). Reduction in cavity size relates in part to the amount of concentric RV hypertrophy produced by the RV outflow tract (RVOT) obstruction (Fig. 39-3).

Histologic appearance of the RV varies. Concentric RV hypertrophy is characterized by increased muscle cell size and diffuse fibrosis. When imaged, this has not been confirmed by other studies (Table 39-1). As a rule, the appearance of pulmonary arterial hypoplasia is probably secondary to low pulmonary blood flow, because the pulmonary arteries are usually normal in size within a few years in those who survive interventional treatment.2

### Right Ventricle

The right atrium is usually large. There is generally at least a patent foramen ovale, and right-to-left shunting across it is a major contributor to arterial desaturation exhibited by many of these neonates.

### Right Ventricular Coronary Artery Fistulae

About 10% of neonates with critical pulmonary stenosis have RV sinusoids, but only 2% have RV coronary arterial fistulae. RV-dependent coronary circulation in such hearts is rare.

### Morphologic Correlates

RV cavity size and tricuspid valve dimension are not highly correlated in this condition, but mild to moderate hypoplasia is the rule in both locations.12 This is in contrast to pulmonary atresia and intact ventricular septum (see Morphology in Chapter 40), suggesting that reduction in RV cavity size in critical pulmonary stenosis is secondary to RV hypertrophy and thickening from outflow obstruction, rather than from genetic or developmentally induced hypoplasia. This is in harmony with the hypothesis that critical pulmonary stenosis develops relatively late in fetal life, in contrast to some types of pulmonary atresia.13

Coexisting Cardiac Conditions

Coexisting cardiac conditions are uncommon. Ebstein malformation, which occurs in about 5% of patients with pulmonary atresia and intact ventricular septum, occurs in about 1% of those with critical pulmonary stenosis.112

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Neonates presenting with critical pulmonary stenosis and intact ventricular septum are usually critically ill, irritable, tachypneic, and severely hypoxic from right-to-left shunting at the atrial level. They usually present for treatment within a few days after birth and are generally of normal birth weight.112 When the atrial septum is intact, which is uncommon, cyanosis is absent.

Tachycardia and severity of heart failure often make auscultatory findings nondiagnostic. Physical findings of tricuspid regurgitation may be present. Chest radiograph usually shows a normal or somewhat enlarged heart. Pulmonary stenosis with hypoplastic RV is associated with less electrocardiographic (ECG) evidence of RV hypertrophy than expected.126 Diminished RV potentials are due to smallness of the RV cavity rather than to diminished muscle mass.

In a critically ill neonate with clear lung fields and a large cardiac silhouette, two-dimensional echocardiography provides near-certain diagnosis. The thick stenotic pulmonary valve is visualized, the RV cavity is seen, and size and cusp thickness of the tricuspid valve can be determined. Additionally, the pulmonary artery branch diameter can be accurately estimated, and color Doppler imaging can suggest presence of coronary artery anomalies such as RV-to-coronary artery fistulae.

Cardiac catheterization is indicated in essentially all cases for both diagnostic reasons (e.g., to define coronary artery anomalies) and therapy, because balloon pulmonary valvotomy is currently the treatment of choice. Cardiac catheterization usually shows peak RV pressure higher than that in the left ventricle (LV) or systemic arteries. Rarely, and in the presence of severe heart failure, peak RV pressure is less than that in the systemic circulation, despite severe valvar stenosis.

Cineangiography provides precise information regarding site of stenosis, size of RV cavity and infundibulum, presence
or absence of tricuspid regurgitation, morphology of the pulmonary trunk and right and left pulmonary arteries, and presence or absence of RV-to-coronary artery fistulae (Fig. 39-5). The tricuspid valve is competent in about 10% of patients, and in the other 90% it is moderately or severely regurgitant (Hanley and colleagues and the Congenital Heart Surgeons Society; personal communication; 1992). Regurgitation, which is not well correlated with degree of RV hypertension (Fig. 39-6), is probably a manifestation of RV failure.

Currently, magnetic resonance and computed tomographic imaging are not routinely used in neonatal critical pulmonary stenosis, simply because these studies provide little added value to echocardiography and the mandatory cardiac catheterization. Recently, fetal echocardiography has been used to predict the postnatal fate of patients with critical pulmonary stenosis.

**Figure 39-4** Cumulative frequency distribution of diameter of tricuspid valve, expressed as z value, in neonates with congenital pulmonary stenosis or atresia and intact ventricular septum. The z value of zero represents mean normal value, −2 represents 2 standard deviations (SD) below mean normal size, and +2 represents 2 SD above mean normal size. Figure is based on data for 247 neonates. Only data for 44 patients with pulmonary stenosis and 77 with pulmonary atresia permitted an estimate of tricuspid valve size. Key: PA, Pulmonary atresia; PS, pulmonary stenosis. (From Hanley and colleagues.)

![Graph showing relationship between tricuspid valve regurgitation and right ventricular peak pressure.](image2)
Chapter 39  Pulmonary Stenosis and Intact Ventricular Septum

pulmonary stenosis. The aim is to predict whether a two- or single-ventricle circulation will result following postnatal therapy. These techniques are more applicable to pulmonary atresia and intact ventricular septum but also have a role, albeit a lesser one, in pulmonary stenosis. Morphologic and physiologic characteristics identified at fetal echocardiographic interrogation can accurately predict the fate of the circulation following birth. These data can be used for planning postnatal therapy, parental counseling, and possibly prenatal intervention.

**NATURAL HISTORY**

Presentation is usually within the first 2 weeks, and mean age at operation in the series at Toronto Hospital for Sick Children was 3.9 days. Most neonates in whom severe hypoxia develops, with or without heart failure, die without treatment, although some may live for a few months.

**TECHNIQUE OF OPERATION**

**Percutaneous Balloon Valvotomy**

The technique of percutaneous balloon valvotomy has been described in detail. Briefly, a guidewire is introduced via the femoral vein across the pulmonary valve and maneuvered through the ductus arteriosus into the descending aorta. A wire-guided balloon 1.2 to 1.3 times the measured size of the anulus is placed across the pulmonary anulus. The balloon is inflated rapidly two or three times. Several case reports of fetal intervention for critical pulmonary stenosis using percutaneous balloon valvotomy have been reported, documenting technical success. Efficacy of the procedure has not yet been documented.

**Open Pulmonary Valvotomy Using Cardiopulmonary Bypass**

When percutaneous balloon valvotomy has not been used or is unsuccessful, open pulmonary valvotomy using CPB is recommended. The surgical procedures of closed pulmonary valvotomy and open valvotomy with simple inflow stasis have also given good results; however, they are not currently recommended in most circumstances. Operation may be performed using one or two venous cannulae and CPB with mild (32°C-34°C) or moderate (25°C-28°C) hypothermia as described in Chapter 2. A single venous cannula and mild hypothermia are chosen when a simple patent foramen ovale is present that will not be closed; two venous cannulae and moderate hypothermia are chosen when an atrial septal defect (ASD) will be closed.

Before establishing CPB, the ductus arteriosus is dissected and ligated immediately after initiating CPB. After establishing CPB and hypothermia, the aorta is clamped and cold cardioplegia administered (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3). Alternatively, operation may be done on the beating heart, without aortic clamping.

If two venous cannulae are used and an ASD is to be repaired, a small-caliber vent can be placed into the left side of the heart through a purse-string suture in the right pulmonary vein. Alternatively, the right atrium is opened through a small oblique incision, and a pump sump-sucker is placed across the foramen ovale and into the left atrium.

The pulmonary trunk is opened through a vertical incision, and fine stay sutures are placed on the edge of the incision for exposure. Two or three fused commissures can usually be seen, and these are opened with a knife, extending the incisions to the pulmonary valve annulus. Because regurgitation is of less concern than residual narrowing, the incisions may be tailored to some extent to ensure that the valve has a wide opening. Portions of the valve are excised only when other methods fail to achieve a wide opening. Less commonly, the valve is dysplastic with three fully formed commissures and markedly thickened, even bulky, cusps. In this case, cusp debulking by partial resection of tissue is necessary to relieve obstruction. Rarely in neonates is there need to resect RV infundibular musculature. The pulmonary trunk is closed with one row of continuous 7-0 polypropylene suture. Usually, operation requires less than 15 minutes, and the aortic clamp, if used, is simply removed and de-airing accomplished. Remainder of the operation is completed in the usual manner (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2).

A patent foramen ovale, if present, is usually left open because the RV is very hypertrophied. The patient will benefit from allowing right-to-left atrial shunting until the RV remodels. If an ASD coexists, the decision is more complex because it is likely the patient will eventually develop significant left-to-right shunting through it once RV remodeling is complete. Judgment must be used in this setting. If there is concern that RV size and hypertrophy will result in perioperative RV failure, the ASD should be left open; it can be addressed at a later time once the RV has remodeled. If the RV is judged to be adequate, the ASD should be closed. Regardless of the initial decision, the physiology should be assessed carefully in the operating room following separation from CPB, and surgical readjustments (either opening or closing the ASD) made as necessary. Remainder of the operation is completed in the usual manner.

A concomitant systemic–pulmonary artery shunt may be added if $P_{a_{o}}$ is severely reduced (<30 mmHg) after discontinuing CPB. The neonate usually comes to the operating room well resuscitated by prostaglandin $E_1$ ($PGE_1$). However, in the rare circumstance in which this is not the case, methods employed for seriously ill adult patients will probably improve results (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3).

Consideration should be given to placing a fine polyvinyl catheter into the RV, inserted through the right atrium across the tricuspid valve. It is used perioperatively to monitor RV pressure and typically is removed 48 hours later in the intensive care unit (see Special Features of Postoperative Care later). Measurements in the operating room after repair are not as informative and cannot serve as a guide to concomitant infundibular resection (see Results).

Transesophageal echocardiography should be used routinely to assess the outflow tract after separation from CPB, paying particular attention to gradients at the valvar and infundibular level, degree of pulmonary and tricuspid valve regurgitation, RV function, and presence and degree of intraatrial shunting.
Transanular Patch

Although the likelihood of needing a transanular patch is greater when the RV cavity is small, the decision to place one at the initial surgical procedure is generally best made during operation.\textsuperscript{12} When surgery is performed as a secondary procedure, the decision is usually made preoperatively. Operation proceeds as described earlier for open pulmonary valvotomy. The interior of the RV infundibulum is inspected by looking through the pulmonary valve orifice. If it appears to be narrowed and if the diameter of the opened pulmonary valve (and thus presumably the “anulus”) has a z value of \( -3 \) or less (see discussion of z value in “Standardization of Dimensions” under Dimensions of Normal Cardiac and Great Artery Pathways in Chapter 1), and particularly when the RV cavity is very small, a transanular patch is probably indicated.

Incision in the pulmonary trunk is carried across the anulus and down to the junction of the sinus and infundibular portions of the RV. The pulmonary valve cusps are excised. Conservative resection of hypertrophied muscular trabeculae in the infundibulum may be accomplished, but this is often impractical in neonates (see Fig. 38-11 in Chapter 38). An enlarging patch is fashioned from glutaraldehyde-treated or untreated autologous pericardium and sewn into place with continuous 6-0 or 7-0 polypropylene sutures (see “Decision and Technique for Transanular Patching” in Section I of Chapter 38). Remainder of the procedure, including placing the polyvinyl catheter, is as described in the preceding text. A systemic–pulmonary artery shunt is added only if \( \text{PaO}_2 \) is severely reduced after discontinuing CPB.

Systemic–Pulmonary Artery Shunt

If a systemic–pulmonary artery shunt is required as an isolated procedure (see Special Features of Postoperative Care later), a polytetrafluoroethylene (PTFE) interposition aorto-pulmonary shunt is made using a 3.5- or 4-mm tube via a median sternotomy. Whether shunting is an isolated procedure or concomitant to valvotomy or transanular patching, the PTFE tube is placed between the brachiocephalic trunk–right subclavian artery junction and the right pulmonary artery (see Technique of Operation in Section I of Chapter 38).

SPECIAL FEATURES OF POSTOPERATIVE CARE

Proper perioperative management of neonates is essential for success. Generally these deeply cyanotic and critically ill infants are started on PGE\(_1\) intravenously in doses of 0.05 to 0.4 \( \mu \)g · kg\(^{-1} \) · min\(^{-1} \) even before any studies are done; the resulting enlargement of the ductus arteriosus increases pulmonary blood flow and \( \text{PaO}_2 \) by the time of operation.\textsuperscript{16,11,03} PGE\(_1\) is continued during percutaneous valvotomy and early thereafter until the RV has a chance to remodel.

Caution must be used lest pulmonary overcirculation develop in a neonate whose pulmonary valve has been widely opened. The infant is left intubated and ventilated. As PGE\(_1\) is discontinued in the hours after the procedure, \( \text{SaO}_2 \) is monitored by pulse oximeter, or \( \text{PaO}_2 \) is measured frequently. If after 24 hours, \( \text{PaO}_2 \) remains well above 30 mmHg and the hemodynamic state is good, the neonate is gradually weaned from the ventilator and extubated. Even though some arterial desaturation persists, so long as \( \text{PaO}_2 \) stays above about 30 mmHg and the clinical condition remains good, the neonate is patiently followed in anticipation of continued improvement as the RV remodels and the pulmonary vascular resistance decreases. If \( \text{PaO}_2 \) falls to 30 mmHg or less, and if residual stenosis is mild or absent, a PTFE systemic–pulmonary artery shunt is performed. If important RVOT obstruction is present along with important hypoxia, a transanular patch as well as a systemic–pulmonary artery shunt is probably necessary.

If a primary surgical procedure is performed on the RVOT, the ductus has typically been ligated, and an appropriately sized systemic–pulmonary artery shunt may also have been placed. When a systemic–pulmonary artery shunt has been performed, the infant should be restudied at about age 6 to 12 months; plans should then be made for shunt closure by percutaneous or surgical means. In some surgical patients who do not receive a shunt at the time of the initial RVOT procedure, persistent cyanosis will occur, requiring return to surgery for placement of a shunt. Patients should be followed after hospital discharge until there is assurance that the RV–pulmonary artery peak pressure gradient is within acceptable limits. If it is not but can be remedied by further valvotomy, percutaneous techniques are generally recommended. In about 10% of patients, follow-up evaluation indicates important residual RV hypertension from “anular” or persistent infundibular narrowing; placing a transanular patch is then required to achieve the desired result.

RESULTS

Survival

Early (Hospital) Death

About 10% of heterogeneous groups of neonates die during initial hospitalization (Fig. 39-7). Risk-adjusted analysis indicates that early death occurs in only 6% of neonates treated by the surgical methods described in this chapter (Fig. 39-8). This very good result in critically ill patients is directly traceable to introduction of PGE\(_1\), general improvement in neonatal cardiac surgery, and advent of percutaneous balloon valvotomy.\textsuperscript{12} Results of balloon valvotomy in neonates compare favorably with those of surgical valvotomy. Tabata- baei and colleagues were able to accomplish balloon dilatation in 35 of 37 neonates with critical valvar pulmonary stenosis (generally with suprasystemic RV pressure),\textsuperscript{11} with only 3 deaths (8%; CL 0%-16%). Others have reported similarly good survival.\textsuperscript{14,15,72,71}

Time-Related Survival

Survival for at least 4 years after birth in heterogeneous groups of treated neonates is about 80% (see Fig. 39-7). The rapidly declining appreciable early rate of death (hazard function) begins to flatten out considerably about 3 months after intervention. Risk-adjusted survival for at least 4 years can be presumed to be 94% (see Fig. 39-8), because death rarely occurred between 6 months and 4 years postoperatively in a large study.\textsuperscript{12} Gudausky and Beekman have reviewed mid- and long-term outcomes following balloon valvotomy in neonates, citing 6 studies since 1995 in addition to their own experience, totaling 221 patients.\textsuperscript{112} There were a total of 249 patients, with successful dilatation in 224 (90%). Follow-up ranged from 1 to 116 months. Twelve serious
complications resulted from the procedure, and 13 total deaths; 5 of the deaths were early and 8 were late.

**Modes of Death**

The mode of virtually all deaths is either hypoxia or acute cardiac failure.

**Incremental Risk Factors for Premature Death**

Although uncommon, RV enlargement of an appreciable degree is a highly lethal coexisting cardiac anomaly. This is probably a special situation in which there is a coexisting cardiomyopathy or tricuspid valve lesion (e.g., Ebstein malformation) already present in fetal life because of genetic or developmental factors. Aside from these rare cases, no general patient-specific risk factors for death are identifiable in neonates. This is unusual in patients with congenital heart disease.

For open pulmonary valvotomy without inflow stasis or CPB and for certain morphologic variants (see text that follows), transanular patching without a shunt is a risk factor, and these procedures should not be used\(^2\) (Table 39-2).

Data from Hanley and colleagues.\(^2\)

\(^1\) Database consists of 101 neonates with critical pulmonary stenosis entered into a multiinstitutional study between January 1987 and 1991.\(^2\) Median age of entry was 3 days. Analysis was of 93 patients, excluding five with Ebstein anomaly, a large right ventricle, or both, and three (two are deceased) in which no procedure was performed.

\(^2\) The three factors listed under transanular patching without a shunt are interaction terms; that is, they pertain only to patients in whom transanular patching without a shunt was performed, not to patients undergoing other types of procedure. Transanular patching without a shunt, when examined without interaction terms, had a low P value of .9.

Key: PT, Pulmonary trunk; RV, right ventricle.

Other procedures give good results, with few differences between them (Fig. 39-9). In neonates and young infants, transanular patching unaccompanied by a systemic–pulmonary artery shunt is an incremental risk factor when the pulmonary “anulus” is severely hypoplastic or when there is important tricuspid regurgitation. Patients in this situation usually have severe RV hypertrophy and reduced cavity size; without a shunt, they tend to have marked hypoxia from right-to-left shunting across a patent foramen ovale secondary to acute RV failure.
Residual Right Ventricular Outflow Tract Obstruction

Limited information is available concerning residual gradients. In about 90%, any important residual gradient has disappeared or been overcome by repeat percutaneous valvotomy within 6 to 12 months of the initial procedure. Ultimately, the RV–pulmonary trunk gradient is usually less than 6 mmHg. About 75% of neonates successfully undergoing pulmonary valvotomy require no further procedure for at least 4 years. About 10% remain hypoxic and require a systemic–pulmonary artery shunt. About 10% remain hypoxic and require a systemic–pulmonary artery shunt. In a few, repeat balloon valvotomy is needed. About 10% of those not initially receiving a transanular patch will need one at some point. Rarely (<2%), a two-ventricle system cannot be attained, and a superior cavopulmonary anastomosis or Fontan-type operation is ultimately required. Similarly, Rao reports occurrence of reintervention was 25% following initial balloon valvotomy.

Occasionally, closure of an ASD is required as the RV remodels and important left-to-right shunting develops in patients in whom the ASD was purposefully left open at the time of the neonatal procedure. The long-term implications of severe pulmonary regurgitation, primarily in those patients who received a transanular patch, remain unclear. In patients who fail to develop adequate SaO₂ (>85% at rest) and right atrial pressure (<12-15 mmHg at rest) with the atrial septum and any systemic–pulmonary artery shunt temporarily closed, a superior cavopulmonary anastomosis can be considered to reduce the workload of the RV, allowing closure of the ASD and systemic–pulmonary shunt. Occasionally, a Fontan-type operation is ultimately indicated.

Morphologic and Functional Changes

Although some neonates initially have at least moderate reduction in RV cavity size, late after pulmonary valvotomy the RV cavity is normal or only mildly reduced in size in 90%. In only about 10% does an important degree of infundibular obstruction, cavity narrowing, or both persist. Following balloon valvotomy, pulmonary anulus and RV chamber size increase, cusp mobility improves, and cusp thickening resolves in the majority of cases studied by echocardiography 6 months to 8 years after intervention.

Whereas most patients have tricuspid regurgitation initially (in some cases, severe), more than 80% have no regurgitation late after valvotomy. However, in a few patients, moderate or severe regurgitation persists, and it is likely that the tricuspid valve is somewhat dysplastic in these patients. Pulmonary regurgitation following balloon valvotomy occurs with increasing frequency and severity over time in 41% to 88% of patients. Need for surgical placement of a competent pulmonary valve prosthesis is unusual but reported.

INDICATIONS FOR OPERATION

Interventional treatment is indicated for all neonates. It may be accomplished by percutaneous balloon valvotomy or by open surgical valvotomy with CPB. Balloon valvotomy is the procedure of choice in most circumstances. An exception is when the patient has severe hypoplasia (z value of −4 or less) of the pulmonary “anulus” and severe reduction of RV cavity size; inserting a transanular patch and concomitantly constructing a systemic–pulmonary artery shunt are indicated as the initial procedure. When only a valvotomy has been performed, a subsequent systemic–pulmonary artery shunt, transanular patch, or both will be indicated in 10% to 20% of patients (see Special Features of Postoperative Care earlier). Surgical valvotomy is also the procedure of choice if expertise in percutaneous balloon valvotomy is lacking.

Section II Pulmonary Stenosis in Infants, Children, and Adults

MORPHOLOGY

Valvar pulmonary stenosis and intact ventricular septum in patients presenting after the neonatal period is a spectrum ranging from critical (pinhole) pulmonary stenosis, through severe pulmonary stenosis with a normal-sized or dilated RV, to moderate or mild valvar pulmonary stenosis that remains relatively stable throughout life.

Figure 39-9 Risk-adjusted predicted percent survival for at least 6 months after first intervention in neonates with critical pulmonary stenosis. Depiction is similar to that in Figure 39-8. It indicates that in 1991 (value entered for date of operation), all procedures other than open pulmonary valvotomy without inflow stasis or cardiopulmonary bypass were followed by a 94% probability of survival for at least 6 months when the z value of right ventricle (RV)–pulmonary trunk (PT) junction (“anulus”) was −4 or larger. When the anulus was severely hypoplastic, survival was not as good as after a transanular patch (TAP) without a shunt (see text). (Data from Hanley and colleagues.)

Key: PA, Pulmonary artery; PT, pulmonary trunk.

Pulmonary Valve

The pulmonary valve is usually better developed in infants and children with severe pulmonary stenosis than it is in neonates. Although the cusp tissue may have a myxomatous appearance and may be irregularly deformed and thickened, the two, three, or even four pulmonary valve cusps are relatively well formed with only partial commissural fusion.$^{510,53}$ In adults, the valve may become calcified, particularly when there has been preexistent infective endocarditis.$^{18}$ In older patients, a variable amount of infundibular hypertrophy results in secondary infundibular stenosis. Occasionally, infundibular stenosis alone accounts for RV outflow tract obstruction (Table 39-3).

Pulmonary Arteries

Post-stenotic dilatation of the pulmonary trunk (see Fig. 39-5) is characteristic of this malformation and is present in about 70% of infants and children with this lesion.$^{1,66}$ The left pulmonary artery may be involved as well.

Right Ventricle

In older patients, in contrast to neonates, important hypertrophy of the RV is uncommon, although marked thickening of the ventricular wall is often seen. When this thickening involves the infundibular septum and free wall of the RV, severe subvalvar obstruction gradually develops.$^{85}$ This has been anecdotally referred to as the “suicidal tendency” of the RV of patients with important pulmonary stenosis. In occasional cases, a low-lying and large moderator band or so-called anomalous muscle bands contribute to infundibular obstruction. In about 10% to 20% of patients, these are the only sites of obstruction, the valve being either normal or (rarely) bicuspid, but not stenotic (see Section V of Chapter 38).

Tricuspid Valve

In infants and children, the tricuspid valve is usually morphologically normal. However, mild regurgitation or, in the face of RV failure, moderate or severe regurgitation may develop.

Right Atrium

The right atrial wall is hypertrophied secondary to increased right atrial pressure. In about one fourth of infants and adults, the atrial septum is intact. However, in most the foramen ovale is patent, or there is a small ostium secundum ASD; right-to-left shunting results in cyanosis.$^{12,13}$ When a left-to-right shunt is present, there is usually a large ASD and only mild or moderate pulmonary stenosis.$^{87}$

Left Ventricle

Alterations in the LV (e.g., myocardial infarction, myocardial dysplasia, obstructive changes in the coronary arteries, abnormal media of the ascending aorta) have been shown occasionally to coexist with pulmonary stenosis and intact ventricular septum.$^{82,86}$ Muscular subaortic stenosis of the variety seen in hypertrophic obstructive cardiomyopathy may coexist. A combination of muscular subaortic and subpulmonary obstruction may be associated with abnormal facies and is a possible variant of Noonan syndrome.$^{N2}$ Important valvar pulmonary stenosis in infants and children can adversely affect LV function.$^{13}$ This is largely the result of RV hypertension that displaces the septum toward the left and alters LV geometry.$^{14}$ Cardiac output and LV function are adversely affected, but the abnormalities revert to normal after correction of the RV outflow obstruction.

Associated Anomalies

Pulmonary stenosis and intact ventricular septum occurs frequently in Noonan syndrome, which is characterized by small stature, hypertelorism, mild mental retardation, cardiac malformations (most commonly pulmonary stenosis), and at times ptosis, undescended testes, and skeletal malformations.$^{1,2}$ It is also associated with intrauterine rubella.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Symptoms

Infants may be symptomatic but usually have less severe symptoms than neonates. After the first year, patients often present because of a murmur only, produced by mild or moderate stenosis. In the second, third, and fourth decades, presentation may be with chronic RV failure. In all, 30% to 40% of patients are asymptomatic when first examined.$^{1,13}$ When symptoms occur, the earliest is often effort dysnea, which results from inability to increase pulmonary (and thus systemic) blood flow with exercise because of the relatively fixed resistance of the pulmonary valve.$^{1,13,14}$

Cyanosis appears when, in the presence of an interatrial communication, the RV becomes less compliant than the LV or its pressure becomes severely elevated. With a normally developed RV, this occurs only when its pressure is suprasystolic, and is associated with ECG evidence of considerable RV hypertrophy. When cyanosis is marked in older patients, polycythemia becomes severe, and all the complications associated with this condition can develop (see “Clinical Presentation” under Clinical Features and Diagnostic Criteria in Section I of Chapter 38).$^{113}$ However, these patients rarely squat for symptomatic relief as do those with tetralogy of Fallot.$^{1,13,14}$
Effort-related precordial pain is not uncommon and is presumably due to RV angina. Sudden death can occur in cyanotic and acyanotic children and in young adults.\textsuperscript{11,83}

Patients in the second and third decades of life with severe and long-neglected pulmonary stenosis and intact ventricular septum show development of right heart failure with elevated jugular venous pressure, hepatomegaly, and ascites, which eventually leads to death.

**Signs**

Except in young infants with severe heart failure, a systolic murmur (best heard in the second left interspace) is present, often with a thrill. Peak intensity of the murmur occurs later in systole in those with severe rather than mild stenosis.\textsuperscript{62} The pulmonary component of the second sound may be normal, decreased, or inaudible, whereas the aortic component is usually obscured by the murmur. The tighter the pulmonary stenosis, the longer the RV ejection time and the greater the delay in pulmonary valve closure.\textsuperscript{62,71}

In severe stenosis, an ejection click is absent because the dome of the pulmonary valve is pushed upward into the pulmonary trunk by the vigorous right atrial contraction before ventricular systole occurs. In some patients with mild stenosis, the abnormality of cusp movement may be insufficient to produce a click, although in other patients it may be prominent, the sound being magnified by a dilated pulmonary trunk.

The hypertrophied RV can often be appreciated as an RV heave palpable to the left of the sternum. The jugular venous “a” wave increases in amplitude as pulmonary stenosis increases in severity and is made more obvious by a noncompliant RV.\textsuperscript{73} In older children, diagnosis of associated RV hypoplasia is suspected when signs of pulmonary stenosis are combined with heart failure and cyanosis in the absence of severe RV hypertrophy on the ECG. Thus, in contrast to pulmonary stenosis with a normally developed RV, cyanosis may occur when its pressure is less than systemic and the ECG is unremarkable.\textsuperscript{51,82}

**Electrocardiography**

Right atrial enlargement from moderate or severe pulmonary stenosis is reflected in prominent P waves in the ECG.\textsuperscript{56} When pulmonary stenosis is mild or moderate, the R-wave height in V\textsubscript{1} is less than 10 mm, or there is a pattern of incomplete right bundle branch block. When it is severe, the R or R’ in V\textsubscript{1} becomes greater than 10 mm and corresponding in its height to degree of RV hypertension.\textsuperscript{63}

**Echocardiography**

In children and adults, as well as neonates, two-dimensional echocardiography can provide near-certain diagnosis. The thickened, immobile, or domed pulmonary valve can be imaged, along with post-stenotic enlargement of the pulmonary trunk and RV thickening. Severity of stenosis can be estimated by Doppler evaluation of the flow across the pulmonary valve in systole, and this can be confirmed by similar evaluation of the velocity of flow in the tricuspid valve regurgitant jet, if present. Echocardiography can also be used to diagnose restrictive RV physiology by demonstrating forward flow across the pulmonary valve in late diastole. This physiology can be present in up to 42% of adults with moderate or severe stenosis and correlates with increased symptoms.\textsuperscript{12}

**Cardiac Catheterization and Cineangiography**

Techniques and findings are the same as those described in Section I.

**NATURAL HISTORY**

Pulmonary stenosis with intact ventricular septum accounts for about 10% of congenital heart disease and is thus a common malformation. Most surgical series show a predominance of females.

Patients Presenting in Infancy

Patients who survive the neonatal period to present later in infancy have a wide variation in degree of pulmonary valve narrowing. About 40% (CL 32%-47%) have mild obstruction, 47% (CL 39%-54%) moderate, and only 14% (CL 9%-20%) severe. However, these percentages probably underestimate the proportion of patients in this age group with severe obstruction. Nugent and colleagues found that 58% (CL 51%-64%) of an unselected group of infants presenting in the first 2 years (n = 81) with this entity had severe RV outflow obstruction.\textsuperscript{73} Even in early life, and probably more so as time passes, infundibular (muscular) narrowing adds to RV output resistance.

When RV outflow obstruction is severe in infants and young children, heart failure, cyanosis, or both are common (more so than in older patients who have developed the same degree of obstruction).\textsuperscript{14,73} Prognosis of this group is poor. Levine and Blumenthal found that 56% of patients with heart failure died during follow-up.\textsuperscript{14}

Even when obstruction is moderate in this young age group, an important proportion have heart failure, with its same poor prognostic implication. It is probable that a degree of RV hypoplasia is often implicated in heart failure under these circumstances. According to Mody’s study of 17 patients with moderate RV outflow tract obstruction in the first year, 53% (CL 38%-68%) experienced progression to a severe lesion in the next several years (average 4.5 years).\textsuperscript{38} Similar conclusions can be drawn from the data of Wennevold and Jacobsen and Danilowicz and colleagues.\textsuperscript{2,81}

Even in asymptomatic infants with mild stenosis, Anand and Mehta reported rapid progression requiring intervention within 6 months in 15%.\textsuperscript{12} Experience of others, however, contradicts this, indicating that progression of mild pulmonary stenosis (gradient of ≤40 mmHg) in infants is rare and is similar to the natural history of mild pulmonary stenosis diagnosed in older children.\textsuperscript{44,66}

Patients Presenting after Infancy

Patients with isolated pulmonary stenosis that produces mild RV outflow obstruction (peak pressure gradient between RV and pulmonary trunk ≤ 25 mmHg or RV peak pressure ≤ 50 mmHg) have a predicted probability of survival equal to that of an age-gender-ethnicity–matched general population.\textsuperscript{44} These patients rarely experience progression of pulmonary stenosis and therefore rarely require interventional
therapy. Recent studies by Rowland and colleagues and Gielen and colleagues corroborate earlier findings.

Patients with moderately severe obstruction (peak pressure gradient between RV and pulmonary trunk > 25 mmHg but < 50 mmHg, or RV peak pressure > 50 mmHg but < 80 mmHg) sometimes experience progression in severity of their RV outflow obstruction. Without progression, as best as can be gleaned from currently available information, predicted probability of survival for at least 25 years is excellent. 

Patients with severe pulmonary stenosis are susceptible to eventual development of chronic heart failure (and thus premature death), the tendency being greater the older the patient. Secondary changes in the severely stenotic valve probably make it more obstructive as time passes, with the outflow tract becoming more hypertrophied and stenotic and the RV becoming thicker, more fibrotic, less contractile, and less compliant. 

In women with severe pulmonary stenosis who are in New York Heart Association functional class I or II, pregnancy is not associated with an increase in fetal or maternal complications, in contrast to similar disease of the mitral or aortic valve.

Effect of Right Ventricular Hypoplasia

RV hypoplasia seems to affect natural history unfavorably. However, some patients with hypoplasia do not die in infancy but present later in life, usually with progressive cyanosis from a right-to-left shunt at atrial level. Left untreated, progressive right heart failure develops and causes death.

TECHNIQUE OF OPERATION

Comment

In infants, children, and adults, as in neonates, percutaneous balloon valvotomy is the treatment of choice for valvar pulmonary stenosis. If this is not successful, or is not indicated, open surgical valvotomy using CPB is performed. Balloon valvotomy is ineffective in most cases of dysplastic pulmonary valve, and when the valve anulus is hypoplastic (\( z \) value < -3). The surgical technique is that described in Section I. When transanular patching is necessary, the technique is also that described in Section I.

Open Operation during Cardiopulmonary Bypass

The general aspects of operation described in Section I are applicable to pulmonary valvotomy in infants and adults. After the pulmonary trunk is opened through a vertical incision, valvotomy is performed (Fig. 39-10). When edges of the cusps are bulky and obstructive, and particularly when the valve is bicuspid, partial or complete valvectomy may be necessary, because a taut bicuspid valve cannot open properly even after incision of the two fused commissures. RV, LV, and pulmonary artery pressures are measured at this point, but they are of little value in decision making (see Special Features of Postoperative Care later). A polyvinyl catheter is placed to measure RV pressure. It can be brought from the pulmonary artery out the low RV or alternatively, can be advanced forward from the right atrium through the tricuspid valve. Pressure measurements made the following morning may indicate the need for return to the operating room for relief of infundibular or anular stenosis.

When an infundibular resection is indicated (Fig. 39-11), a vertical infundibular incision is preferred. After resection, the incision is closed using an oval-shaped patch of PTFE or pericardium. In a few patients, a transanular patch is required because of a small pulmonary valve anulus. Patients requiring this often have dysplastic pulmonary valves. Cineangiogram or echocardiogram may suggest need for the transanular patch, but the final decision is usually made in the operating room. At the time of valvotomy through the pulmonary arteriotomy, the anulus is sized with Hegar dilators. If it is small (\( z \) value of -3 or less), the arteriotomy is carried across the anulus and down the infundibular free wall. If there is doubt about need for transanular patching, the pulmonary arteriotomy is left open and a vertical incision made in the infundibulum.

After muscle resection has been accomplished, the anulus is again sized by Hegar dilators passed through the valve from below. If it is too small, the two incisions are joined by cutting across the anulus, and a transanular patch is inserted (see “Decision and Technique for Transanular Patching” under Technique of Operation in Section I of Chapter 38). Deleon and colleagues have described a reconstructive operation for patients with dysplastic pulmonary valve with hypoplastic anulus that preserves valve function. However, the experience involves only two patients, and follow-up is limited.

In the occasional patient with stenosis of the pulmonary trunk or branches in whom these have not, or cannot, be treated adequately by balloon dilatation and stenting, the narrowed pulmonary branch is dissected to a point beyond the stenosis and an enlarging repair made (see Technique of Operation in Section I of Chapter 38). Preliminary dissection of these branches is best made during CPB cooling. These stenoses must be identified in detail at preoperative cardiac catheterization.

SPECIAL FEATURES OF POSTOPERATIVE CARE

Postoperative care is accomplished as described in Chapter 5. One special feature is that RV pressure should be assessed on the first postoperative day. This is accomplished by monitoring the RV pressure or withdrawal of the pulmonary artery pressure catheter that was placed at operation into the RV. These pressures are more reliable in predicting late results from operation than those taken in the operating room. However, if the patient’s hemodynamic state is good, reoperation within a few days of the initial procedure is rarely necessary, even when RV pressure is high, because of the known tendency for infundibular hypertrophy to regress with time.

RESULTS

Survival

Early (Hospital) Death

Hospital mortality is essentially zero after percutaneous balloon valvotomy. It is very low after surgical valvotomy as well and has been for many years. It approaches zero when patients with severe RV hypoplasia or advanced chronic heart failure are excluded.

Young age (down to 1 month) is not a risk factor. The few deaths that occur are associated either with severe
PART VII  Congenital Heart Disease

Jarrar and colleagues report no late deaths in 62 patients during follow-up. Hemodynamic Outcomes and Reintervention

Immediate relief of the gradient usually is obtained, and it is rare for adequate initial relief of obstruction to be temporary. On average, a peak RV pressure of 128 mmHg before valvotomy is reduced to 51 mmHg shortly after valvotomy. Completeness of relief of pulmonary stenosis can be determined only by late postoperative studies because of the usual, but not invariable, tendency for RV peak pressure to decrease over time after valvotomy. This decline is believed to be due primarily to regression of RV hypertrophy and lessening of infundibular narrowing. It is known, however, that adequate isolated pulmonary valvotomy does not invariably provide excellent relief of pulmonary stenosis, even in infants. Roos-Hesselink and colleagues report a low but definable incidence of restenosis. In 64 patients with follow-up ranging from 22 to 33 years, the reintervention rate was 15%. Two patients required reoperation for recurrent RVOT obstruction at 2 and 3 years after initial surgery, and Jarrar and colleagues report no late deaths in 62 patients during follow-up.

Time-Related Survival

Long-term survival is the rule after surgical treatment. In the early Mayo Clinic experience, survival out to 25 years after hospital discharge was 91% in the overall group, but this was importantly affected by age at operation. Survival for at least 25 years after hospital discharge was 93% for those aged 0 to 4 years at operation, 100% for those aged 4 to 10 years at operation, 92% for those aged 11 to 20 years, and 71% for those older than 21 at operation. Although neonates were not represented in this experience, infants were, and this probably accounts for the effect of age in that era.

In a more recent longitudinal study of 51 patients, with follow-up ranging from 22 to 33 years (mean 25 years), late survival was 96%. Long-term survival is now available following balloon valvotomy. Fawzy and colleagues report 2- to 17-year follow-up (mean 10 years) in 90 patients, with no late deaths. All patients were older at the time of balloon intervention in this study, ranging from 15 to 54 years. Gupta and colleagues reported a single death in 166 patients and RV hypoplasia or, particularly in adults, advanced chronic heart failure.

In Figure 39-10, Pulmonary valvotomy through pulmonary trunk during cardiopulmonary bypass. A, Overview showing vertical incisions in pulmonary trunk and high right ventricle (RV). B, View of funnel-like stenosis of pulmonary valve. C, Commissures are incised sharply with a knife. As this is done, the surgeon and an assistant must carefully stabilize the cusp on either side to avoid inaccuracy in making the incision. If necessary, thickened valve tissue around the orifice may be resected, or a cusp may be partially detached. However, this is done only if the opening is otherwise unacceptable, because some degree of regurgitation results. When infundibular dissection and resection are also required, RV is opened through a vertical incision in the infundibulum. After performing the dissection and resection, vertical ventriculotomy is closed with a small oval patch of polytetrafluoroethylene or pericardium inserted with continuous polypropylene suture.
Figure 39-11 Infundibular resection for pulmonary stenosis with intact ventricular septum. In contrast to the situation in tetralogy of Fallot, this is a resection of muscle from the entire circumference of the severely hypertrophied outflow tract. A, Approach is through a vertical incision that will be closed with a polytetrafluoroethylene (PTFE), polyester, or pericardial patch as in tetralogy of Fallot. B, Working from below upward, muscle is cored out with a knife up to valve level. More muscle can be excised from recesses in front of either end of the infundibular septum than elsewhere. Excision is often also necessary from the walls (anterior, medial, and lateral) for a short distance below ventriculotomy.

Continued
two required subsequent balloon dilatation at 16 and 18 years postoperatively. Additionally, six other patients required surgical reintervention, ranging from 16 to 24 years postoperatively, for severe pulmonary regurgitation. Five of these six had a transanular patch placed at initial operation. Moderate to severe pulmonary regurgitation was present at late follow-up in 37% of patients.

Earing and colleagues, on the other hand, reported more concerning long-term reintervention. In 53 patients with a mean follow-up of 33 years, reintervention for recurrent pulmonary stenosis was similarly low, but 21 patients (40%) required pulmonary valve replacement for severe regurgitation. This may reflect the extremely long follow-up, because other authors have recognized the progressive increase in symptomatic pulmonary regurgitation the longer the follow-up; however, equally important is that this cohort of patients underwent their original surgery in a different era. To this point, in this study, closed pulmonary valvotomy was importantly associated with need for late reoperation.

Hemodynamic results after percutaneous balloon valvotomy are similar to those just described (see Results in Section I). Fawzy and colleagues report a reduction in pulmonary valve gradient from 105 mmHg to 34 mmHg in their series of 90 patients (mean age 24 years). The infundibular gradient was large immediately following the procedure in 43 patients, all of whom underwent later recatheterization. The gradient decreased from 42 mmHg following the initial procedure to 13 mmHg at repeat study. Other reports document similar results.

Gudausky and Beekman summarize results from five large studies reported between 1994 and 2003. A total of 866 non-neonatal cases were included. Restenosis occurred in 20%, with 7% requiring repeat balloon valvotomy and 7% requiring surgery. Severe pulmonary insufficiency was present in 1%. Freedom from either surgical or balloon reintervention at 5 and 10 years after intervention, reported by Rao and colleagues, was 88% and 84%, respectively (Fig. 39-12).

**Comparison of Surgery and Balloon Valvotomy**

Peterson and colleagues studied comparative outcomes between surgical and balloon valvotomy. Between 1969 and 2000, 62 patients underwent surgery, and 108 balloon valvotomy. Both techniques were effective, but there were differences at 10-year follow-up. Surgery reduced the gradient across the pulmonary valve more effectively than balloon valvotomy and had lower rates of restenosis and overall reintervention. Balloon valvotomy had a lower rate of moderate pulmonary regurgitation, which did not appear to influence reintervention rates in the two groups. Nevertheless, balloon valvotomy is today the procedure of choice because of its lower cost, shorter hospital stay, lower degree of invasiveness,
and effectiveness. Based on the study of Earing and colleagues, it can be inferred that the reintervention rate in the surgery group studied by Peterson and colleagues will continue to rise with longer follow-up as symptoms from pulmonary regurgitation develop.

Cyanosis

Cyanosis may persist late postoperatively when the foramen ovale or ASD is not closed, even when stenosis has been relieved, as a result of impaired RV compliance. This can occur occasionally with a normally developed, severely hypertrophied RV, presumably secondary to diffuse fibrosis, but it is the rule in the hypoplastic RV. Data from Freed and colleagues suggest that the reversed atrial shunt may lessen as an infant or young child grows and as the RV increases in size, and later closure of the ASD thus may not be required. This favorable sequence cannot be expected in patients with hypoplastic RV, and it is well known that important hypoxia can occur from a right-to-left shunt through a small atrial communication.

Morphologic Changes

The sinus portion of the RV enlarges and becomes normal in size in most patients. The infundibulum enlarges in many patients, but as in tetralogy of Fallot (see Chapter 38), a narrow pulmonary anulus may fail to enlarge as the child grows. The apparent size of the pulmonary arteries increases, and in most patients they become normal sized. Tricuspid regurgitation, even when severe preoperatively, is usually absent or mild late postoperatively.

Functional Capacity

Most patients have an excellent late functional result. Stone and colleagues have shown that during exercise, children who have undergone pulmonary valvotomy have a normal relationship between cardiac output and oxygen consumption, no increase in RV end-diastolic pressure (preoperatively it increased), and less increase than preoperatively in RV peak systolic pressure. The late result in patients with a hypoplastic RV is inferior to that in patients with a normally developed ventricle. Late mortality is higher, there may be a reversed shunt through an unclosed atrial communication, and there may be residual infundibular obstruction. There may also be persistent or recurrent right heart failure despite complete relief of stenosis. Although there are no techniques proven to be beneficial in managing the hypoplastic RV, a number of options are available in selected cases. Late heart failure may be prevented in this group, particularly in those who are young, by a complete valvotomy combined with enlargement of the RV cavity by excision of trabeculations. This may be particularly helpful if extensive endocardial fibrosis is present. In patients with persistent RV failure, volume unloading by creating a bidirectional superior cavopulmonary anastomosis may be beneficial.

INDICATIONS FOR OPERATION

When patients first show signs and symptoms at age 1 month or more, they are usually less critically ill than those presenting as neonates. Nonetheless, when diagnosis of severe stenosis is made, pulmonary valvotomy is advisable. As in critical pulmonary stenosis in neonates, percutaneous balloon valvotomy is usually the intervention indicated. Only in special circumstances is surgical intervention indicated. These include dysplastic valves, severely hypoplastic valves, severe infundibular stenosis, and associated intracardiac lesions requiring surgery.

Intervention is similarly advised in asymptomatic infants with severe stenosis. In those with moderate stenosis, intervention in infancy is debatable; it is not recommended when stenosis is mild. In older patients, management differs only in the group with moderate stenosis. In this subset, the older the age at diagnosis, the less likely there will be important progression and therefore less need for intervention.

In all patient groups beyond the neonatal period, a gradient across the pulmonary valve of 50 mmHg or greater is considered an indication for intervention. Presence and degree of RV hypoplasia are taken into account when deciding on intervention. Because of its effect in increasing cyanosis and heart failure, severe RV hypoplasia makes intervention more urgent in infants. In older children and adults presenting with this lesion, indications for intervention do not differ unless there is severe heart failure unresponsive to medical measures. Under these circumstances, risk of intervention is increased.

SPECIAL SITUATIONS AND CONTROVERSIES

Right Ventricular Hypoplasia in Children and Adults

When the RV is severely hypoplastic, symptoms and signs are substantially altered. Important symptoms are not necessarily present in infancy, but when they appear they tend to progress rapidly. Classically, there is a markedly prominent a wave and reversed (expiratory) splitting of the second heart sound. Pulmonary stenosis with hypoplastic RV is associated with less than the expected degree of RV hypertrophy, and in severe hypoplasia, LV forces are dominant despite severe stenosis. Diminished RV potentials are due to smallness of its cavity rather than to diminution in muscle mass. Balloon valvotomy may not be as effective in this group because of (1) frequent presence of organic infundibular obstruction, (2) necessity of closing the atrial communication to abolish the otherwise persistent right-to-left shunt, and (3) probable benefits of enlarging the RV cavity by excising muscle from its sinus portion. Taking all these factors into consideration, a surgical approach may be required. However, when severe heart failure is present, prognosis is still poor with any approach. In this setting, reducing volume load on the RV by performing a superior cavopulmonary anastomosis may be of benefit (see Special Situations and Controversies in Section III of Chapter 41).

Supravalvar Pulmonary Stenosis

The rarest form of pulmonary stenosis and intact ventricular septum is supravalvar pulmonary stenosis. It has been called bowstring pulmonary stenosis and is characterized by narrowing of the sinutubular junction, similar to that seen in supravalvar aortic stenosis. This lesion, like pulmonary valve dysplasia, does not respond to balloon dilatation; surgery is required. Various technical approaches have been described, all similar to those described for supravalvar aortic stenosis.
(see Section III of Chapter 47). The technique of repair can involve patching from the main pulmonary artery across the sinusuticular junction into the sinus of Valsalva. Alternatively, repair using only native pulmonary artery tissue has been described. 11

**Definition**

Pulmonary atresia and intact ventricular septum is a congenital malformation in which the pulmonary valve is atretic and no ventricular septal defect exists. It coexists with variable degrees of right ventricular (RV) and tricuspid valve hypoplasia, and variable degrees of coronary artery abnormalities. This chapter discusses this malformation in the setting of atroventricular and ventriculoarterial concordant connections.

**Historical Note**

In 1839, Peacock collected records of seven patients with pulmonary atresia and intact ventricular septum and gave credit to John Hunter for reporting the first case in 1783. Hunter described a premature male who died 13 days after birth. The RV had “scarcely any cavity,” and the tricuspid valve was “especially small.” Coronary sinusoids and RV–coronary artery fistulae were recognized by Grant in 1926 and later by others. RV-dependent coronary
circulation began to be recognized at least in 1975 by Essed and colleagues and more recently by others.\textsuperscript{87,126,267}

In 1955, Greenwold and colleagues at Mayo Clinic described two types of RV in this malformation: (1) small and (2) normal-sized or large.\textsuperscript{411,412} Subsequently, the idea evolved that values for RV cavity size and tricuspid valve dimensions, as well as morphologic details, comprised a spectrum embracing virtually all values between the extremes.\textsuperscript{414,222} Greenwold and colleagues also suggested that pulmonary valvotomy was appropriate treatment when the RV was near normal in size.\textsuperscript{411,412} In 1961, Davignon and colleagues at Mayo Clinic suggested that a systemic–pulmonary artery shunt be performed when the RV was small.\textsuperscript{143} Reports of successful surgery from the University of Minnesota, Mayo Clinic, and Henry Ford Hospital appeared in 1961.\textsuperscript{88,122}

The combination of a systemic–pulmonary artery shunt with an RV outflow operation was described by Bowman and colleagues in 1971 and by Trusler and colleagues in 1976.\textsuperscript{88,122}

In 1993, Hanley and colleagues introduced the concept that optimal outcomes are best achieved when neonatal and subsequent surgical management are specifically tailored to the variable morphology of this malformation.\textsuperscript{111}

**MORPHOLOGY**

Hearts with pulmonary atresia and intact ventricular septum include a spectrum extending from mild concomitant abnormalities of the RV and tricuspid valve to the most severe. Whether the entity of pulmonary stenosis and intact ventricular septum, particularly critical pulmonary stenosis in neonates, is part of this spectrum can be debated (see Section I of Chapter 39). Evidence supporting the continuum of these two entities is that at least some hearts at adjoining ends of the spectra have similar RV and tricuspid valvar abnormalities.

It has been hypothesized that the later the narrowing of the pulmonary valve develops in fetal life, including progression to atresia, the more fully and normally developed are the tricuspid valve, RV cavity, and RV myocardium. Conversely, the earlier these developments occur in fetal life, the more likely that these structures will be hypoplastic and abnormal.\textsuperscript{412,421,71} This hypothesis is also consistent with the concept that there is a continuity of the spectra of pulmonary atresia with intact ventricular septum and pulmonary stenosis with intact ventricular septum.

**Pulmonary Valve**

The nature of the structure at the junction of the RV and pulmonary trunk is arguable. Van Praagh and colleagues imply that fibrous components are pulmonary valve remnants.\textsuperscript{82} Others point out that in many cases, there is only poorly structured imperforate fibrous tissue overlying muscular atresia.\textsuperscript{\textsuperscript{415,412,222}} In any event, commissural ridges may be prominent and converge to meet in the center of the “valve,” an appearance similar to that in pulmonary valve stenosis.\textsuperscript{222} In some patients, commissural ridges are present only in the periphery, the center being a smooth fibrous membrane.\textsuperscript{39} In the combined U.K.-Ireland multicenter study of 183 patients, 75% had membranous atresia and 25% muscular atresia.\textsuperscript{121} Of greater importance is the nature of the structures immediately below the RV–pulmonary trunk junction (see “Right Ventricle” and “Tricuspid Valve” in text that follows).

Data from Hanley and colleagues.\textsuperscript{87}

\textsuperscript{a}Based on data from 171 neonates with pulmonary atresia and intact ventricular septum in the Congenital Heart Surgeons Society study. Size of pulmonary arteries was known in 84.

\textsuperscript{b}Cavity size was graded (0, normal to −5, severe hypoplasia) based on echocardiographic and cineangiographic findings.

\textsuperscript{c}Five of six patients with moderate or severe hypoplasia of right and left pulmonary arteries on cineangiography had severely reduced ventricular cavity size (information available for 84 of 136 patients).

\textsuperscript{d}In addition, eight patients had enlarged right ventricular cavities, and one (12%) of these had moderately hypoplastic pulmonary arteries.

Key: RV, Right ventricle.

**Pulmonary Arteries**

The pulmonary trunk is usually nearly normal in size, but uncommonly is severely hypoplastic.\textsuperscript{413,439,411,32,222} Rarely, the pulmonary trunk is represented only by a fibrous cord.\textsuperscript{71}

Right and left pulmonary arteries are usually normal in diameter or slightly hypoplastic.\textsuperscript{42,413,71} Uncommonly, they are moderately or severely hypoplastic, usually in patients with severely reduced RV cavity size (Table 40-1). Rarely, there are major arborization abnormalities of the native pulmonary arteries in association with large aortopulmonary collaterals. Four such patients have been encountered by F.L. Hanley and colleagues (personal communication, February 2012).

**Right Ventricle**

Size of the RV cavity is variable. In about 5% of patients, it is enlarged (see Chapter 38, Fig. 38-2 and Chapter 39, Table 39-1). Ebstein malformation and severe tricuspid regurgitation may coexist with the latter.\textsuperscript{57,128,84,10,78,43,41,93,422} Many individuals with this combination die in fetal life.\textsuperscript{45} Rarely, the RV wall may be very thin (\textit{thin anomaly or parchment right ventricle}\textsuperscript{103}) and the cavity nontrabeculated adjacent to the tricuspid valve and heavily trabeculated in its apical half.

Much more frequently, cavity size is reduced, severely so in about 60% of patients. This appears to be the result of massive wall hypertrophy extending into the ventricular cavity. Often, this completely obliterates the infundibular cavity, and the atresia can be termed \textit{muscular} in such cases.\textsuperscript{514} At times, the apical-trabecular cavity is completely obliterated; in the most extreme cases, both portions are obliterated. Although these cavities are obliterated, the respective portions of the RV are not absent. Cavity obliteration can be localized by echocardiography as well as by anatomic studies.\textsuperscript{85} Cavity obliteration has been further characterized in the U.K.-Ireland multicenter study.\textsuperscript{121} All three components of the RV (inlet, trabecular, and infundibular) were present in all cases, but with different degrees of cavity obliteration from muscular ingrowth. A “unipartite” ventricle due
to muscular obliteration of the infundibular and trabecular components was present in 8%. A “bipartite” ventricle due to muscular obliteration of the trabecular component alone was present in 34%. There were no cases of muscular obliteration of the infundibulum alone. A “tripartite” ventricle was present in the remaining 58%.

There is associated diffuse fibrosis of the hypertrophied muscle and, especially when the RV cavity is small, a modest degree of RV endocardial fibroelastosis. Bulkley and colleagues found typical myocardial fiber disarray in 69% of the RV free wall and in 73% of the ventricular septum in this condition. The potential for impaired left ventricular (LV) as well as RV dysfunction is evident.

Right Ventricular–Coronary Artery Fistulae

Coronary sinusoids, or dilated portions of the coronary microcirculation, can be detected by cineangiography in about half of patients (Table 40-2). In some cases, fistulous connections between the RV cavity and these sinusoids form multiple small communications into branches of left or right coronary arteries. Occasionally they converge into a single large vessel that empties into the left anterior descending or right coronary artery. In many cases, the fistulae are minor. In the multicenter U.K.–Ireland study, 58% of patients had completely normal coronary circulation, 15% had minor filling of the coronary arteries with RV injection at catheterization, and about 25% had major fistulae, with about one third of these having no coronary connection to the aorta.

Prevalence of RV–coronary arterial fistulae is inversely related to dimensions of the tricuspid valve (and hence of the RV cavity) (Fig. 40-1) and amount of tricuspid regurgitation. It is also directly related to RV systolic pressure. However, the milieu for development of fistulae may be a consequence of genetically or developmentally induced myocardial abnormalities. Immunohistochemical studies demonstrate abnormal density and orientation of capillaries and myocyte disarray in the presence of fistulae. Desaturated RV blood, although vital in the presence of proximal coronary obstructions, compromises myocardial oxygen supply in regions to which it is distributed by these fistulae. This may account in part for the myocardial abnormalities described later in this chapter. Complexity of oxygen delivery to the myocardium is evidenced by the fact that the left anterior descending artery (or any coronary artery) may fill through these fistulae from the RV in systole, and from the aorta in the normal manner during diastole. There results a spectrum of percentages of LV myocardium dependent on the RV for coronary perfusion, albeit desaturated; the percentage depends on location and severity of proximal coronary artery stenoses as well as on the fistulae. At some critical point, sufficient myocardium is in jeopardy of developing such severe ischemia when RV hypertension is relieved that RV decompression becomes contraindicated as a surgical option. In an analysis by Giglia and colleagues of 16 patients with coronary angiography and subsequent RV surgical decompression, 7 of 7 (100%; CL 77%-100%) with no coronary stenosis survived, 4 of 6 (67%; CL 39%-88%) with stenosis in one major coronary survived, and 0 of 3 (0%; CL 0%-46%) with stenosis in two major coronaries survived.

When less severe coronary abnormalities are present in association with fistulae, regional LV wall motion abnormalities are commonly identifiable before RV decompression, and they increase after decompression; however, severe global LV dysfunction is unusual. In about 10% of patients (20% of those with RV–coronary fistulae), coronary circulation or some critical part of it is derived entirely or nearly so from the RV in the manner described, defining RV-dependent coronary circulation. This may occur because of development of arterial obstructions in the left main or right coronary arteries, or both, or in the proximal portion of the left anterior descending artery. RV cavity or RV wall thickness may be increased in RV–coronary fistulae. Proximal coronary arterial occlusions etiologic to the dependence may develop in fetal life; some develop or progress after birth.
RV-dependent coronary circulation is a major consideration in planning therapy (see Indications for Operation later in this chapter). The difficulty is in deciding how much myocardium at risk is considered too much, triggering the management decision to avoid decompressing the hypertensive RV. To address this difficulty, Calder and colleagues identified coronary abnormalities in 116 patients. They determined that presence of coronary fistulae alone did not correlate with mortality. The presence and extent of coronary interruptions, and the amount of LV myocardium that was RV dependent (determined with a 15-point scoring system), did correlate with mortality.

The problem, however, is even more complex than solely determining the amount of myocardium at risk, because even a small amount of extremely ischemic myocardium may be the source of a life-threatening dysrhythmia. Recently, LV coronary abnormalities unrelated to the presence of fistulae, sinusoids, or coronary interruptions have been discovered. Hwang and colleagues showed that patients with pulmonary atresia with intact ventricular septum, regardless of the presence of fistulae, have decreased density of intramyocardial arterioles relative to normal and hypertrophied hearts.

Tricuspid Valve

The tricuspid valve is usually abnormal in this malformation. Occasionally the abnormality is simply small size, but usually the leaflets are thickened and the chordae are abnormal in number and attachment. Local agenesis and incomplete leaflet separation occur. The importance of these abnormalities has been emphasized by Davignon and colleagues and by Paul and Lev.

In about 10% of neonates, the value of the tricuspid valve is less than 2.2, and in 50% it is less than 2.2 or less (Fig. 40-2). (See Appendix Fig. 40A-1 for a nomogram for estimating the value of the tricuspid valve.) Dimensions of the tricuspid valve are well correlated with those of the RV cavity, in contrast to dimensions in neonates with critical pulmonary stenosis, in whom they are not correlated.

In uncommon cases in which dimensions of the tricuspid valve are large, its leaflets usually show features of Ebstein malformation, with enlargement of the anterior leaflet and downward displacement onto the ventricle of the origin of a dysplastic septal leaflet. The posterior leaflet may or may not be abnormal. These valves are usually severely regurgitant. Another pathologic lesion of the tricuspid valve has been recognized in patients with dilated RV and severe tricuspid regurgitation—that of unguarded tricuspid orifice, in which the inferior (mural) leaflet is absent rather than displaced.

Right Atrium

The right atrium is enlarged, and it is more enlarged when there is severe tricuspid regurgitation. An interatrial communication is present in all cases, usually a patent foramen ovale of adequate size. However, shortly after birth the foramen becomes restrictive in some patients. The eustachian valve is frequently prominent.

Left-Sided Chambers

The left atrium is usually hypertrophied and somewhat enlarged, and the mitral orifice is usually larger than normal. The LV shows some hypertrophy and endocardial fibroelastosis. Occasionally the interventricular septum into the LV cavity has been noted, with some speculate that this might produce subaortic obstruction. Clinical and postmortem studies have demonstrated evidence of LV myocardial ischemia in virtually all patients, perhaps related to this, LV compliance is depressed in many.

Aorta

The aorta usually has adult morphology without ischemic narrowing and is usually left sided.

Ductus Arteriosus

The ductus arteriosus is patent at birth but has the usual tendency to close. Orientation of the ductus is typical for pulmonary atresia of all forms, with an obtuse proximal and acute distal angle at its aortic attachment. Usually the bronchial arteries are normal, and important aortopulmonary collateral arteries absent.

Coexisting Cardiac Anomalies

Other than Ebstein malformation, coexisting cardiac anomalies are uncommon.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Symptoms and Signs

Fetal distress is usually not evident except in those with a large RV. Delivery is typically uncomplicated and at term. The babies are generally well developed (Fig. 40-3) and are likely initially to appear healthy except for cyanosis. Cyanosis is usually obvious on the first day and becomes rapidly more severe as the ductus closes and there is respiratory distress and progressing metabolic acidosis. In the New England series, 81% of babies presented during the first week.

---

**Figure 40-2** Relationship between diameter of the tricuspid valve (by echocardiography), expressed as z value, and size of the right ventricular cavity (grade estimated subjectively from echocardiographic and cineangiographic studies) in patients with pulmonary atresia and intact ventricular septum (n = 71). (From Hanley and colleagues.)
QRS axis in the frontal plane is usually normal or shows a rightward deviation, and the RV hypertrophy pattern usually present in the neonate is absent. However, electrocardiographic evidence of RV hypertrophy may be present even though the RV cavity is small, precluding its use to predict RV cavity size.

Echocardiography

Two-dimensional echocardiography is diagnostic (Fig. 40-5). Also, dimensions of the tricuspid valve, RV cavity size, and nature of the outflow obstruction (membranous or muscular) can be determined with confidence. Of importance is the fact that RV–coronary artery fistulae can be identified accurately by two-dimensional echocardiography with pulsed Doppler color flow ultrasound imaging (Fig. 40-6). However,
PART VII  Congenital Heart Disease

1492

stenoses, coronary sinusoids, and RV-coronary fistulae. If these are present, extent of LV myocardial dependence on the RV must be established.

Right atrial mean pressure is usually higher than left, and a prominent $a$ wave can be seen on the pressure tracing. RV peak pressure is usually higher than or equal to systemic pressure, although it may be less in association with severe tricuspid regurgitation and a thin-walled RV. Systemic arterial saturation is low, but varies according to flow through the patent ductus arteriosus. Size and configuration of the RV cavity can be displayed by RV angiography (Fig. 40-7). In Ebstein anomaly with severe tricuspid regurgitation presenting in the neonatal period in association with high pulmonary vascular resistance, RV systole may fail to open a normal pulmonary valve; high-quality angiography will prevent the mistaken diagnosis of pulmonary atresia.

Quantitative cineangiographic studies indicate reduced RV function in essentially all cases. LV function and end-diastolic volume are also abnormal unless a normal LV mass is present.

Cardiac Magnetic Resonance Imaging and Computed Tomography Angiography

These imaging modalities are not typically used during the neonatal period. They may, however, be useful in evaluating older patients. Evaluation of cavity size and degree of musculature of the RV can be accurately determined using cardiac magnetic resonance (CMR) imaging (Fig. 40-8). Delayed-enhancement CMR can be used to determine the status of the myocardium as well (Fig. 40-9). Volume-rendered computed tomography (CT) angiography imaging can also accurately define abnormal coronary connections (Fig. 40-10).

NATURAL HISTORY

Pulmonary atresia and intact ventricular septum is an uncommon malformation, occurring in 1% to 1.5% of individuals born with congenital heart disease. It was present in 3% of critically ill infants with congenital heart disease in the New England series. It is highly lethal, with about 50% of individuals dying within 2 weeks of birth and about 85% by age 6 months (Fig. 40-11). Death is caused by severe hypoxia and metabolic acidosis and usually coincides with spontaneous closure of the ductus arteriosus. Rarely, patients survive into young adult life. McArthur and colleagues describe a 21-year-old whose pulmonary blood flow came from a right coronary–pulmonary arterial fistula, and Robicsek and colleagues describe another patient of similar age who survived because of a congenital aortopulmonary window.

TECHNIQUE OF OPERATION

Overview

No single neonatal operation is standard for pulmonary atresia with intact ventricular septum; rather, several surgical procedures, either in isolation or in combination, are indicated based on the details of the morphology in each case (see Indications for Operation later in this chapter for a description of the best initial operation for each morphologic variant). The initial operation most commonly indicated for
patients will ultimately require a bidirectional cavopulmonary shunt as part of their overall surgical management. A prostaglandin E₁ (PGE₁) infusion is started as soon as possible to maintain ductal patency and is continued until after the surgical procedure. The full dose is 0.1 mg · kg⁻¹ · min⁻¹; when the ductus is confirmed to be open, the dose often can be reduced.

Figure 40-7 Cineangiograms in neonates with pulmonary atresia and intact ventricular septum. A, Right ventriculogram, frontal view. Small right ventricle (RV) has smooth borders, infundibular cavity is obliterated, and tricuspid valve shows severe regurgitation. B, Right ventriculogram from another patient in (B1) frontal and (B2) lateral views. The RV is very small, but its walls are trabeculated. Sinusoid channels are connected with coronary circulation. C, Left ventriculogram in frontal view in another patient. The left ventricle (LV) has its usual appearance and supports the aorta. A right Blalock-Taussig shunt has been made. Key: AO, Aorta; IVC, inferior vena cava; RA, right atrium; RPA, right pulmonary artery; RSA, right subclavian artery; SVC, superior vena cava.

this entity is concomitant transanular patching, systemic-pulmonary artery shunting, and ductal ligation. The next most common procedure is an isolated systemic-to-pulmonary artery shunt and ductal ligation.

For all of the procedures described, postnatal preoperative management is similar. Following birth, an arterial pressure monitoring catheter is placed, preferably into the left radial artery. (A right radial artery catheter should be avoided because of the possibility that a systemic-to-pulmonary artery shunt originating from the right subclavian artery will be part of the surgical procedure.) A reliable intravenous line is placed into either the femoral or umbilical vein. In general, deep intravenous lines into the upper body, such as into the subclavian or jugular veins, should be avoided to minimize thrombosis in the upper body venous system, because many patients will ultimately require a bidirectional cavopulmonary shunt as part of their overall surgical management. A prostaglandin E₁ (PGE₁) infusion is started as soon as possible to maintain ductal patency and is continued until after the surgical procedure. The full dose is 0.1 mg · kg⁻¹ · min⁻¹; when the ductus is confirmed to be open, the dose often can be reduced.

Endotracheal intubation and mechanical ventilation are usually necessary, either as part of general resuscitative measures, or as a result of inhibition of intrinsic ventilatory drive due to PGE₁. A low inspired oxygen fraction and controlled hypercarbia are used to counter the tendency for overcirculation through the ductus arteriosus. Low-dose inotropic support with dopamine or milrinone may be needed to support the systemic circulation.
Concomitant Placement of Transanular Patch and Systemic–Pulmonary Artery Shunt

A median sternotomy is made through an incision that is carried a little farther into the neck than usual to provide better exposure of the brachiocephalic trunk and subclavian arteries. After the pericardium is opened and stay sutures applied, the right pulmonary artery between the aorta and superior vena cava is dissected.

A 3.5-mm expanded polytetrafluoroethylene (PTFE) tube (3.0 mm if the neonate is smaller than about 2.5 kg) is cut to proper length. Without giving heparin at this time, a fine...
Cardiopulmonary bypass (CPB) is established, with the perfusate warm and normocalcemic. The neonate’s temperature is maintained at approximately 34°C during CPB. The surgically created shunt is temporarily occluded by placing a vascular clamp on the PTFE tube. The operation may be done with the heart beating, or cold cardioplegia and controlled reperfusion may be used (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3).

A longitudinal incision is made in the pulmonary trunk, and the cartilaginous valve plate is incised. The incision is carried proximally onto the RV, taking care to find and stay in the cavity of the infundibulum and to extend it to the sinus portion and distally along the pulmonary trunk, stopping just before the bifurcation. The patch, preferably made from glutaraldehyde-treated autologous pericardium, is sewn into place with 7-0 polypropylene continuous suture. The suture line does not include the full thickness of the incised RV wall, but rather incorporates the epicardium and about 30% of the outer thickness of the RV wall. The foramen ovale must not be closed.

The aortic clamp is released (or controlled reperfusion accomplished), and preparations are made for discontinuing CPB. The vascular clamp is removed from the PTFE tube, and when normothermia is regained, CPB is discontinued and the remainder of the operation completed as usual.

Other Initial Operations

Other initial operations are indicated based on specific morphology. These include isolated placement of a systemic to pulmonary artery shunt and ductal ligation; isolated placement of a transanular patch and ductal ligation using CPB; pulmonary valvotomy, placement of a systemic-to-pulmonary artery shunt, and ductal ligation using CPB; and isolated pulmonary valvotomy and ductal ligation using CPB (Fig. 40-12).

**SPECIAL FEATURES OF POSTOPERATIVE CARE**

Postoperative care is the same as described under “Special Features of Postoperative Care” in Chapter 39 for critical pulmonary stenosis in neonates. As in the case with pulmonary stenosis, need for an additional surgical procedure is continually assessed.

**RESULTS**

**Survival**

**Early (Hospital) Death**

Overall hospital mortality of a heterogeneous group of neonates with pulmonary atresia and intact ventricular septum, virtually all of whom have had one or more procedures, has been about 20%.$^{11}$ However, the hazard function for death does not level off appreciably until 3 to 6 months (Fig. 40-13). This plus the wide variability of morphology and of procedures makes the unadjusted figure of little value. More recent studies that have followed, in general, the guidelines described under *Indications for Operation* (see later) show improved early survival. In one study,$^{13}$ there was 1 hospital death among 47 patients (2.1%; CL 0.4%-6.8%), and in another,$^{14}$ 5 early deaths among 44 patients (11%; CL

Data from Hanley and colleagues. Based on 171 neonates with pulmonary atresia in the Congenital Heart Surgeons Society study (1987-1991). Excluded were patients with Ebstein malformation or right ventricular cavity size greater than normal (n = 13, 11 of whom died) and those having no procedure (8, among whom 7 died; 3 are among the 13 just mentioned), leaving 153 neonates who actually underwent a procedure. Time zero was time of first intervention. Coefficients, their standard deviation, and other details of the multivariable equation resulting from the analysis are in cited article. Key: RV, Right ventricle.

**Figure 40-14** Survival after various initial procedures in a heterogeneous group of patients with pulmonary atresia and intact ventricular septum. In addition, eight patients (seven of whom died) underwent no procedure, and one underwent an unknown procedure. No patient had an initial percutaneous procedure. In general, patients who received a pulmonary-systemic shunt (with or without atrial septectomy) had the smallest tricuspid valves (z value ≤ −3). Key: TAP, Transanular patching. (From Hanley and colleagues.)

**Table 40-3** Incremental Risk Factors for Death in Pulmonary Atresia and Intact Ventricular Septum

6.7%-18%). A 40-year single-institution study of 210 patients also documents that survival has improved over time.

**Time-Related Survival**

Only about 60% of a heterogeneous group of neonates with pulmonary atresia and intact ventricular septum were alive 1 year after entrance into the hospital for treatment, as were 60% at 2 years and 58% at 4 years. The hazard function for death remains high but declining for the first 3 months, but after about 36 months it is only a little higher than that of an age-sex-race-matched general population. Patients with an abnormally large RV, with or without Ebstein malformation, have a particularly poor outlook regardless of treatment; about 85% die within the first year. Excluding this small group of patients, 1-month, 1-year, and 4-year survival has been somewhat better than in the heterogeneous group (see Fig. 40-13). Some recent single-institution reports suggest slightly better long-term outcome.

**Modes of Death**

The most common modes of death are acute heart failure and hypoxia.

**Incremental Risk Factors for Premature Death**

Survival after different initial procedures has varied widely (Fig. 40-14), but prevalence of small tricuspid valves and RV cavities has varied among the procedure groups. A more reliable understanding of the patient-specific and procedural risk factors for death is obtained by multivariable analysis (Table 40-3); validation of the analysis is shown in Appendix Fig. 40B-1.
Early mortality was low and unrelated to RV size. Interestingly, however, they demonstrated that interim mortality (defined as occurring after successful neonatal surgery but before the second-stage operation) was substantial: 15%. Furthermore, when they evaluated only patients with very small RV cavities, interim mortality was 24%.

Right Ventricular–Dependent Coronary Circulation

An RV-dependent coronary circulation is a powerful risk factor for death. In a study among 12 such patients, only 4 (CL 18%-52%) survived 1 or more years. There is evidence, however, that even this powerful risk factor has recently been neutralized to some extent (see Fig. 40-16). In a 2006 study focusing only on patients with RV-dependent coronary circulation, overall mortality was 19%. All patients were managed as neonates with a systemic-to-pulmonary artery shunt only; all deaths occurred within 3 months of the procedure. Notably, all three patients with no coronary-to-aorta connection died. All surviving patients have gone on to a bidirectional cavopulmonary connection or Fontan without further mortality. In another recent study, 2 of 5 patients (CL 14%-71%) with RV-dependent coronary circulation died.

The severity of coronary abnormalities and fistulae affect more than survival; they are also associated with reduced LV function at late follow-up.

Systemic–Pulmonary Artery Shunt

In the past, systemic–pulmonary artery shunting alone has been associated with lower overall survival than when other procedures were used (see Fig. 40-14). More recently, survival with a shunt alone has improved strikingly (see Fig. 40-16). This is the only procedure associated with reasonable survival in patients with very small tricuspid valves.

Birth Weight

As in nearly all types of congenital heart disease requiring treatment early in life, low birth weight is an important risk factor for death.

Interim Interventions after Initial Procedure

This section discusses further interim interventions performed before the definitive intervention leading to a separated two-ventricle system or a single-ventricle Fontan system. Patients whose initial procedure is a transanular patch and a systemic–pulmonary artery shunt generally do not require further interim procedures. This is an important advantage of this operation as the initial procedure. With it, the opportunity for maximal RV (and tricuspid valve) growth exists during the critical early weeks and months of life when myocardial hyperplasia is possible.

Among patients whose initial procedure is pulmonary valvotomy or placement of a transanular patch without a concomitant systemic–pulmonary artery shunt, about half require a systemic-pulmonary shunt within a few weeks (Fig. 40-17). The smaller the dimensions of the tricuspid valve, the greater the probability that a subsequent systemic–pulmonary artery shunt will be needed ($P = .04$) (Fig. 40-18).

Patients whose initial procedure is a pulmonary valvotomy with or without a concomitant shunt often subsequently require placement of a transanular patch (Fig. 40-19). No correlates with subsequent placement of such a patch have been identified. This suggests that a transanular patch should

**Figure 40-15** Nomogram of a specific solution of a multivariable equation illustrating effects of dimension of tricuspid valve (expressed as $z$ value) and type of initial procedure on survival in neonates with pulmonary atresia and intact ventricular septum (see Table 40-3). Values for other variables entered into equation are birth weight 3.1 kg, right ventricular (RV)-dependent circulation, number, and in the case of a shunt operation, date of operation. This nomogram is a rational basis for therapy. (From Hanley and colleagues.)

**Figure 40-16** Nomogram of a specific solution of multivariable equation (see Table 40-3) demonstrating improvement in survival after an initial shunt procedure that has occurred across time, and effect of a right ventricular (RV)-dependent circulation. Value entered for birth weight is 3.1 kg. (From Hanley and colleagues.)

**Dimensions of Tricuspid Valve**

Small size ($z$ value of diameter) of the tricuspid valve is a strong risk factor for death (Fig. 40-15). An exception is the case of neonates in whom the initial procedure is a systemic–pulmonary artery shunt alone. When that procedure is used, survival is unrelated to dimension of the tricuspid valve (see Fig. 40-15). Survival after shunting appears to have improved recently, probably related to increased experience with making systemic–pulmonary artery shunts in neonates (Fig. 40-16). The recent two-center study by Fenton and colleagues is relevant to this discussion. They assessed survival among 35 patients who underwent a shunt-alone initial procedure. Although they did not measure tricuspid valve diameter, they evaluated RV cavity size, which is known to correlate with tricuspid valve size. Early mortality was low and
Definitive Procedures

It is not possible at present to know the prevalence of achieving (at some time) a separated two-ventricle repair. It appears to be about 60% to 70% in patients with a tricuspid valve \( z \) value of \(-2\) or greater, and less than 10% in those with very small \( z \) values.\(^{11}\)

Theoretically, in all patients in whom a separated two-ventricle repair cannot be accomplished, a single-ventricle Fontan system should eventually be achievable. The limiting factor in this group is survival to the time of a Fontan operation. Thus, the problem is analogous to that in patients with hypoplastic left heart physiology. Results of the Fontan operation in patients with pulmonary atresia and intact ventricular septum appear to be the same as in patients with other congenital cardiac anomalies.\(^{2,11}\) Patients with severe coronary abnormalities may, however, be at increased late risk.\(^{16}\)

A more difficult question is whether all patients not able to achieve a two-ventricle repair should eventually undergo a Fontan, or whether an alternative procedure should serve as the definitive operation in selected patients. For example, certain patients with tricuspid valve \( z \) values that are moderately small may best be served by a definitive operation consisting of a bidirectional superior cavopulmonary shunt combined with closure of the atrial septal defect and a procedure creating unobstructed RV to pulmonary artery flow, the so-called one-and-a-half ventricle repair.\(^{4,8,10,12,13}\) (see Special Situations and Controversies). In patients in whom the tricuspid valve and RV are functional, procedures may occasionally be necessary to correct tricuspid valve regurgitation.\(^{11}\)

Other Outcomes

Myocardial perfusion has been shown to be abnormal at mid- to late follow-up.\(^{23}\) The abnormalities are not restricted to patients with identified coronary fistulae, but include patients with apparently normal coronary arteries. Exercise capacity is

**Figure 40-17** Freedom from a subsequent shunt operation in neonates with pulmonary stenosis or atresia and intact ventricular septum undergoing an initial valvotomy (balloon or surgical) or insertion of a transanular patch without a concomitant shunt \((n = 105)\). (Format is as in Fig. 40-13.) Patients with Ebstein malformation or with a right ventricular cavity size greater than normal, or both, were not included in this analysis. (From Hanley and colleagues; see citation for coefficients and their standard deviation.)

**Figure 40-19** Freedom from a transanular patch (TAP) in neonates with pulmonary atresia and intact ventricular septum undergoing an initial pulmonary valvotomy with or without a concomitant shunt operation \((n = 46)\). (Format is as in Fig. 40-13.) Patients with Ebstein malformation, right ventricular cavity size greater than normal, or both were not included in this analysis. Multivariable analysis identified no risk factors for this event. (From Hanley and colleagues.\(^{11}\))
INDICATIONS FOR OPERATION

Presence of the malformation is generally an indication for operation because of its high lethality. As soon as the diagnosis is suspected, the neonate is resuscitated and stabilized, as described under Technique of Operation. Once the diagnosis is established and the baby is stabilized and in good condition, operation is undertaken, but in view of the favorable effect of PGE₁, it is not done as an emergency.

Selection of the initial intervention is based in large part on the estimated probability that a separated two-ventricle system will ultimately be possible. Indications given in this section are based on the work of de Leval and colleagues and on the findings of the Congenital Heart Surgeons Society study, (see Table 40-3 and Figs. 40-15 to 40-19). These two studies are entirely consistent with each other, as are those of other recent studies.

The inference from all available information is that the best guide to the type of initial operation is size of the tricuspid valve. A z value equal to or less than −4 (and by implication a very small RV chamber) makes probability of death after placement of a transanular patch with a concomitant shunt greater than after a systemic–pulmonary artery shunt alone (see Fig. 40-15). Furthermore, an achieved separated two-ventricle system has been extremely uncommon when the original z value of the tricuspid valve has been less than −3. This line of reasoning could be altered were it to be shown that growth of the hypoplastic tricuspid valve could be made disproportionally greater than that of the body as a whole.) Thus, in patients with pulmonary atresia and a z value of the tricuspid valve equal to or less than −4, an initial systemic–pulmonary artery shunt is indicated.

At age 3 to 6 months, a bidirectional superior cavopulmonary shunt is performed, followed by a Fontan operation (see Indications for Operation in Chapter 41). So long as a total cavopulmonary type of connection is used for the Fontan procedure, nothing need be done to the tricuspid valve. Any evident RV–coronary artery fistula should be closed, unless there is RV-dependent coronary circulation. When the z value of the tricuspid valve is greater than −4, the inference is that risk of death will be no greater (see Fig. 40-15), and probability of a separated two-ventricle system greater, when a transanular patch is placed (or, in special circumstances, a pulmonary valvotomy performed) and a concomitant shunt is placed rather than a systemic–pulmonary artery shunt alone.

Ideally, some objective method of determining need for a transanular patch should be available, but the decision must rest on the subjectively evaluated “adequacy” of the infundibular cavity, the “anulus,” and the pulmonary valve tissue itself. In the absence of any clear evidence of a substantial advantage of valvotomy in this setting, and because about 40% of those in whom a valvotomy has been done have required a subsequent transanular patch, a transanular patch should be used whenever doubt arises.

When an RV outflow operation is being performed as described, need for a concomitant systemic–pulmonary artery shunt is moderately related to RV cavity size and thus to dimension of the tricuspid valve (see Fig. 40-18). As a general guide, a concomitant systemic–pulmonary artery shunt should be performed, especially when the z value of the tricuspid valve is less than about −2 (indicating a small RV cavity).

When the initial procedure has been done under the hypothesis that a separated two-ventricle system will be possible, testing of that hypothesis should begin 6 to 12 months after the initial procedure. The shunt is temporarily occluded, ideally percutaneously. If arterial oxygen saturation remains high, the shunt is permanently closed by percutaneous or surgical techniques (for percutaneous technique, see “Percutaneous Closure of Large Aortopulmonary Collateral Arteries” under Special Situations and Controversies in Section II of Chapter 38). The atrial septal defect is temporarily occluded, again ideally by percutaneous techniques. If right atrial pressure remains below 12 to 15 mmHg, cardiac output is adequate, and oxygen saturation of blood in the right atrium is maintained (any decrease in cardiac output is compensated for by rise in arterial oxygen saturation), the defect should be closed permanently by a surgical or percutaneous technique (see “Closure of Atrial Septal Defects by Percutaneous Techniques” under Special Situations and Controversies in Chapter 30).

When the patient does not tolerate shunt closure, a separated two-ventricle system may not be possible, and consideration should be given to beginning the process leading to a Fontan operation or some other definitive procedure, such as the “one-and-a-half ventricle” repair as discussed earlier under “Definitive Procedures.” When closure of the atrial septal defect is not well tolerated, a prolonged period of procrastination may be wise if the patient’s clinical state is good.

Neonates with RV-dependent coronary circulation represent a special problem (see “Right Ventricular–Coronary Artery Fistulae” earlier under Morphology). When after detailed study, a considerable portion of the LV myocardium is judged to be in jeopardy of developing severe ischemia, decompression or thrombolytic exclusion of the RV is contraindicated. The recent study by Calder provides quantitative information on the amount of LV myocardium at risk of ischemia and how it relates to outcome. These patients may be treated the same as other patients with severely hypoplastic tricuspid valves and RVs, so long as the type of Fontan operation allows fully saturated blood to enter the RV. In time, cardiac transplantation may prove the optimal treatment for this small subset of patients.

SPECIAL SITUATIONS AND CONTROVERSIES

Percutaneous Valvotomy

It has been recognized for some time that percutaneous techniques could become the initial procedure for neonates in whom the pathway through the infundibulum is reasonably wide and the atresia “membranous.” In 1991, this was achieved successfully by laser valvotomy followed by balloon dilatation. Other reports have followed, with mixed outcome. Shinebourne and colleagues recommend percutaneous valvotomy in all cases of membranous atresia with an RV and tricuspid valve that have the potential for a biventricular repair. Even in this favorable subgroup, 60% will remain duct dependent and require a systemic-to–pulmonary artery
shunt. Similarly, Humpf and colleagues attempted percutaneous valvotomy in a highly selected subgroup. Of 30 patients, the valve could not be perforated in 3 (10%; CI 4.6%-19%), 14 required a shunt (47%; CI 36%-57%), and 4 (13%; CI 7.1%-23%) required RV outflow surgery. Thus, more than two thirds of the group required surgical intervention. In the study by Hirata and colleagues, only 2 of 17 patients (12%; CI 4.2%-25%) undergoing percutaneous valvotomy did not require an additional neonatal surgical procedure involving either a shunt or the RV outflow tract. Similar outcomes were observed by McLean and Pearl.

In the U.K.-Ireland multicenter study, neonates undergoing percutaneous valvotomy had an increased risk of reintervention to increase pulmonary blood flow relative to those undergoing initial surgery. Thus, this method has the same limitations as surgical valvotomy or transanular patching without a concomitant shunt—particularly the potential delay of weeks or months in maximizing the stimulus to RV growth—and is associated with a higher likelihood of reintervention than these initial surgical procedures (see “Interim Interventions after Initial Procedure” earlier under Results).

**Formalin Infiltration of Ductus Arteriosus**

In 1975, Rudolph and colleagues introduced formalin infiltration of the wall of the ductus via a left thoracotomy as a means of maintaining patency and avoiding need for an artificial shunt. In carefully selected patients with favorable anatomy, this technique may provide outcome similar to that of surgical intervention. Others have observed ductal closure within a few weeks or months of the procedures, and its use is not currently recommended.

**Right Ventricle–to-Aorta Conduit**

Use of an RV-to-aorta conduit for patients with RV-dependent coronary circulation has been used by several groups to limit myocardial ischemia. Although outcomes have been good, the extremely limited use of this procedure prevents adequate assessment of its effectiveness.

**Tricuspid Valve Closure in the Presence of Right Ventricle–Coronary Fistulae**

Several groups advocate closing the tricuspid valve orifice in the setting of RV-coronary fistulae without major coronary abnormalities. Limited experience prevents adequate analysis of this procedure.

**Tricuspid Valve Growth**

The tricuspid valve and RV cavity tend under some circumstances to increase in size as the patient grows. However, there is little evidence that disproportionate enlargement occurs as growth of the child proceeds, no matter what the surgical procedure. The only evidence for disproportionate growth comes from a recent study by Huang and colleagues of 40 patients undergoing initial neonatal surgical pulmonary valvotomy and shunt. They showed that on average, there was no change in tricuspid valve z value over time; however, on an individual patient basis, 32% showed tricuspid valve enlargement of at least +2 z values at follow-up.

There is evidence that the RV cavity increases in size, but this may result from iatrogenic pulmonary or tricuspid regurgitation or both (Fig. 40-20). The tricuspid valve appears to grow proportionally with the child when there is forward flow across the tricuspid and pulmonary valves, but not otherwise (Fig. 40-21). With growth of the RV, right ventricular–coronary artery fistulae may disappear. However, important abnormalities of RV compliance usually remain. Thus, there is at present no basis for determining treatment on anything other than z value of the tricuspid valve before initial therapy.

**Bidirectional Cavopulmonary Shunt in Right Ventricle–Dependent Coronary Circulation**

It is widely acknowledged that the blood entering the RV (and thus perfusing the coronary circulation) following a total cavopulmonary connection type of Fontan in patients with RV-dependent coronary circulation will be fully or almost fully saturated. Miyaji and colleagues recently have shown that the blood entering the RV after a superior cavopulmonary shunt (“bidirectional Glenn”) is also more saturated than that under conditions of a systemic-to-pulmonary shunt. This raises the question of whether there is value...
in performing an early superior cavopulmonary shunt in patients with RV-dependent coronary circulation.

Right Ventricular Sinus Myectomy

Because it is well accepted that the RV in this malformation is intrinsically tripartite and only becomes bipartite or unipartite from muscular ingrowth and cavity obliteration, it is logical to infer that removal of the excess muscle may have therapeutic value in selected cases. Bryant and colleagues studied this in 16 patients. They concluded that the procedure leads to an immediate increase in RV volume and is associated with achievement of a biventricular repair in 87% of selected patients. Of concern, they also noted that tricuspid valve growth in relation to somatic growth was minimal, potentially limiting long-term success of this procedure.

Assessment of Functional Benefit of Biventricular Versus Univentricular Definitive Procedures

Evidence supporting the generally held view that a biventricular repair is superior to a Fontan is limited at best. Redington and colleagues showed that a biventricular repair in patients with this malformation had restrictive RV physiology, with antegrade flow across the pulmonary valve during atrial contraction. This implies limited functional capacity. Exercise capacity was assessed by Sanghavi and colleagues and found to be similar in patients with biventricular repair and Fontan. Patients in both groups had subnormal peak VO₂, with increasing impairment associated with increasing age. Based on these findings, it is not surprising that Numata and colleagues were unable to demonstrate a benefit in exercise capacity of the so-called one-and-a-half ventricle repair over the Fontan.
**Figure 40A-1** Nomogram for conversion of diameter of tricuspid valve (obtained by echocardiography) to $z$ value. Nomogram assumes a circular shape of tricuspid valve, which is usually the case in patients with pulmonary atresia and intact ventricular septum. (For a description of $z$ value and its method of determination, see “Dimensions of Normal Cardiac and Great Artery Pathways” in Chapter 1.)

**Figure 40B-1** Validation of multivariable risk factor equation (see Table 40-3) for death after initial procedure in patients with pulmonary atresia and intact ventricular septum. Patients with Ebstein malformation, right ventricular cavity size greater than normal, or both were not included in this analysis. Symbols represent nonparametric survival estimates, and vertical bars represent confidence limits for each of the three major treatment groups. Solid lines indicate parametrically estimated survival, and dashed lines enclose their 70% confidence limits, which are obtained by averaging parametric estimates for each patient within each group (see “Parametric Hazard Function Regression” in Section IV of Chapter 6). Note close correspondence of average parametric estimate to nonparametric estimate. (From Hanley and colleagues.)

Section 1  Tricuspid Atresia and Single-Ventricle Physiology

DEFINITION

Tricuspid Atresia

Tricuspid atresia is a congenital cardiac malformation in which the right atrium, in the setting of ventricular D-loop, fails to open into a ventricle through an atrioventricular (AV) valve. Thus, there is univentricular AV connection consisting of a left-sided mitral valve between morphologically left atrium and left ventricle (LV). Atrial situs is almost invariably solitus (normal) in association with ventricular D-loop, and the right ventricle (RV) is hypoplastic. A ventricular septal defect (VSD) usually is present. Ventriculoarterial connection may be concordant or discordant (transposed great arteries). Rarely, tricuspid atresia occurs in situs inversus with ventricular L-loop (mirror-image pattern).

Patients with atrial situs solitus and ventricular L-loop in which the left-sided left atrium is separated from a left-sided hypoplastic morphologically RV by an atretic left-sided (tricuspid) AV valve are excluded from this discussion; they are considered in Chapter 56.

Single-Ventricle Physiology

Single-ventricle physiology is present when there is impossibility or inadvisability of surgically reconstructing a functional two-ventricle heart with separated in-series pulmonary and systemic circulations. The spectrum of surgical management of single-ventricle physiology is generally similar for tricuspid atresia, other types of univentricular AV connection (see Chapter 56), and other anomalies without two adequate ventricles (see “Fontan versus Intracardiac Repair for Complex Morphology” later in this section) and is based on the Fontan operation. All such anomalies have in common the limitation of single-ventricle physiology, regardless of their specific morphology. Therefore, the Fontan operation and all its modifications and applications, as well as the spectrum of pre-Fontan palliative operations, are discussed fully in this chapter.

HISTORICAL NOTE

In 1906, Kuhne apparently recognized the entity of congenital tricuspid atresia and described its two basic morphologic subsets: hearts with concordant ventriculoarterial connection and hearts with discordant connection.31 In 1949, Edwards and Burchell further emphasized these two subsets and added presence or absence of pulmonary stenosis as another categorizing feature.31 Tandon and Edwards added further descriptive features in 1974.72 The clinical features of tricuspid atresia were described by Bellet and colleagues in 1933 and by Taussig and by Brown in 1936.99,23,7a Controversy arose early and continues as to whether tricuspid atresia should be considered a subset of single ventricle (see Historical Note in Chapter 56).83 From a surgical point of view, it is best considered as such, but tradition and its prevalence support presenting it as a separate entity.

Systemic–pulmonary arterial shunts developed in 1945 by Blalock and Taussig and later by Potts and by Waterston (see Historical Note in Section I of Chapter 38) were soon applied to cyanotic patients with tricuspid atresia. In 1958, Glenn specifically applied the superior vena cava–to–right pulmonary artery anastomosis to patients with tricuspid atresia.920 The basis for the classic Glenn shunt was experimental studies reported by Carlton and colleagues in 1951, by Glenn and colleagues, and by Robicsek and colleagues, showing that systemic venous pressure was adequate to drive pulmonary blood flow.6,6,21,20,9,2,4,11 In Moscow, Bakuljev and Kolesnikov independently developed these same concepts.31 In 1966, Haller and colleagues demonstrated experimentally the possibility of performing a bidirectional superior cavopulmonary anastomosis.14 This was applied clinically by Azzolina and colleagues in 1974, and in 1985, Hopkins and colleagues further refined the procedure with an end-to-side anastomosis of superior vena cava (SVC) to undivided right pulmonary artery (RPA).23,14 Abrams and colleagues applied this idea in the form of a side-to-side anastomosis of SVC to undivided RPA.41 In 1984, Kawashima and colleagues added a further improvisation in patients with either one or two SVCs, and azygos or hemiazygous continuation of the inferior vena cava (IVC) into an SVC, with only splanchic and coronary venous blood draining into the right atrium.410 They divided the SVC (both, if there were two), closed its cardiac end, and anastomosed the SVC end to side to the pulmonary artery after closing the pulmonary trunk. This total cavopulmonary shunt was an incompletely Fontan operation in which only splanchic and coronary venous blood drained directly to the systemic arterial circulation.21,10,31,19

Successful repair of tricuspid atresia with separation of right and left circulations was accomplished in 1968 by Fontan and colleagues and was reported in 1971.11,1,16 This was preceded by experimental studies in 1943 by Starr and colleagues, demonstrating that destroying a dog’s RV did not result in systemic venous hypertension;84 in 1949 by Rodbard and Wagner, demonstrating that the RV could be bypassed;1,16 and in 1954 by Warden, DeWall, and Varco, demonstrating the feasibility of bypassing the RV with a right atrial–pulmonary artery anastomosis.83 Based on these experiments, Hurwitt and colleagues reported an unsuccessful attempt to correct tricuspid atresia by a right atrial–to–pulmonary artery anastomosis in 1955.121 Fontan’s procedure involved constructing a cavopulmonary (Glenn) anastomosis with, in
the first patient, a direct anastomosis between right atrial appendage and proximal end of the divided RPA. In the subsequent two patients, one of whom had discordant ventriculoarterial connection, an aortic allograft valved conduit was placed between right atrium and RPA. In all three patients, an allograft valve was inserted into the IVC ostium, foramen ovale closed, and pulmonary trunk ligated or divided. In 1973, Kreutzer and colleagues reported a modification of Fontan’s operation in which the patient’s pulmonary trunk with its intact pulmonary valve was excised from the RV and anastomosed to the right atrial appendage after closing the VSD and atrial septal defect (ASD). A Glenn procedure was not performed, and no IVC valve was used.28

Other early reports of successful repairs were those of Ross and Somerville and of Stanford and colleagues.2,22,23 Fontan subsequently modified the operation that he and Baudet had originally performed,22,23 many others have as well.2,18,21,22,28,29 Bjork described direct anastomosis between right atrial appendage and RV outflow tract in patients with a normal pulmonary valve, using a roof of pericardium to avoid a synthetic tube graft.9,15 Direct right atrial–pulmonary artery connection, used by Fontan in his first case, has been modified and widely used.14,22,26,63

The extracardiac conduit Fontan modification, in which the IVC is disconnected from the right atrium and connected by a prosthetic tube to the RPA outside the heart, has become popular. A bidirectional superior cavopulmonary connection completes the procedure. This was first described by Humes for use only in special cases of complex venous anatomy.120 It was subsequently modified for use as the procedure of choice for all Fontan candidates by Marcelletti and colleagues and further modified as a closed heart, partial bypass, or off-bypass procedure by Petrossian and colleagues.89,41

Choussat and Fontan and colleagues formalized a set of risk factors (“ten commandments”) for the Fontan operation in 1979.21 In 1988, Laks and colleagues introduced the concept of deliberately making the separation between caval and pulmonary venous pathways incomplete, and then adjusting or closing the communication early postoperatively by percutaneous manipulation of a snare.81,1,3,1,6 Bridges and colleagues modified this approach by closing the residual aperture using catheter techniques late postoperatively.129 Although the Fontan operation was introduced as a treatment for tricuspid atresia, it was soon realized that it was applicable to many other forms of univentricular AV connection. In 1976, Yacoub reported its use for single ventricle,80 and pulmonary venous pathways incomplete, and then adjusting or closing the communication early postoperatively by percutaneous manipulation of a snare.81,1,3,1,6 Bridges and colleagues modified this approach by closing the residual aperture using catheter techniques late postoperatively.129 Although the Fontan operation was introduced as a treatment for tricuspid atresia, it was soon realized that it was applicable to many other forms of univentricular AV connection. In 1976, Yacoub reported its use for single ventricle,80 and by 1980, for many other anomalies with one severely hypoplastic ventricle.310 The Fontan operation has subsequently been used to treat a group of patients who have two adequate ventricles and AV valves but who are judged by some surgeons to have intracardiac morphology too complex for biventricular repair.224

MORPHOLOGY AND MORPHOGENESIS

In tricuspid atresia, there is no direct connection between right atrium and RV, but the left atrium connects through the mitral valve to the LV. Atria is usually muscular (75% of cases), meaning the AV connection is absent; it may be membranous with an imperforate AV connection.17,54 In the muscular type, presence of a tiny dimple in the right atrial floor may or may not represent the atretic valve. The dimple has been said to lie above the LV or ventricular septum in most cases and may then transilluminate from the LV.17,15,11,20,36 In such instances, it may represent a remnant of membranous AV septum.18

The membranous type has three variants. In one, a fibrous diaphragm blocks the AV orifice, and remnants of the valvar apparatus are occasionally found beneath the membrane in the RV. This has been called tricuspid atresia with imperforate valve membrane.16,54 It is often associated with left-sided juxtaposition of atrial appendages and discordant ventriculoarterial connection.71 Overall, juxtaposed atrial appendages are found in 11% of patients with tricuspid atresia.17 In a second, there is classic Ebstein anomaly (see Chapter 42) that is imperforate because of completely fused leaflets that are also fused to the wall of a small RV9,41,36 (Fig. 41-1). In a third and rarer variant, there is an AV septal defect in which the right-sided valve is imperforate and blocks the opening between right atrium and RV (Fig. 41-2). An autopsy series, focused on left-sided structures in tricuspid atresia, identified a high prevalence of mitral valve and LV abnormalities, including cleft mitral valve, muscularized subvalvar apparatus, and abnormal muscle bundles.73

There are two major morphologic subsets of tricuspid atresia:

■ Origins of great arteries are normal (concordant ventriculoarterial connection; 60% to 70% of cases).
■ Origins of great arteries are transposed (discordant ventriculoarterial connection; about 30% to 40% of cases).80,1,25

Rarely, the ventriculoarterial connection is double outlet right ventricle (DORV) or double outlet left ventricle (DOLV) or single outlet with truncus arteriosus.17 Other rare variants exist, and it has been estimated that only about 80% of patients diagnosed as having tricuspid atresia actually have the typical two morphologies.16,17

Tricuspid Atresia and Concordant Ventriculoarterial Connection (Normally Related Great Arteries)

This form of tricuspid atresia was referred to as type I by Edwards and Burchell and by Vlad.1,16,11 Atria are usually in situ solitus. The right atrium and its appendage are enlarged and thick walled, and an interatrial communication is present, usually through a fossa ovalis ASD (Fig. 41-3). The valve of the fossa ovalis may be redundant and bulge into the left atrium and contain multiple fenestrations. The ASD is generally large; by hemodynamic studies, Dick and colleagues found that only 4% of patients had a restrictive ASD.516 Uncommonly, the defect is an ostium primum ASD in association with a cleft left AV valve, and rarely there is a common atrium (see Morphology in Chapter 34).

The eustachian valve is often prominent, and in about 5% of cases it extends superiorly to form a veil or partition across the right atrium, so-called cor triatriatum dexter (see Morphology in Chapter 32).15,73 At operation, this may be confusing to the unprepared surgeon.

The left atrium is morphologically normal but enlarged from obligatory shunting of systemic venous blood across the ASD. The mitral valve is usually larger than normal, as is the LV, because both systemic and pulmonary venous return pass through them. The LV is also hypertrophied and its
Figure 41-1  Specimen and cineangiogram of tricuspid atresia coexisting with Ebstein malformation. A, Exterior view of heart shows displaced left anterior descending coronary artery (LAD) and small right ventricle (RV) to its right. Cordlike pulmonary trunk remnant wraps around proximal aorta where it arises from left ventricle (LV). B, Interior of RV and right atrium (RA). Septal and posterior leaflets are downwardly displaced from tricuspid anulus (dotted line). All three leaflets are loosely adherent to RV wall and join to form an imperforate membrane. Aneurysmal bulge of septal leaflet covers a potential ventricular septal defect. The blind RV is markedly hypertrophied. C, Cineangiogram frame from a similar patient in right anterior oblique projection shows site of tricuspid anulus (arrow) and blind diverticulum formed by fused leaflets. Key: A, Anterior leaflet; AN, aneurysm, septal leaflet; Ao, aorta; D, diverticulum; FO, fossa ovalis; LAA, left atrial appendage; P, posterior tricuspid leaflet; PT, pulmonary trunk; RAA, right atrial appendage; S, septal tricuspid leaflet; SVC, superior vena cava.

Figure 41-2  Specimen of tricuspid atresia with an atrioventricular (AV) septal defect. A, Frontal view with thin-walled, small right ventricle (RV) and pulmonary trunk (PT) open. Rightward portions of AV valve are fused to form an imperforate fibrous membrane. Note large, thick-walled left ventricle (LV). Pulmonary valve is normal. Ventricular septal defect (VSD) is not visible in this view. B, View of opened LV to show typical scooped-out ventricular septal crest and superior and inferior leaflets of left side of AV valve. VSD is adjacent to inferior leaflet. Key: A, Imperforate membrane; AML, left AV valve leaflets; Ao, aorta; RAA, right atrial appendage.
PART VII  Congenital Heart Disease

size and position and is sometimes multiple. In general, the larger the VSD, the larger the RV. The VSD usually lies below the infundibular (conal) septum, and from the LV side is separated from the noncoronary aortic cusp by infundibular muscle. When the VSD is large, it may extend inferiorly to the membranous septum, or it may be entirely muscular, lower in the septum, and sometimes slit-like. The VSD and trabeculated portion of the RV into which it opens are frequently separated from the smooth-walled distal portion by a narrow opening that looks like an os infundibulum (see “Infundibulum” under Morphology in Section I of Chapter 38). Like other VSDs, it frequently narrows spontaneously and is therefore often small and may close completely. In some hearts, the RV is large and has a true sinus portion (Fig. 41-5).

In 85% to 95% of patients, pulmonary blood flow is obstructed. Obstruction most commonly occurs at the os infundibulum, or it may occur at the VSD or throughout the entire infundibulum (Fig. 41-6). The pulmonary valve is bicuspid in about 20% of cases, but usually it and the “anulus,” trabeculations typically fine, although anomalous muscle bands near the posterior papillary muscle are occasionally present.

The normally positioned RV is highly abnormal and typically similar to the small RV of double inlet left ventricle (DILV; see Morphology in Chapter 56). In most hearts it consists of a distal tubular smooth-walled portion with a thin free wall and a smaller proximal trabeculated portion into which a VSD usually opens (Fig. 41-4). The VSD varies in

Figure 41-3  Cineangiogram frame in tilted left anterior oblique projection in tricuspid atresia that shows right-to-left atrial shunt through a stretched patent foramen ovale (large arrow). Valve of fossa ovalis is outlined by small arrows. There is no right ventricular filling. Key: LA, Left atrium; RA, right atrium.

Figure 41-4  Cineangiogram of tricuspid atresia and concordant ventriculoarterial connection in four-chamber view. Injection is into left ventricle, which is mildly enlarged. Severely hypoplastic sinus portion of right ventricle is evident, as is the infundibular outlet portion. Pulmonary valve “anulus” and pulmonary arteries are slightly small but not restrictive. Bifurcation of pulmonary trunk is normal, as is usually the case.

Figure 41-5  Cineangiogram in left anterior oblique projection of tricuspid atresia and a reasonably large right ventricle (RV). A, Systolic frame shows a large ventricular septal defect (VSD) entering RV and a wide channel to pulmonary trunk (PT). B, Enlargement of both right and left ventricles in diastole and large mitral valve orifice. Key: Ao, Aorta; LV, left ventricle; M, mitral orifice.
although a little smaller than normal, are not obstructive (diameter usually within 1 standard deviation of normal). The pulmonary trunk and branch pulmonary arteries are usually a little small, but only uncommonly (about 5% of patients) are they severely hypoplastic and restrictive to flow.\textsuperscript{B15, C33}

In about 10% of cases in this subset, the pulmonary valve is atretic. Under these circumstances, trunk and branch pulmonary arteries are usually small, and pulmonary blood flow (Qp) is via a patent ductus arteriosus or aortopulmonary collateral artery. The RV is usually extremely small, represented only by a minuscule endothelium-lined slit that is often inapparent on gross examination.\textsuperscript{B15} The same is usually true when a VSD is absent. However, an RV chamber may be found in tricuspid atresia without a VSD.\textsuperscript{E1, M12, M44}

\textit{Absent pulmonary valve} is rarely described with type 1 tricuspid atresia. In a report documenting three newly described cases, it was noted that only 24 previous cases had been described.\textsuperscript{L22} A number of associated lesions that are atypical for the more usual forms of tricuspid atresia are commonly found when there is absent pulmonary valve, including absence of a VSD, RV myocardial dysplasia, and abnormalities or even absence of the right coronary artery.

Some 5% to 15% of cases have no infundibular or pulmonary stenosis and normal or increased Qp.\textsuperscript{S25} The VSD is larger than usual. Coronary arteries are normally distributed, and the system is usually right dominant. The well-formed anterior descending coronary artery is displaced rightward by the large LV. The conduction system is basically normal but is affected by abnormalities present. Thus, the AV node is in its usual position in the AV septum between coronary sinus and dimple of atretic tricuspid valve.\textsuperscript{B13, D18} It penetrates the abnormally formed central fibrous body to the left side of the ventricular septum and becomes the branching bundle in the lower confines of the pars membranacea.\textsuperscript{B14, G26} Here it gives off most of the posterior radiation of the left bundle branch. Bifurcation of the bundle and formation of the right bundle branch occur at the posteroinferior angle of the VSD on the LV side. The right bundle branch proceeds here on the LV side and then intramyocardially along the inferior (caudal) border of the VSD. Then it emerges on the RV side and proceeds along the hypoplastic trabecula septomarginalis (septal band) (Fig. 41-7).

Major associated anomalies in this subset of tricuspid atresia are uncommon, but a persistent left SVC entering the coronary sinus occurs in about 15% of cases. Partially unroofed coronary sinus with coronary sinus–left atrial communication (see Morphology in Chapter 33) occurs in 1% to 5% of patients. This is important for the atriopulmonary type of Fontan repair, when high right atrial pressure will produce an important right-to-left shunt through it, even though a shunt was not apparent preoperatively.

\textbf{Tricuspid Atresia and Discordant Ventriculoarterial Connection (Transposed Great Arteries)}

In this tricuspid atresia subset (called \textit{type 2} by Edwards and Burchell\textsuperscript{E1}), the aorta arises from the RV, and the pulmonary trunk from the LV (Fig. 41-8). Generally, the aorta is anterior and to the right of the pulmonary trunk (D-malposition) in the position characteristic of transposition of the great arteries (see Morphology in Chapter 52), but uncommonly there is L-malposition.\textsuperscript{S2, T3}

Atrial anatomy is generally similar to that described in the preceding text. However, left juxtaposition of the atrial...
Tricuspid atresia and discordant ventriculoarterial connection. Injection is into left ventricle (LV) in this long axis view; aorta is seen to arise from right ventricle (RV), which is usually larger than when aorta arises from LV. Single ventricular septal defect is large and subaortic in position. There is moderate subpulmonary stenosis (poorly seen in this view) in LV outflow tract, and LV is typically larger than normal.

apparatus occurs in about 10%, and in about half, the ASD is small.215,216

The RV is larger and thicker walled than usual. It tends to be a single smooth-walled cavity without a proximal trabeculated portion and is, in actuality, a subaortic outlet chamber. The VSD is usually subaortic in position. Commonly it is small, or becomes small, and then represents important subaortic stenosis. In one series, aortic or subaortic stenosis was present in 40%.215 The VSD, however, may be large and unobstructive.

The LV is normal although enlarged. Pulmonary valve and anulus are usually normal or as large as the pulmonary trunk. Thus, Qp is usually large. Subpulmonary stenosis in the LV occurs in about 20% to 30% of cases, and occasionally pulmonary atresia is present. These conditions result in low Qp and hypoxia.

Coronary arteries usually arise from the posterior aortic sinuses of Valsalva, those facing the pulmonary trunk, as in transposition of the great arteries (see “Coronary Arteries” under Morphology in Chapter 52). Associated cardiac anomalies usually involve the aortic arch. Obstruction coexists in about 25% to 35% of cases, with coarctation occurring more frequently than interrupted aortic arch.

Other Aspects of Single-Ventricle Physiology

Wolff-Parkinson-White syndrome is associated with tricuspid atresia.11 The morphology that results in single-ventricle physiology has other systemic effects. For example, levels of natriuretic peptides (both atrial natriuretic peptide and B-type natriuretic peptide) are abnormal; furthermore, they are distinctively abnormal compared with other forms of heart disease, including congenital defects with biventricular physiology.140

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Symptoms and Signs

Tricuspid Atresia and Concordant Ventriculoarterial Connection

Patients in this subset of tricuspid atresia are usually cyanotic from birth because of limited Qp from RV outflow obstruction. Dick and colleagues reported that in 50% of patients, congenital heart disease is recognized on the first day of life.216 Cyanosis is severe, progressive, and often accompanied by hypoxic spells characterized by increased cyanosis, dyspnea, and occasionally syncope. These spells may occur in the first 6 months and are a grave prognostic sign. In patients with increasing obstruction to pulmonary blood flow from progressive infundibular stenosis or VSD closure, cyanosis becomes rapidly more severe, and those who were previously acyanotic may become cyanotic in a matter of a few months. Clubbing of the fingers is common in children who survive beyond the first 2 years, but it may occasionally develop as early as 3 or 4 months. Squatting is uncommon, but dyspnea is often apparent with crying or feeding.

Most patients have loud, harsh, ejection systolic murmurs that are loudest over the lower left sternal border; these may be associated with an apical mid-diastolic rumble from large mitral valve flow. In cases of progressive obstruction to pulmonary flow, murmurs decrease or disappear. A continuous ductus arteriosus murmur may also be heard in patients with pulmonary atresia and occasionally in infants with pulmonary stenosis.

A minority of patients have no obstruction to pulmonary blood flow and a nonrestrictive VSD. These patients may present in infancy with signs and symptoms of excessive pulmonary blood flow, or they may have more or less normal Qp and only mild cyanosis. In the latter, physical findings, chest radiograph, and electrocardiogram (ECG) are similar to those of other patients with normal origin of the great arteries.

Tricuspid Atresia and Discordant Ventriculoarterial Connection

Patients in this subset of tricuspid atresia often present in early life with symptoms and signs of excessive pulmonary blood flow (see “Clinical Findings” under Clinical Features and Diagnostic Criteria in Section I of Chapter 35). Usually an apical mid-diastolic rumble is heard, and there is fixed splitting of the second heart sound at the base. However, moderate subvalvar pulmonary stenosis occasionally results in either mildly increased or normal Qp. Such patients usually present after the neonatal period and sometimes after infancy, with mild cyanosis and few if any symptoms. Physical findings are similar to those in patients with tricuspid atresia and concordant ventriculoarterial connection. If aortic coarctation or interrupted aortic arch is present, the neonate presents with a duct-dependent systemic circulation and pulmonary overcirculation.
Chest Radiography

Chest radiography is usually characteristic of reduced $Q_p$ and RV hypoplasia in typical pulmonary undercirculated patients with tricuspid atresia and concordant ventriculoarterial connection. Pulmonary vascular markings are reduced and hilar shadows diminutive. The left apical heart border may be rounded, forming a high, arched contour. The vascular pedicle is narrow, and the left border in the area of the pulmonary trunk is usually concave. Radiographic appearance of the heart may resemble that of tetralogy of Fallot or occasionally appear normal.

Chest radiography in patients with tricuspid atresia and discordant ventriculoarterial connection usually shows pulmonary plethora and cardiomegaly, and the narrow supracardiac waist and LV contour make it resemble simple transposition.

Electrocardiography

The ECG in the subset with concordant ventriculoarterial connection demonstrates left axis deviation ($0^\circ$ to $-90^\circ$) in about 90% of patients, LV hypertrophy in virtually all, and abnormalities of the P wave,\(^{266,268}\) which is frequently tall (>2.5 mV) and notched.

The ECG may show left axis deviation in the subgroup with discordant ventriculoarterial connection, but a normal QRS axis between 0 and +90 degrees is present in more than half of patients.

Two-Dimensional Echocardiography

Echocardiography with color flow Doppler interrogation confirms the clinical impression of tricuspid atresia and usually provides definitive diagnosis (Fig. 41-9). Position of the great arteries and size and position of the diminutive RV and large LV can be determined (Fig. 41-10). In discordant ventriculoarterial connection, size of VSD relative to aortic “anulus” must be determined because this importantly affects the surgical procedure chosen. The aortic arch is examined for obstruction. RV size is determined because in this setting, it is functionally a subaortic outlet chamber. LV contractility is assessed. Flow across the atrial septum is assessed, which is unobstructed in most but not all cases.

Cardiac Catheterization and Cineangiography

Cardiac catheterization and cineangiography are not routinely performed. Indications for catheterization include inadequate echocardiographic evaluation, suspicion of inadequate or abnormal pulmonary arteries, concerns about pulmonary vascular resistance ($R_P$), and need for catheter-based intervention (e.g., restrictive atrial septum).

Computed Tomography and Magnetic Resonance Imaging

Computed tomography (CT) and magnetic resonance imaging (MRI) are rarely indicated in the newborn period. They can, however, be of great value at subsequent stages to assess valve abnormalities, complex subaortic obstruction, arch obstruction, ventricular mass, ventricular function, peripheral and central vascular dynamics, and abnormal venous and arterial connections associated with chronic single-ventricle physiology.\(^{212}\)

**NATURAL HISTORY**

Tricuspid atresia occurs more commonly than any other type of univentricular AV connection and accounts for 1% to 3% of congenital heart disease. The early natural history is determined primarily by presence and severity of obstruction to pulmonary blood flow and later by LV cardiomyopathy that develops in response to volume overload (see “Cardiomyopathy” later in this section).

Tricuspid Atresia and Concordant Ventriculoarterial Connection

Patients in this subset usually have important RV outflow obstruction and are cyanotic at birth. In most, the VSD narrows rapidly (in common with the general tendency of muscular VSDs to close spontaneously [see “Spontaneous Closure” under Natural History in Section I of Chapter 35]), $Q_p$ diminishes still further, cyanosis worsens, and hypoxia increases, causing the death of 90% of surgically untreated patients by age 1 year\(^{24,81}\) (Fig. 41-11).

When these patients have a normal or increased $Q_p$, natural history is more favorable than in any other subset (see Fig. 41-11). Some die in early infancy of heart failure secondary to large $Q_p$, but spontaneous VSD narrowing and progression of infundibular narrowing usually produce a more balanced flow and better hemodynamic state within a few months of birth. Mild cyanosis and mild to moderate exercise intolerance persist at a plateau level for several years. Spontaneous narrowing of most VSDs continues, however, and

---

*Figure 41-9* Four-chamber echocardiogram view of tricuspid atresia and concordant ventriculoarterial connection. Note restrictive ventricular septal defect (VSD) and hypoplastic right ventricular (RV) chamber. There is platelike tricuspid atresia present, with an atrial septal (S) defect and bowing of atrial septum from right to left. Pulmonary veins (PV) can be seen draining to back of left atrium. Left atrium (LA), mitral valve (MV), and left ventricle (LV) are of normal size. Key: RA, Right atrium.
approximately 90% of patients are dead by age 10 years.\textsuperscript{R1,R2} A few survive into their second and third decades and even beyond, presumably because neither VSD nor RV outflow tract continues to narrow.

In patients who survive into the second decade and longer, chronic LV volume overload usually produces a secondary LV cardiomyopathy and reduced systolic function (Fig. 41-12), and mitral regurgitation may develop. These factors produce a lower LV output and consequently increasing cyanosis and heart failure.

Tricuspid Atresia and Discordant Venticuloarterial Connection

Surgically untreated patients in this subset usually have markedly increased Qp, because the LV ejects directly and without restriction into the pulmonary trunk. Any tendency to VSD closure worsens the pulmonary plethora and, by producing subaortic stenosis, reduces systemic blood flow (Qs). This unfavorable situation results in death of most babies by age 1 year (see Fig. 41-11). If there is coexisting important aortic

Right atrium (RA), right ventricle (RV), left ventricle (LV), and ascending aorta (Ao) are shown. Aorta is aligned with LV without obstruction. Ventricular septal defect (VSD) is small and restrictive, and RV cavity is hypoplastic.

**Figure 41-11** Free-hand representation of life expectancy of surgically untreated patients with tricuspid atresia. a), Patients with concordant ventriculoarterial connection and reduced pulmonary blood flow at birth. b), Patients with concordant ventriculoarterial connection and normal or increased pulmonary blood flow at birth. c), Patients with discordant ventriculoarterial connection (transposition) and increased pulmonary blood flow at birth. d), Patients with discordant ventriculoarterial connection and decreased or normal pulmonary blood flow at birth. (Data in part from Vlad\textsuperscript{V10} and Dick and colleagues.\textsuperscript{D16})

**Figure 41-12** Left ventricular ejection fraction in patients with tricuspid atresia (TA) and surgically created systemic–pulmonary arterial shunts (solid squares) compared with normal subjects (shaded area). Note that it becomes progressively more depressed as patients age. (From LaCorte and colleagues.\textsuperscript{L1})
coarctation or interruption, natural history is heavily influenced by duct-dependent systemic perfusion. The majority of such infants suffer circulatory collapse and death in the first weeks of life within hours or days of ductal closure.

A few patients have mild or moderate LV (subpulmonary) outflow narrowing at birth and decreased Qp. Progression of VSD narrowing (and RV outflow obstruction) is slower in this subset, so approximately 50% of patients survive to about age 2 years (see Fig. 41-11). Hypoxia worsens with time, however, and about 90% of surgically untreated subjects are dead by age 6 or 7 years.

Cardiomyopathy

The volume-overloaded LV, receiving both pulmonary and systemic venous return in patients with tricuspid atresia, plays an important role in natural history. Surgically untreated infants with diminished Qp have depressed LV systolic function (reduced ejection fraction) and end-diastolic volume larger than normal. Reduced ejection fraction at this young age may be related to hypoxia. In patients who live beyond about age 5 years, ejection fraction becomes progressively more depressed (see Fig. 41-12) and LV volume progressively larger. This is related to progression of LV cardiomyopathy secondary to chronic volume overload. In some patients, this leads to gradual development of mitral regurgitation in the second, third, and fourth decades. Recent evidence suggests the cardiomyopathy is due to a combination of volume overload and ischemia, with the ischemia partially due to an inadequately developed capillary network within the LV.

**Figure 41-13** Left ventricular end-diastolic volume (LVEDV) in patients with tricuspid atresia (TA) and systemic–pulmonary arterial shunts. Presentation is as in Fig. 41-12. Note progressive increase with time in LV size. Key: pts., Patients; yr, years. (From LaCorte and colleagues.)

Physiology and presentation, technique of operation, special features of postoperative care, results, indications for operation, and special situations and controversies of each palliative stage are discussed in separate sections that follow.

### Specific Techniques of Operation

Morphologic variations of tricuspid atresia encompass most of the physiologic circumstances encountered when managing all other forms of single-ventricle physiology; therefore, specific discussion of the surgical management of tricuspid atresia presents an excellent opportunity to outline most techniques for managing all forms of single-ventricle physiology, from birth to Fontan completion. Several unique exceptions exist and are discussed in Chapters 49 and 58.

#### RESULTS

Results of first-stage palliation are presented in Section II, those of second-stage palliation in Section III, and those of third-stage palliation (Fontan operation) in Section IV.

Overall outcome for single-ventricle patients followed from early infancy was assessed in 405 patients by Lee and colleagues. These patients had the entire spectrum of single-ventricle morphology, but included only 14 with hypoplastic left heart physiology; thus, this relatively high-risk lesion did not have a major influence on overall results. Tricuspid atresia, double inlet ventricle, DORV, and unbalanced

---

**TECHNIQUE OF OPERATION**

**General Plan for Surgical Management of Single-Ventricle Physiology**

The Fontan operation is considered the surgical end point for patients whose cardiac anomalies do not allow a two-ventricle circulation. The original Fontan operation was performed exclusively in patients with tricuspid atresia, but it is now applied to all forms of univentricular AV connection (see Chapters 40, 49, and 56), as well as to a number of other conditions in which complete two-ventricle circulations cannot easily be achieved (see Chapter 58). Soon after the original operative description, Fontan himself modified the procedure; it therefore seems unnecessary to term each subsequent modification a “modified Fontan.” All forms of Fontan operation aim to divert systemic (with or without coronary) venous return to the pulmonary arterial circulation (either directly or by pathways through the heart), leaving one ventricle to provide essentially all energy driving blood flow in an in-series circulation. Each of the various techniques of achieving this separated pulmonary and systemic in-series circulation has advantages and disadvantages. Widely used techniques are described in sections that follow, and techniques that may be useful in specific cases are described under Special Situations and Controversies in Section IV.
A7 Kaplan-Meier survival from birth of 140 patients

**Figure 41-14** Surgical management and current status of 405 single-ventricle patients. Key: BCPS, Bidirectional cavopulmonary shunt; F/U loss, lost to follow-up; PAB, pulmonary artery band; SV, single ventricle; waiting, waiting for Fontan. (From Lee and colleagues.135)

AV septal defect accounted for 379 of the 405 cases. Patients were managed with a variety of surgical procedures (Fig. 41-14), but the goal was to achieve a Fontan circulation. Survival was thus influenced by operative mortality at each operation, interstage mortality, and mortality following the Fontan operation. The study showed a 10-year survival of 60%. Lan and colleagues examined 140 cases of DILV or tricuspid atresia. (From Lan and colleagues.19)

**Figure 41-15** Kaplan-Meier survival from birth of 140 patients with transposed great arteries and either double inlet left ventricle or tricuspid atresia. (From Lan and Lakes.19)

INDICATIONS FOR OPERATION

Patients in whom only one ventricle has an AV connection and is of sufficient size and power to provide energy for generating in-series pulmonary and systemic blood flows are considered for the Fontan operation. In most of these patients, the heart has a univentricular AV connection (see “Atrioventricular Connection” under Morphology in Chapter 56), one subset of which is tricuspid atresia. The Fontan operation may also be indicated for a few patients with concordant or discordant AV connections in whom one ventricle is too small or dysplastic, or both, to provide sufficient energy for generating adequate blood flow in a two-ventricle circulation (see Chapters 40, 49, and 58). Also, there are some cases in which two adequately sized and functioning ventricles exist in association with adequate inlet valves, but they cannot be septated because of complex relationships among the ventricles, great arteries, and VSDs. Such patients may best be treated with a Fontan procedure (see Chapter 53).24

Some data suggest that a hypoplastic RV of less than 30% normal size does not contribute to the circulation, indicating that the Fontan operation should be performed if this threshold value is met.14

SPECIAL SITUATIONS AND CONTROVERSIES

Moderately Hypoplastic Ventricle

If the RV is hypoplastic but greater than 30% normal size, then it may be of benefit to incorporate it into the right-sided circulation with a functioning inlet and outlet valve and a superior cavopulmonary anastomosis.25-28 This procedure has been called the one-and-a-half ventricle repair.

Although definite proof of its efficacy is lacking, the one-and-a-half ventricle repair, used both to avoid the Fontan operation and to unload the normally developed but failing RV, has gained fairly wide acceptance as a useful procedure in both settings.25,27,38,69,95

Fontan versus Intracardiac Repair

for Complex Morphology

Under certain morphologic circumstances, biventricular repair, although theoretically possible, may not be advisable, and consideration should be given to performing the Fontan operation. These circumstances include but are not limited to:

- Unbalanced AV septal defect
- Moderate right heart hypoplasia
- Moderate left heart hypoplasia
- DORV with uncommitted VSD
- Tricuspid atresia with VSD and moderately developed RV
- Pulmonary atresia with intact ventricular septum with moderate RV hypoplasia or dysfunction
- Ebstein anomaly with moderate RV hypoplasia or dysfunction
- Marked straddling of one AV valve, with AV and ven-triculoarterial discordant connections, in association with VSD and pulmonary atresia or stenosis

In these anomalies, there may be two reasons to question a standard biventricular repair:

- Concern about ability of the hypoplastic ventricle or AV valve to function adequately
- Overall complexity of the procedure required to achieve a standard biventricular repair

Occasionally, both ventricles and inlet valves are of normal size and morphology is not particularly complex, but one ventricle demonstrates marked dysfunction (e.g., tetralogy of Fallot with markedly reduced RV function). In these circumstances, biventricular repair, Fontan operation, superior cavopulmonary anastomosis with intracardiac repair (one-and-a-half ventricle repair) and transplantation are...
Some patients will not meet physiologic criteria for the definitive operation for patients with single-ventricle physiology. Alternative definitive operations prior to development, or at least wide acceptance, of the Fontan operation.

The operation is followed in many patients by redistribution of pulmonary blood flow in the right lung. Using ventilation/perfusion lung scans, Cloutier and colleagues demonstrated a decreased ratio of upper lobe–to–lower lobe pulmonary blood flow. Presumably as a more advanced manifestation of the same underlying process, right-sided pulmonary arteriovenous fistulae form late after the Glenn procedure, generally confined to the right lower lobe. In Kopf and colleagues’ 30-year follow-up study, pulmonary arteriovenous fistulae developed in the right lung of 33% of patients. They found that a longer interval between operation and observation increased the probability of these fistulae being present. Right-to-left shunting and cyanosis usually develop with sufficient severity to warrant therapeutic fistula embolization in about one third of patients. Right-to-left shunting and cyanosis usually develop with sufficient severity to warrant therapeutic fistula embolization in about one third of patients. Right-to-left shunting and cyanosis usually develop with sufficient severity to warrant therapeutic fistula embolization in about one third of patients. Right-to-left shunting and cyanosis usually develop with sufficient severity to warrant therapeutic fistula embolization in about one third of patients.
delay placing the band until $Q_p/Q_s$ increases somewhat, in concert with the normal postnatal decrease in pulmonary resistance ($R_p$) (see “Timing of Pulmonary Trunk Banding” under Indications for Operation later in this section).

**Technique of Operation**

**Preoperative Management**

Before undertaking any surgical procedure, overall cardiopulmonary stability should be ensured. These neonates are typically stable and come to the operating room breathing spontaneously and on little pharmacologic support other than, in some cases, prostaglandin $E_1$ ($PGE_1$) infusion to maintain ductal patency. However, if they present in an uncompensated state, either with overcirculation of the pulmonary circuit or with undercirculation and profound cyanosis, it is prudent to resuscitate them aggressively before operation. This may include use of $PGE_1$, inotropic agents, diuretics, mechanical ventilation with appropriate manipulations, nutritional support, and treatment of sepsis. Following stabilization, a period of observation is usually beneficial to allow recovery of systemic end-organ damage before surgical intervention. However, circumstances may require urgent operation despite inadequate resuscitation. For example, a previously undiagnosed and stable infant may present at several weeks of life with a recently closed ductus, resulting in ongoing critical cyanosis.

**Systemic–Pulmonary Arterial Shunt**

After anesthesia induction, an indwelling arterial catheter is placed, preferably in the left radial artery. Reliable intravenous access is achieved, preferably via peripheral extremity vein; subclavian and internal jugular veins should be specifically avoided because they tend to develop deep venous thrombosis that can importantly complicate subsequent management at the time of superior cavopulmonary shunt (see Section III). It is similarly important to avoid femoral vein cannulation, because most patients with univentriicular AV connection require multiple cardiac catheterization evaluations, preferably via the femoral vein.

The preferred incision for performing a systemic–pulmonary arterial shunt is median sternotomy. This incision has multiple advantages over traditional lateral thoracotomy:

- Both lungs can be completely ventilated throughout the procedure. This can be especially important in unstable infants.
- The shunt can be placed more centrally on the left or right branch pulmonary artery, thereby reducing prevalence of right or left upper lobe pulmonary artery branch stenosis.
- Maximal flexibility is achieved.
- If the ductus arteriosus is to be ligated during the shunt procedure, it can be accomplished effectively.
- If central pulmonary artery stenosis at the site of ductus insertion is present or suspected, pulmonary arterioplasty can be performed.
- If the patient becomes unstable during the procedure and requires cardiopulmonary bypass (CPB), there is access for cannulation.
- Occurrence of musculoskeletal deformities induced by a lateral incision, such as scoliosis, is eliminated.

The single disadvantage of median sternotomy is risk of hemorrhage from inadvertent cardiotomy on repeat sternotomy at subsequent procedures. This can be minimized by leaving intact the anterior aspect of the pericardial sack overlying the ventricular mass at the first procedure.

Median sternotomy is performed (see “Incision” in Section III of Chapter 2). The typically large thymus gland is mobilized or partially removed, and only the upper pericardial reflection over the great arteries is opened, leaving intact the portion overlying the ventricular mass. Sites on both systemic and pulmonary circuits are chosen for placing the shunt (see “Systemic–Pulmonary Arterial Shunt” under Special Situations and Controversies later in this section). Usually a modified Blalock-Taussig shunt is performed (Fig. 41-16) using an expanded polytetrafluoroethylene (PTFE) vascular graft of specified internal diameter, placed between the brachiocephalic–right subclavian artery junction, and central portion of the RPA (see “Systemic–Pulmonary Arterial Shunt” under Special Situations and Controversies later in this section). Systemic and pulmonary arterial sites are prepared using sharp dissection. The patient is heparinized ($3 \text{ mg} \cdot \text{kg}^{-1}$ intravenously). An appropriately sized partial occlusion vascular clamp is used to isolate the brachiocephalic–right subclavian arterial segment, which is incised over a length appropriate to create an orifice that matches the expanded PTFE graft.

Focus on detail is necessary to create a functional and reliable shunt. Attention is given to the angle of takeoff of the brachiocephalic artery origin and brachiocephalic-subclavian arterial junction. The expanded PTFE graft is tailored with a bevel to maximize laminar flow at the arterial graft anastomosis. Anastomosis is then performed with running 7-0 nonabsorbable monofilament suture.

After the anastomosis is completed, the partial occlusion clamp on the arterial segment is removed and replaced with a small clamp occluding the graft. This allows the arterial segment to assume its natural position, thereby permitting the surgeon to judge exactly the length of the graft in preparation for its anastomosis to the RPA. Attention to detail is necessary because a graft tailored to an inappropriate length may kink or distort the involved arteries. Typically, no bevel is necessary at the graft-RPA connection, and end-to-side anastomosis is performed at a 90-degree angle. After trimming the graft to an appropriate length, a partial occlusion clamp is placed on the central portion of the RPA that lies to the right of the ascending aorta and left of the SVC; it should not involve the right upper pulmonary artery. An incision of appropriate length is made in the sequestered segment of RPA, and anastomosis proceeds using a technique similar to that of the previous anastomosis. Before completing it, heparinized saline may be infused into the graft and pulmonary artery segments to flush remnants of blood that may have accumulated. The clamp is then removed from the RPA.

Before removing the clamp on the shunt, the ductus arteriosus (if present) is exposed, and a heavy silk ligature with a snare is placed around it. The clamp is then removed from the shunt, and the snare on the ductus is gently tightened to occlude it.

A period of hemodynamic adjustment then ensues. The surgeon should pay careful attention to change in systemic arterial oxygen saturation ($S_aO_2$) as indicated by pulse oximetry and by change in hemodynamics as indicated by heart rate and systolic, diastolic, and mean blood pressures. New
Figure 41-16  Right modified Blalock-Taussig shunt through median sternotomy. Although either anastomosis can be performed first, here the graft–right pulmonary artery (RPA) anastomosis is performed first, followed by the graft–subclavian artery anastomosis. (See text for description of procedure in opposite order.) A, After median sternotomy, thymus gland is subtotally resected and pericardium opened along its upper aspect. Aorta is retracted to left side, and superior vena cava to right side, exposing RPA. Brachiocephalic artery and its bifurcation into right subclavian and carotid arteries are dissected cephalad to brachiocephalic vein. B, Side-biting vascular clamp is placed on RPA in such a way that clamp itself holds aorta to patient’s left. Care is taken that incision in superior aspect of RPA does not encroach on its bifurcation into upper and lower branches, but is kept as central as possible. An appropriately sized polytetrafluoroethylene (PTFE) tube graft is then connected to RPA incision, using a continuous suture technique and 7-0 nonabsorbable monofilament suture (see text for a more detailed discussion of factors involved in determining choice of shunt size). Posterior aspect of anastomosis is performed first, followed by anterior aspect. C, After the graft to pulmonary artery anastomosis is completed, a side-biting vascular clamp is placed on exposed right subclavian artery or right subclavian–brachiocephalic artery junction. Sequestered segment of artery is incised over an appropriate length to match circumference of PTFE tube graft. Graft is tailored to an appropriate length and beveled to avoid kinking or distorting subclavian and right pulmonary arteries. Anastomosis is performed using a technique similar to that described for graft-to–pulmonary artery anastomosis (B). D, Shunt is shown with anastomoses completed and aorta and superior vena cava in their normal positions. Additionally, ductus arteriosus has been ligated with a 5-0 polypropylene suture following blunt circumferential dissection with a small right-angled clamp.
steady-state values for these variables are judged against baseline conditions, which may vary among infants. In general, \(\text{SaO}_2\) between 75% and 85% is considered acceptable. \(\text{SaO}_2\) below this range should raise concerns about a technical problem with the shunt, an inadequately sized shunt, or unsuspected distal pulmonary artery problems. \(\text{SaO}_2\) above this range should raise concern that the shunt is too large. This latter concern is heightened if systemic arterial diastolic blood pressure is less than 25 to 30 mmHg.

Once stability has been achieved, the snare is removed from the ductus, and it is permanently ligated. PGE\(_1\) infusion is stopped. Mediastinal drainage and closing the median sternotomy are as usual (see “Completing Operation” in Section III of Chapter 2).

**Pulmonary Trunk Banding**

Pulmonary trunk banding is usually performed via median sternotomy, lateral thoracotomy, or anterior parasternal incision. Median sternotomy is preferred for the same reasons described in the preceding text for placing a systemic–pulmonary arterial shunt; patient preparation is also similar. If the surgeon prefers a lateral thoracotomy or anterior parasternal incision, it is performed on the left side. In other patients with univentricular AV connection with conotruncal abnormalities that result in position of the pulmonary trunk to the right of the aortic root, a right lateral incision is chosen.

Preferred median sternotomy is performed as described in Chapter 2, and the thymus gland is mobilized or partially removed. The pericardium is opened only at its superior border over the great arteries, with care taken to leave it intact over the ventricular mass. The tissue plane between ascending aorta and pulmonary trunk is developed over a limited area halfway between the sinutubular junction of the pulmonary trunk and origin of the RPA (Fig. 41-17, A).

Aggressive dissection in this area is discouraged because it increases the chances of migration of the band over time. Once circumferential access to the pulmonary trunk is achieved, the band is placed around it. Choice of band material may vary; however, material that prevents important fibrosis and calcification and has a low risk of erosion into the pulmonary trunk should be chosen. Width of band material should be broad (at least 2.5 mm) to minimize erosion. Preferred choice of band is a 3-mm-wide strip fashioned from a relatively thick (0.3 to 0.4 mm) silicone rubber sheet. This material incites minimal reaction in surrounding tissues.

After placing the band around the pulmonary trunk (Fig. 41-17, B), its free ends are secured together to create a circumferential ring (Fig. 41-17, C). Formulas can be used to estimate the appropriate circumferential length, but individual physiologic variability usually dictates adjustments be made. Free ends of the band are initially secured together at a point that allows only minimal circumferential narrowing of the pulmonary trunk. Following this initial placement, two sutures are placed at points 180 degrees opposite each other on the circumference of the band, attaching the band to the adventitia of the proximal portion of the pulmonary trunk (see Fig. 41-17, C). These sutures prevent pressure-driven distal band migration on the pulmonary trunk. Migration is common if the band is not secured.

Once the band is positioned, but before it has been adjusted to its final circumference, it is prudent to temporarily place a catheter into the distal pulmonary trunk to measure pressure distal to the band. Difference in systemic arterial and
distal pulmonary artery pressure provides an accurate assessment of band gradient. The surgeon then gradually reduces band circumference, evaluating both band gradient and $\text{Sao}_2$ as end points. Both vary depending on physiologic circumstances; however, a typical band gradient in a neonate will be in the range of 40 to 70 mmHg, and $\text{Sao}_2$ should range between 75% and 85%. Band circumference is adjusted by placing metal clips in the vicinity where the two free ends of the band were initially secured together (see Fig. 41-17, C). These clips are placed sequentially, with each subsequent clip placed just below the most recently placed one, gradually approaching the physiologic end points just described. Appropriately adjusting $\text{Qp}$ with a pulmonary trunk band can be somewhat difficult. This is because pulmonary blood flow occurs only in systole, and the band is a two-dimensional resistor with little length. As a result, small changes in band circumference result in marked resistance changes and, therefore, marked $\text{Qp}$ changes. Because flow across the band occurs only in systole, $\text{Qp}$ varies with changes in systemic arterial pressure. It is therefore critical that the anesthesiologist create circumstances during band adjustment such that systemic blood pressure approximates that expected in the awake infant. This can usually be achieved by appropriate choice of anesthetic and volume management.

Once the band is appropriately adjusted, an indwelling right atrial catheter and atrial and ventricular pacing wires are placed as described earlier in this section for the systemic–pulmonary arterial shunt. Mediastinal drainage and median sternotomy closure are as described in “Completing Operation” in Section III of Chapter 2.

**Special Features of Postoperative Care**

**Systemic–Pulmonary Arterial Shunting Procedures**

After completing the procedure, it is not necessary to reverse the heparin with protamine; instead, the heparin is allowed to metabolize slowly. Beginning on the first postoperative night, aspirin is given rectally (1 mg·kg$^{-1}$·day$^{-1}$) to prevent thrombus formation in the shunt.

Some degree of hemodynamic instability and modest metabolic acidosis are common in the first few postoperative hours. It is prudent to support the patient over the first postoperative day with mechanical ventilation and close observation. Occasionally, low-dose inotropic support is indicated.

**Pulmonary Trunk Banding**

As $\text{Rp}$ gradually decreases after placement of a pulmonary trunk band, it is occasionally necessary to reoperate to tighten the band further. Need for readjusting it can be minimized by appropriately timing the initial banding (see “Timing of Pulmonary Trunk Banding” under Indications for Operation later in this section).

**Results**

**Systemic–Pulmonary Arterial Shunting Procedures**

Early mortality for patients with tricuspid atresia and other types of univentricular communications and reduced $\text{Qp}$ is low (Tables 41-1 and 41-2) and similar to that for shunts performed for palliation of tetralogy of Fallot (see “Interim Results after Classic Shunting Operations” in Section I of Chapter 38). As expected, early mortality from multi-institution reports is somewhat higher than in the single-institution reports cited in these tables. A three-institution report revealed 3 early deaths in 23 cases (13%; CL 6%-24%).$^{97}$ Under most circumstances, pulmonary artery distortion by the shunt is uncommon. $^{33}$

In patients who cannot subsequently have a Fontan operation, palliation has been good, and 5-year survival without definitive operation is about 90%. $^{33}$ Intermediate time-related survival, including mortality of subsequent interventions, is about 85% at 10 years when the shunt is initially performed after the first few months of life. $^{2,3,5,7,11,19}$ (Fig. 41-18). However, substantially worse survival was reported by Franklin and colleagues for a patient group in which many required operation early in life; this may be more representative $^{18,8,19}$ (Fig. 41-19). Risk of dying is highest in the first few months following the shunt procedure (Fig. 41-20). Then, after 5 to 10 years, many patients begin to deteriorate. This is related to cyanosis, which is due to relative narrowing of the Blalock-Taussig shunt commensurate with patient growth, as well as to LV cardiomyopathy secondary

aSeven exploratory cardiotoomies, including or not including pulmonary valvotomy or a valved extracardiac conduit (seven cases, one hospital death), and two revisions of previous procedures (one hospital death).

Data from Stefanelli and colleagues.335

to chronic volume overload, which worsens with time (see "Cardiomyopathy" under Natural History in Section I).

Pulmonary Trunk Banding

Early mortality after pulmonary trunk banding has been reported to be substantial—25% to 35%.113,113,335 This high mortality likely reflects that this information spans many years and thus includes many patients receiving bands in the 1970s, when mortality in general was high for complex cases. It may also reflect difficulty of achieving physiologic balance of Qp and Qs compared with a systemic–pulmonary arterial shunt. In the current era, mortality of less than 5% should be expected (see Tables 41-1 and 41-2). Low mortality (no early deaths in 10 cases) (0%; CL 0%-17%) in the current era is confirmed even in multi-institutional reports.111

Outcome following pulmonary trunk banding, like systemic–pulmonary arterial shunting, is somewhat influenced by intracardiac anatomy. For example, with tricuspid atresia or DILV and discordant ventriculoarterial connection, the tendency for subaortic stenosis to develop or progress is a frequent and unfavorable sequel to the banding procedure (see "Physiology and Presentation" under Discordant Ventriculoarterial Connection later in this section).220,222,225,23,17,229 Subaortic stenosis not only increases risk of death before definitive repair but also after the Fontan operation; this is due to the resulting increase in main ventricular chamber muscle mass and corresponding decrease in ventricular compliance.312
Indications for Operation

**Systemic–Pulmonary Arterial Shunt**
Presence of severe cyanosis (SaO₂ < 70%-75%) early in life or of duct dependency are indications for performing a systemic–pulmonary arterial shunt. Causes for cyanosis other than restrictive Qp (e.g., reversible lung disease, anemia, obstructive pulmonary venous connection) must be ruled out.

The shunt does not facilitate later decision making about a Fontan operation, and it somewhat complicates its later performance.

**Pulmonary Trunk Banding**
When Qp is large enough to produce serious heart failure early in life, the pulmonary trunk should probably be banded. If increased Qp is insufficient to produce important heart failure in the early weeks of life, banding is not performed.

**Timing of Pulmonary Trunk Banding**
If a pulmonary trunk band is placed too early following birth when distal Rp is still high, the surgeon will be limited by the patient’s cyanosis when attempting to tighten the band to an appropriate level. As Rp gradually decreases after placing such a band, it is commonly necessary to reoperate to tighten the band further. Need for readjusting the band can be minimized by appropriately timing the initial banding. The ideal time varies based on individual physiologic characteristics, but the procedure is usually best performed in the second, third, or fourth week of life. In the physiologic setting of low distal Rp and relatively high Qp, the situation is optimal for placing the band with an appropriate tightness that ensures long-term balance between Qp and Qs.

**DISCORDANT VENTRICULOARTERIAL CONNECTION**

**Clinical Features and Diagnostic Criteria**

In this subset, neonates typically present a different set of physiologic considerations from those with concurrent ventriculoarterial connection. Because the pulmonary valve is in fibrous continuity with the mitral valve and arises directly from the LV, obstruction to pulmonary blood flow is unusual and unrestrictive Qp the rule. The aorta arises from the hypoplastic RV, and as a result, the LV must eject through the VSD (bulboventricular foramen) and underdeveloped RV into the aorta. If the outflow tract from LV to aorta and the aortic arch are well developed, the patient can be managed effectively in a fashion similar to that described for tricuspid atresia and concordant ventriculoarterial connection with excessive Qp using a pulmonary trunk band as described in the preceding text.

Tricuspid atresia and discordant ventriculoarterial connection, however, commonly manifests with important obstruction in the systemic circulation.⁷ Obstruction typically occurs at two levels: subaortic and aortic arch. **Subaortic obstruction** is due to a combination of restrictive VSD and muscular obstruction in the underdeveloped incomplete RV. Any type of coexisting aortic arch obstruction increases by sevenfold the probability that severe subaortic stenosis will be present.⁸ Any type of coexisting aortic arch obstruction increases by sevenfold the probability that severe subaortic stenosis will be present.⁸ Narrowing may be accelerated by maneuvers that reduce volume load on the heart, such as pulmonary trunk banding or takedown of a systemic–pulmonary arterial shunt at the time of a bidirectional superior cavopulmonary shunt or Fontan procedure. Some studies suggest that subaortic stenosis will ultimately develop in up to 80% of such patients who undergo pulmonary banding early in life.⁹,¹⁰,¹¹,¹²

Even when the VSD is large at the time of a Fontan operation, it may narrow thereafter and subaortic stenosis may appear.²⁵ Narrowing may occur immediately at the time of the Fontan operation if important volume unloading occurs, either by removing a pulmonary artery band with pulmonary trunk occlusion or by removing a systemic–pulmonary arterial shunt. However, if the patient is undergoing three-stage palliation, it is more likely for the volume load to be dramatically reduced at the time of second-stage bidirectional superior cavopulmonary shunt, and subaortic stenosis is more likely to develop at that time.

In summary, subaortic stenosis is a potential problem in patients in whom the aorta arises above an incomplete ventricle (or outlet chamber). Probability of its appearance is increased by smallness of the VSD (bulboventricular foramen), coexisting aortic arch obstruction, and maneuvers that reduce ventricular volume load. Even in the absence of associated factors, it may still develop. Subaortic stenosis is least likely to occur when the aortic valve is large, the VSD is large, and no arch obstruction is present.

**Technique of Operation**

**Preoperative Management**
Neonates with this morphology have the potential to be acutely ill in a manner similar to those with hypoplastic left heart physiology; therefore, preoperative stabilization should be similar to that for patients with hypoplastic left heart physiology (see Box 49–1 under “Definition,” and
“Preoperative Management” in Chapter 49). Even when the VSD is large at birth, it may spontaneously narrow, and subaortic obstruction then becomes apparent.

**Pulmonary Trunk Banding and Aortic Arch Reconstruction**

This technique is described for tricuspid atresia and discordant ventriculoarterial connection with aortic arch obstruction, but is applicable to any patient with univentricular AV connection, aortic arch obstruction, and excessive Qp (Fig. 41-21). The patient is positioned in right lateral decubitus position, and a standard left posterolateral thoracotomy is made through the fourth intercostal space [see “Alternative Primary Incisions” under Incisions in Section III of Chapter 2]. Description of the arch repair is similar to that for isolated coarctation in the neonate [see Technique of Operation in Section I of Chapter 48 for details].

Following arch reconstruction, a longitudinal incision in the pericardium is made 1 cm anterior to the left phrenic nerve. Depending on extent of the thymus gland, modest mobilization of its left lobe may be necessary. Once the pericardium is opened, the pulmonary trunk is identified in the transposed position, posterior and to the left of the ascending aorta. (In patients with DILV and L-transposition, the pulmonary trunk is posterior and to the right.) The plane between adjacent walls of ascending aorta and pulmonary trunk are carefully dissected, gaining circumferential access around the pulmonary trunk midway between its sinutubular junction and origin of the RPA. The RPA origin is particularly difficult to visualize through a left thoracotomy incision; however, it must be carefully located before positioning the band. Following this, details related to placing and adjusting the band are similar to those described previously [see “Pulmonary Trunk Banding” under Technique of Operation earlier in this section] for placing a pulmonary artery band through a median sternotomy [see Fig. 41-17].

**Proximal Pulmonary Trunk to Aortic Connection with Arch Repair**

This technique is described for tricuspid atresia and discordant ventriculoarterial connection with subaortic and arch obstruction, but is applicable to all forms of univentricular AV connection with subaortic and arch obstruction34 (Fig. 41-22). After anesthesia induction, placing indwelling peripheral arterial and venous catheters, and supine positioning, a median sternotomy is performed [see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2]. The thymus gland is subtotally removed and the pericardium opened anteriorly over the heart. The plane between pulmonary trunk and ascending aorta is carefully dissected and the entire aortic arch mobilized, including the first 1 to 2 cm of each arch vessel. The central pulmonary artery, ductus arteriosus, and descending aorta to the level of the first pair of intercostal arteries are also mobilized. The patient is then prepared for CPB. If the aortic arch is hypoplastic but not preocclusive (>2-3 mm in diameter), adequate perfusion on CPB can be achieved by cannulating the aortic system alone using a 6F or 8F aortic cannula.27 If the ascending aorta is of adequate size, it can be cannulated directly (as shown in Fig. 41-22), or alternatively, if it is hypoplastic, the base of the brachiocephalic artery can be cannulated. The arterial cannula (or cannulae) is secured in place with standard purse-string sutures and snares. If the aortic arch is interrupted, or

is in continuity but with preocclusive narrowing at the isthmus and coarction, dual arterial cannulation of the proximal pulmonary trunk and the aortic system is performed. (This variation is not shown in Fig. 41-22, but see Technique of Operation in Chapter 48 for a detailed description of cannulation technique and CPB management when the arch is interrupted.) Temporary occlusion of branch pulmonary arteries is achieved either with snares or vascular clamps if perfusion is performed through the pulmonary trunk and ductus arteriosus to the descending thoracic aorta.

Venous cannulation is through a purse string in the right atrial appendage. After cannulation, CPB is instituted and preferably carried out using continuous antegrade cerebral perfusion [see Fig. 41-22]. Alternatively, some surgeons prefer to use circulatory arrest [see “Technique in Neonates, Infants, and Children” in Section IV of Chapter 2]. These CPB management techniques are also discussed in detail in the description of the Norwood procedure for hypoplastic left heart physiology [see “Norwood Procedure Using Continuous Perfusion” under Technique of Operation in Chapter 49]. In particular, the techniques described in Chapter 49 for performing continuous antegrade cerebral perfusion are widely applicable to all forms of neonatal arch obstruction with associated hypoplastic arch and ascending aorta. Once the target perfusion temperature is reached, antegrade cerebral perfusion established, and cardiac arrest induced with cardioplegia, the obstructed aortic arch is addressed, as described in Fig. 41-22.

If the aortic arch is in continuity but hypoplastic, the aortic isthmus is ligated with a 5-0 polypropylene suture, and ductus and coarctation tissue distal to it are removed [see Fig. 41-22, A]. A small vascular clamp can be placed across the descending aorta at the level of the first set of intercostal vessels to stabilize the aorta and deliver it into the anterior mediastinum. A longitudinal incision is made in the posterior aspect of the upper ascending aorta and proximal aortic arch [see Fig. 41-22, B], and the descending aorta is anastomosed to this incision with a running 7-0 monofilament absorbable suture, thereby repairing the arch obstruction [Fig. 41-22, B]. In the case of true aortic arch interruption, the isthmus ligature is not necessary, and arch repair otherwise proceeds as described.

With the arch obstruction addressed, antegrade cerebral perfusion is terminated and full-body bypass is again established [see “Norwood Procedure Using Continuous Perfusion” under Technique of Operation in Chapter 49]. Attention is turned to the proximal pulmonary trunk–aortic anastomosis. This can be accomplished in several ways, one of which is described in detail in Fig. 41-22, B. Although unusual in neonates with tricuspid atresia, if preoperative evaluation suggests that potential or real obstruction exists at the atrial septum, the right atrium is opened during continuous bypass, and the septum primum is removed to create an unobstructed atrial communication. During this maneuver, the single venous cannula in the right atrium must be temporarily clamped, and cardiomyopathy suction devices used within the two veno caval orifices to provide exposure for the atrial septal resection. The right atriotomy is then closed with a running 6-0 polypropylene monofilament suture. Venous drainage via the right atrial cannula is then reestablished and rewarming begun.

An appropriately sized expanded PTFE tube graft is then used to create a modified Blalock-Taussig shunt [see Fig.
Chapter 41  Tricuspid Atresia and Single-Ventricle Physiology

Figure 41-21  Repair of hypoplastic aortic arch and pulmonary trunk band placement via left thoracotomy. A, Standard left posterolateral thoracotomy is performed through fourth intercostal space, and ribs are retracted. Adventitia overlying distal aortic arch and left pulmonary artery is shown. Positions of phrenic and vagus nerves are indicated. Large ductus arteriosus is noted, along with severe hypoplasia of aortic isthmus and moderate hypoplasia of distal aortic arch. Great arteries are in transposed position, with aorta anterior and pulmonary trunk posterior. Left lung has been deflated and retracted in an inferior direction. B, Adventitia overlying distal aortic arch is opened and retracted with sutures. Aortic arch obstruction is managed in standard fashion for neonatal aortic coarctation (see Section I of Chapter 48 for full discussion of technical and management issues related to aortic arch obstruction in the neonate). After appropriate dissection of aorta and ductus, vascular clamps are placed, and ductus arteriosus is ligated and divided, as is hypoplastic aortic isthmus. All remaining ductal tissue is removed from descending aorta, and a longitudinal incision is made on undersurface of aortic arch (dashed lines). Descending aorta is connected end to side to undersurface of aortic arch between left subclavian and brachiocephalic arteries. C, Repaired arch with ligated and divided hypoplastic aortic isthmus and ligated and divided ductus arteriosus. D, Inferiorly retracted lung is now repositioned with more direct posterior retraction to better expose proximal intrapericardial great arteries. Incision in pericardial sack is made anterior and parallel to phrenic nerve to expose proximal pulmonary trunk in preparation for placing pulmonary trunk band. Pulmonary trunk is carefully dissected in limited fashion just above tops of pulmonary valve commissures and below origin of right pulmonary artery (see Fig. 41-17). Identification of right pulmonary artery origin may be difficult from the left thoracotomy perspective. Using a small right-angled clamp, circumferential dissection is achieved and a 3-mm-diameter band, taken from a sheet of reinforced silicone rubber, is placed around proximal pulmonary trunk. Band is then tightened and secured to prevent migration, as described in Fig. 41-17.

Details of the shunt procedure are similar to those described earlier in this section for isolated neonatal systemic–pulmonary arterial shunt.

Principles of rewarming and separation from bypass are those described in “Completing Cardiopulmonary Bypass” in Section III of Chapter 2. Following separation from CPB, management considerations with regard to pharmacology, physiology, and sternal wound (immediate or delayed sternal closure) are the same as described in the management of hypoplastic left heart physiology following the Norwood procedure (see “Special Features of Postoperative Care” in Chapter 49).
**Modified Norwood Anastomosis**

The Norwood anastomosis used in this setting is a slight modification of the procedure used in first-stage repair of patients with classic hypoplastic left heart physiology. It combines the Damus-Kaye-Stansel anastomosis with extensive augmentation (enlargement) of the hypoplastic aortic arch and upper descending thoracic aorta (see Chapter 49). It is important to emphasize that the augmentation patch used is of a slightly different shape from that described for the typical patient with hypoplastic left heart physiology. This is necessary because with either tricuspid atresia and discordant ventriculoarterial connection, or with double inlet ventricle with L-loop and discordant ventriculoarterial connection, orientation of the great arteries is different from that in patients with normally related great arteries (i.e., found in aortic atresia and other classic forms of hypoplastic left heart physiology).

**Muscular Resection to Relieve Subaortic Obstruction**

This technique is described for patients with tricuspid atresia and discordant ventriculoarterial connection with subaortic obstruction at the bulboventricular foramen (VSD) or incomplete RV, but is applicable to all patients with univentricular AV connection in whom the aorta arises from an incomplete ventricle. Other lesions that result in a similar problem include DILV with discordant ventriculoarterial connection, and mitral atresia with concordant ventriculoarterial connection (see Chapter 56).

Patient preparation, median sternotomy, and cardiac exposure are similar to that described in the preceding text. In the unusual case that there has been no previous surgery, upon opening the pericardium, it is immediately noticed that aorta and diminutive RV are anterior. More commonly, previous surgery (including previous median sternotomy) has been performed. Caution should be exercised upon repeat median sternotomy, because the anterior aorta may be in close proximity to the posterior sternal table. The patient is prepared for CPB by placing purse strings in the ascending aorta just below the brachiocephalic artery origin and in SVC and IVC. Aortic and bicaval cannulation is then performed in standard fashion, the patient is placed on CPB, and moderate hypothermia is achieved. The aorta is clamped, and cardioplegia is administered through the aortic root (see “Single-Dose Cold Cardioplegia in Neonates and Infants” in Chapter 3).

The VSD is best approached through an incision in the incomplete ventricle (outlet chamber) just below the aortic
valve (Fig. 41-23, A). This incision is later closed by an enlarging patch. Alternatively, the VSD may be approached through the aorta; however, this exposure may be limited because the aortic valve and aorta are typically hypoplastic. Some have considered the risk of surgically induced heart block to be high in this procedure, but risk is substantially reduced using currently available knowledge about the location of the conduction tissue. When the VSD is observed through an incision in the outlet chamber (morphologic RV), the relationship of the conduction system to the VSD is the same as with any conoventricular VSD, with the conduction tissue at the posterior inferior rim of the defect. This is true whether the underlying morphology is tricuspid atresia and discordant ventriculoarterial connection, or double inlet single LV and discordant AV and ventriculoarterial connections. Confusion regarding this issue has arisen because the conduction system appears to be positioned on the “anterior” rim of the VSD when viewed from the perspective of the main ventricular chamber of either tricuspid atresia and discordant ventriculoarterial connection or DILV and discordant AV and ventriculoarterial connections. This confusion is the result of difficulty in conceptualizing the spatial arrangement of the two ventricular chambers and ventricular septum with this exposure, which involves an atrial incision, substantial rotation of the heart, and visualization of the VSD through an AV (typically mitral) valve.

The preferred approach is a vertical incision made in the outlet chamber free wall directly in line with the course of the ascending aorta (see Fig. 41-23, A). This incision should be made only after all major coronary artery branches are identified, because the incision should not cut across any of these. Once the outlet chamber has been entered, the VSD is identified and a full-thickness wedge of septum is removed from the anterior and anterior apical aspects of the rim of the defect (Fig. 41-23, B).

Obstructing muscle bundles within the outlet chamber are excised. The outlet chamber is enlarged by closing the ventriculotomy with an enlarging patch, typically of polyester or glutaraldehyde-treated pericardium, using running monofilament suture (Fig. 41-23, C). The process of separation from bypass and chest closure is standard.

**Special Features of Postoperative Care**

These are detailed under Special Features of Postoperative Care in Chapter 49.

**Results**

**Pulmonary Trunk Banding and Aortic Arch Reconstruction**

In early-era reports, both early and intermediate-term survival have been unfavorable in patients with single-ventricle physiology following initial coarctation repair, with or without pulmonary trunk banding (see Fig. 41-19) (see “Results of Repair of Coarctation in Patients with Other Major
Coexisting Intracardiac Anomalies” in Section I of Chapter 48). Risk of death early after the procedure has been particularly high (see Fig. 41-20). This may be due to associated instability that accompanies single-ventricle physiology. Although these data are for patients with DILV with arch obstruction, it is likely that similar outcomes pertain to patients with tricuspid atresia and discordant ventriculoarterial connection with aortic arch obstruction. More recent reports show better early and midterm outcomes. Odim and colleagues reported no early mortality (0%; CL 0%-12%) and an 87% survival at mean follow-up of 68 months in 15 patients undergoing aortic arch reconstruction and pulmonary trunk banding.38

Proximal Pulmonary Trunk to Aortic Connection with Arch Repair

This procedure carries a substantial early mortality (=35%).325 Although limited data are available for evaluating it, certain insights can be gained by comparing the Damus-Kaye-Stansel and shunt procedure with the Norwood procedure, because there are important parallels between them (see “First-Stage Reconstruction [Norwood Procedure]” under Results in Chapter 49). Regurgitation of the original aortic or pulmonary valve, either immediate or delayed (perhaps due to distortion of the great arteries), and hemodynamic instability relating to a pulmonary circulation arising from a systemic–pulmonary arterial shunt all can be problems if the Damus-Kaye-Stansel procedure is used in this setting. Despite high early mortality, intermediate-term results in hospital survivors appear to be good.7,8,12,21,27

Modified Norwood Anastomosis

Early mortality ranges from 0% to 35%.24,25 Reports with better outcomes tend to be from more recent series.24 It should be expected that outcomes from the modified Norwood procedure will be somewhat better in this morphologic population compared with patients with aortic atresia and other forms of hypoplastic left heart physiology because of fewer morphologic risk factors.

Muscular Resection to Relieve Subaortic Obstruction

Knowledge of results of this operation is incomplete because of the great heterogeneity of patients receiving it, relatively small experience with it, and lack of complete and long-term follow-up.1,5,17,13,23,28 Hospital mortality of 11% (CL 1%-33%) has been reported by Cheung and colleagues among 9 patients.17 The death occurred in a patient operated on in the first year of life at the time of VSD enlargement. One patient required repeat surgical enlargement. Deaths after hospital dismissal were related to subsequent procedures. More recently, Cerillo and colleagues reported no early mortality after 6 resections (0%; CL 0%-27%).59

Indications for Operation

When designing the appropriate operative procedure, the status of the aortic arch must be assessed. If the ascending aorta and arch are widely patent, associated subaortic obstruction is less likely. If obstruction is identified at the aortic arch, the subaortic region must be carefully evaluated because obstruction at this level is commonly present. Accurately evaluating the subaortic region may be difficult in the preoperative setting of a patent ductus arteriosus, because the LV ejects only part of the systemic cardiac output (upper-body component) across the VSD to the aortic valve; the remainder (lower-body output) is delivered from the LV directly across the pulmonary valve and ductus arteriosus to the thoracic aorta. As a result, absence of a gradient (determined either by echocardiography or cardiac catheterization) between LV and aorta is an unreliable gauge of future outflow tract adequacy once the aortic arch is repaired and the ductus arteriosus removed. Under these circumstances, the entire systemic

Figure 41-23  Direct relief of subaortic obstruction in univentricular hearts with transposed great arteries. A, Median sternotomy exposure and standard cardiopulmonary bypass technique using moderate hypothermia and cardioplegic myocardial protection are utilized. Longitudinal incision in subaortic area of incomplete right ventricular (RV) chamber is used to expose subaortic obstruction. B, Internal anatomy of incomplete and hypoplastic RV chamber is shown. Dashed lines show incisions used to resect muscle that result in enlarging the ventricular septal defect (VSD). Wedge of full-thickness septal muscle between these two incisions is removed, taking care to avoid injury to adjacent aortic valve and underlying atrioventricular valve. Position of wedge resection is also designed to avoid conduction tissue positioned along posteroinferior rim of VSD, represented by open circles. C, Incision in free wall of incomplete RV is closed with a patch designed to augment subaortic chamber. Patch material can be polyester, glutaraldehyde-treated autologous pericardium, or polytetrafluoroethylene. Care is taken to avoid injury or obstruction to major coronary branches running along free wall of incomplete RV during incision closure.

A

B

Conduction tissue

C

PART VII  Congenital Heart Disease
cardiac output must cross the VSD and subaortic region. Because physiologic variables are unreliable, one must rely on morphologic details of the sizes of the VSD, subaortic region, and aortic valve itself in judging adequacy of the LV-to-aortic outflow tract. Echocardiographic characterization of VSD size has been suggested as a predictor of long-term adequacy of the LV outflow tract.\textsuperscript{M18}

However, if obstruction is documented preoperatively in this setting, then the systemic LV outflow tract will be clearly inadequate. If so, the operative procedure entails repair of the obstructed aortic arch, creating a proximal pulmonary trunk–to-aortic anastomosis (Damus-Kaye-Stansel procedure) and a systemic–pulmonary arterial shunt. This combination essentially achieves the same result as that achieved by aortic arch reconstruction in the Norwood procedure for hypoplastic left heart physiology (see Indications for Operation in Chapter 49). The Damus-Kaye-Stansel procedure with aortic arch reconstruction, or modifications of Norwood aortic arch reconstruction that some surgeons prefer, can be applied to other forms of univentricular AV connection in the setting of aortic arch and subaortic obstruction, most commonly DILV with discordant ventriculoarterial connection and mitral atresia with VSD and concordant ventriculoarterial connection (see Indications for Operation in Chapter 56).\textsuperscript{R26,V4}

For a detailed description of aortic arch reconstruction in hypoplastic left heart physiology, see the description of the Norwood operation under Technique of Operation in Chapter 49. Most forms of aortic arch obstruction in combination with subaortic obstruction occur in the setting of ventriculoarterial discordant connection. Orientation of the great vessels, therefore, is quite different from that in typical hypoplastic left heart physiology. As a result, the Norwood type aortic arch reconstruction is somewhat modified.

### SPECIAL SITUATIONS AND CONTROVERSIES

#### Concordant Ventriculoarterial Connection

**Systemic–Pulmonary Arterial Shunt**

**Site** Systemic–pulmonary arterial shunts can be placed at sites on the systemic and pulmonary arterial systems other than that described previously in this chapter. These alternative sites may be chosen for practical reasons relating to individual anatomy or simply surgeon preference. Anatomic variations that may determine site of the shunt include situs inversus, atrial isomerism, right-sided aortic arch, and abnormal arch branching patterns. In patients with small central pulmonary arteries, it may be wise to site the pulmonary arterial anastomosis on the pulmonary trunk segment, if one is present, to avoid distorting or occluding either left or right pulmonary arteries. Regardless of site, the systemic–pulmonary arterial connection is performed using a specific length and diameter of extended PTFE tube graft (see text that follows).

**Size** Diameter of the expanded PTFE graft is the most important determinant of resistance within a systemic–pulmonary arterial connection and therefore is the prime regulator of $Q_p$. Other factors, such as graft length and site of origin on the systemic circulation, also influence resistance but to a lesser degree (Poiseuille resistance relationships). Once the appropriate diameter is chosen for the graft, these other factors can be used in individual patients to help further regulate pulmonary blood flow to create the ideal balance between $Q_p$ and $Q_s$. A 3.5-kg infant is typically well served using a 3.5-mm-diameter graft connected to the brachiocephalic–right subclavian arterial junction. A larger infant, or one who has particularly small pulmonary arteries or manifests physiology indicative of elevated $R_p$, might best be served by a similar 3.5-mm tube graft connected directly to the brachiocephalic artery or even ascending aorta. With these adjustments, resistance in the artery giving rise to the tube graft is reduced, and therefore overall resistance across the connection is less, compared with a graft constructed with a more distal (smaller diameter) systemic connection. On the other hand, a smaller infant or one who manifests physiology indicative of very low $R_p$ preoperatively may best be served by a 3.5-mm-diameter graft connected entirely to the right subclavian artery. In this case, the subclavian artery contributes additional resistance to that of the tube graft. A 3-mm-diameter tube graft may be considered in particularly small infants, such as those with a body weight 2.5 to 3 kg or less (see “Type” in text that follows).

**Type** Technique of Operation in this section describes the preferred modified Blalock-Taussig shunt using an expanded PTFE tube graft. Systemic–pulmonary arterial shunts using direct arterial tissue-to-tissue connection, such as end-to-side connection of the subclavian artery to the RPA (classic Blalock-Taussig shunt),\textsuperscript{T2} direct ascending aorta–to-RPA connection (Waterston shunt), descending aorta–to-left pulmonary artery connection (Potts shunt), and central ascending aortic–to-pulmonary trunk connection, are rarely if ever used in the setting of normally developed branch pulmonary arteries. These connections all have disadvantages of unreliable regulation of $Q_p$ or high prevalence of pulmonary artery distortion.

There is no foolproof formula for choosing optimal shunt diameter and connection to create perfectly balanced $Q_p$. Careful evaluation of patient size, pulmonary arterial anatomy, and physiologic behavior of the pulmonary vasculature preoperatively, and the surgeon’s own experience, all are considerations when choosing size, site, and type of shunt that will best serve an individual patient. A surgeon who typically uses precise and accurate surgical technique will achieve a 3.5-mm orifice at systemic and pulmonary artery anastomoses when a 3.5-mm tube graft is used; one who typically uses less precise and accurate technique will likely create anastomoses at both sites that are smaller than the 3.5-mm tube graft. In this case, a surgeon may come to realize over time that a larger-diameter graft provides the appropriate degree of pulmonary flow.

**Aspirin Use** Although the use of aspirin following shunt placement is widely practiced, until recently there has been little documented evidence of its efficacy. The recent multicenter study by Li and colleagues\textsuperscript{L20} shows that risk of thrombosis and death are both lower when aspirin is used. The study involved a wide range of morphologic lesions, and aspirin daily dosage varied, with 80% of patients receiving 20 to 40 mg · day\textsuperscript{−1}. The efficacy of aspirin did not vary with dosage.

**Left Pulmonary Artery Stenosis** Occasionally, infants with this subset of tricuspid atresia have either hypoplasia or a discrete stenosis in the proximal left pulmonary artery in the region of the ductus arteriosus. This lesion will almost certainly become rapidly progressive once PGE\textsubscript{2} infusion is stopped. It is usually prudent to address it at the initial shunt procedure. Individual judgment is required regarding the method of relieving the stenosis. A patch can
Repair of periductal left pulmonary artery (LPA) stenosis in neonate.  

To achieve satisfactory reconstruction, the pulmonary trunk–to-aortic connection (Damus-Kaye-Stansel anastomosis) with arch reconstruction, or a modified Norwood procedure can be performed without using CPB, allowing the shunt to perfuse the right lung only during left pulmonary artery reconstruction. Occasionally with more complex central pulmonary artery stenosis, CPB support is necessary to achieve satisfactory reconstruction.

Discordant Ventriculoarterial Connection  
Aortic Arch Obstruction without Apparent Subaortic Obstruction  
When this subset of tricuspid atresia exists with important aortic arch obstruction but without evidence of clear subaortic obstruction, surgical management in the neonatal period is controversial. Some surgeons prefer to act on the established observation that presence of aortic arch hypoplasia increases the likelihood of subaortic obstruction, and in all such cases they perform a proximal pulmonary trunk–to-aortic connection (Damus-Kaye-Stansel anastomosis) with arch reconstruction, or a modified Norwood procedure. This approach has the advantage of removing uncertainty related to adequacy of LV systemic outflow. Its disadvantages are magnitude and risk of the procedure, which usually involves a prolonged period of CPB, myocardial ischemia, and in many hands, cerebral ischemia. This risk is warranted if subaortic obstruction exists; it may not be warranted if in fact the equivocal subaortic region is adequate.

Thus, some surgeons prefer to make an individual evaluation of the subaortic region. If its morphologic characteristics suggest the LV-to-aortic outflow tract will be adequate, an isolated arch repair and pulmonary trunk band is performed. The advantage of this approach is that CPB and organ ischemia are avoided, and complexity of the procedure minimized. Acute morbidity and mortality with this operation are clearly lower than with the former approach. The disadvantage, however, is that the subaortic region remains a concern. Therefore, careful and frequent evaluation of the subaortic region, beginning in the immediate postoperative period, must be undertaken.

Mild subaortic obstruction for a short period may not negatively affect function of the single ventricle. Recent evidence suggests that patients with subaortic gradients up to 40 mmHg for up to about a 6-month duration, who initially underwent pulmonary artery banding and only later DKS procedures, did not have negative effects on ventricular function or reduced candidacy for later Fontan.  

Assessment of the subaortic area must be ongoing over the course of the patient’s life. If LV-to-aortic outflow obstruction develops, the patient must undergo one of several subsequent procedures to relieve it. If subaortic obstruction occurs in the first several months following aortic arch repair and pulmonary trunk banding, the most appropriate procedure is a proximal aortic–to–pulmonary trunk connection (Damus-Kaye-Stansel anastomosis) and systemic–pulmonary artery shunt. Before this procedure is done, the banded pulmonary trunk must be assessed carefully to confirm that no damage to the pulmonary valve has occurred from the band. Distortion or damage to the pulmonary valve resulting from the banding procedure may increase the chances of important neoaortic regurgitation following the proximal pulmonary trunk–to-aortic connection. When careful attention is given to technical details, competence of the native pulmonary valve can usually be preserved. If the pulmonary valve is
regurgitant, the only remaining surgical alternative is to incise and excise the obstructing subaortic muscle at the level of the VSD and hypoplastic RV chamber. Such a procedure, however, carries an important risk of morbidity in the small infant or neonate with respect to ventricular function and conduction integrity.

If subaortic obstruction develops later in infancy following neonatal arch reconstruction and pulmonary trunk banding, proximal aortic to pulmonary trunk connection (Damus-Kaye-Stansel anastomosis) can be performed at the time of superior cavopulmonary connection, obviating need for a systemic–pulmonary artery shunt. Again, careful evaluation of the adequacy of the pulmonary valve must be undertaken, and the alternative of a subaortic muscle resection must be given consideration.

If subaortic obstruction develops in a patient who previously received arch reconstruction and pulmonary trunk banding as a neonate, and who has subsequently undergone either a superior cavopulmonary shunt or a Fontan procedure, risk/benefit analysis of each of the two procedures that can be used to relieve the obstruction is substantially altered. Forward flow across the pulmonary valve is eliminated or markedly reduced at the time of the superior cavopulmonary shunt and must be eliminated at the time of the Fontan. If subaortic obstruction develops subsequently, long-standing lack of flow across the pulmonary valve, with stasis of the valve cusps, increases concern about its long-term function in the systemic circulation. Muscle resection to enlarge the VSD and subaortic region, although never without morbidity, becomes a more attractive option under these circumstances. In the larger patient, accurate resection at the level of the VSD may relieve obstruction with less risk of injuring the conduction system or major coronary branches in the septum.

**Arterial Switch Operation**

The technique used for neonates with simple transposition of the great arteries (see “Arterial Switch Operation” under Technique of Operation in Chapter 52) has been described in a limited number of patients with subaortic obstruction complicating the various forms of univentricular AV connection described in this chapter. This technique has one major disadvantage and as a result is not commonly used. Although the arterial switch itself relieves subaortic obstruction completely, restriction at the VSD and outlet chamber regulates Qp. Obstruction can be quite variable and, as a result, regulation of Qp can be unpredictable, resulting in patient instability or need for further procedures to stabilize or rebalance Qp.

A single report is the basis for assessing risk of the procedure in this setting. From this experience, 5 of 6 (83%; CL 54%-98%) critically ill neonates were hospital survivors of the arterial switch procedure (accompanied by aortic arch repair and atrial septectomy), and 4 of the 6 (67%; CL 38%-88%) were still awaiting definitive Fontan operation at the time of the report. No late follow-up of this experience is available.

**Other Palliative Operations**

Early mortality after palliative procedures discussed in the text that follows should be low. Procedures should not interfere with, and indeed should facilitate, later Fontan operation, and they should provide good long-term palliation for patients in whom the completed Fontan operation is not possible.

**Atrial Septectomy**

Atrial septectomy, usually performed for patients with mitral atresia, can be performed with low mortality either as an isolated procedure or combined with pulmonary trunk banding or a systemic–pulmonary arterial shunt procedure (see Table 41-2). This success, however, is not universal. Shore and colleagues report a high mortality (23%; CL 10%-41%).

**Hybrid Palliation**

The hybrid procedure, initially designed as a neonatal alternative to the Norwood operation for patients with aortic atresia and other forms of hypoplastic left heart physiology (see Chapter 49), has occasionally been applied to other single-ventricle patients with systemic outflow obstruction and unobstructed pulmonary blood flow.

**Other Operations in Neonatal Period**

Other operations are indicated for specific physiologic circumstances. These primarily include anomalous pulmonary venous connection and occasionally AV valve regurgitation. Outcomes after surgical management of single-ventricle patients with associated anomalous pulmonary venous connection, especially when obstructed, are poor. Sznizobahmya and colleagues report 1-year actuarial survival of 31%. Lodge and colleagues report 1-year survival of 53%, but when transplantation is included, midterm survival without need for transplant is about 25%.

---

**Section III Second-Stage Palliation**

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

The second stage of the three-stage management plan for patients with tricuspid atresia and other forms of single-ventricle physiology has three purposes:

- Eliminate inefficiencies of the completely mixed circulation as early in life as possible
- Correct or eliminate existing morphologic abnormalities before Fontan operation
- Allow for ventricular remodeling in response to the acute reduction in volume load

Eliminating physiologic inefficiencies of the completely mixed circulation is accomplished by partially separating pulmonary and systemic venous circuits. By directing desaturated SVC blood exclusively into the pulmonary arteries, using a superior cavopulmonary shunt or hemi-Fontan connection, efficiency of gas exchange is improved such that the systemic–pulmonary arterial connection (via either a systemic–pulmonary arterial shunt or pulmonary trunk band) can be eliminated or markedly reduced. This results in dramatic reduction in workload of the single ventricle to a level that approaches that in an intact normal circulation. The new physiology has important positive implications for
improved functional status and long-term preservation of the myocardium. This is an important consideration because failure of the myocardium is one of the most important causes of long-term morbidity and mortality in single-ventricle patients, both with and without Fontan physiology (see “Cardiomyopathy” under Natural History in Section 1). \(^{(15, 22)}\) Reduction in ventricular work is accomplished without compromising gas exchange or \(\text{SaO}_2\), which typically remains above 80%. Additionally, diastolic shunt runoff is eliminated, increasing aortic diastolic pressure and improving coronary perfusion.

Considering the beneficial effects of the physiology associated with the superior cavopulmonary shunt compared with that of a completely mixed circulation, it seems prudent to perform the cavopulmonary shunt as soon as it is safe to do so. The major deterrent to performing it in the neonate is elevated pulmonary resistance (Rp) following birth. In theory, the superior cavopulmonary shunt should be possible within 4 to 8 weeks after birth when Rp has decreased to normal. Based on these concepts, there has been a general trend toward performing the superior cavopulmonary shunt in early infancy. \(^{(5, 10, 13, 26, 22)}\) This experience has shown that it can be performed at age 8 to 10 weeks, with morbidity similar to that seen in infants age 6 months and older. However, the experience of one of the authors (Hanley FL: personal communication, 2002) has shown that the procedure is associated with increased morbidity when performed between age 4 and 6 weeks. \(^{(7)}\) This experience shows that the morbidity is not related to persistent elevation inRp, because pressure in the cavopulmonary system is not elevated. Rather, it is related to unacceptable cyanosis. It thus appears that factors other than elevated Rp, such as poor ventilation/perfusion matching or exaggerated responses in the lungs to CPB, may play important roles in determining the lower age limit for safely performing the superior cavopulmonary shunt.

The second purpose for performing the second-stage operation is to correct or eliminate any existing morphologic abnormalities before the Fontan procedure is performed. The second-stage procedure is preventive in this regard. Early removal of the synthetic systemic–pulmonary arterial shunt and creation of a tissue-to-tissue cavopulmonary connection prevent branch pulmonary artery distortion and eliminate any possibility of developing pulmonary vascular obstructive disease. Additionally, the second-stage operation provides the opportunity to correct other malformations such as branch pulmonary artery hypoplasia or stenosis, arch obstruction, subaortic obstruction, AV valve regurgitation, restrictive atrial septum, or anomalous pulmonary venous connection. Careful early attention to these issues preserves and maximizes overall cardiopulmonary function and markedly simplifies the technical procedure at the Fontan operation.

The third purpose of the second-stage operation is to allow for ventricular remodeling, which necessarily occurs with acute reduction in volume loading, to happen prior to the Fontan. Acute volume reduction results in temporary relative ventricular hypertrophy, lower ejection fraction, and diastolic filling abnormalities. \(^{(22, 24)}\) These changes resolve over time. Thus, ventricular mass and function will return toward normal well before the Fontan operation if a second-stage procedure is performed. The acute ventricular changes associated with volume reduction are better tolerated under conditions of the superior cavopulmonary shunt physiology than under conditions of Fontan physiology.

### TECHNIQUE OF OPERATION

#### Preoperative Management

Prior to proceeding with second-stage palliation, assessment with echocardiography, and usually cardiac catheterization, is performed. Echocardiography primarily evaluates existing intracardiac morphologic abnormalities and identifies new or evolving ones, such as AV valve regurgitation or ventricular outlet obstruction. Cardiac catheterization primarily is used to evaluate morphology of pulmonary artery branches and measureRp, a critically important value in determining the advisability of creating a cavopulmonary shunt (see Indications for Operation later in this section). At catheterization, pulmonary artery pressure can accurately be estimated by measuring pulmonary venous wedge pressure, thus simplifying the procedure. \(^{(25)}\) Recently, some have argued that routine catheterization is not necessary and should be performed only when noninvasive evaluation by echocardiography, computed tomography angiography (CTA), or cardiac MRI suggests that abnormalities of ventricular end-diastolic pressure and Rp are likely to be present. \(^{(20, 23, 29, 31, 26, 29)}\)

#### Bidirectional Superior Cavopulmonary Shunt

This palliative operation diverts SVC blood from either one or bilateral superior venae cavea to the pulmonary arteries, with preservation of continuity between right and left pulmonary arteries. Usually, patients will have undergone previous palliative procedures involving either a systemic–pulmonary arterial shunt or a pulmonary trunk band. Operation is typically performed through a median sternotomy with or without CPB.

#### Using Cardiopulmonary Bypass

When CPB is used, the ascending aorta and SVC at the brachiocephalic–jugular vein junction are cannulated, and a calcium-supplemented blood prime is used with either mild or no hypothermia (Fig. 41-25, A). After partial bypass is initiated, the heart is allowed to remain beating, and all sources of systemic-to-pulmonary blood flow are controlled. If the decision is made to remove all extra sources of pulmonary blood flow permanently, it can be done at this point. If a systemic–pulmonary arterial shunt is present, it is ligated either with heavy suture material or metal clips and always divided (see Fig. 41-25, A). If a pulmonary trunk band is present or any forward flow exits from heart to pulmonary arteries, the pulmonary trunk is transected between vascular clamps, and proximal and distal ends are oversewn with running monofilament suture. Care should be taken to avoid creating a blind pouch when the proximal pulmonary trunk is transected, because this pouch may serve as a nidus for thrombus formation, with the potential for systemic embolization. If the decision is made to keep an extra source of pulmonary blood flow, the systemic–pulmonary arterial shunt is temporarily controlled with vascular clamps, whereas a pulmonary trunk band need not be addressed at this time in the procedure.

Vascular clamps are placed across the SVC at the cavoatrial junction and close to the venous cannulation site. The SVC is transected as it crosses the RPA. Theazygos vein is ligated to avoid late decompression of superior cavopulmonary shunt flow into the lower body. The SVC stump attached to the right atrium is oversewn with a running monofilament suture.
suture. An appropriately sized partial occlusion vascular clamp is then placed on the cephalad aspect of the RPA, and it is incised over an appropriate length to accommodate the circumference of the transected SVC. If a systemic–pulmonary arterial shunt has been previously placed into the RPA, all shunt material is completely removed from it before creating the anastomosis between SVC and RPA (Fig. 41-25, B). An end-to-side anastomosis of SVC to RPA is performed using 7-0 absorbable monofilament suture. The patient is then separated from CPB, and cannulae are removed (Fig. 41-25, C). Atrial pressure is monitored with an indwelling catheter, and pulmonary artery pressure is measured before chest closure.

If the patient has a preexisting systemic–pulmonary arterial shunt and the decision is made to allow the shunt to remain patent as an extra source of pulmonary blood flow, it is usually necessary to reduce shunt flow substantially (Fig. 41-25, E). It can be reduced by placing either sutures or

---

**Figure 41-25** Creation of right-sided bidirectional superior cavopulmonary shunt. A, Surgical exposure is through a standard median sternotomy as shown. Procedure can be performed on partial cardiopulmonary bypass (CPB), as shown here, by cannulating ascending aorta and cephalad portion of superior vena cava (SVC). At institution of CPB, the dissected and exposed previously placed right subclavian artery–to–pulmonary artery shunt is immediately ligated at its proximal origin and divided. As shown in the two insets, azygos vein is doubly ligated and divided. B, SVC has been divided between clamps and cardiac end oversewn with a continuous monofilament suture. Old polytetrafluoroethylene shunt is completely removed from right pulmonary artery (RPA), and RPA opening is enlarged to accommodate diameter of SVC. Cephalad portion of SVC is then connected to RPA end to side using absorbable fine monofilament suture. Posterior aspect of anastomosis is completed first, as shown, followed by anterior component. SVC clamp is then removed, and patient is separated from CPB in standard fashion. C, Completed procedure.
Exposure is through median sternotomy. Previously placed pulmonary trunk band is shown. After mobilizing SVC and RPA, two appropriately sized right-angled venous cannulae are inserted into SVC at brachiocephalic–jugular vein junction and into right atrial appendage. They are carefully de-aired and connected together following full heparinization to provide continuous SVC-to-right atrial flow while creating the SVC-to-RPA anastomosis. After cannulae are secured and flow established through them, vascular clamps are placed on SVC just inferior to upper cannula and at SVC–right atrial junction. SVC is transected as it crosses over RPA. Transected cardiac end of SVC is oversewn with a continuous monofilament suture. A partial occlusion clamp is placed on superior aspect of RPA, taking care not to disrupt forward flow through pulmonary trunk band site to left pulmonary artery, and an incision is made in sequestered portion of RPA to accommodate circumference of SVC. SVC is connected end to side to RPA using a fine absorbable monofilament suture with continuous technique. Upon completion of anastomosis, SVC and RPA clamps are removed, and caval and right atrial cannulae are clamped and removed, establishing bidirectional superior cavopulmonary shunt-to-pulmonary artery flow. Based on patient’s hemodynamic response, pulmonary trunk band is further tightened, or pulmonary trunk is completely occluded (see text for full discussion of factors involved in this decision). Similar to D, except that existing pulmonary blood source is through a left modified Blalock-Taussig shunt rather than from forward flow across banded pulmonary trunk. Reconstruction proceeds exactly as in D, except that at completion of procedure, after physiologic assessment of patient has been made, shunt is modified appropriately or eliminated using medium-sized metal clips (see text for full discussion of factors involved in shunt management at time of bidirectional superior cavopulmonary shunt). As shown in inset, shunt diameter is narrowed using several metal clips.
metal clips along the length of the shunt to partially reduce its internal diameter. Shunt flow can be reduced in a quantitative fashion by carefully observing changes in hemodynamics as shunt diameter is narrowed, and by adhering to the following process. Preoperative catheterization data are reviewed, and thus the surgeon has a good idea of amount of flow through the shunt under baseline preoperative conditions. After the bidirectional superior cavopulmonary shunt is completed and the patient removed from CPB and in a hemodynamic steady-state, the change in systemic diastolic blood pressure that occurs when the temporarily occluded shunt is opened is observed. This maneuver can be repeated several times to get a reliable measurement. The shunt can then be permanently narrowed to achieve a diastolic blood pressure at a level between the two values observed when the shunt was completely open and when it was occluded. This provides a semiquantitative estimate of reduction in shunt flow. Additional information that can be used to adjust the extra source of flow is absolute pressure within the SVC and pulmonary arteries following the bidirectional superior cavopulmonary shunt. As a general rule, mean pulmonary arterial pressures should be less than 15 mmHg, and pulse pressure in the pulmonary artery should be less than 5 mmHg.

If the preexisting source of pulmonary blood flow was through a pulmonary trunk band or stenotic pulmonary valve and it is decided to leave this as an extra source of flow, it is usually necessary to adjust the band or further narrow the pulmonary trunk after creating the bidirectional cavopulmonary anastomosis. Changes in systemic diastolic blood pressure are insensitive indicators of changes in flow across a pulmonary trunk band; measuring distal mean pulmonary arterial pressure and pulsatility responses with the band site open and with it temporarily occluded is the best way to adjust flow across the pulmonary valve or pulmonary trunk band. The standard method for placing and adjusting a pulmonary trunk band is used (see Fig. 41-21, D).

Without Using Cardiopulmonary Bypass
When CPB is not used, it is prudent to decompress the upper-body venous system while creating the cavopulmonary anastomosis if a single SVC is present. Before placing venous cannulae, the patient is fully heparinized (3 mg · kg⁻¹). Two venous cannulae are placed, one in the SVC and the other in the right atrial appendage, de-air ed, and connected together (Fig. 41-25, D).

If bilateral SVCs are present, decompression is usually not needed. If the preexisting source of pulmonary blood flow is either a right- or left-sided systemic–pulmonary arterial shunt, the operation proceeds by creating the first cavopulmonary anastomosis on the side opposite the preexisting source of pulmonary blood flow. Once this anastomosis is completed, it can serve as an adequate source of pulmonary blood flow while the systemic–pulmonary arterial shunt is removed in preparation for creating the second cavopulmonary connection on the side where the shunt existed.

Hemi-Fontan Operation
The hemi-Fontan operation is physiologically similar to a bidirectional superior cavopulmonary shunt, but important differences exist. The hemi-Fontan requires hypothermic CPB and cardiac arrest because it is an open cardiac procedure, technical details of the operation are more complex, and potential for sinoatrial node injury is increased. Some surgeons prefer the hemi-Fontan operation because it is believed that this procedure makes a subsequent lateral tunnel Fontan simpler to perform. Others who use the lateral tunnel Fontan prefer the bidirectional superior cavopulmonary shunt. If the subsequent Fontan operation will be an extracardiac conduit Fontan, the hemi-Fontan operation provides no advantage.

The hemi-Fontan operation consists of diverting SVC flow to the pulmonary arteries by creating a right atrial–to-RPA anastomosis. After CPB, hypothermia, and cardiac arrest are achieved in standard fashion, an incision in the roof of the right atrium is spiraled onto the back of the SVC (Fig. 41-26, A). A complementary incision is made on the caudad aspect of the RPA, and the two structures are sewn together to complete the anastomosis (Fig. 41-26, B-C). A right atrial free-wall incision is made, and a pulmonary allograft patch is placed inside the superior aspect of the right atrium, partitioning the inferior vena caval, coronary sinus, and pulmonary venous flow from the hemi-Fontan anastomosis (Fig. 41-26, D). A large atrial septal opening is created if necessary, and any central pulmonary artery abnormalities may be corrected at the same procedure. Managing preexisting sources of pulmonary blood flow is similar to that described in the preceding text for the bidirectional superior cavopulmonary shunt. Upon completion of the Fontan operation, if a lateral tunnel Fontan is to be used, the intraatrial patch is removed, and the lateral tunnel baffle can be easily placed while working solely within the right atrium.

The hemi-Fontan operation can be simplified by performing a standard bidirectional superior cavopulmonary shunt and connecting the cardiac stump of the transected SVC into the caudad surface of the RPA. The procedure is completed within the right atrium by placing a patch over the right atrial–SVC orifice. Although this modification simplifies the surgical anastomosis, it also requires hypothermic CPB and cardiac arrest, because it is an open cardiac procedure. At the time of the Fontan operation, the intraatrial patch is removed.

SPECIAL FEATURES OF POSTOPERATIVE CARE
In general, care is routine. Hemodynamics are typically stable. The patient should be positioned with the head elevated 30 degrees because of the elevated SVC pressure. Aggressive pulmonary toilet is particularly important because important desaturation can occur with this physiology if gas exchange is not efficient. The hematocrit should be maintained at 45% at least. Duration of mechanical ventilation should be minimized; however, while the patient is mechanically ventilated, care should be taken to keep PaCO₂ at approximately 45 mmHg.

RESULTS
Bidirectional Superior Cavopulmonary Shunt
Hospital mortality is about 5% to 10%. However, this may partly reflect additional risk from concomitant procedures. Early palliation has generally been excellent, with SaO₂ averaging 85%. Midterm results can be estimated from only limited data, because currently
most patients receiving a bidirectional Glenn procedure go on to a Fontan operation. Available reports suggest 1-year survival of about 90% and 5-year survival of more than 80%. A8, H8, P17 Risk factors for death include elevated pulmonary artery pressure, total anomalous pulmonary venous connection, heterotaxy, RV morphology, AV valve regurgitation, and very young age. A8, R6, S5, S23 Age between 2 and 6 months and bidirectional superior cavopulmonary shunt as a second-stage operation in appropriately selected patients are not risk factors for death. C13, P14, B6

Risk factors for prolonged intensive care and hospital stays include length of CPB, RV morphology, elevated central venous pressure, elevated transpulmonary gradient, and low weight for age at the time of the procedure. A13, E22

The operation facilitates, more so than the classic Glenn operation, a subsequent completed Fontan operation, because the RPA has not been divided. In patients not suitable for the completed Fontan operation, long-term palliation, although not known, will probably be similar to that achieved by the classic Glenn operation (see “Classic Glenn Operation” under Special Situations and Controversies in Section I).

Hemi-Fontan Operation

Early mortality for the hemi-Fontan operation is in the range of 5% to 10%. D23, J6 The operation considerably facilitates the subsequent procedure of conversion to the lateral tunnel form of completed Fontan procedure, but does not facilitate conversion to the extracardiac conduit form. There is evidence that the hemi-Fontan compromises sinus node function at least temporarily. C28
INDICATIONS FOR OPERATION

Second-Stage Palliation

Although there is no absolute indication for the bidirectional superior cavopulmonary shunt or hemi-Fontan as the second stage of a three-stage plan to completion Fontan, it is widely believed that the second-stage procedure is beneficial and therefore indicated in most patients with single-ventricle physiology.215,53,110 (see “General Plan for Surgical Management of Single-Ventricle Physiology” in Section 1). The procedure should be performed between age 3 and 6 months to achieve maximum benefit. The bidirectional superior cavopulmonary shunt and hemi-Fontan achieve the same physiologic result; however, morbidity of the procedures may be different (see “Hemi-Fontan Operation” under Technique of Operation in this section). If an extracardiac conduit Fontan is contemplated, the bidirectional superior cavopulmonary shunt is the clear choice for the second-stage procedure, whereas if a lateral tunnel Fontan is contemplated, the hemi-Fontan may produce certain technical advantages.

Generally accepted contraindications to the procedure are:

- Age younger than 6 weeks
- Mean pulmonary artery pressure greater than 30 mmHg regardless of Rp
- Rp greater than 4 units · m²
- Pulmonary venous obstruction

These must be eliminated or corrected, sometimes with interim surgical or interventional procedures, before proceeding with the superior cavopulmonary shunt or hemi-Fontan. A recent study suggests that patients with baseline (room air) Rp as high as 6 units · m² can successfully undergo a superior cavopulmonary anastomosis if the Rp falls to less than 3.5 units · m² in 100% oxygen, albeit with increased risk of death.122 Inhaled nitric oxide may be beneficial in such high-risk cases.3

Bidirectional Superior Cavopulmonary Shunt as Primary Procedure

Patients who are not dependent on the ductus arteriosus for pulmonary blood flow, who maintain SaO₂ greater than 70% to 75%, and who do not have excessive Qp with pulmonary hypertension (mean pulmonary artery pressure > 25 mmHg) or failure to thrive may be considered for a primary bidirectional superior cavopulmonary shunt at about age 8 weeks.

SPECIAL SITUATIONS AND CONTROVERSIES

Three-Stage Palliation Plan

The three-stage surgical plan is neither mandatory nor universally practiced. Some centers selectively choose patients for the Fontan procedure following neonatal (first-stage) palliation only, whereas others routinely follow the three-stage plan. Currently, however, it is most commonly held that advantages of the second-stage bidirectional superior cavopulmonary shunt outweigh its disadvantages.215,517 Its main advantages are described at the beginning of this section. Additionally, evidence suggests that other complex measures of ventricular mechanics improve following the second-stage procedure.74,75 Disadvantages cited by some include acute surgical risks of an additional procedure, inadequate pulmonary artery growth under conditions of low Qp, development of aortopulmonary collateral vessels in response to low Qp and cyanosis, development of abnormal venovenous channels, and formation of intrapulmonary arteriovenous malformations.212,48,31,32,35 Important controversy exists regarding the clinical relevance of many of these disadvantages. It is generally believed, however, that the mortality risk (which is low) associated with the bidirectional superior cavopulmonary shunt is outweighed by its benefits, pulmonary artery size (diameter) may not correlate with Fontan outcome, and pulmonary artery growth may continue relatively normally following the shunt. Also, it is recognized that both acquired aortopulmonary collaterals and intrapulmonary arteriovenous malformations usually form gradually and in a small fraction of patients.14,35 As a result, interventional catheterization or an early Fontan procedure, when necessary, can eliminate or minimize these developments in most patients.829

Retaining Additional Source of Pulmonary Blood Flow

Another important management issue at the time of the second-stage procedure is whether to retain an additional source of pulmonary blood flow along with the bidirectional superior cavopulmonary shunt.229 Proponents of this practice argue that a controlled extra source of flow can provide a “normal” (Qp/Qs of 1) or close to normal amount of flow to the lungs, promoting normal pulmonary artery growth and possibly providing necessary humoral or hemodynamic factors (flow and pulsation) to eliminate or reduce the tendency for developing aortopulmonary collaterals and intrapulmonary arteriovenous malformations, with few or no ill effects.310,7,37,36 Opponents make two points:

- Even if the extra flow causes pulmonary artery growth and reduces collateral formation, there is no clinical benefit in terms of eventual Fontan candidacy or outcome.24,23,56
- Evidence exists that morbidity is increased and that an extra source of flow continues to place an increased, albeit limited, volume load on the single ventricle.7,18

Although the controversy is unresolved, a middle ground with appropriate patient selection and operative management might well maximize overall outcome. For example, patients with RV morphology, reduced ventricular function, or a common or regurgitant AV valve might best be managed without an extra source of pulmonary blood flow, based on careful risk/benefit analysis. On the other hand, patients with normal ventricular function, especially those with LV morphology or two ventricles, normally formed and competent AV valves, small pulmonary arteries, or certain forms of heterotaxy syndrome (that predispose to forming intrapulmonary AV malformations) might benefit from a carefully constructed extra source of pulmonary blood flow that augments Qp/Qs by an accurately determined additional 0.3 to 0.5.

Use of Cardiopulmonary Bypass

It has been shown that the superior cavopulmonary anastomosis can be created safely without the use of CPB.212,1,23 The decision regarding use of CPB is based on several practical
considerations. Avoiding CPB is an option if an existing source of pulmonary blood flow can be maintained while the bidirectional superior cavopulmonary shunt is being constructed, such as when the original source of pulmonary blood flow is a pulmonary artery band, central shunt, or shunt placed on the opposite side of the proposed bidirectional superior cavopulmonary shunt, or when bilateral superior venae cavae are present. When one of these exists, surgeon preference determines whether to use CPB or to avoid it. Even when these conditions do not exist, techniques have been devised to avoid bypass (see Fig. 41-25, D-E). The only situation in which CPB is absolutely necessary is when there is a single source of preexisting pulmonary blood flow through a systemic–pulmonary arterial shunt that is positioned such that the shunt must be completely removed to perform the bidirectional superior cavopulmonary shunt. This situation is commonly present when the SVC is unilateral and on the right side and the patient has received a previous right-sided modified Blalock-Taussig shunt.

**Section IV  Third-Stage Palliation (Fontan Operation)**

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

In typical three-stage surgical palliation for patients with tricuspid atresia, as well as for other forms of single-ventricle physiology, the patient presents for the Fontan procedure having already undergone a bidirectional superior cavopulmonary shunt or a hemi-Fontan procedure. At the time of the Fontan operation, all IVC blood flow is directed into the pulmonary circulation, leaving only pulmonary venous blood and coronary sinus blood to return to the common atrial chamber and single ventricle. Thus, this operation achieves almost complete separation of systemic and pulmonary circulations. Some centers routinely create a separate communication between systemic and pulmonary venous circulations (adjustable ASD, or fenestrated Fontan). In certain circumstances, this may provide a hemodynamic benefit, although it is achieved at the expense of increased mixing of desaturated blood with pulmonary venous return, thereby reducing SaO2.

At the time of the Fontan operation, other morphologic and hemodynamic issues may also require attention. If any systemic–pulmonary arterial connections exist, either natural or surgically created, every effort must be made to eliminate them, either at operation or by the interventional cardiologist at the time of preoperative cardiac catheterization. Additionally, other issues such as distortion or hypoplasia of branch pulmonary arteries, AV valve regurgitation, obstruction at any level in the systemic circulation, and abnormal systemic venoatrial connections should be addressed at the time of the Fontan.

In some cases, patients have not previously undergone typical first-stage neonatal palliation and second-stage bidirectional superior cavopulmonary shunt. Sometimes only one or the other of these procedures has been performed, and occasionally no previous surgical intervention has been required. If a bidirectional superior cavopulmonary shunt has not been performed, it is performed at the Fontan operation along with the IVC-to–pulmonary artery connection.

**Preoperative Evaluation**

Standard preoperative evaluation involves cardiac catheterization and echocardiography. Echocardiography is performed primarily to evaluate ventricular function and define details of intracardiac anatomy and physiology such as AV valve morphology and function. Cardiac catheterization is performed for two reasons:

- As a diagnostic study to evaluate morphology and hemodynamics that cannot be directly assessed by echocardiography. These include morphology of the distal pulmonary arterial system, which is assessed by angiography, and hemodynamic variables, including atrial filling pressure, ventricular end-diastolic pressure, pulmonary artery pressure, Qp : Qs, and systemic vascular resistance (Rs) and pulmonary vascular resistance (Rp). These data are used to select appropriate patients to undergo the Fontan operation and provide details for designing the operation. The specific physiologic data used to select patients for the Fontan operation are discussed under Indications for Operation later in this section.
- To determine whether any cardiac intervention will be needed before surgery. Potential interventional procedures include closing systemic–pulmonary arterial shunts, systemic–pulmonary artery collateral vessels, and systemic venoatrial connections, as well as balloon dilation or stenting of peripheral pulmonary arteries or aortic coarctation.

Recently, some have argued that routine catheterization is unnecessary; in their view, catheterization should be performed only when noninvasive evaluation by echocardiography, CT, angiography, and cardiac MRI suggest that abnormalities of end-diastolic pressure and pulmonary vascular resistance are likely to be present. Currently, this approach is taken by only a small minority of programs that manage Fontan patients. (The approach is taken somewhat more frequently during preoperative evaluation prior to the superior cavopulmonary anastomosis.) An important argument for preoperative catheterization is that acquired aortopulmonary collaterals develop in essentially all patients with single-ventricle physiology and present a potential volume load on the single ventricle. These can be coil occluded at the time of catheterization. Although there is universal acknowledgment of the development of these collaterals, opinions differ regarding their clinical significance.

In patients with prior atriopulmonary Fontan and atrial dysrhythmias, formal electrophysiologic evaluation is performed preoperatively.

**TECHNIQUE OF OPERATION**

Fontan connection can be achieved in a number of ways. Currently, the two most frequently used methods are the extracardiac conduit and lateral tunnel total cavopulmonary connections. The Society of Thoracic Surgeons (STS) Congenital Heart Database indicates that as of 2009, about two thirds of Fontans are of the extracardiac conduit type. In their classic forms, both include a bidirectional superior
cavopulmonary shunt or hemi-Fontan. The *atriopulmonary* connection, formerly the most frequently performed Fontan variant, is no longer considered a first-line option because of its related complications.

Other recently described techniques for creating the IVC-to-pulmonary artery connection are options. They include the extracardiac lateral tunnel technique, 

extracardiac pericardial tube technique, and direct IVC-to-pulmonary trunk connection. The latter is applicable only in a limited number of patients who have morphology favorable for a direct tissue-to-tissue connection. These procedures are not yet widely embraced.

Experimental evidence using computational fluid dynamics suggests that a Y-graft extracardiac conduit demonstrates better flow characteristics, during both rest and exercise, than a single tube either with or without an offset between IVC and SVC connections. 

This design has not been tested clinically, and concerns about thrombosis in the smaller-diameter limbs of the graft remain a concern at present.

**Extracardiac Conduit Fontan Operation**

Preparations for operation and median sternotomy are generally as described under “Incision” in Section III of Chapter 2. Operative technique is described for the patient with tricuspid atresia who has previously undergone neonatal palliation and subsequent second-stage palliation with a bidirectional cavopulmonary shunt. However, the general operative plan can be applied to all patients with single-ventricle physiology who have undergone similar neonatal and second-stage palliation. Details of the procedure require modifications appropriate to morphology, such as atrial isomerism, situs inversus, interrupted IVC, and distortions in pulmonary artery, systemic venous, or pulmonary venous systems. Techniques applicable to these morphologic variations are discussed in other chapters.

It is particularly important for the skin overlying the femoral vessels to be prepped into the surgical field. This is prudent for the usual reasons relating to reoperative sternotomy, but also because in some patients, especially those weighing more than 20 kg, peripheral venous cannulation may simplify the surgical procedure (see “Cardiopulmonary Bypass Established by Peripheral Cannulation” in Section III of Chapter 2).

After median sternotomy, complete dissection of the previously created superior cavopulmonary shunt and pulmonary artery system out to the hilum bilaterally is performed, including the pulmonary artery segment under the ascending aorta (Fig. 41-27, A). It is important to mobilize any adhesions around right-sided pulmonary veins as they enter the left atrium. The RPA is mobilized beyond the origin of the right upper lobe pulmonary artery such that it and lower-lobe pulmonary arteries are clearly identified circumferentially (see Fig. 41-27, A). A standard arterial purse string is placed in the ascending aorta and, in patients weighing less than 20 kg, a purse string is placed in the IVC at the reflection of the ascending aorta (Fig. 41-27, B). This completely isolates the central pulmonary artery system. In some cases, it may be necessary to disconnect the pulmonary trunk from the heart if this has not been done previously. The inferior (caudal) surface of the central pulmonary trunk and RPA is then opened, beginning in the periphery at approximately the level of the previously placed bidirectional superior cavopulmonary shunt and extending it centrally to the pulmonary trunk beneath the ascending aorta.

A PTFE tube graft is then selected to create the extracardiac conduit. The tube graft should be at least 2 cm in diameter and larger if possible, to accommodate growth to adulthood. Placing large conduits in small children may create IVC–conduit diameter mismatch, raising concerns about flow disruption and thrombosis. A 2-cm graft generally fits nicely in children who weigh 15 kg or more, although there can be wide variation in IVC diameter for the same body surface area. Akio and colleagues have reported a series of extracardiac conduits in patients weighing less than 10 kg without an increase in morbidity (see “Timing of Fontan Operation” under Indications for Operation later in this section). In patients who weigh more than 20 kg, a 22- or even 24-mm PTFE tube graft can easily be accommodated. Itatani and colleagues argue that smaller-diameter conduits (16 to 18 mm) provided superior flow characteristics when studied 1 year postoperatively in 3-year-old patients, however, there are concerns that these conduits may be of inadequate size as these children grow.

Before creating the proximal anastomosis, the PTFE graft is beveled such that the free edge of the graft matches the length of the extensive incision in the right and central pulmonary arteries. In this way, the proximal anastomosis can also be used to patch-augment any central pulmonary artery distortion or hypoplasia. Occasionally the proximal anastomosis must be extended across the central pulmonary artery to the left pulmonary artery if there is proximal left pulmonary artery stenosis. This can easily be accomplished, because the left pulmonary artery is controlled by a vascular clamp obliquely across the peripheral RPA close to the bidirectional superior cavopulmonary shunt anastomosis, such that a long segment of the inferior (caudal) aspect of the pulmonary trunk and RPA is isolated. The left pulmonary artery is clamped on the left side of the ascending aorta (Fig. 41-27, B). This completely isolates the central pulmonary artery system. In some cases, it may be necessary to disconnect the pulmonary trunk from the heart if this has not been done previously. The inferior (caudal) surface of the central pulmonary trunk and RPA is then opened, beginning in the periphery at approximately the level of the previously placed bidirectional superior cavopulmonary shunt and extending it centrally to the pulmonary trunk beneath the ascending aorta.

The conduit to the right lung is anastomosed end-to-end to the peripheral RPA close to the bidirectional superior cavopulmonary shunt anastomosis. The pulmonary trunk is beveled such that the free edge of the graft matches the diameter limbs of the graft remain a concern at present.

Usually the upper anastomosis of the Fontan connection can be performed before instituting CPB.

A segment of central pulmonary trunk and RPA proximal to the previously placed bidirectional superior cavopulmonary shunt is isolated in preparation for the upper anastomosis. This is accomplished without interrupting flow from the SVC to right lung by placing a vascular clamp obliquely across the peripheral RPA close to the bidirectional superior cavopulmonary shunt anastomosis, such that a long segment of the inferior (caudal) aspect of the pulmonary trunk and RPA is isolated. The left pulmonary artery is clamped on the left side of the ascending aorta (Fig. 41-27, B). This completely isolates the central pulmonary artery system. In some cases, it may be necessary to disconnect the pulmonary trunk from the heart if this has not been done previously. The inferior (caudal) surface of the central pulmonary trunk and RPA is then opened, beginning in the periphery at approximately the level of the previously placed bidirectional superior cavopulmonary shunt and extending it centrally to the pulmonary trunk beneath the ascending aorta.

Before creating the proximal anastomosis, the PTFE graft is beveled such that the free edge of the graft matches the length of the extensive incision in the right and central pulmonary arteries. In this way, the proximal anastomosis can also be used to patch-augment any central pulmonary artery distortion or hypoplasia. Occasionally the proximal anastomosis must be extended across the central pulmonary artery to the left pulmonary artery if there is proximal left pulmonary artery stenosis. This can easily be accomplished, because the left pulmonary artery is controlled by a vascular clamp at the left hilum. The anastomosis itself is performed with running 5-0 or 6-0 monofilament suture (Fig. 41-27, C). \(\text{SaO}_2\) is well maintained with ongoing SVC flow into the right lung only.

On rare occasions, the appropriate length of pulmonary artery cannot be cannulated without causing either hemodynamic instability or inadequate oxygenation, and CPB must be instituted to create the proximal anastomosis of the conduit to the RPA. When this is necessary, a separate purse string is placed in the SVC, and normothermic CPB is initiated after cannulating the ascending aorta, SVC, and IVC in standard fashion. A calcium-supplemented blood prime allows the heart to remain beating throughout the procedure.
Figure 41-27 Extracardiac conduit Fontan operation. A, Exposure is through standard median sternotomy. Most often this a reoperative median sternotomy, because most patients will have undergone several previous procedures. Typically, a bidirectional superior cavopulmonary shunt has been previously performed, as shown here. In this case, there is no additional source of pulmonary blood flow. Once sternum is opened, adhesions are dissected in order to completely mobilize previous superior vena cava (SVC)-to-right pulmonary artery (RPA) anastomosis. Pulmonary artery system is dissected from right upper and lower arterial branch junction to pulmonary trunk, working from right to left under ascending aorta. Occasionally, proximal left pulmonary artery (LPA) is dissected as well, working on left side of ascending aorta. Goal of this dissection is to mobilize an extensive length of RPA and pulmonary trunk for proximal Fontan anastomosis. B, Patient is heparinized, and central portion of pulmonary artery is isolated by placing two vascular clamps, one obliquely across RPA close to previously constructed bidirectional superior cavopulmonary shunt, and the other on the central or LPA as far to the left as possible. In this depiction, LPA is controlled on left side of ascending aorta. Inferior surface of right and central pulmonary artery is incised (dashed line) over an appropriate length to accept the circumference of a sharply beveled 20-mm-diameter expanded polytetrafluoroethylene (PTFE) tube graft. Care is taken that clamp adjacent to previously placed superior cavopulmonary anastomosis does not obstruct SVC flow to RPA, which is required for systemic oxygenation. C, Anastomosis between graft and pulmonary artery is performed using nonabsorbable fine monofilament suture and a continuous technique, beginning with posterior aspect and finishing with anterior aspect of anastomosis.

Assuming that CPB is not used, after the proximal anastomosis is completed, the graft and pulmonary arteries are de-aired, a vascular clamp is placed across the PTFE graft, and the branch pulmonary artery clamps are completely removed (Fig. 41-27, D). This reestablishes bidirectional superior cavopulmonary flow.

The ascending aorta and IVC are cannulated and connected to a centrifugal pump at approximately 50 mL · kg · min⁻¹ without an oxygenator, to achieve pump-assisted IVC decompression. Two large vascular clamps are placed across the IVC, one at the cavoatrial junction and the other just at the level of IVC cannulation (Fig. 41-27, E-F). If the femoral vein is used for lower body venous cannulation instead of the IVC, the clamp on the IVC is placed at the level of the diaphragm. The IVC is then transected and the cardiac stump oversewn with a running 3-0 polypropylene suture. The PTFE graft is then tailored to the appropriate length and anastomosed end to end to the IVC at the diaphragm with
Proximal anastomosis is completed, and pulmonary artery vascular clamps have been removed. These are replaced with a single clamp on midportion of tube graft. This allows reestablishing bidirectional SVC-to–pulmonary artery flow. Inferior vena cava (IVC) is examined, and PTFE graft is tailored to appropriate length for end-to-end graft to IVC. An IVC purse string is placed at its diaphragmatic reflection. During graft to IVC anastomosis, interruption of caval flow is necessary. During this period, IVC blood can be rerouted into either right atrium or ascending aorta in several ways as described in text. Once IVC decompression is accomplished, two large vascular clamps are placed on it, one at the atrio caval junction and the other just cephalad to venous cannula. IVC is transected between clamps. IVC remnant on right atrium is oversewn with a nonabsorbable heavy monofilament continuous suture technique. PTFE tube is connected end to end to diaphragmatic component of IVC using a nonabsorbable fine monofilament suture and a continuous technique as shown, with anastomosis beginning at posterior aspect of circumference of IVC. Completed extracardiac conduit Fontan with previously placed bidirectional superior cavopulmonary shunt.

a running 5-0 polypropylene suture (Fig. 41-27, G). This anastomosis can typically be performed in about 10 minutes.

Alternative extracorporeal circulation techniques can be used to construct the IVC-to–PTFE conduit anastomosis. One of these eliminates use of the pump described in previous text. Purse strings are placed on the right atrial appendage and IVC, and both are cannulated with large venous cannulae, which are then connected together to provide passive IVC decompression to the right atrium while the IVC is clamped and transected and the PTFE graft–to-IVC anastomosis performed. This technique is currently used by the authors as well as others. Another technique involves
simply clamping the IVC (which completely interrupts IVC flow) while the PTFE-to-IVC anastomosis is performed.\(^{320}\)

Following completion of the anastomosis, the patient is decannulated as needed (Fig. 41-27, H). Pressure-monitoring catheters are placed in the common atrium and IVC at the cannulation site to measure Fontan pathway and left-sided filling pressures and calculate transpulmonary gradient. These catheters are removed as soon as hemodynamic stability is ensured. Temporary atrial and ventricular pacing wires are placed along with appropriately positioned drainage tubes in the pleural and pericardial spaces, and the sternotomy is closed in standard fashion.

Extracardiac Conduit Fontan Operation with Deliberately Incomplete Atrial Partitioning

Incomplete atrial partitioning with the extracardiac conduit Fontan is usually unnecessary, particularly when the procedure is performed without CPB or with minimal CPB.\(^{112}\) (The reasons for this are detailed in “Fontan Operation with Deliberately Incomplete Atrial Partitioning” under Indications for Operation later in this section.) In essence, in creating a complete extracardiac conduit Fontan, the damaging effects of both CPB and myocardial ischemia are avoided, attenuating the transient hemodynamic disturbances that have made incomplete atrial partitioning necessary to ensure superior outcomes.

If hemodynamics following the Fontan procedure requires a communication between the Fontan conduit and atrium, this can be assessed after completing the Fontan as described; the connection can be accomplished without CPB. With the patient still heparinized, side-biting clamps are placed on the free wall of the right atrium and adjacent conduit, and a connection is made between these structures in one of two ways. First, a carefully controlled punch incision of predetermined diameter can be made in the conduit to regulate size of the fenestration. A second larger incision can be made in the sequestered segment of atrial wall, and free edges of the atrial incision can then be sewn widely around the punch hole in the conduit to create a fenestration. Second, small incisions can be made in both conduit and right atrial free wall, and a PTFE tube graft of approximately 8-mm diameter can be sewn between the two structures to create a tunnel-like communication. One of the authors (FLH) has used both of these techniques since 1992.\(^{113}\) Either communication can be regulated with a large snare if the surgeon prefers. The tube graft fenestration can also be closed using interventional catheterization.\(^{325}\)

Lateral Tunnel Fontan Operation

Preparation for operation and median sternotomy incision are generally those described in “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2. After anesthesia induction, a short double-lumen catheter is inserted percutaneously into the right internal jugular vein and advanced centrally (see subsequent text about early removal). In small patients, it may extend too far, interfering with SVC cannulation or with a total cavopulmonary connection; in that case the surgeon cuts off excess length. Inserting a polyvinyl catheter through the right superior pulmonary vein into the left atrium to measure ventricular loading is particularly important.

Risk of thrombosis around catheters in caval veins and their branches is increased in patients undergoing a Fontan operation (or bidirectional superior cavopulmonary shunt); therefore, any inserted for operation should be removed early postoperatively as soon as hemodynamic stability is achieved.

Aortic cannulation and cardioplegia purse-string sutures are placed as usual, as are those for direct SVC and IVC cannulation (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2, and Fig. 41-23). However, particular attention is paid to placing the SVC purse string as far cephalad as possible so that it does not interfere with a bicaval-pulmonary connection if chosen. Also, an elliptical shape of the purse string, with the long access of the ellipse oriented longitudinally, is particularly important so that tying it down later only minimally narrows the SVC. Purse string and cannulation may be on the brachiocephalic vein. Any previously made systemic–pulmonary arterial anastomosis is dissected (see “Repair of Tetralogy of Fallot after Blalock-Taussig orPolytetrafluoroethylene Interposition Shunt” under Technique of Operation in Section I of Chapter 38) and closed immediately after start of CPB.

CPB is established, systemic hypothermia achieved, aorta clamped, and cold cardioplegic infusion given. Perfusate temperature is rapidly lowered on CPB by taking the heat exchanger water bath to 4°C. Body temperature is stabilized, usually at 25°C, before administering cardioplegia. The technique of controlled myocardial reperfusion can be used after repair is completed (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3).

Although practiced in only a small minority of programs, some surgeons perform the operation using hypothermic circulatory arrest, in which case the body temperature is brought to 15°C to 18°C. During cooling, a left atrial vent may be inserted through the base of the right superior pulmonary vein, or the field may be freed of blood by a pump-oxygenator sump-sucker placed across the foramen ovale after the right atrium is opened.

The pulmonary trunk is completely dissected away from the ascending aorta, and right and left pulmonary arteries are mobilized out to their first branch. This is usually begun before CPB is established, but is completed after establishing CPB and closing any systemic–pulmonary arterial anastomoses (Fig. 41-28, A). To prevent serious bleeding after CPB, meticulous hemostasis must be obtained with electrocautery as dissection is being accomplished.

The right atrium is opened through an oblique incision placed a little more anteriorly than usual (to preserve more posterior right atrial wall to serve as part of the intraatrial tunnel that will be created), and the pump-oxygenator sump-sucker is placed across the foramen ovale into the left atrium (see Fig. 41-28, A).

The pulmonary trunk is transected as close to the valve as convenient, and the proximal end is closed with two rows of continuous 4-0 polypropylene sutures (Fig. 41-28, B). During dissection, division, and closure of the pulmonary trunk, care is taken not to disturb the left coronary artery. It is tempting to leave the distal end of the pulmonary trunk open for later anastomosis to the cardiac end of the transected SVC, but this anastomosis can rarely be performed without tension and angulation of the trunk and first part of the left pulmonary artery. Therefore, the distal end of the pulmonary trunk is usually closed with two rows of continuous 6-0
Lateral tunnel Fontan operation. Operation is shown for tricuspid atresia and normally related great arteries with well-developed main and branch pulmonary arteries. A, Exposure is through a standard median sternotomy, and standard cardiopulmonary bypass (CPB) with moderate hypothermia and cardioplegia is used. In this case, a bidirectional superior cavopulmonary shunt has not yet been performed. Dashed line indicates incision to be made in right atrial appendage. Operation proceeds by separating pulmonary trunk from aorta using sharp dissection. B, Right and left pulmonary arteries are dissected to their first branches in a manner similar to that used for arterial switch operation. After separating ascending aorta and pulmonary trunk, superior vena cava (SVC) is mobilized andazygos vein identified. CPB is then instituted with aortic cannulation and separate high SVC and inferior vena cava (IVC) cannulae. If any systemic–pulmonary arterial connections exist, these are also taken down immediately upon institution of CPB. Pulmonary trunk is transected at level of pulmonary valve, and each end is oversewn with a continuous monofilament suture. Dashed line on SVC shows point of eventual transection required to completed Fontan procedure. Somewhat anteriorly placed incision on right atrial free wall is also shown. Entry into right atrium provides access to left side of heart, allowing a pump sump-sucker to be placed across foramen ovale to decompress it. C, Anastomosis between cephalad portion of divided SVC and an incision in the superior surface of right pulmonary artery (RPA) is performed as shown, using a continuous 7-0 monofilament absorbable suture. This is performed exactly as shown in technique used for bidirectional superior cavopulmonary shunt (see Fig. 41-22). Cardiac end of divided SVC is connected to incision in inferior aspect of RPA as shown, using a continuous 7-0 monofilament absorbable suture.

polypropylene sutures placed as a whip stitch (see Fig. 41-28, B). However, if the distal pulmonary trunk segment has little length (which may be the case when a pulmonary trunk band has previously been placed too far distally), a patch of pericardium or allograft pulmonary artery is used for closure to maintain a wide pathway between right and left pulmonary arteries.

Success requires that the central unbranched hilar portions of right and left pulmonary arteries be enlarged if they are small. This can be accomplished by making a long incision in the midportion of the anterior wall of the left and right pulmonary arteries extending to the area of origin of the first branch on both sides. Inserting a widening patch-graft is accomplished with continuous 6-0 polypropylene sutures. If available, a pulmonary arterial allograft serves best as the patch-graft material. Otherwise, aortic allograft or autologous pericardium, untreated or treated with glutaraldehyde, may be used. Incision for anastomosis to the right atrium or cavae is then best made in the native pulmonary arterial wall rather than in the patch. This procedure can neutralize the incremental risk of small central right and left pulmonary arteries only if the branching portions of these arteries are of reasonable size.

If a previous bidirectional superior cavopulmonary shunt has not been performed, the SVC is transected at the point where it crosses the RPA; the transection is usually
just proximal to the azygos vein, which is divided between ligatures to help mobilize the cephalic end of the SVC. A longitudinal incision is made along the superior surface of the RPA, and the cephalic end of the SVC is anastomosed to this opening (Fig. 41-28, B-C). A longitudinal incision is made along the inferior surface of the RPA, a little more medially placed than the previous incision, and anastomosis made between the central end of the divided SVC and this opening (see Fig. 41-28, C). In most cases the sinus node artery can be seen and avoided.

A tunnel within the right atrium is required to conduct IVC and hepatic venous blood to the cardiac end of the SVC; generally, some heavy atrial trabeculations must be excised to clear that pathway. The ASD may need to be enlarged, particularly if the right AV valve will be the main pathway for pulmonary venous blood to reach the systemic ventricle (Fig. 41-28, D). A patch cut from a PTFE tube is selected, trimmed, and sewn into place. The suture line is started between the coronary sinus and IVC orifices and continued cephalad along the atrial septum as near the ASD as possible until the leftward edge of the SVC is reached. With the other arm of the suture, the suture line is carried over the IVC orifice, along the inside of the right atrial wall, and then over the SVC (Fig. 41-28, D-E).

The coronary sinus, as with the extracardiac conduit Fontan, now drains into the low-pressure left atrium; this arrangement is physiologically preferred, in contrast to an atroipulmonary Fontan, in which the coronary sinus drains to the high-pressure systemic venous circuit. Ilbawi and colleagues have shown that coronary sinus pressure greater than 15 mmHg depresses systemic ventricular output, although Ward and colleagues’ and Eicken and colleagues’ data appear to disprove this.\textsuperscript{3,13,15,20}

Collateral blood flow to the pulmonary circulation is often large in patients undergoing the Fontan operation, and particular care must be taken to avoid overdistention of the left atrium (and pulmonary veins) and systemic ventricle during final stages of repair. This can be accomplished by suction on the vent placed across the foramen ovale into the left atrium and by free drainage of blood from the pulmonary arteries into the right atrium through the anastomoses. The vent can be conveniently introduced through the right atrial appendage. In any event, as the right atrium is being closed, necessitating removal of the pump sump-sucker, care must be used
to prevent undue elevation of left atrial and ventricular pressure until cardiac action has returned. Toward this end, the caval tapes may be released before the atrium is closed, and suction on the caval cannulae can help decompress the pulmonary arteries and thereby the left atrium. After the heart is closed, aortic root reperfusion is established and de-airing begun. The remainder of operation is completed in the usual manner (see “Completing Operation” in Section III of Chapter 2).

At times, it may be more convenient to use a right atrial flap as the inner part of the wall of the tunnel.\(^\text{19}\) Depending on the anatomic situation in the individual patient, this atrial inner wall may be made from either anterior or posterior portions of right atrial wall.

Some prefer not to use the orifice of the cardiac end of the transected SVC to make the anastomosis to the RPA, but rather to close the central end and use a separate incision in the superior aspect of the right atrium for the anastomosis. A roof for the anastomosis is then made with allograft pulmonary arterial wall or pericardium. The intraatrial baffle is constructed so that it conducts IVC blood to the new opening.

When possible, as the repair is being completed, provision is made for measuring pressure in the pulmonary artery, venae cavae, and left atrium. Sites of insertion of fine polyvinyl catheters depend on the specific procedure used. Two right atrial and two RV myocardial electrodes are placed at the end of operation.

Provision for adequate drainage of the pericardium is particularly important. While the patient is still on CPB, a large window is made between the pericardial and right pleural spaces by excising a large piece of pericardium anterior to the phrenic nerve. A window is made between the pericardial and left pleural spaces by tilting the heart up anteriorly and making a large incision in the posterior pericardium well behind the phrenic nerve from within the pericardium. One posteriorly placed and one anteriorly placed drainage tube is brought out from each pleural space.

Lateral Tunnel Fontan Operation with Deliberately Incomplete Atrial Partitioning

Under some circumstances (see Indications for Operation later in this section), incomplete atrial partitioning is considered advantageous in performing the Fontan operation.\(^\text{G13}\) This has been accomplished in two ways in the setting of the lateral tunnel procedure.

Laks and colleagues leave a small defect in the suture line that attaches the PTFE to the atrium. They place one pledgeted polypropylene mattress suture through the edge of the PTFE at the site of the defect, bring the suture outside the heart through the posterior atrial wall, and pass the ends through another pledget and secure them on a snugger (a section of an 8F pediatric suction catheter)\(^{L3,L4,P6}\) (Fig. 41-29, A). The end of the suture is left beneath the closure of the linea alba (Fig. 41-29, B). Pushing the snugger down makes

---

**Figure 41-29** Lateral tunnel Fontan operation with deliberately incomplete atrial partitioning using “adjustable atrial septal defect.” **A**, After intraatrial polytetrafluoroethylene (PTFE) lateral tunnel baffle is placed, a small (approximately 6 mm) aperture is left in midportion of baffle suture line where baffle is attached to right atrial free wall, as shown. This aperture is controlled by a mattress suture using heavy 2-0 polypropylene suture with felt pledgets placed on both sides, connected to a snare. Length of snare is tailored to reach subxyphoid area prior to closure of right atrium. Snare is tested to demonstrate effectiveness of mechanism for opening and closing the aperture. Right atrium is then closed and patient separated from cardiopulmonary bypass in standard fashion. Prior to closing sternal incision, hemodynamics are assessed and aperture adjusted to maximize early hemodynamics. **B**, Prior to closing sternum, snare length is carefully determined to reach the subcutaneous position in subxyphoid region. Snare is secured at determined level of aperture patency that results in ideal early hemodynamics by placing multiple large metal clips at subcutaneous end of snare. This allows easy access to snare either early or late postoperatively for further aperture adjustment. Metal clips serve not only to stabilize snare but also as a convenient radiologic and tactile landmark, should early or late aperture adjustment be necessary.
the interatrial communication smaller. The residual aperture is adjusted to an appropriate size before closing the chest. In the intensive care unit (ICU), the aperture is made larger, smaller, or nonexistent by simply removing a few sutures from the skin and linea alba closure, removing clips holding the snagger in position, and repositioning and securing the snagger.

An alternative is a fixed fenestration in the lateral tunnel PTFE baffle. At operation, after the tunnel is placed in the atrium, a hole is made in equidistant from the two suture lines and somewhat inferior to the center of the tunnel. The hole is made with a 4-mm aortic punch for patients weighing less than about 12 kg, with a 5-mm punch for those weighing about 12 to 30 kg, and with a 6-mm punch for larger patients.\textsuperscript{524} Postoperatively, the patient is evaluated continuously for the possibility and proper time, if at all, for closure of the interatrial communication (see Special Features of Postoperative Care later in this section). When the time is appropriate, the patient is taken to the cardiac catheterization laboratory, where the communication is temporarily closed by a percutaneously inserted balloon; if the hemodynamic state remains good, the communication is closed permanently with a percutaneously inserted occlusion device.\textsuperscript{526} Otherwise, the communication is left open and closure is reconsidered later.

**SPECIAL FEATURES OF POSTOPERATIVE CARE**

Care usually given after intracardiac operations is appropriate (see Section IV of Chapter 5). However, some aspects of care are of particular importance.

Monitoring

The patient leaves the operating room with catheters in the IVC and left atrium as well as the usual arterial catheter. Not only are these devices useful in general management of patients after a complete or partial (bidirectional superior cavopulmonary shunt, hemi-Fontan, or fenestrated) Fontan operation, they also provide information critical to making rational decisions for patients who are not convalescing normally. Catheters in caval veins are removed as soon as possible.

General Measures

The patient is nursed in semi-Fowler’s position, and positive end-expiratory pressure is not used.\textsuperscript{911} Because of the adverse effect of positive intrathoracic pressure on $Q_p$, inspiratory ventilation pressures are kept as low as possible, and spontaneous breathing is encouraged as early as possible.\textsuperscript{78,810} Extubation is usually accomplished within 2 to 48 hours of operation. Stay in the ICU is usually 48 to 72 hours, rather than the usual 24 hours, because cardiac physiology is not fully normalized.

There is more than the usual tendency for fluid to leave the intravascular compartment and pass into the interstitial space and into the pleural, pericardial, and peritoneal cavities. The cause is multifactorial and includes increase in microvascular permeability resulting from CPB (if used), and at least mild increase in right atrial and caval pressures.\textsuperscript{\textsuperscript{510,14,227}} Because of this tendency for transcapillary fluid loss, 5% albumin or stable plasma protein solution may be necessary to maintain adequate ventricular loading.

Every effort is made to keep body cavities free of fluid and atrial and caval pressures low. Pleural effusions drain through the tubes placed at operation, and the wide opening made between the pericardial space and both pleural spaces prevents pericardial tamponade. On occasion, a peritoneal catheter may have to be inserted in the ICU to drain rapidly developing ascites.

Occasionally, serous drainage may insidiously become chylous, perhaps because the leaking microvascular pores gradually enlarge with time with passage of macromolecules, such that ultimately chylomicrons can pass.\textsuperscript{527} In any event, when the fluid becomes chylous, ligation of the thoracic duct rarely is useful, and surgical attempts to promote pleural symphysis often fail. Adequate tube drainage, high caloric intake, fluid restriction, and aggressive use of diuretics are the mainstays of treatment (see “Chylothorax” in Section II of Chapter 5). In cases of persistent chylous effusion, more aggressive measures can be effective in eliminating it. These include nothing by mouth (NPO) status, with all nutrition provided parenterally, and administration of synthetic somatostatin analogs such as octreotide.\textsuperscript{\textsuperscript{5}26,511}

Careful follow-up is required for at least 3 to 6 weeks. The tendency to fluid retention, hepatomegaly, and ascites may persist for most of this time, making sodium and fluid restriction and diuretic therapy necessary. Also, fluid retention and even chylous accumulations may appear to be mild during hospitalization, but with increased activity after hospital dismissal, larger accumulations of fluid or chyle may develop in body cavities. This may be recognized only when pulmonary or cardiac dysfunction appears to develop rather suddenly. If this occurs, immediate hospitalization and intensive treatment are necessary; these late accumulations can be rapidly fatal if untreated.

**Preventing Atrial Thrombosis**

Although atrial or Fontan pathway thrombosis is uncommon (see “Thromboembolic Complications” under Results later in this section), it is a serious complication warranting special consideration. It appears reasonable to believe that this is more apt to occur in patients with elevated Fontan pathway pressures or in those who are slow to recover because of chronic effusions or some other complication. Thus, patients in these categories are placed on warfarin therapy beginning about 3 days postoperatively and continuing for 6 to 12 weeks. Thereafter, lifelong therapy with aspirin (80 mg · day\textsuperscript{-1}) is advisable. It should be noted that for the atrio pulmonary Fontan, Fontan pathway thrombosis is atrial thrombosis; for the lateral tunnel Fontan, atrial thrombosis may be in the Fontan pathway or in the systemic side of the atrium; and for the extracardiac conduit Fontan, the atrium is completely excluded from the Fontan pathway and is not at risk for thrombosis.

Should acute thrombosis occur early postoperatively, particularly if it causes obstruction or is associated with pulmonary embolization, immediate surgical exploration, or in some cases thrombolytic therapy, is indicated.\textsuperscript{522}

**Strategic Importance of Fontan Pathway Pressure**

Patients often have a Fontan pathway pressure of 16 mmHg or less a few hours after entering the ICU, and they generally convalesce well. When pressure is higher than this, and
particularly when it progressively increases—often as a result of a need to augment blood volume to maintain cardiac output—a potentially lethal situation may be developing, and a thoughtful and prompt analysis is indicated. When a fenestrated Fontan operation has been performed, the warning sign may be severe arterial desaturation rather than elevation of Fontan pathway pressure. Narrowing the fenestration may simply substitute elevation of pressure for arterial desaturation; therefore, treatment strategies for these two developments are similar.

Treatment strategy for these patients first considers left atrial pressure (LA). If it is elevated to within a few mmHg of Fontan pathway pressure and if it too rises as the hours pass, main chamber ventricular dysfunction or AV valve dysfunction (regurgitation or stenosis) is probably etiologic to the poor hemodynamic state. PLA greater than 10 mmHg is not well tolerated, because this results in unacceptably high Fontan pathway pressure, even in the face of a normal Rp and transpulmonary pressure gradient. Two-dimensional echocardiographic examination in the ICU is indicated. If ventricular dysfunction is present, an increase in inotropic support may improve the hemodynamics. If new-onset AV valve regurgitation is present, reoperation and valve repair should be considered. If these efforts are unsuccessful or are not feasible, the only option is mechanical ventricular support in preparation for transplantation (see Chapter 21).

If Fontan pathway pressure remains 12 mmHg or more higher than PLA, and pulmonary arterial pressure is similarly elevated, then pulmonary vascular disease, pulmonary arteriolar spasm, or small size of pulmonary arteries may be responsible. The patient is hyperventilated to an arterial PaO₂ of 25 to 30 mmHg, arterial PaO₂ is maximized (short of having an FiO₂ of 1.0), and inhaled nitric oxide is initiated in a dose of 20 to 40 ppm. If these do not soon bring about improvement, it must be concluded that the problem is pulmonary vascular disease or small pulmonary arteries, and not pulmonary arteriolar spasm. Modification or takedown of the Fontan operation must be considered. Improved knowledge of stress-related metabolic and hormonal changes, and of inflammatory responses to surgery, may provide additional modes of therapy. Aprotinin has been associated with reduced Fontan pathway pressure.

If Fontan pathway pressure is high and left atrial and pulmonary artery pressures are not, then an obstruction exists in the newly created pathways. If Fontan pathway pressure is greater than 16 mmHg or if pressure increases as the hours pass, serious consideration must be given to reoperation for obstruction of the pathway. Echocardiographic or angiographic study may be desirable before the final decision is made.

Takedown or Modification of Fontan Operation

Under certain circumstances, and usually within 12 hours of operation, the hemodynamic state of the patient may be sufficiently poor that probability of survival seems low, and modification or takedown of the Fontan operation is advisable as an emergency procedure.

When a completed Fontan operation has been performed, takedown should be done as soon as circumstances requiring it are identified. These are a poor hemodynamic state and presence of an elevated pulmonary arterial pressure (greater than 18 mmHg) and elevated PLA (>10 mmHg) with a relatively normal transpulmonary pressure gradient. In the case of a lateral tunnel Fontan, after CPB and cardioplegia are established, the right atrium is opened and the patch placed to form the intraatrial tunnel is removed, resulting in a wide open interatrial communication. The cardiac end of the SVC is closed by a patch placed from within the right atrium. Essentially, this is conversion of a completed Fontan operation to a hemi-Fontan. The extracardiac conduit Fontan can be taken down simply by removing the conduit from the undersurface of the pulmonary artery and connecting it to the side of the right atrium. This procedure is performed using normothermic, beating-heart CPB with aortic and IVC cannulation. A large partial-occlusion vascular clamp is used to sequester the portion of the right atrial wall that will receive the IVC conduit.

When a poor hemodynamic state exists in the setting of elevated pulmonary artery pressure and low PLA—that is, an elevated transpulmonary pressure gradient—establishing a fenestration if one is not present or enlarging an existing fenestration or adjustable ASD may be beneficial. Following a complete lateral tunnel Fontan, this requires return to CPB, opening the right atrium, and creating an appropriately sized hole in the PTFE patch. If a complete extracardiac conduit Fontan exists, the communication can be performed without return to CPB by placing an 8-mm-diameter PTFE tube graft between the extracardiac conduit and right atrial appendage using partial occlusion vascular clamps to isolate segments of the conduit and the right atrium (see “Extracardiac Conduit Fontan with Deliberately Incomplete Atrial Positioning” under Technique of Operation earlier in this section). If an incompletely Fontan with an adjustable ASD had been performed originally, then opening the skin and fascia overlying the controlling snare around the ASD is performed and ASD size adjusted. If these maneuvers fail to improve the hemodynamic state, Fontan takedown is undertaken.

Fontan Operation with Deliberately Incomplete Atrial Partitioning

It has been hypothesized that some failures and deaths after a completed Fontan operation are due to temporary pulmonary vascular or parenchymal dysfunction (presumably related to the damaging effects of CPB) and to temporary myocardial dysfunction (presumably related to inadequate myocardial management). This hypothesis is supported by the finding of increased ventricular wall thickness (myocardial edema) and decreased ventricular compliance and volume immediately after the Fontan operation, with regression of these responses to surgery over the several weeks or months thereafter.

Thus, in the early postoperative period, when SaO₂ increases to 85% or greater and Fontan pathway pressure decreases to 15 mmHg or less, closure of the aperture by snugging down the suture controlling the adjustable ASD or by a percutaneously placed device may be considered. A valuable indicator that the incompletely Fontan operation can be made complete is cessation in formation of pleural effusions. With closure of the residual aperture, SaO₂ should approach 100%, but Fontan pathway and PLA responses can be variable. Fontan pathway pressure may increase to greater than 15 mmHg, PLA may decrease to less than 7 to 8 mmHg, and the cardiac index may fall, evidence that the aperture should be reopened. When Fontan pathway pressure
pressure remains at or less than 15 mmHg, and PLa remains sufficiently high that cardiac output remains good, the residual aperture can be permanently closed.

Although this general plan has often been successful, at times morbidity is increased by closing the residual aperture. In the early postoperative period, timing of atrial communication closure remains controversial. Delayed closure several months after the Fontan operation is practiced at many centers, and this strategy may be more prudent than one that attempts to close the communication in the postoperative period. In essence, there is little reason to close the communication early unless SaO2 decreases to unacceptable levels (<75%) in association with low pressure (<15 mmHg) in the pulmonary arteries, indicating that the communication is too large. Regardless of timing of closure, assessing hemodynamic consequences of closure should be made by temporarily closing the communication first. In some cases, hemodynamic response will suggest that the communication be left open permanently. Fenestration closure may benefit patients at midterm follow-up, however, others argue that patients are better off with the fenestration left open.

RESULTS

Completed Fontan Operation

A considerable body of knowledge is available about early and late results after completed Fontan operation. Effects of temporary or permanent partial Fontan operations, of lateral tunnel and extracardiac conduit variations, and of minimal use or avoidance of CPB have been documented at early but not late follow-up.

Survival

Early (Hospital) Death Thirty-day or hospital mortality has improved over the past decade and currently is 0% to 4%, substantially better than earlier reports of about 20% in heterogeneous groups of patients. Improvement in survival is documented both in series that report Fontan operations performed exclusively in more recent calendar years and in series that cover a wider range of calendar years in which improved survival is documented for more recent calendar years. Equal results have been achieved with extracardiac conduit and lateral tunnel techniques, and with the entire spectrum of CPB management techniques, from off-pump series to series using hypothermic circulatory arrest.

Time-Related Survival Overall, in heterogeneous groups of patients undergoing completed Fontan operation in the time period from approximately 1970 to 1985, 5-, 10-, and 15-year survivals, including early mortality, were about 70%, 65%, and 50%, respectively. In a series of 216 tricuspid atresia patients undergoing the Fontan over a 25-year period at the Mayo Clinic, overall survival was 79%.

Outcomes improved substantially within each decade of this experience, with 56/59 patients alive from the final decade. Long-term follow-up is becoming available for more recent patients who have undergone a bidirectional superior cavopulmonary shunt (bidirectional Glenn or hemi-Fontan) followed by a lateral tunnel or extracardiac conduit total cavopulmonary Fontan. Midterm survival is markedly improved, with 1- to 5-year survival approaching and exceeding 90%.

Survival after a “Perfect” Fontan Operation Because many deaths after the Fontan operation have been due to circumstances that can be avoided in the present era, the persistent and rising hazard function for death (see Fig. 41-30, B) could be a result of now avoidable circumstances. However, analysis of survival under circumstances that can be considered ideal indicates that the late, slow-rising phase of hazard is still present (Fig. 41-32, A). Under ideal circumstances, 15-year survival is predicted to be 73% (Fig. 41-32, B), a prediction supported by the experience of others.

A recent analysis revisiting the idea of the perfect Fontan shows that in the modern era, using an extracardiac conduit for the Fontan, outcomes equal to that predicted by Fontan and colleagues.
colleagues’ original “perfect Fontan” equations can be achieved routinely in all patients. Other recent series document 10-year survival superior to that achieved with the classic “perfect Fontan” (see Fig. 41-31). These data simply reflect the gradual improvement in outcome that has occurred over the last 2 decades.

Declining survival late postoperatively and rising late hazard for death under good circumstances are different from those after repair of tetralogy of Fallot (see “Time-Related Survival and the Question of ‘Cure’” under Results in Section I of Chapter 38), as is the gradually declining functional capability after the Fontan operation (Fig. 41-33). These suggest that the Fontan operation should be considered an excellent palliative operation but not a curative one. The fact that no risk factors (other than older age at operation) have been identified for the late phase of hazard suggests that this is related to the circulatory state after the Fontan operation. This state may predispose to subtle morphologic and functional changes in the pulmonary circulation similar to those that occur after the bidirectional superior cavopulmonary shunt. Also, there may be gradual deterioration of structure and function of the congenitally abnormal ventricular chamber. The latter could be contributed to by high coronary sinus pressure, unless it has been diverted into the left atrium. Also, additional congenital cardiac and myocardial anomalies are common in the univentricular hearts of patients who undergo the Fontan operation, and these may gradually impair cardiac function as time passes. It remains to be seen whether the proposed advantages of the extracardiac-conduit Fontan procedure—which removes the atrium from the Fontan circuit, avoiding right atrial foreign material and suture, eliminating myocardial ischemia at operation, and removing the coronary sinus from the Fontan circuit—will result in improved laminar flow, reduced dysrhythmias, preserved ventricular function, and reduced thrombotic and obstructive complications, thereby reducing the slope of the late hazard phase.

**Figure 41-31** Freedom from Fontan failure, including death, take-down, and transplantation, after 216 extracardiac conduit Fontan procedures. Vertical bars are 70% confidence limits. (From Petrossian and colleagues.)

**Figure 41-32** Survival after a “perfect” Fontan operation. Solid lines are parametric estimates enclosed between 70% confidence limits. Dash-dot-dash line represents estimates for a matched general population. A, Nomogram of predicted hazard function for death. Equation for nomogram is based on multivariable risk factor equation (see Table 41-4), entering optimal values within the realm of realism for each risk factor. Details are described in the publication. Note that greatly expanded vertical axis makes hazard function appear to be higher than that of Fig. 41-30, B; in fact, it is lower. B, Corresponding predicted survival. (From Fontan and colleagues.)

**Figure 41-33** Time-related New York Heart Association (NYHA) functional class of patients after Fontan operation. Parentheses enclose number of patients followed up within intervals. Squares, circles, and triangles represent actual percentages; solid lines are parametrically determined percentages, with dashed lines enclosing 70% confidence limits around the percentages for NYHA classes I and III (see “Longitudinal Outcomes” in Section IV of Chapter 6). (From Fontan and colleagues.)
Modes of Death
For patients undergoing the Fontan operation in the 1970s and 1980s, acute cardiac failure early postoperatively was the most common mode of death. Chronic cardiac failure, which first appears several years before death, and sudden death are the most common modes late postoperatively.

Assigning a mode of death after a Fontan operation is difficult because of frequent occurrence of fluid retention, which may have obvious hemodynamic causes (e.g., myocardial failure, elevated Rp, Fontan pathway obstruction) or may occur in the absence of any specific hemodynamic abnormality other than the existence of the Fontan itself. This fluid retention often appears primarily as persistent accumulations of pleural fluid or, less often, of ascitic or pericardial fluid. This tendency has been shown to be considerably less when a bidirectional superior cavopulmonary shunt has preceded the Fontan procedure.\(^2\) In any event, in only about 10% of patients who die does persistent fluid accumulation in pericardial, pleural, or peritoneal spaces without hemodynamic insufficiency appear to be the mode of death (Table 41-3).

Incremental Risk Factors for Death

Acute Ventricular Decompression An important potential risk factor still remains to be investigated: namely, sudden “decompression” of the ventricular chamber by the Fontan operation. Decompression at the time of Fontan can be avoided by surgical staging, as described in this chapter, using one of two techniques: bidirectional superior cavopulmonary shunt or a hemi-Fontan operation.\(^4\) In this case, decompression is achieved at the time of second-stage palliation (see Section III), not at the time of the Fontan operation. It has not been shown definitely that avoiding ventricular decompression at the time of the Fontan improves outcome.

Deterioration The incremental risk factor for a late rising phase of hazard for death may be the post-Fontan state. It may result from:

- Long-standing nonpulsatile pulmonary artery flow generated by the systemic venous pressure
- Abnormality of the dominant ventricle per se

The latter may be an immutable congenital anomaly or may be acquired during postnatal life, either from the abnormal hemodynamic state existing before Fontan repair or from myocardial ischemia at previous operations. (A similar late-rising phase of hazard occurs in patients with discordant AV connection undergoing a two-ventricle repair.)

Younger Age at Operation In older studies, younger age at time of the Fontan operation was a risk factor for death (or complete takedown of a Fontan operation) early after operation\(^6,26,F14,E20\) (Table 41-4). The nature of the relationship was such that risk of death (or takedown) early postoperatively began to increase as age of operation approached 3 years, and then increased more steeply as age was reduced to younger than 2 years\(^6,F14,M23\) (Fig. 41-34). Good results can be obtained from performing the Fontan operation in infants and children younger than 2 years, yet the probability of surviving has been documented to be less than in older patients\(^,M23,M24,W5\). It should be emphasized, however, that this documentation is now 15 to 20 years old.

Certainly, mortality of 55% for patients younger than 4 years\(^M24\) in older reports is no longer the case.\(^M23,M58,S37\) The incremental risk of young age may have been neutralized by staged, fenestrated, incompletely Fontan operations, and by avoiding use of CPB, although this is not yet fully documented\(^E4,M50\).

Older Age at Operation Older age at operation is not a risk factor for death early postoperatively.\(^H20\) Burkhardt and colleagues\(^B33\) report an 8.3% operative mortality, Otrovskii and colleagues\(^G11\) and Veldtman and colleagues\(^V7\) 13%, and Fujii and colleagues\(^F30\) 4%, when operation is performed in

Data from Fontan and colleagues.\(^1\) Shaping parameters and coefficients are in original publication.\(^1\) Key: AV, Atrioventricular; PT, pulmonary trunk; RA, right atrium; RV, right ventricle.
selected adults. It slightly increased risk of death late after the Fontan operation (Fig. 41-34, B) in one study, but this was not found by others.\textsuperscript{26,34b,77}

**Cardiac Morphology** Cardiac morphology has been reported to be importantly related to outcome after the Fontan operation; specifically, tricuspid atresia has been found to have more favorable outcomes than other anomalies, and all anomalies with the morphologic LV as the main chamber have been reported to have more favorable outcomes than those with a right or indeterminate main ventricle.\textsuperscript{6,8,26,29,319,24,78} There are exceptions; three studies found no influence of ventricular morphology on outcome.\textsuperscript{41,316,176}

A related morphologic feature that has also been identified as a risk factor is left AV valve atresia.\textsuperscript{12} (see Table 41-4). This may not be a morphologic risk factor per se, but rather a morphologic arrangement that until recently resulted in use of a complex baffle for partitioning the atria. Such baffles often resulted in some obstruction of the pulmonary venous pathway to the right or a common AV valve, and this probably was the true risk factor.\textsuperscript{12} Various forms of total cavopulmonary connection, including the extracardiac conduit and lateral tunnel Fontan techniques (see Figs. 41-27 and 41-28), have overcome this problem, and left AV valve atresia may not be a risk factor in the future.

**Small Size of Central Right and Left Pulmonary Arteries** Small size of central right and left pulmonary arteries has been identified by some as a risk factor for death (or takedown) early after the Fontan operation,\textsuperscript{14} although others have not found this to be so.\textsuperscript{22} As is often the case, the controversy may relate to differing patient populations, patient data, and surgical techniques. In nearly all studies, only the prebranching pulmonary artery dimensions have been studied. If small size is limited to prebranching portions of right and left pulmonary arteries and if these portions are enlarged by patch-grafting at Fontan repair, one may expect to find little relationship between small size and outcome, as was the case in the study of Bridges and colleagues.\textsuperscript{27} Failure to perform surgical enlargement may leave small pulmonary artery size as a risk factor. Thus, according to the combined University of Bordeaux–UAB experience, when the prebranching portions of the right and left pulmonary arteries are small (McGoon ratio less than about 1.5 [see Figs. 1F-1, 1F-2, and 1F-3 in Chapter 1]), a z value of less than about −3.5, or a cross-sectional area index [Nakata index] of less than about 160 mm\(^2\) \(·\) m\(^3\), risk of early death is increased\textsuperscript{14} (Fig. 41-35). Nakata and colleagues suggested, as a more restrictive guideline for considering patients at high risk, an index of less than 250 mm\(^2\) \(·\) m\(^3\).\textsuperscript{22} However, rarely was augmentation of the central pulmonary arteries performed in these patients.

By contrast, the Mayo Clinic group has suggested that size of right and left pulmonary arteries measured in the operating room is not related to outcome, even when augmentation is not done. However, the patients on whom they made measurements were selected based on not having small pulmonary arteries, so inferences about small size are not possible from their data. There are few studies relating size of pulmonary arteries measured after enlargement to outcome.

If pulmonary arterial narrowing extends into more distal portions of right and left pulmonary arteries, their small sizes may be a risk factor for death. Pulmonary artery “distortion” was found to be a powerful risk factor for death, but such distortion has been uncommonly found.\textsuperscript{37,23,148}

**Elevated Pulmonary Artery Pressure and Pulmonary Vascular Resistance** Elevated mean pulmonary artery pressure (Ppa) and Rp have been known to increase risk of the Fontan operation since Choussat and colleagues’ classic paper;\textsuperscript{21} this has been confirmed in subsequent studies.\textsuperscript{8,29,26,24,12} Risk is particularly elevated when Ppa is greater than 15 to 20 mm Hg, unless the elevation is explained by a large Qp or important AV valve regurgitation. Rp would be expected to predict outcome more precisely, but in many patients it is difficult to measure determinants of this value, and the value is not highly sensitive to presence of multiple peripheral thrombi.\textsuperscript{12} Nonetheless, with Rp greater than 2 to 4 units \(·\) m\(^2\), probability of good outcome is less.\textsuperscript{8}

**Advanced Main Chamber Ventricular Hypertrophy** Advanced main chamber ventricular hypertrophy and increased muscle mass is an important risk factor for death,\textsuperscript{26,24,14,50,12} (see Table 41-4). Early survival (out to 6 months) after a Fontan operation in a 5-year-old child with favorable features and mild LV hypertrophy is estimated to be 99%, but it is 78% when moderately severe LV hypertrophy
is present. This risk factor adversely affects ventricular compliance (diastolic function) and, when advanced, systolic function as well. These observations have led to the widely held current practice of aggressive surgical relief of ventricular outflow obstruction in the staging of patients with single-ventricle physiology (see Section III). Although not advisable, relief of ventricular outflow obstruction can be performed simultaneously with the Fontan.

Atrial Isomerism Atrial isomerism (see Chapter 58), with its usually concurrent asplenia or polysplenia, has been identified as a risk factor for death. This risk factor may relate in large part to abnormal systemic venous connections to the heart, and these may be neutralized by modifications of surgical technique (see “Persistent Left Superior Vena Cava with Hemiazygos Extension of Interior Vena Cava” under Special Situations and Controversies later in this section). Recent techniques may have neutralized the risk of heterotaxy. Early mortality in 21 patients undergoing operation from 1995 to 2004 was only 9.5% (2 deaths; CL 3.3%-21%), and 10-year survival of a larger cohort of 142 patients from the same series was 57%. In other studies, recent experience defines the risk of early mortality at 0% to 13%. Risk may also relate to dysfunction of the common AV valve, which is often present.

Functional Status Many patients consider themselves fully active after the Fontan operation; it was previously reported that 94% of patients are in New York Heart Association (NYHA) functional class I or II. Now that intermediate-term follow-up information is available out to at least 20 years, it is known that NYHA functional class gradually deteriorates. Nearly 90% of patients are in NYHA functional class I at 1 year after operation, but this is true in only about 56% of patients at 10 years (see Fig. 41-33). This information supports the inference that the Fontan operation is a palliative procedure, with increasing disability developing in some patients by 10 years and in an increasing percentage thereafter. In patients with lateral tunnel or extracardiac conduit connections, exercise capacity is also well below normal, and
daily activity limitations are related to older age, further supporting this inference.\textsuperscript{244,213,215} Other variables may affect functional status. In a large multicenter study, the extracardiac conduit Fontan was noted to have better functional status than the lateral tunnel Fontan as measured by oxygen consumption during exercise testing.\textsuperscript{214} In the same study, LV morphology also was associated with better functional status than either RV or indeterminate ventricular morphology. In a large multicenter evaluation, the presence of heterotaxy did not affect functional status.\textsuperscript{212} The study by Shiraiishi and colleagues suggests that in patients undergoing an extracardiac conduit Fontan, earlier age at completion of the procedure results in better long-term hemodynamics and exercise capacity.\textsuperscript{216} In contrast, the study by Napoli and colleagues found no differences based on age at which the Fontan was performed.\textsuperscript{217} Whether the RV is incorporated into the Fontan circuit or not, pharmacologic afterload reduction does not improve exercise tolerance.\textsuperscript{218,219} Others have documented subnormal performance on objective exercise testing in patients who claim unrestricted activity with complete absence of symptoms. Nevertheless, subnormal performance represents a considerable improvement over preoperative status.\textsuperscript{219,220,221,222} Exercise capacity is severely restricted in Fontan patients at moderately high altitudes.\textsuperscript{215}

Somatic growth does not improve after the Fontan operation if the patient had previously undergone a bidirectional superior cavopulmonary shunt, mainly because catch-up growth has already occurred (somatic growth does improve after the bidirectional superior cavopulmonary shunt, demonstrating catch-up growth that was lost during the volume overloaded previous state).\textsuperscript{211}

\textbf{Hemodynamic Status}

Notwithstanding good functional status in most patients for at least several years after the Fontan operation, objectively studied hemodynamic state is usually subnormal.\textsuperscript{219,220,221,222} Peterson and colleagues, studying 16 patients (5 of whom had a valve used in the Fontan repair) with average follow-up of 25 months, found that resting and exercise cardiac indexes were not different from those of healthy children.\textsuperscript{219} The mechanism used by the patients to achieve high cardiac outputs during exercise was an increase in heart rate. However, ventricular ejection fraction was low, 0.45 ± 0.11 at rest and 0.51 ± 0.13 at peak exercise, and ventricular end-diastolic volumes were considerably greater than those of healthy children. Findings by Shachar and colleagues were similar, indicating reduced ejection fraction and increased left ventricular end-diastolic volume at rest and exercise.\textsuperscript{214}

An important aspect of the hemodynamic state after the Fontan operation is increase in Fontan pathway pressure during exercise.\textsuperscript{214,215} Its elevation can lead to reflux into caval and hepatic veins during atrial systole.\textsuperscript{220} Observant patients occasionally note that garments become tight around the waist during exercise, presumably because of increased Fontan pathway pressure and hepatic swelling. Qp is biphasic after the atroipulmonary Fontan operation, from both right atrial relaxation and contraction as well as left atrial emptying into the main ventricular chamber.\textsuperscript{212,214,215,219}

Not surprisingly, the respiratory cycle strongly affects Qp after certain types of Fontan operations, and perhaps after all types.\textsuperscript{119} Qp is increased with normal inspiration and is considerably augmented during strenuous inspiration. It is nearly stopped during the Valsalva maneuver.

Ventricular morphology influences hemodynamics. The presence of LV morphology results in better ejection fraction, AV valve function, and semilunar valve function compared with right or indeterminate ventricular morphology.\textsuperscript{214}

De Leval and colleagues have studied flow characteristics of the total cavopulmonary connection, finding that laminar flow is maintained to a greater extent when SVC and IVC pulmonary artery connections are offset, avoiding direct collision of the two bloodstreams, and when 90-degree angled configurations of the cavopulmonary connections are avoided.\textsuperscript{218} Experimental studies have shown that the extracardiac conduit connection provides superior hemodynamics when compared with either the atriopulmonary or lateral tunnel connection\textsuperscript{219}; clinical studies have not been performed. Using three-dimensional phased-contrast MRI in the clinical setting, altered flow patterns in the pulmonary arteries were found equally in atriopulmonary and lateral tunnel Fontans.\textsuperscript{219,220} Extracardiac conduit Fontans were not evaluated.

\textbf{Cardiac Rhythm}

Importance of sinus rhythm postoperatively remains arguable, primarily because of uncertainty about hemodynamic events after the Fontan operation. There is little doubt that sinus rhythm enhances performance of the main ventricular chamber, because of “atrial kick.” Dynamics of flow from cavae to pulmonary arteries are less firmly established. Acute animal experiments of Matsuda and colleagues and of Shemin and colleagues indicate that loss of sinus rhythm does not alter flow through an atriopulmonary conduit regardless of whether it contains a valve.\textsuperscript{220,211} However, using Doppler techniques, Bull and colleagues showed that in patients with an atriopulmonary connection, pulmonary flow accelerates during atrial systole.\textsuperscript{212} This was also observed by Ishikawa and colleagues using low-pressure contrast injection into the pulmonary artery.\textsuperscript{17}

Although sinus rhythm may not have a demonstrable direct effect on flow from right atrium to pulmonary arteries, it may influence this flow indirectly by permitting a lower PLa than otherwise would be the case. Also, because sinus rhythm seems to provide at least some pulsatility in the pulmonary arterial circulation, it may be advantageous in minimizing late changes in the pulmonary circulation. Loss of sinus rhythm and other supraventricular dysrhythmias, especially atrial flutter, are common after the atriopulmonary Fontan and increase with longer follow-up.\textsuperscript{15,19} Freedom from supraventricular tachydysrhythmias at 20 years after the atriopulmonary-type Fontan can be as low as 46%. Electrophysiologic ablation procedures are initially successful, but recurrence is common.\textsuperscript{219}

The lateral tunnel Fontan is also associated with a high prevalence of loss of sinus rhythm in some studies.\textsuperscript{210,213,216} In contrast, one study finds a greater loss of sinus rhythm in extracardiac conduit than in lateral tunnel Fontans; however, the follow-up period was almost twice as long in the extracardiac conduit group, putting the validity of this comparison into question.\textsuperscript{219} Experimental work in animal models suggests that the foreign body and suture line inherent in the lateral tunnel and hemi-Fontan techniques can induce supraventricular rhythm disturbance.\textsuperscript{22,26} Early and midterm follow-up studies indicate that loss of sinus rhythm and
other supraventricular dysrhythmias are markedly reduced following the extracardiac conduit Fontan compared historically with lateral tunnel and atrio pulmonary Fontan operations. It should be emphasized, however, that randomized and long-term follow-up studies are not available.

Loss of sinus rhythm and occurrence of supraventricular dysrhythmias may have complex etiologies and likely are not exclusively the result of the type of Fontan connection. Influence of previous operations, such as atrial septectomy or AV valve repair or replacement, myocardial ischemia from prior insults both intraoperatively and perioperatively, type of superior cavopulmonary connection (bidirectional superior cavopulmonary shunt vs. hemi-Fontan), and prior hemodynamic circumstances (chronic volume loads or obstructions) are all likely to affect atrial rhythm.

Sudden death has occurred in some patients late after operation (see Table 41-3). Multiform premature ventricular contractions appear to be present late postoperatively in about one third of patients and asymptomatic bradycardia in about 20%. These findings suggest that disturbances of cardiac rhythm may cause some late failures of the Fontan operation. Many of the factors mentioned in the previous paragraph may influence ventricular rhythm as well.

Complete heart block is rare after the Fontan operation.

Abnormalities of Pulmonary Circulation
Decrease in upper-to-lower lobe pulmonary blood flow perfusion ratio was observed by Cloutier and colleagues in most patients after the Fontan operation, similar to that seen in those who had undergone the classic Glenn operation (see “Classic Glenn Operation” under Special Situations and Controversies in Section 1). To date, however, pulmonary arteriovenous fistulas have been observed uncommonly after the Fontan operation.

A longer interval between operation and time of observation clearly increases prevalence of pulmonary arteriovenous fistulas after a classic Glenn operation. Thus, long follow-up is required to document the impression that this complication is uncommon.

Nevertheless, it is becoming increasingly clear that pulmonary arteriovenous fistulas are much less likely to form following Fontan completion. There is increasing anecdotal evidence that fistulas that form after a bidirectional superior cavopulmonary shunt regress following the Fontan. Pathophysiology of these fistulas remains elusive, and various etiologic factors have been suggested, including reduced Qp, nonpulsatile flow, cyanosis, and lack of splanchnic venous blood in the pulmonary circulation. Using contrast echocardiography, a sensitive method for identifying pulmonary arteriovenous fistulae, it has been shown that patients with single-ventricle physiology at any stage in their surgical reconstruction—that is, at the stage with completely mixed circulation with a systemic–pulmonary arterial shunt or at the stage with a bidirectional superior cavopulmonary shunt—were more likely to show evidence of fistulae than patients with isolated circulations. Echocardiographic evidence of fistulae, however, did not necessarily predict clinical cyanosis.

Protein-Losing Enteropathy
An important complication of the Fontan operation is protein-losing enteropathy. It is characterized by depressed serum albumin concentration with no obvious cause. It may be suggested by late postoperative onset of generalized edema and pleural or peritoneal fluid accumulations. Patients may or may not have diarrhea. Antitrypsin clearance is abnormally high, and because of low serum protein, total serum calcium is abnormally low. Special studies show excessive loss of serum proteins from the gastrointestinal tract; endoscopic investigations show prominent lymph vessels in the jejunal mucosa. This gastrointestinal protein loss occurs before clinical evidence of protein-losing enteropathy.

About 13% of patients develop evidence of protein-losing enteropathy by 10 years, and interval between operation and its appearance ranges widely, from 1 month to 16 years. Protein-losing enteropathy is associated with death, with near 50% mortality 5 years after diagnosis.

Protein-losing enteropathy is not limited to patients who have undergone the Fontan operation. It has been reported in almost all situations in which there is chronically elevated central venous pressure, including heart failure, chronic constrictive pericarditis, and atrial switch operations for transposition of the great arteries. It has also been observed in patients who have undergone SVC-RPA anastomosis and in patients with isolated SVC obstruction after an atrial switch operation. Presumably, the combination of increased lymph production from increased IVC pressure and impaired lymph drainage from increased SVC pressure contribute to this complication. Other potential influences are an elevated systemic inflammatory state and changes in mesenteric vascular resistance.

It may be relieved by reoperations that result in a lower right atrial pressure, such as when bidirectional superior cavopulmonary shunt or Fontan revisions are used to relieve systemic venous pathway obstruction. However, there is considerable early mortality after reoperation.

Correcting other hemodynamic abnormalities when right atrial pressure is low has resulted in regression. Creating a late fenestration has been reported to result in resolution of protein-losing enteropathy in three of five cases. Nonsurgical therapy, including use of steroids and heparin, has been associated with its resolution. Resolution has been reported after pacemaker placement in two patients with sinus node dysfunction, and in two patients following diaphragm pllication for phrenic nerve palsy. In a multicenter study, transplantation was found to effectively reverse protein-losing enteropathy.

Thromboembolic Complications
The cumulative occurrence of thrombotic complications ranges from 3% to 16%, and of embolic complications from 3% to 19%, according to a recent literature review. However, essentially all the primary reports reviewed involved patients predominantly receiving their operation prior to the modern era. Most of the studies indicate that these complications occur either early, within the first year after the Fontan, or late, beyond 10 years after surgery. Massive thrombi may form in the right atrium, particularly in atriopulmonary Fontan connections. Thus, in about half of the few cases reported, thrombi developed within a few weeks of operation; in the other half, they became evident a number of years later. Although infrequent, occurring early or over the intermediate term in about 10% of patients, this complication is of importance because a large thrombus or a piece of it may migrate from the right atrium and occlude the Fontan anastomosis or fill the RV or pulmonary arteries with sufficient thrombi to be fatal. Recently, a high prevalence of
thrombus has been documented in the Fontan pathway when this complication was sought by routine echocardiography in asymptomatic patients, and embolic complications have been reported as high as 29%.\textsuperscript{155} Presumably, slower-than-normal flow through the cavae and presence of foreign material predispose patients to thrombus formation and subsequent embolization. However, acquired abnormalities of the clotting system may be involved. In a study of this specific problem, the most common and most pronounced of these was a presumably acquired deficiency of protein C.\textsuperscript{156} Additional deficiencies in proteins and factor VII have been identified, which may relate in part to chronic impairment of liver function.\textsuperscript{157-159} The extracardiac conduit and lateral tunnel Fontan techniques currently favored by most centers may reduce thrombotic complications by maintaining laminar flow and reducing stasis. At mid-term follow-up, the risk of thrombosis is almost nonexistent in a large series of extracardiac conduit Fontans.\textsuperscript{160}

**Neurologic Complications**

Neurodevelopmental outcome is reported to be generally within the normal range.\textsuperscript{161-163} Thromboembolic cerebrovascular events have been reported, but their true prevalence is not known. Association of these events with ligated pulmonary artery segments and with fenestrations have been cited.\textsuperscript{164,165} Intracerebral venous thrombosis has been reported. Overall prevalence of stroke ranges from 3% to 9% over a 15-year period.\textsuperscript{166}

**Desaturation after Fontan**

Early and late systemic desaturation can occur from various systemic venous channels connecting to the pulmonary veins, coronary sinus, or left-sided atrial structures that may become manifest immediately or develop over time.\textsuperscript{167,168,169} Evaluation with cardiac catheterization is indicated to distinguish these entities from lung disease or intrapulmonary arteriovenous malformations, and to define specific morphology of the venous connections. Surgical or interventional closure of the connection is indicated.

**Reoperation**

**Takedown**

Reoperation for takedown of the Fontan operation has been necessary in a few patients in whom death has seemed otherwise inevitable. In earlier eras, risk of takedown (with substitution of a systemic–pulmonary arterial shunt) has been high, with 3 of 7 patients dying after the procedure in the combined University of Bordeaux–UB experience (43%; CL 20%-68%).\textsuperscript{170} Most of these patients were seriously ill when takedown was performed.

Mayer and colleagues also reported a high mortality (100%; CL 79%-100%) among 8 patients treated in this manner, but 2 survived and did well after takedown to a bidirectional superior cavopulmonary shunt (0%; CL 0%-61%).\textsuperscript{171} With this latter type of takedown, results in the future may be better (see “Takedown or Modification of Fontan Operation” earlier under Technique of Operation).

**Reoperation for Pathway Obstruction**

Reoperation for pathway obstruction has been the most common type of reoperation after the Fontan operation, and freedom from it has not been as high as desirable\textsuperscript{172} (Fig. 41-36). Furthermore, in this group of patients, instantaneous risk of requiring reoperation for pathway obstruction increased throughout follow-up, suggesting that with certain techniques of creating these pathways (see text that follows), nearly all patients will at some time require surgical revision of the pathway.\textsuperscript{173} Hospital mortality after reoperation has been high: 5 of 21 patients (24%; CL 14%-37%) in the University of Bordeaux–UAB experience.\textsuperscript{174} However, among hospital survivors, late survival and functional status have been as satisfactory as after the original Fontan operation. Need for reoperation for pathway obstruction has varied considerably, depending on the type of Fontan operation. Direct nonvalved connections between right atrium and either RV or pulmonary trunk have had a low prevalence of reoperations for pathway obstruction (Table 41-5), specifically, 4 instances among 200 patients (2%; CL 1%-3.6%). By contrast, 17 of 134 patients (13%; CL 9.6%-16%) receiving conduit connections, either valved or nonvalved, underwent reoperations for pathway obstruction.\textsuperscript{175} Pathway obstruction has not been evident following the extracardiac conduit and lateral tunnel Fontans, but follow-up has been shorter than for older procedures.\textsuperscript{176,177,178}

**Other Reoperations**

In about 5% of patients undergoing the atripulmonary Fontan operation for double inlet ventricle, closure of the right-sided AV valve dehisced and required reoperation.\textsuperscript{179} Likewise, re-repair of the ASD has been required in about 2% of patients. Cardiac transplantation was required late postoperatively in four patients in the combined University of Bordeaux–UAB experience for progressive myocardial failure.\textsuperscript{180} This final form of treatment may be required with increasing frequency in the future.

Data from Fernandez and colleagues.15

Key: RA, Right atrial.

As the extracardiac conduit and lateral tunnel Fontan procedures have come into favor, they are being used with increasing frequency to revise atrio-pulmonary and AV Fontan connections. Indications include obstruction in the systemic venous Fontan pathway, thrombus formation in the right atrium, right pulmonary vein compression, and atrial dysrhythmias.18,42,46 Use of the maze procedure, its modifications (see “Maze III Procedure” and “Modified Maze Procedures” under Results in Section IV of Chapter 16), or intraoperative cryoablation may be indicated in a substantial portion of these patients.621 These Fontan revisions have achieved substantial improvement in almost all patients. Operative mortality is about 10%.411 It has been suggested from experimental studies that simply performing a bidirectional superior cavopulmonary shunt in patients with an atrio-pulmonary Fontan and dilated right atrial chamber and impaired hemodynamics may be beneficial, although there are no clinical data to support this.411

Fontan Operation with Deliberately Incomplete Atrial Partitioning

A number of operations have evolved that, despite their name, are not a Fontan operation. They have in common partial diversion of systemic venous blood to the pulmonary arteries and thus, an incomplete separation of pulmonary and systemic circulations. Some are intended as preliminary procedures to a Fontan operation, whereas others, such as the permanently “fenestrated Fontan,” replace the Fontan operation. Results of these operations have to be considered separately from those of a completed Fontan operation, although it is not yet known whether they are different.

The Fontan operation with deliberately incomplete atrial partitioning (fenestrated Fontan, Fontan with adjustable ASD) is difficult to evaluate because of the small number of patients in whom it has been performed and absence of risk-adjusted comparisons with other approaches. Early mortality has been 0% to 5%.29,31,34,38,52 Early closure of the residual aperture has been possible in at least 50% of patients, but this proportion, as well as the early and late results, varies according to characteristics of the patients being operated on and policies of the responsible physicians.29 Both techniques, the method of Laks and colleagues44 and that of percutaneous catheter closure,518 are well controlled and achieve secondary closure of the residual aperture (when this is elected) with low risk and good success. Late results of the specific subgroup of patients receiving permanently fenestrated Fontan operation have not yet been determined.

INDICATIONS FOR OPERATION

Fontan Operation

Most patients will have previously undergone palliative operations as newborns and again later in infancy, although a small group will have undergone one or no previous procedures. The Fontan procedure is rarely performed before age 1 year and typically not before age 18 to 24 months. Certain physiologic and morphologic criteria must be met for the Fontan to succeed. Currently, there are no clear indications for specifically performing either the extracardiac conduit Fontan or the lateral tunnel Fontan, although there is general consensus that these forms of total cavopulmonary Fontan are preferred over variations that include the right atrium.21,31,34,38,42 Despite lack of established superiority of one or the other of these, important differences between the two operations exist.39,713 These differences may ultimately be found to be important factors influencing outcome (see “Extracardiac Conduit versus Lateral Tunnel Fontan” in Special Situations and Controversies).

Many criteria, classically expounded by Choussat, Fontan, and colleagues, for performing a completed Fontan operation are arguable.21 However, Rp greater than about 4 units · m² seems a clear contraindication. Pathologic data from lung biopsy have not aided in making this decision.518 When Rp is 2 to 4 units · m², a bidirectional superior cavopulmonary shunt (or a hemi-Fontan procedure21) or a fenestrated Fontan operation rather than a completed Fontan operation may be indicated (see Section III). If subsequent evaluation confirms adequacy of the pulmonary vascular bed, the preliminary procedure can be converted to a total cavopulmonary connection. Evaluation of Qp and Rp should be performed shortly before the intended Fontan procedure, because they can be affected over time by factors such as chronic pulmonary microemboli.67

When branches of right and left pulmonary arteries are small, a Fontan operation will probably not succeed, although it can be argued that this should be the case only if they are small enough to cause elevation in Rp.513 For these cases, only
Because two thirds of all Fontans are extracardiac conduits, this indicates that many extracardiac conduit Fontans are also being fenestrated. It is not clear from the STS report whether it is primarily the extracardiac conduits performed using CPB that are receiving a fenestration, or whether particular institutions and surgeons are using the fenestration independent of CPB management. The lateral tunnel Fontan requires full CPB, hypothermia, and aortic clamping with administration of cardioplegia, and thus patients undergoing this procedure typically have perioperative perturbations in ventricular filling pressure and Rp. Most institutions that routinely perform the lateral tunnel Fontan use incomplete atrial partitioning, but some never do.

The argument remains whether a fenestrated Fontan operation should be done as a routine procedure or only in high-risk situations. In any event, use of some form of incomplete atrial partitioning seems advantageous in high-risk patients, especially when CPB is used to perform the procedure.

**SPECIAL SITUATIONS AND CONTROVERSIES**

**Definitive Palliation Other Than Fontan Operation**

Although the predominant view is that the Fontan is the best available definitive palliation for patients with single-ventricle physiology, few or no definitive data support this view. Some studies suggest that final palliation in the form of superior cavopulmonary shunt or aortopulmonary shunt provide long-term palliation that compares favorably with the Fontan.\(^7\)

**Conversion of Atriopulmonary Fontan to Cavopulmonary Fontan Operation**

Increasingly, patients who have previously undergone Fontan surgery with atriopulmonary connections of various kinds present with complications specifically related to them, including giant right atrium, right atrial thrombosis, compression of right pulmonary veins, atrial dysrhythmias, and obstruction at the atriopulmonary connection. They may present for Fontan revision, but only if ventricular function and Rp are adequate to sustain the Fontan circulation once the complications described previously are surgically addressed (if ventricular function is compromised and it is not due to a surgically correctable hemodynamic cause, or if the Rp is elevated, the only option is transplantation\(^11,18\)). The Fontan conversion operation entails removing the atriopulmonary connection and creating either an extracardiac conduit IVC–to–pulmonary artery connection or a lateral tunnel inferior cavopulmonary connection. Additionally, atrial reduction plasty, thrombus removal, and atrial dysrhythmia surgery, such as a formal maze procedure or one of its modifications (see “Interruption of Macro-reentrant Circuits” in Section IV of Chapter 16), may also be performed.\(^4,14,30,11,26\)

Another reason for Fontan conversion is to remove coronary sinus drainage from the high-pressure systemic venous compartment and place it in the low-pressure pulmonary venous compartment. It has been argued that elevated coronary sinus pressure reduces coronary perfusion pressure, which in theory may reduce coronary flow reserve; however,
Recent data suggest that the site of the coronary sinus drainage does not influence coronary flow reserve.\textsuperscript{3,4} Giardini and colleagues\textsuperscript{8} have documented that peak oxygen uptake improved and heart failure symptoms resolved when studied 6 months after conversion. Most conversions have been performed using the extracardiac conduit.\textsuperscript{4,6,17} However, Morales and colleagues\textsuperscript{14,22} provide evidence that lateral tunnel and extracardiac conduit revisions have equal outcomes.

In appropriately chosen candidates, early mortality is 0% to 5%.\textsuperscript{4,6,17,26,417} Outcomes will be optimized if appropriate preoperative medical management of the failing Fontan is undertaken.\textsuperscript{415}

**Routine Use of Fontan Operation with Deliberately Incomplete Atrial Partitioning**

Some institutions routinely fenestrate,\textsuperscript{12,34} and others rarely or never do.\textsuperscript{417,212} The advantages of fenestrating are reported to be improved hemodynamics, lower early mortality, and reduced pleural effusions. The need for routine fenestration has been supported\textsuperscript{35} and has been questioned.\textsuperscript{10,31,212}

Improvement in perioperative hemodynamics does occur in selected cases—specifically in those that have a systemic inflammatory response or temporary myocardial dysfunction as a result of the operation. These perturbations are more likely to occur when CPB is used and when cardiac arrest is used during CPB. Thus, fenestration is likely to be beneficial when the Fontan is performed using CPB, and of little or no benefit in most cases when CPB is not used.

The evidence that fenestration improves early mortality and reduces duration of effusions is not convincing. Table 41-6 shows that the majority of studies examining the effects of fenestration on effusions indicate that absence of a fenestration is not a risk factor for effusions, and Table 41-7 shows no difference in duration of effusions based on whether a fenestration is performed. Table 41-8 lists all studies examining the association between fenestration (or not) and early death. Four of the eight studies, and importantly the four most recent ones, show no association. Table 41-9 lists early mortality in studies that routinely use a fenestration, and in those that do not. Results are similar.

### Extracardiac Conduit versus Lateral Tunnel Fontan Operation

When usual morphologic variants are being considered, there remains considerable difference of opinion as to the best way to construct the Fontan physiology. Currently, extracardiac conduit or lateral tunnel cavopulmonary variants are preferred by most surgeons, largely because of the many long-term complications associated with the atriopulmonary connection. These complications include atrial dysrhythmia, loss of sinus node function, giant right atrium, atrial thrombus formation, compression of right pulmonary veins, and loss of laminar flow (see Clinical Features and Diagnostic Criteria earlier in this section). Any form of total cavopulmonary connection will address many of these complications, but controversy exists as to whether the lateral tunnel or the extracardiac conduit is better. According to the STS database, two thirds of all recent Fontans are extracardiac conduits, and one third are lateral tunnels.\textsuperscript{30} Some surgeons perform both operations, having specific indications for each, but most surgeons perform predominantly one or the other in the belief that they are choosing the operation that provides the least overall morbidity.

No definitive data support the superiority of either the lateral tunnel or extracardiac conduit Fontan. There are distinct differences between these two techniques, and it is a matter of speculation as to how these differences translate into patient benefit. The lateral tunnel procedure provides reasonable laminar flow and has the advantage of growth potential; however, it is an open cardiac procedure requiring CPB, hypothermia, and myocardial ischemia, which may have both immediate postoperative effects and long-term implications. The procedure also requires substantial manipulation of tissue in the region of the sinoatrial node and sinoatrial nodal artery, and atrial suture and foreign body load exposed to the systemic circulation is substantial. As a result, there are concerns regarding maintaining sinus rhythm and avoiding atrial dysrhythmias. The extracardiac conduit provides hemodynamics that most closely approximate laminar flow.\textsuperscript{110} It can be performed as a closed cardiac procedure without hypothermia, myocardial ischemia, or CPB, reducing the risks related to CPB, as well as the CPB-related systemic inflammatory response\textsuperscript{39} and the transient physiologic perturbations that increase the need for fenestration.\textsuperscript{212} Minimal or no manipulation of the right atrium is typical, and suture and foreign body load in the right atrium is eliminated, removing stimuli for dysrhythmia and systemic thromboembolic phenomena.\textsuperscript{212,213} The sinoatrial node and sinoatrial nodal artery regions are completely avoided. It can be argued, therefore, that the immediate postoperative and long-term ventricular mechanics, sinus node function, and atrial rhythm status are maximized. The extracardiac conduit, however, does not have growth potential and in general is performed in slightly older children to allow for a full-sized conduit. This delay until Fontan completion, and concern regarding long-term obstructive problems, have been cited as theoretical disadvantages.

Although there are no randomized trials comparing the two procedures, there exists a substantial body of data evaluating a wide spectrum of outcomes for each. Mahnke and colleagues noted a greater occurrence of cerebrovascular accidents in lateral tunnel than in extracardiac conduit Fontans, but follow-up was shorter in the latter group.\textsuperscript{33} Azakie,\textsuperscript{24}

Nurnberg et al., Lee, and Robbers-Visser and their colleagues all identified the lateral tunnel as an independent risk factor for both early and midterm atrial dysrhythmias, but Hakacova and colleagues did not. Fiore and colleagues showed that there was no difference in outcomes for the two operations with respect to early or late mortality, dysrhythmias, thromboembolic events, neurologic complications, or readmissions for effusions; however, they noted that the extracardiac conduit required fewer fenestrations but used a greater amount of resources. In contrast, Kumar and colleagues examined multiple outcome measures both early and midterm and found no differences between the groups, including resource utilization. None of these studies note an increased thrombosis risk for extracardiac conduit Fontans, and Petrossian and colleagues have documented a close to zero occurrence of thrombosis both early and up to 10 years after the extracardiac conduit operation.

Midterm follow-up of a large series of extracardiac conduit Fontan procedures indicates that performing the Fontan procedure at 3 to 4 years of age does not result in development of significant complications such as pulmonary arteriovenous malformations or acquired systemic to pulmonary artery collaterals. It is also well documented that the extracardiac conduit operation can be performed without aortic clamping and even without CPB, whereas the lateral tunnel operation requires both. Longer length of hospital stay has been linked to a greater need for perioperative fluid administration, which is secondarily linked to use of CPB. Avoiding CPB and reducing its length are associated with reduced effusions, providing indirect evidence supporting the advantages of the extracardiac conduit technique. There is no evidence to support the contention that the extracardiac conduit develops stenosis over time. Follow-up of up to 10 years reveals that the extracardiac conduit does not develop obstruction as the child grows, and formal measurement of the conduit by angiography at midterm follow-up indicates the conduit diameter shows little or no change from the diameter at insertion. In the Pediatric Heart Network multicenter study that retrospectively examined outcomes for the Fontan in 546 patients, the lateral tunnel Fontan was shown to have lower exercise performance than the extracardiac conduit Fontan.

Transplantation Following Fontan Operation

Patients with Fontan physiology may become candidates for transplantation for several reasons. One is that a critically important physiologic variable becomes abnormal, and as a result, the circulation can no longer be sustained. There are two such variables: ventricular function and Rp. If ventricular function decreases to the point that end-diastolic filling pressure becomes elevated, or if Rp becomes elevated, the Fontan circulation will fail, and transplantation is the only therapeutic option. Another reason is that intractable complications of the Fontan circulation develop, despite preserved ventricular function and low Rp. These complications include protein-losing enteropathy and plastic bronchitis. Patients who present for transplantation with preserved ventricular function and Fontan-related complications may have a particularly high mortality, implying that earlier transplantation may be necessary when these intractable complications develop. Protein-losing enteropathy will reverse after successful transplantation. Some studies report that survival after transplantation in Fontan patients is similar to that of patients undergoing transplantation for other causes, with 1-year survival of 72% and 5-year survival of 68%, whereas others report much higher early and late mortality. In a multicenter study assessing 98 patients, survival after transplantation in Fontan patients was slightly less than in other children with congenital heart disease and in those without congenital heart disease.

Hepatic Function in Fontan Patients

Hepatic dysfunction is universally recognized following the Fontan operation. Liver abnormalities correlate with older age and with time since the Fontan operation. Some studies correlate elevated systemic venous pressure and poor cardiac
function with liver abnormalities, and others do not. Liver abnormalities include fibrosis and cirrhosis, with their attendant consequences, and synthetic dysfunction, which particularly affects the coagulation system.

Use of Long-Term Anticoagulation

It is well recognized that the Fontan population is at high risk for thrombotic complications, second only to the nonbiological prosthetic valve population. Thus, anticoagulation therapy is an important consideration in this population. There are currently no prospective studies examining the efficacy of long-term anticoagulation following the Fontan operation; however, one study that recognized pulmonary emboli in 17% of Fontan patients also found that this complication did not occur if patients were on warfarin therapy. Another study showed no benefit for the use of warfarin. Nevertheless, practices vary widely. Some advocate no routine therapy but use varying pharmacologic regimens including aspirin, warfarin, or heparin for patients with risk factors for thrombosis. Others recommend aspirin routinely but no additional therapy. Still others recommend warfarin therapy, citing their experience that this approach reduces thrombosis when compared with no therapy or aspirin therapy.

Type of Operation for Tricuspid Atresia

When the cardiac malformation is tricuspid atresia and concordant ventriculoarterial connection, most patients will undergo either an extracardiac conduit or lateral tunnel Fontan; however, there is a possibility that the RV can become sufficiently functional to provide some benefit to the pulmonary circulation. Therefore, consideration can be given to performing an initial nonvalved right atrial–RV connection, generally at age 3 to 5 years. The RV enlarges considerably after this procedure, at least in some patients. If the ventricle becomes 30% or greater of normal size, the secondary insertion at age 8 to 10 years of an allograft valved conduit between right atrium and RV should provide a reasonably effective two-ventricle system. However, risk of conduit compression by the sternum must be overcome for this to be a generally useful alternative.

Bowman and colleagues were the first to demonstrate progressive RV enlargement when a valved right AV conduit was used. Pumping action of the enlarged ventricle can contribute to Qp and reduction of Fontan pathway pressure. Moreover, pulmonary artery systolic and pulse pressures can increase almost to normal. Fontan and colleagues also reported data from standardized exercise testing supporting the idea that an allograft valve in the connection between right atrium and RV provides a better late functional result than does a nonvalved connection. Del Toro and colleagues also noted less abnormality in both ejection fraction and hemodynamic response to exercise in patients with an AV connection than in those with an atrio-pulmonary connection. Magnitude of the hemodynamic advantages of a valved connection between right atrium and RV seem sufficient to affect functional status and survival late postoperatively, but this remains to be proven.

Valved Fontan Pathway

Studies suggest that a valve does not function when the RV is totally excluded, as in the Kreutzer modification of the Fontan procedure, even though the valve remains structurally perfect. Bull and colleagues also showed echocardiographically that the valve in a valved allograft conduit between right atrium and pulmonary artery closed momentarily or not at all. In similar circumstances, Sharratt and colleagues demonstrated delayed opening and slow closing of the conduit valve, suggesting that its presence in the pulmonary circuit may not contribute much to the hemodynamic state. Finally, in acute animal experiments, Shemin and colleagues showed that flow through a right atrial–to–pulmonary artery conduit was similar whether a valve was present or not.

Persistent Left Superior Vena Cava with Hemiazygos Extension of Inferior Vena Cava

As a part of the complex cardiac anatomy that usually coexists with atrial isomerism (see Morphology in Chapter 58) and sometimes in the absence of atrial isomerism, a persistent left SVC receiving IVC return via the hemiazygos vein may drain into the upper left corner of the left or common atrium. When the hepatic veins attach to the atrium well to the right, a slightly modified form of lateral tunnel total cavopulmonary connection can be used in which the left SVC is disconnected from the left atrium, the atrial opening oversewn, and the end of the left SVC anastomosed end to side to an incision in the left pulmonary artery. Occasionally, the left SVC lies virtually parallel to the left pulmonary artery, and then a side-to-side anastomosis without caval division permits a better fit of the two structures. In this case, the left SVC-atrial junction should be closed securely with a ligature and several

pledged mattress transfusion sutures. The right-sided SVC is managed as usual in this variant of the lateral tunnel total cavopulmonary connection, but the intratrial tunnel brings only hepatic vein blood (not IVC blood) to the anastomosis of the cardiac end of the SVC to the RPA. Alternatively, the extracardiac conduit technique can be used, with the conduit connecting the hepatic venous confluence to the pulmonary artery system.119

In some hearts with these complex venous drainages, the hepatic veins enter a common atrium in the midline or to the left of it. This, and sometimes position of orifices of pulmonary veins, can make connection of hepatic veins to the cardiac end of the SVC possible only by a long and circuitous tunnel if the lateral tunnel technique is being considered. The extracardiac conduit Fontan does not present this limitation under these morphologic circumstances and can be used effectively. The conduit can be routed to either the left or right of the cardiac mass to reach the pulmonary arterial system. The total cavopulmonary shunt of Kawashima, which permanently leaves hepatic vein blood draining to the pulmonary venous atrium, has also been suggested as an option under these circumstances.120 After this operation, resting SaO2 has been between 87% and 92% but decreases with exercise.120 There is also the important concern of pulmonary arteriovenous malformations, which develop frequently following this procedure. As a result, the Kawashima variant is no longer recommended as a long-term solution.

Preoperative Cardiac Catheterization

Some have suggested that the Fontan operation can be performed without cardiac catheterization, but this approach is not widely accepted. Other studies suggest that catheterization should be performed using actual measurement of oxygen uptake rather than relying on predicted oxygen uptake in calculating cardiac output and pulmonary vascular resistance, because predicted values underestimate Rp.126

Several other studies indicate that pulmonary artery pressure can be accurately estimated by measuring pulmonary venous wedge pressure in single-ventricle patients, thus obviating the need to directly measure pulmonary artery pressure.125,128

Ebstein Anomaly

DEFINITION

Ebstein anomaly is a congenital defect of the tricuspid valve in which origins of the septal or posterior leaflets or both are displaced downward into the right ventricle, and the leaflets are variably deformed. Characteristically, the anterior leaflet is enlarged and “sail-like.” There is a wide spectrum of severity; in the mildest asymptomatic forms, the valve may appear normal at first sight, and classification as Ebstein anomaly may be debatable.57

This chapter discusses Ebstein anomaly in hearts with atrioventricular concordant connection and without other major cardiac anomalies. Ebstein-type tricuspid atresia and Ebstein anomaly associated with pulmonary atresia and with atrioventricular discordant connection are discussed elsewhere (see Chapters 40, 41, and 55). Details of Wolff-Parkinson-White syndrome, which is occasionally associated with Ebstein anomaly, are presented in Chapter 16.

HISTORICAL NOTE

Wilhelm Ebstein’s scholarly description of the tricuspid valve abnormality bearing his name was published in 1866.61 His report describes a single autopsy specimen and includes a hypothesis of pathophysiology based on correlation of the morphology with clinical notes on the deeply cyanosed patient supplied by a colleague (Ebstein did not apparently...

Data from GLH group.
1Obliteration of the functional ventricle was present in 15, of the atrialized chamber in 4, and of the tricuspid anulus in 12. There was an atrial communication in all specimens (small probe-patent foramen ovale in 2, an enlarged foramen ovale in 7, and fossa ovalis atrial septal defect in 7).
In two hearts, the whole cusp was adherent.
In three hearts, up to half the leaflet was missing.
In three hearts, the elongation was slight.

see the patient, Joseph Prescher, alive.) According to the historical review by Mann and Lie, the second case was not described until 20 years later, and the first description in the English literature was by MacCallum in 1900. The eponym Ebstein’s disease was first suggested by Arnstein in 1927 and was used by Yater and Shapiro in their 1937 review article that reported the sixteenth case and the first to be examined by both radiography and electrocardiography. These investigators commented that “it would appear impossible to make the diagnosis during life.” In 1950, Engle and colleagues as well as Reynolds suggested that the disease was associated with a clinical syndrome that should make diagnosis possible. In 1951, Van Lingen and colleagues and Soloff and colleagues made the diagnosis during life using cardiac catheterization and angiography, respectively. In 1955, Lev and colleagues described a patient with coexisting Wolff-Parkinson-White (WPW) syndrome and provided histologic details of the course of the conducting tissue in this anomaly.

Palliative surgery was attempted unsuccessfully using a Blalock-Taussig shunt in 1950. A superior vena cava–to–right pulmonary artery anastomosis (Glenn procedure) was used successfully by Gasul and colleagues in 1959 and subsequently by McCredie and colleagues and Scott and colleagues. Barnard and Schrire were the first to report the use of prosthetic valve replacement in 1962, followed by Cartwright and colleagues and Lillehei and colleagues. Hardy and colleagues reported the first successful valvuloplasty in 1964 based on the concepts of Hunter and Lillehei. A similar technique was used by Bahnsen in 1965.

MORPHOLOGY AND MORPHOGENESIS

Tricuspid Valve

Both the origin of the tricuspid valve from the atrioventricular (AV) ring and its chordal attachments within the right ventricle (RV) are malpositioned, and the leaflets are malformed. The leaflets are either enlarged or reduced in size and are frequently dysplastic (thickened and distorted). These deformities vary widely in severity (Table 42-1). In the mildest forms, the valve is functionally near normal; in the fully developed syndrome, function is severely compromised. Displacement of the origin of the leaflets from the AV ring is reasonably constant. The septal leaflet appears always to be affected, the posterior leaflet nearly always, and the anterior leaflet seldom (Fig. 42-1). As noted by Anderson and colleagues, when both the septal and posterior leaflets are displaced, the point of maximum displacement is usually at the commissure between them. Thus, the functional tricuspid anulus is rotated apically and anteriorly (Fig. 42-2). In the few cases in which the anterior leaflet is displaced, the commissural area between it and the septal leaflet, attached to the right trigone at the point of penetration of the bundle of His, remains in normal position (see Fig. 42-1). In many patients, the apparent displacement is due to adherence of the base of the leaflet to the RV wall (see Table 42-1 and Fig. 42-1). Adherence of leaflet tissue to the underlying myocardium is thought to represent a failure of delamination during development. This failure effectively moves the hinge points of the septal and posterior leaflets (the functional anulus) into the ventricular cavity. When adherence is incomplete, there is a potential or obvious pocket beneath the leaflet.

The septal or posterior leaflet may be partially absent, in which case the belly of the leaflet is small or absent (see Fig. 42-1). The posterior leaflet is more often elongated than reduced in size (see Table 42-1), due in part to lack of a commissure between the posterior and anterior cusps. This was the case in 8 of 15 hearts examined at autopsy at GLH. The septal–posterior leafllet commissure may also occasionally be absent. Leaflet enlargement and elongation are characteristic of the anterior leaflet, which has been described as sail-like. The leaflet is usually diffusely thickened or ridged and occasionally consists partly of muscle. All the leaflets are frequently dysplastic, and isolated accessory leaflets may occur.

Distal leaflet attachments are variable and usually abnormal. Displaced and dysplastic posterior and septal leaflets frequently have multiple short chordae connecting to multiple small papillary muscles (see Fig. 42-1). The sail-like anterior leaflet may also have multiple short chordae arising around most of its free edge, binding it relatively closely to the septum and occasionally to the free wall, or the leaflet edge may be directly adherent to the anterior papillary muscle and moderator band or the posterior edge of the septal band. Presence of a free anterior leaflet is an important morphologic detail, because it greatly increases the likelihood of a successful repair. Leafllet fenestrations are common, with the opening typically guarded by a single papillary muscle, which gives rise to chords that attach to the periphery of the fenestration.

If the entire free margin of the leaflets is adherent and imperforate, one variety of tricuspid atresia is produced (see Chapter 41). When the adherence is partial, the large
Figure 42-1 Autopsy specimens of Ebstein anomaly with varying degrees of tricuspid valve deformity. Right atrium and right ventricle have been opened. A, Site of true atrioventricular ring is marked by dashed line between arrows. All three leaflets are enlarged and elongated (anterior leaflet is poorly displayed). Septal leaflet is completely adherent to ventricular septal surface and has abnormal distal chordal attachments, as does posterior leaflet. Note normal leaflet origin at right trigone (anteroseptal commissure). B, Septal leaflet origin is displaced well downward into ventricle, and leaflet tissue is diminutive and dysplastic. Posterior leaflet is adherent from the ring to point marked with large asterisk. Anterior leaflet origin is normal, its belly is mildly elongated and cleft, and there are multiple short chordal attachments.

Continued

anterior leaflet produces a variable degree of stenosis between the portion of ventricle proximal to it (atrialized ventricle) and that distal to it (functional or ventricularized ventricle), because blood can pass only between openings that remain between the leaflet margin and ventricular wall (or through the commissures when these are present) (Fig. 42-3). Stiffness of the anterior leaflet contributes to stenosis.

Although important stenosis is uncommon, most Ebstein valves are regurgitant, often severely so (Fig. 42-4). This is contributed to by marked dilatation of the true tricuspid anulus and the RV, as by well as by morphologic abnormalities of the tricuspid valve.

The functional tricuspid orifice is determined by the hinge points of the valve leaflets, which rotate around the aortic root. The resultant functional valve orifice resides at the junction of the inlet and apical trabecular portions of the RV. We emphasize Anderson’s focus on this rotational understanding of Ebstein anomaly to differentiate it from
tricuspid valve dysplasia, which is often mistaken for Ebstein anomaly.

Right Ventricle
Rotational displacement of the valve divides the RV into proximal (atrialized) and distal (ventricularized) portions. The proximal portion lies between the true tricuspid anulus and the valve attachment and comprises a variable portion of the posterior and inferior (diaphragmatic) aspects of the ventricular cavity (see Figs. 42-3 and 42-4). The right coronary artery denotes location of the true tricuspid anulus.

The proximal portion is atrialized in about one fourth of hearts in which the posterior and septal leaflets are severely displaced (Fig. 42-5). This atrIALIZED portion of ventricular wall is dilated. Uncommonly, it is so thin as to seem aneurysmal, in which case it is largely fibrous tissue, and the endocardium is smooth. When very thin, it moves paradoxically during ventricular systole and may also expand during atrial systole. Its electrical potentials are ventricular, but its

Figure 42-1, cont’d  C, Septal leaflet is absent except for a strand of fibrous tissue. Anterior leaflet origin is downwardly displaced (except at right trigone), as is the posterior leaflet origin. Darkened, bruised portion of ventricular wall is thinned, atrialized ventricle. D, Elongated anterior and posterior leaflets originating normally from ring (arrow) but with poor commissural development. Central part of distal anterior leaflet edge is completely fused to a broad muscle group on the right ventricular free wall; adjacent to this are thickened, short chordae. Septal leaflet is not visible. Key: A, Anterior tricuspid valve leaflet; At, atrialized ventricle; CoS, coronary sinus; P, posterior tricuspid valve leaflet; S, septal tricuspid valve leaflet.
ventricle is usually thinner walled than normal and contains few muscle fibers. Anderson and Lie suggested there may be a congenital paucity of myocardial cells in the RV, such that dilatation of both portions of the ventricle is part of the developmental anomaly rather than entirely its hemodynamic consequence.

In 1988, Carpentier proposed a classification system based on size of the functional RV and adequacy of the anterior leaflet for repair:\cite{55}

- **Type A**: volume of true RV is adequate.
- **Type B**: a large atrialized component of RV is present, and anterior leaflet of tricuspid valve moves freely.

The functional ventricularized portion of the RV lies distal (downstream) to the displaced valve and is therefore smaller than the normal RV. However, this feature is modified by RV dilatation, which is an almost constant finding. The functional portion consists of the infundibulum (conus), trabeculated apex, and that portion of the ventricle beneath the large anterior cusp (anterolateral recess)\cite{44} (Figs. 42-6 and 42-7).

Ebstein anomaly is more than a valve abnormality, in that the RV has an underlying myopathy. The dilated functional ventricle is usually thinner walled than normal and contains fewer muscle fibers. Anderson and Lie suggested there may be a congenital paucity of myocardial cells in the RV, such that dilatation of both portions of the ventricle is part of the developmental anomaly rather than entirely its hemodynamic consequence.\cite{45}

In 1988, Carpentier proposed a classification system based on size of the functional RV and adequacy of the anterior leaflet for repair:\cite{46,47,48}:

- **Type A**: volume of true RV is adequate.
- **Type B**: a large atrialized component of RV is present, and anterior leaflet of tricuspid valve moves freely.

Figure 42-2 Functional tricuspid valve annulus in Ebstein anomaly. A, Normal proximal tricuspid attachments at atrioventricular junction (circular dotted line) and direction of hinge line (square dotted line). Displacement of valve orifice is rotational (flat arrow). B, Location of functional orifice of the abnormal valve (black ovals) as observed in the series of hearts examined by Schreiber and colleagues.\cite{55} Key: ARV, Atrialized right ventricle; CS, coronary sinus; IVC, inferior vena cava; RA, right atrium; SVC, superior vena cava; TRV, true right ventricle.

Figure 42-3 Cineangiogram in right anterior oblique projection of Ebstein anomaly. Injection is into a large atrIALIZED right ventricle, demonstrating dome formed by the fused leaflets. Free reflux is present into right atrium (RA) through atrioventricular ring (arrows). Relatively small functional (ventricularized) ventricle is poorly outlined because displaced valve is stenotic (virtual tricuspid atresia). Key: A, Atrialized portion of right ventricle; F, functional portion of right ventricle.

Figure 42-4 Cineangiogram in right anterior oblique projection of neonate with pulmonary atresia and Ebstein anomaly. Injection was into right ventricle, but catheter has recoiled into right atrium. Curved margin (black arrowheads) represents a dome formed by abnormally tethered distal edge of tricuspid leaflets. This margin separates atrialized ventricle from functional ventricle. There is severe tricuspid regurgitation. Normally positioned atrioventricular ring is readily identified (white arrow). Key: A, Atrialized portion of right ventricle; F, functional portion of right ventricle.
Type C: movement of anterior leaflet is severely restricted and may cause obstruction of RV outflow tract.

Type D: RV is nearly completely atrialized, except for a small infundibular component.

Right Atrium

The right atrium is enormously dilated in advanced cases. There is usually an interatrial communication (60% of autopsy specimens, 42% at catheterization, and 21 of 22 surgical cases in Watson’s collective review), most commonly a patent foramen ovale, although an atrial septal defect (ASD) of any type may be present.81 Interatrial communication was present in 94% of patients at operation in the series reported by Danielson and colleagues.84 Rarely, an ostium primum AV septal defect coexists.

The bundle of His and AV node lie in their usual locations, although the right bundle and node may be compressed by thickened endocardium (a possible explanation of the frequent right bundle branch block pattern in the electrocardiogram).87,15,12,13 WPW syndrome is present in about 14% of persons with Ebstein anomaly.84,75

Left Ventricle

Monibi and colleagues and Ng and colleagues report that abnormal left ventricular contraction and contour and mitral valve prolapse are frequently present.91,95 Marked dilatation of the RV produces leftward septal shift and compression and posterior displacement of the left ventricle. Daliento and colleagues studied nine autopsied hearts and found the ventricular septum normal in six and thin in three, which could account for the exaggerated leftward diastolic movement observed by angiography in 24 of 26 patients.81 Severe leftward displacement produced a “banana” appearance of the left ventricle. Regional left ventricular wall motion abnormality was observed in 67% of patients. In a Mayo Clinic experience of over 500 surgical patients with Ebstein anomaly, 9% had moderate or severe LV dysfunction.94 When mitral valve prolapse is present, the valve is frequently nodular and thickened.91,81,12,82 A Mayo Clinic study of 106 patients identified left ventricular abnormalities in 39%, of whom 18% had left ventricular dysplasia resembling noncompaction.81

Lungs

In severe Ebstein anomaly associated with fetal and neonatal distress or death, both lungs are usually hypoplastic but otherwise normal. The hypoplasia is secondary to gross cardiomegaly from severe tricuspid regurgitation.11
left-sided valves are regurgitant, this is frequently due to Ebstein anomaly. \(^5,\!^6,\!^6\) This Ebstein anomaly differs from the usual right-sided form in that dilatation of the AV ring and separation of the morphologic RV into atrialized and ventricularized portions are uncommon. The anterior leaflet is also less prominent and may be cleft (see Chapter 55).

### CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

**Mechanisms Underlying Clinical Presentation and Natural History**

Three primary pathophysiologic features predominate in patients with Ebstein anomaly:

- RV abnormalities
- Tricuspid valve abnormalities
- Accessory conduction pathways (WPW syndrome)

Their severity determines secondary pathophysiologic features, clinical presentation, and natural history.

**Right Ventricular Abnormalities**

Severity of RV abnormality is partly related to the extent to which the number of muscle fibers in the ventricular wall is reduced. \(^6,\!^7\) Nearly all patients have at least mild RV cavity enlargement and wall thinning. In the most severe cases, the RV cavity is greatly enlarged and free wall extremely thin. \(^6,\!^7\) The ventricular septum is often abnormal as well, with leftward bulging and consequent reduction in cavity size of the left ventricle, impairing left ventricular function. \(^6,\!^6,\!^1\) In the most advanced examples, the RV free wall is paper thin, a condition referred to as Uhl disease.

Extensiveness of the atrialized portion of the RV, which exhibits systolic expansion rather than contraction, importantly affects RV performance. RV dysfunction, along with tricuspid valve regurgitation, is responsible for right atrial enlargement and its wall thickening, which are at times extreme.

In aggregate, these abnormalities of RV structure and function underlie the variable cardiomegaly exhibited by patients with Ebstein anomaly: hepatomegaly, ascites, and fluid retention that may be advanced; cyanosis that is occasionally extreme, resulting from right-to-left shunting across a patent foramen ovale or ASD; and paroxysms of supraventricular and occasionally ventricular tachyarrhythmias that can cause advanced disability and sometimes sudden death.

**Tricuspid Valve Abnormalities**

Tricuspid regurgitation, usually present to some degree, exacerbates the abnormalities of RV structure and function. Degree of regurgitation is determined by the valve’s morphologic anomalies. Those valves in which the anterior leaflet is tightly tethered and adherent to the underlying RV free wall and septum and, to a lesser extent, those in which the posterior leaflet is displaced and immobilized, are more likely to be regurgitant. \(^6,\!^7\)

Pulmonary hypoplasia, a feature that contributes to neonatal death, is correlated with the degree of tricuspid regurgitation, occurring in association with severe regurgitation and gross cardiomegaly. If these features are corrected, the lungs presumably grow normally. \(^1\)

Deep notch (arrow) represents attachment of a dysplastic posterior leaflet to inferior wall. **B**, Later frame showing more extensive filling of atrialized ventricle and right atrium (RA). X marks position of true atrioventricular ring. Key: A, Atrialized right ventricle.
**Wolff-Parkinson-White Syndrome**  
Arrhythmic features of WPW syndrome, present in about 14% of patients, may dominate the clinical picture in patients whose tricuspid valve and RV anomalies are mild (see Section III in Chapter 16).

**Associated Anomalies**  
In general, coexisting cardiac anomalies have little impact on the clinical features and course of patients with Ebstein anomaly. Exceptions are congenital pulmonary stenosis or atresia; when these coexist with Ebstein anomaly, death in utero or soon after birth is common. A patent foramen ovale or ASD, present in many patients, is necessary for right-to-left shunting and for the occasional paradoxical embolus or cerebral abscess that develops, but otherwise usually plays little role in the etiology of signs and symptoms. However, in the uncommon circumstance of only mild RV and tricuspid abnormalities, important left-to-right shunting may occur across an ASD.

**Symptoms and Signs**  
Breathlessness in association with cyanosis, severe cardiomegaly, and often heart failure may appear during the first week of life. However, many patients have milder symptoms and do not present until later in life. Nonetheless, objective exercise testing shows that their functional capacity is less than normal. Oxygen saturation at rest is a major predictor of exercise tolerance. Mild dyspnea and fatigue may become evident in childhood or early adult life, or more severe symptoms and signs of various types may develop. If heart failure develops, the patient becomes severely limited by breathlessness and fatigue.

Cyanosis is a common sign of Ebstein anomaly, occurring in more than half of patients and severe in about one third. It may appear at birth, but in most patients, onset is in infancy or early childhood.

Palpitations caused by various types of arrhythmia are also common. Severe arrhythmic symptoms are frequent in patients of all ages and may be disabling. WPW syndrome is the best known type of arrhythmia, but less specific types of supraventricular tachycardias are more common. Numerous electrophysiologic abnormalities have been identified, which no doubt account for the frequent occurrence and persistence of arrhythmic symptoms even after operation. Symptoms are more severe when there are important associated cardiac anomalies.

A malar flush, similar to the so-called mitral facies, was noted by Ebstein’s colleague and occurs in about one third of patients. It is unrelated to cyanosis or polycythemia or to cardiac output.

The left anterior chest is often prominent in association with marked cardiomegaly, and there may be a systolic thrill along the left sternal edge originating from the tricuspid valve. Characteristically, the precordium and apex remain quiet despite marked cardiomegaly. Jugular venous pressure is generally unremarkable and rarely suggests tricuspid regurgitation or stenosis, even though free tricuspid regurgitation is revealed by imaging studies. This is related to the large size and compliance of both the right atrium and atrialized RV, as well as the low RV and pulmonary artery pressure.

**Chest Radiography**  
In classic Ebstein anomaly, the chest radiograph shows marked cardiomegaly with a rounded or boxlike cardiac contour beneath a narrow pedicle. In the posteroanterior view, the whole of the silhouette is formed by the right atrium and RV, and because of their minimal excursion and the normal or oligemic lung fields, the silhouette has a peculiarly sharp edge. However, as with other features of the disease, there is wide variation in heart size. In a few cases, it remains normal; in most, it is only moderately enlarged.

---

*Figure 42-8* Chest radiograph of a 12-year-old girl with classic Ebstein anomaly.
Electrocardiography

A right bundle branch pattern together with a relatively low-amplitude R wave in right-sided chest leads and right atrial hypertrophy are characteristic of the anomaly. According to Kumar and colleagues, height of the P wave varies inversely with arterial oxygen saturation ($r = .82$, $P < .001$).\textsuperscript{11} In addition, the taller the P wave, the shorter the survival time ($P < .001$). RV hypertrophy does not occur in uncomplicated Ebstein anomaly, and inverted T waves in leads V\textsubscript{1} to V\textsubscript{4} are fairly common. Using intraluminal electrode catheters, Kastor and colleagues demonstrated prolonged intra–right atrial and infranodal conduction in patients with a large right atrium and well-defined atrialized ventricle.\textsuperscript{2}

In approximately 14% of patients, the electrocardiogram shows type B (right-sided) WPW syndrome. In any cyanotic patient with this type of preexcitation, Ebstein anomaly should be considered. Supraventricular arrhythmias occur in more than half of patients, and they may be paroxysmal and recurrent. Paroxysmal atrial tachycardia, atrial fibrillation, and nodal rhythm can all occur, as can first-degree heart block. Serious ventricular arrhythmias resulting from RV dilatation may also occur.\textsuperscript{10}

Cardiac Catheterization and Cineangiography

Currently, cardiac catheterization and cineangiography are required only when specific hemodynamic details need to be identified,\textsuperscript{3} or in patients about aged 40, when the coronary tree should be examined.

In the past, cardiac catheterization showed that the mean right atrial pressure is often modestly elevated, and the pressure pulse may have either a dominant $a$ or $v$ wave. These correlate poorly with degree of tricuspid regurgitation or stenosis. An additional $s$ wave preceding the $v$ wave and interrupting the $e$ wave is said to indicate tricuspid regurgitation.\textsuperscript{5,11,53} The right atrial waveform is also recorded in the atrialized portion of the RV so that the tricuspid valve is noted to be displaced well toward the left of the spine. An electrocatheter may define the position and size of the atrialized RV chamber.\textsuperscript{49,53} RV systolic pressure is normal or low, and RV end-diastolic pressure is frequently elevated, more so when there is the syndrome of chronic heart failure. It is uncommon to record an important gradient across the tricuspid valve, although Takayasu and colleagues noted this in 8 of 26 cases and considered that stenosis could still be important in its absence.\textsuperscript{11,51}

When there is an interatrial communication, the shunt through it is usually right to left in association with systemic arterial desaturation and a reduced pulmonary blood flow ($Q_p$). The right-to-left shunt can be quantified by indicator dilution. The shunt may occasionally be left to right, and the resultant increase in $Q_p$ may be associated with heart failure.\textsuperscript{38} Direction of shunting is no doubt influenced by RV compliance.

In the newborn with Ebstein anomaly, a functional pulmonary outflow obstruction can occur.\textsuperscript{4} Thus, a normal pulmonary valve may fail to open following a right-sided injection of contrast media because of the combination of massive tricuspid regurgitation, poor RV contraction, and a high neonatal pulmonary vascular resistance with or without a large shunt at ductal level. High-quality imaging is therefore necessary to distinguish this situation from true pulmonary atresia.

Cineangiography (see Figs. 42-3 to 42-7) is usually diagnostic as long as there is important displacement and dysplasia of the septal or posterior leaflets.\textsuperscript{11} In the right anterior oblique projection, the conjoined posterior and anterior leaflets, and therefore the distal limit of the atrialized ventricle, can frequently be identified. Contrast media trapped beneath the posterior leaflet can indicate the degree of its adherence to, and level of its origin from, the diaphragmatic border of the RV, which may be notched at this point.\textsuperscript{317} The site of the true anulus is also visible more proximally. An injection into the functional RV enables tricuspid regurgitation to be assessed together with size and behavior of the functional ventricle. Angiography in left anterior oblique projection also permits visualization of the right-to-left shunt at atrial level, and any ventricular septal defects can be localized by left ventriculography.

**Figure 42-9** Two-dimensional echocardiogram of Ebstein anomaly. There is characteristic displacement of hinge point of septal leaflet below natural tricuspid anulus and adherence to septal wall. Anterior leaflet is elongated.
with more frequency in babies of mothers who are on lithium medication during pregnancy.\textsuperscript{15,81}

The natural history is determined primarily by the three primary pathophysiologic features described in Clinical Features and Diagnostic Criteria earlier in this chapter. Extent and severity of these relate to age at presentation; thus, age at presentation tends to correlate with prognosis. The presentation takes two general forms: symptomatic neonatal and infant presentation, and presentation in older children and adults.

date from Celermajer and colleagues.\textsuperscript{64}

Key: \textit{ARV}, Atrialized right ventricle; \textit{LA}, left atrium; \textit{LV}, left ventricle; \textit{RA}, right atrium; \textit{RV}, right ventricle.

The outlook is generally poor for patients with Ebstein anomaly who survive after presentation early in life have a good chance of long-term survival.\textsuperscript{53}

Many studies have probably underestimated the incidence and severity of this entity in neonates. The review by Vacca and colleagues of 108 clinical or autopsy cases reported between 1866 and 1957 recorded only two patients younger than 1 month.\textsuperscript{61} In Watson’s collective review of 505 cases, only 35 (7%) were younger than 1 year (half were younger than 1 month).\textsuperscript{51} In Bialostozky and colleagues’ review of 65 patients, neonates were not included.\textsuperscript{69} In a Mayo Clinic series, only 10 of 67 patients were diagnosed in infancy.\textsuperscript{65} In a Boston Children’s Hospital series, 12 of their 55 patients (22%) were seen during the first week of life, and 34 (64%) were younger than 2 years.\textsuperscript{11} Eleven of the 34 died early. These series must have been in some way selective and therefore are not useful in assessing natural history. In contrast, Schiebler and colleagues’ earlier study from the Mayo Clinic found that 12 of 23 patients presented during the neonatal period, and of these, 5 died.\textsuperscript{33} Roberson and Silverman reported that among 16 consecutive patients diagnosed in utero or presenting during the first 3 days of life, 7 died before age 3 months; all had severe RV and tricuspid morphologic abnormalities.\textsuperscript{87} In the 40-institution administrative registry of the Pediatric Health Information System (PHIS), of 464 neonates diagnosed with Ebstein anomaly from January 2003 to January 2008, 415 with complete data, mortality during initial hospitalization among 257 (62%) managed medically was 22% (56/257; CL 19%-25%).\textsuperscript{67}

Presentation during First Week of Life

Ebstein anomaly is a recognized cause of death in utero.\textsuperscript{64,34,13} When severe tricuspid regurgitation accompanies Ebstein anomaly at birth, the elevated newborn pulmonary vascular resistance worsens it, \( Q_p \) may be ductal dependent. The resultant severe hypoxemia (right-to-left shunting through an ASD), coupled with marked right-sided heart failure, may also be accompanied by low cardiac output if the ASD is restrictive. This is because maintenance of normal cardiac output requires shunting at the atrial level through a nonrestrictive ASD. Low cardiac output may also result from abnormal ventricular interactions caused by paradoxical septal bowing and flattening of the left ventricle. The hypoxemia may be aggravated by pulmonary dysfunction secondary to lung compression by marked cardiomegaly. Although lung hypoplasia has been suggested\textsuperscript{68,11} pathologic studies indicate that the lungs are rarely hypoplastic in surviving newborns, but are instead compressed by the enlarged heart.\textsuperscript{12}

Celermajer and colleagues from Great Ormond Street identified neonates with good and poor outcomes based on a score (Celermajer Score or Great Ormond Street Ratio)\textsuperscript{69,63} derived from echocardiographic measurements of the right atrium, RV, left atrium, and left ventricle.\textsuperscript{66} The score is calculated from a four-chamber echocardiographic view in which the combined area of the anatomic right atrium plus atrialized RV is divided by the sum of the areas of the functional (nonatrialized) RV, left atrium, and left ventricle (Table 42.2). The outlook is generally dismal for patients with Celermajer grades 3 or 4\textsuperscript{64,62} (severe Ebstein anomaly; Fig. 42.10).

Presentation in Infancy

Presentation in infancy is associated with less risk of death and milder symptoms than occur with neonatal presentation (Fig. 42-11), although some studies suggest an increased mortality until presentation is beyond about 6 months. Beyond this age, Watson’s series indicates a prognosis similar to that of older children. He states that “whereas 72% of those under 1 year were in heart failure, 71% of the children and adolescents had little or no disability.”

Presentation in Childhood and Adult Life

Patients presenting after infancy often have mild symptoms. Prognosis is generally good, consistent with less severe RV and tricuspid valve pathophysiology. Patients presenting in adult life are often acyanotic and have a normal-sized heart. However, even these patients, who report few symptoms, have clearly definable abnormalities. Without preexcitation, nearly half have episodic supraventricular tachyarrhythmias, although these usually produce few symptoms. Exercise tolerance measured by objective testing is often reduced. The degree of tricuspid regurgitation does not correlate with symptoms, but as time passes, left ventricular dysfunction often appears as symptoms develop.

Death in this group of patients is often due to paroxysmal embolization or paradoxical supraventricular tachycardia, with heart failure appearing either much later or not at all. An atrial level communication increases the risk of paradoxical embolism, brain abscess, and sudden death.

Modes of Death

Heart failure is the mode of death in somewhat less than half of patients who die of causes related to their heart disease after the neonatal period. Sudden death, presumably caused for the most part by arrhythmias other than those associated with WPW, occurs in about 60% (CL 43%-77%) of these patients. Sudden death correlates with marked cardiomegaly, rather than with New York Heart Association (NYHA) status. Cerebral abscess and paradoxical emboli account for most of the remaining deaths, particularly in patients older than about 50 years. Infective endocarditis is rare.

TECHNIQUE OF OPERATION

Repair of Tricuspid Valve and Atrial Septal Defect Closure

The usual preparations are made for operation, anesthetic management (see Chapter 4), and cardiopulmonary bypass (CPB) (see Chapter 2). Before commencing CPB, the atrialized portion of the RV is assessed, noting particularly whether it moves paradoxically.

CPB is established using two venous cannulae, and the patient’s body temperature is lowered to about 25°C. The aorta is occluded and tourniquets secured around the venae cavae and cannulae. Cold cardioplegia may be administered directly into the aortic root or into the coronary sinus after the atrium is opened (see “Technique of Retrograde Infusion” in Chapter 3). The right atrium is incised parallel to the AV groove. A sump-sucker is placed across the atrial septum into the left atrium.

The atrial septum and tricuspid valve are examined (Fig. 42-12). The anterior leaflet of the tricuspid valve is studied with particular care, because successful repair of a regurgitant tricuspid valve relies on it. The anterior leaflet is rarely displaced into the RV, but if it is, the tricuspid valve may require replacement (see “Replacement of Tricuspid Valve” in text that follows). However, if the displacement is limited to that portion near the commissure, repair may be possible. Extreme thickening of the anterior leaflet, and particularly the dense attachment of its free edge to the underlying RV endocardium, makes successful repair unlikely and therefore contraindicates it.

Tricuspid valve repair with ASD closure is the preferred operation. Most repairs are designed to convert the tricuspid valve into a monoleaflet valve using the anterior leaflet to establish valve competence. The most important features that predict successful repair are a mobile, free leading edge of the anterior leaflet and attachment of more than 50% of it at the anatomic tricuspid anulus. A variety of maneuvers have been used to mobilize and extend this leading edge, with or without plication of the atrialized portion of the RV.

The method devised by Danielson and colleagues is the best tested. It plicates the atrialized portion of the ventricle, narrows the tricuspid orifice in a selective manner, and results in a monoleaflet valve that is usually competent or nearly so. A modification of the Danielson method in which the tricuspid valve anulus is remodeled by an anuloplasty ring is shown in Fig. Dearani and colleagues have also recommended moving the anterior leaflet closer to the ventricular septum by displacing the major papillary muscles supporting the anterior leaflet to a position closer to the septum. This is accomplished by placing pledgeted mattress sutures from the papillary muscle to the ventricular septum. An alternative is the Carpentier repair, in which the anterior leaflet is mobilized and detached from the anulus. The atrialized ventricle is plicated vertically, at right angles to the direction used by Danielson. This is accomplished by placing pledgeted mattress sutures from the papillary muscle to the ventricular septum.
Figure 42-12  Morphology of interior of right atrium in Ebstein anomaly at operation. Septal and posterior leaflets of tricuspid valve are adhered to septum and right ventricular (RV) wall. Downward displacement of tricuspid valve divides RV into a proximal atrialized portion and a distal ventricularized portion. Anterior leaflet is enlarged and elongated, described as sail-like. There is a foramen ovale type of atrial septal defect. Coronary sinus, atrioventricular node, and bundle of His are in their usual locations.
Figure 42-13  Repair of regurgitant tricuspid valve in Ebstein anomaly using a modification of the Danielson method.\textsuperscript{D3,D6,D14}  
\textbf{A}, A series of pledget-reinforced mattress sutures are placed at base of the septal and posterior leaflets of tricuspid valve. Stitches are continued to plicate atrialized portion of right ventricle (RV) up to the natural location of the valve anulus. Stitches are passed through a Carpentier anuloplasty ring. Atrial septal defect is closed by pericardial patch.  
\textbf{B}, Plication sutures are tied over anuloplasty ring to remodel the anulus and obliterate atrialized portion of the RV to complete the repair. Large anterior leaflet occludes the atroventricular orifice.
Figure 42-14  Diagram of modified Mayo Clinic method of tricuspid valve repair technique used for Ebstein anomaly. A, Two papillary muscles arise from free wall of right ventricle, with short chordal attachments to leading edge of anterior leaflet. Septal leaflet is diminutive and only a ridge of tissue. Posterior leaflet is not well formed and is adherent to underlying endocardium. A small patent foramen ovale is present. B-C, Base of each papillary muscle is moved toward ventricular septum at the appropriate level with horizontal mattress sutures backed with felt pledgets. Patent foramen ovale is closed by direct suture. D, Posterior angle of tricuspid orifice is closed by bringing right side of anterior leaflet down to the septum and plicating the nonfunctional posterior leaflet in the process. E, A posterior anuloplasty is performed to narrow diameter of tricuspid anulus; the coronary sinus marks posterior and leftward extent of anuloplasty. F, An anterior purse-string anuloplasty is performed to further narrow tricuspid anulus. This anuloplasty stitch is tied down over a 25-mm valve sizer in an adult to prevent tricuspid stenosis. G, Completed repair that allows anterior leaflet to function as a monoleaflet valve. (From Dearani and colleagues. Used with permission of Mayo Foundation for Medical Education and Research.)
Figure 42-15  Repair of regurgitant tricuspid valve in Ebstein anomaly using the Carpentier method. A, Three fourths of the enlarged anterior leaflet and as much as possible of the posterior leaflet are detached from the anulus. Incision is continued to the point at which valve begins to be displaced on ventricular wall at atrialized portion of right ventricle (RV). B, Detached leaflet is everted to expose support mechanism. There is usually chordal fusion, which may be marked in some cases. Fenestrations are made in the support mechanism to lengthen chordae and relieve obstruction below leaflets. C, Unique aspect of repair is placing pledget-reinforced plication stitches in atrialized portion of RV to create a vertical plication. Plication stitches are continued from base of leaflet attachment to ventricle to true anulus. Anulus is narrowed by this technique. A few stitches are placed in floor of right atrium. Plication stitches may be woven across atrialized portion for better obliteration of this portion of ventricle.
Others have used autologous or bovine pericardium to augment the anterior leaflet or septal leaflet (Fig. 42-18) to increase the area of leaflet coaptation. Midterm follow-up on a small number of patients has indicated good valve function.

Use of a bidirectional cavopulmonary shunt as an adjunctive procedure to create a one-and-a-half ventricle repair is an important surgical option to consider in valve reconstruction procedures. A protocolized approach to application of a one-and-a-half ventricle strategy (see Special Situations and Controversies) may increase the frequency of successful valve repair with aggressive anuloplasty techniques that may create some degree of tricuspid valve stenosis in order to eliminate regurgitation.

Replacement of Tricuspid Valve

In about 20% to 30% of patients, immobility or morphology of the tricuspid valve prevents repair and valve replacement is required. For this, the leaflet tissue is excised (Fig. 42-19, A), leaving a more generous portion of the base of the anterior and septal leaflets where they attach to the membranous septum and right trigone at the point of penetration of the bundle of His. The general suture technique for inserting the valve prosthesis is described in Chapters 11 and 14. When the septal and posterior leaflets are displaced into the RV, or the septal leaflet is absent, sutures may be passed through the usual location of the tricuspid ring. Alternatively, the suture line in this area can be placed well posterior to the AV node area and coronary sinus, as described by Barnard and Schrire. The replacement valve is usually a large mechanical prosthesis (Fig. 42-19, B) or stent-mounted xenograft. A pulmonary allograft mounted in a short polyester sleeve has been used. A mitral allograft could also be considered.

Figure 42-15, cont’d  D, Detached portion of tricuspid leaflet is rotated clockwise to cover tricuspid orifice beyond plication and as far toward septum as it will reach comfortably. Leaflet is reattached to anulus by continuous suture. E, Repair is supported by a Carpentier anuloplasty ring, which also remodels shape of anulus. It is attached to tricuspid anulus by a series of mattress sutures placed at perimeter of anulus. These stitches are most easily placed before anterior leaflet is reattached. A gap in the anuloplasty ring protects conduction system from injury.
Figure 42-16  Operative steps for Ebstein anomaly repair with cone procedure. A, Opened right atrium showing displacement of tricuspid valve. B, Detached part of anterior and posterior leaflet forming a single piece. C, Clockwise rotation of posterior leaflet edge to be sutured to anterior leaflet septal edge and plication of true tricuspid anulus (TTA). D, Completed valve attachment to true tricuspid anulus and valved closure of atrial septal defect (ASD). Key: CS, Coronary sinus. (From da Silva and colleagues.)

Figure 42-17  “Play it where it lies” approach to repair of Ebstein anomaly. Operation involves limited plication of tricuspid valve. Points A and B are approximated with one or two mattress sutures at the level of the native valve, not to the level of the true tricuspid anulus. This results in approximating apical aspects of septal and anterior leaflets, effectively creating a bicuspid valve. (From Malhotra and colleagues.)

Figure 42-18  Leaflet augmentation procedure for Ebstein anomaly. Patch of polytetrafluoroethylene is tailored to form a new septal anulus, attached to the atrium remote from the area of the atrioventricular node. Accommodation for coronary sinus is made by placing a notch in the patch. Tailored patch in place, defining a new septal anulus and an armature, onto which leaflet advancement is performed, attached at the plane of the reconstructed anulus. All suture material is remote from the atrioventricular node and bundle of His. (From Bichell and colleagues.)
Figure 42-19 Replacement of tricuspid valve in Ebstein anomaly. A, Valve is excised. B, Valve is replaced with a mechanical prosthesis or stent-mounted xenograft. Device is attached to anulus by pledget-reinforced mattress sutures. Atrialized portion of the right ventricle may be plicated by sutures used to attach the prosthesis. (From Doty and colleagues.)

When the atrialized ventricle is thin walled and fibrous and moves paradoxically, it is plicated by passing sutures used to position the valve first through tissue that forms the margin of the atrialized ventricle (corresponding to attachment of the displaced septal and posterior leaflets) and then through the true tricuspid ring. The valve is seated and sutures tied and cut. If the atrialized ventricle has been plicated, this portion may be further obliterated by a running polypropylene suture placed from outside the heart, taking care not to compromise the arterial supply of the remainder of the RV.
by occluding large coronary arteries. Plication is probably unnecessary in most cases when valve replacement is performed.\textsuperscript{[62]}

The interatrial communication is closed. In many instances, the septal tissue is stretched and the fossa ovalis tissue thinned. A patch must then be used (pericardium is ideal); it is positioned without tension using a continuous 4-0 polypropylene suture (see Fig. 42-13, A). Direct suture is avoided unless the tissues are strong and the defect small, which is uncommon. The left atrium is deliberately not emptied of blood, and the patch suture line is completed at the highest point (superiorly) to avoid air entrapment on the left side of the septum.

The right atriotomy is closed. When the atrium is very large, its size may be reduced by excising an ellipse from the lateral wall. The procedure is completed in the usual fashion, including placement of atrial and ventricular pacing wires and left and right atrial pressure catheters (see Chapter 2).

Simple Atrial Septal Defect Closure

Simple ASD closure may be done as described for closure in conjunction with valve replacement. However, this procedure is rarely indicated in patients with Ebstein anomaly.

Ventricular Exclusion in Critically Ill Neonates (Starnes Operation)

The Starnes operation is designed to abolish the detrimental tricuspid regurgitation by patch closing the tricuspid valve, creating a widely opened and nonrestrictive ASD, and establishing controlled pulmonary blood flow through a systemic-to-pulmonary artery shunt. A single ventricle palliation strategy is then pursued.\textsuperscript{[518]} CPB is established. Bicaval cannulation may be used (see “Venous Cannulation” in Section III of Chapter 2) and the operation performed during hypothermic CPB. Alternatively, a single venous cannula may be used and the intraatrial portion of the operation performed during hypothermic circulatory arrest. Cold cardioplegia is used (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3). The right atrium is opened obliquely. The ASD is enlarged by excising all remnants of the septum primum (floor of the fossa ovalis). The tricuspid valve is closed by sewing into place an appropriately sized pericardial patch, sewn at the anatomic level of the tricuspid anulus. The coronary sinus is maintained on the atrial side of the patch. The patch is fenestrated with a 4-mm punch (Fig. 42-20). The right atrium is reduced in size by removing a segment of the right atrial free wall, and then is closed. If this portion of the procedure is done during hypothermic circulatory arrest, CPB is reestablished. If pulmonary regurgitation is present, the proximal main pulmonary trunk is closed.

A systemic-pulmonary shunt is created. Starnes and colleagues prefer a central shunt of 4-mm polytetrafluoroethylene (PTFE) tube interposed between the ascending aorta and pulmonary trunk.\textsuperscript{[518]} Alternatively, a 3.5- or 4-mm PTFE tube may be interposed between the brachiocephalic–right carotid artery junction and the medial aspect of the right pulmonary artery (see “Reconstructive Surgery” in Chapter 49), or between the right lateral aspect of the ascending aorta and anterior aspect of the right pulmonary artery. After rewarming has been accomplished, the remainder of the operation is completed in the usual manner (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2). The sternum is generally left open and the skin closed with a patch of bovine pericardium. The sternum can usually be closed in the intensive care unit 48 to 72 hours later.

Treatment of Arrhythmias

Dearani and colleagues at the Mayo Clinic\textsuperscript{[69]} recommend routine electrophysiologic evaluation in children and adults undergoing Ebstein repair. If arrhythmic substrate is identified (e.g., WPW syndrome is present), and there is a history of life-threatening paroxysmal arrhythmia, the accessory conduction pathways are divided at the same operation, after proper electrophysiologic study.\textsuperscript{[512,588]} (see Technique of Intervention in Section III of Chapter 16). This is generally done before valve repair or replacement. Alternatively, these pathways may be obliterated preoperatively in the electrophysiology laboratory.\textsuperscript{[62]}

Supraventricular arrhythmia such as atrial flutter and fibrillation may occur paroxysmally or chronically as the right atrium enlarges. A right-sided maze procedure may be done at the time of operation.\textsuperscript{[519,74]}

SPECIAL FEATURES OF POSTOPERATIVE CARE

Postoperative care is as usual after repair or replacement of the tricuspid valve for Ebstein anomaly (see Chapter 5). Convalescence is generally rapid and normal.

Critically ill neonates undergoing the Starnes operation, however, require the type of care accorded all neonates in whom pulmonary blood flow originates exclusively from the systemic circulation (see “General Care of Neonates and Infants” in Chapter 5). Additionally, pulmonary artery vasodilatation is encouraged by nitric oxide administration (see Chapter 5). Lowering pulmonary vascular resistance decreases the tendency to RV distention (see Special Situations and Controversies). Further operations and procedures follow the Fontan pathway strategies (see Indications for Operation and Special Situations and Controversies in Section IV of Chapter 41).

RESULTS AFTER REPAIR

Survival

Mortality after Surgery in the Neonatal Period

Historically, hospital mortality has been high (>50%) for critically ill neonates who undergo emergency or urgent operation. However, with current techniques of intensive neonatal medical management and surgical and percutaneous therapy as needed, survival has importantly improved. Thus, in the 40-institution report of the PHIS, overall hospital mortality of neonates initially managed by percutaneous procedures with or without surgery was 22% (9/40; CL 15%-31%), for those managed by systemic-to–pulmonary shunting 27%, for those undergoing tricuspid valve repair 31%, and for those receiving a transplant 0% (Table 42-3). Notably, half the neonates were medically managed, and 15% were managed by placement of a systemic-to–pulmonary system shunt, 9.6% by a percutaneous procedure, 8.7% by single ventricle palliation, and 3.9% by tricuspid valve repair.

Among 16 neonates undergoing surgical intervention between 1992 and 2005, Starnes and colleagues reported a hospital mortality of 31% with a variety of surgical procedures (Reemtsan 2006). The best survival occurred in the 10 patients (80% hospital survival; CL 59%-93%) who underwent patch fenestration as part of a RV exclusion procedure (Starnes operation). No late deaths were reported, all had undergone a subsequent bidirectional Glenn, and three had a completed Fontan.

Knott-Craig and colleagues have pursued tricuspid valve repair and two-ventricle physiology, creating a competent monolateral valve based on the anterior leaflet, partially closing the ASD, and performing a reduction atriotomy. Hospital survival among neonates exceeded 65%, but mortality was 55% (6/11; CL 35%-73%) among patients with anatomic pulmonary atresia.

An experience with surgical intervention in 24 neonates with Ebstein anomaly reported by Shinkawa and colleagues supports a policy of shunt only in the presence of refractory cyanosis without severe tricuspid regurgitation. In the presence of severe regurgitation and refractory heart failure, RV exclusion provided possibly superior hospital (73%, 8/11; CL 53%-87%) and late survival (63%) compared with tricuspid valve repair (25%, 1/4; CL 4.0%-62% for hospital and late survival).

Early (Hospital) Death in Children and Adults

Thirty-day mortality in the Mayo Clinic series of 539 patients (1972-2006) was 6.1% (33 deaths; CL 5.0%-7.4%), but 2.7% after 2001, which is representative of what can be accomplished in these often ill patients. Augustin and colleagues reported two hospital deaths among 60 patients (3.3%; CL 1.1%-7.7%) (1974-1995). These results are improved over those obtained in an earlier era. A multicenter study from the European Congenital Heart Surgeons Association reported a hospital mortality of 8.3% (CL 5.4%-12%) among 96 patients undergoing tricuspid valve repair or replacement between 1992 and 2005. In patients operated on from September 1993 to September 2008, Malhotra and colleagues report no early (0%; CL 0%-3.3%) or late mortality in a group of 57 non-neonatal patients (median age 8 years, range 7 months to 40 years), among whom 95% had valve repairs and 54% had concomitant cavopulmonary shunts. Using near routine excision of atrialized RV, detachment and repair of the tricuspid valve leaflets, and anulus plication, Wu and colleagues reported no early mortality (0%; CL 0%-2.3%) among 83 patients operated on between 1997 and 2006. Among 52 children aged 5 months to 12 years undergoing repair of Ebstein anomaly at the Mayo Clinic between 1974 and 2003, early mortality was 5.8% (3/52; CL 2.6%-11%), with no deaths since 1984 (0/31; CL 0%-5.9%). da Silva and colleagues reported a 2.5% hospital mortality (1/40; CL 0.4%-8.2%) among 40 patients undergoing the cone procedure between 1993 and 2005.

Mode of death is usually acute cardiac failure, probably related to preoperative RV enlargement and dysfunction. Improved methods of myocardial management, increasing prevalence and success of tricuspid valve repair rather than replacement, and possibly selective use of bidirectional cavopulmonary shunts have contributed to reduced early mortality.

Time-Related Survival

The seriousness of Ebstein anomaly is well demonstrated in a long-term follow-up study of a heterogeneous group of patients without major associated cardiac anomalies, 18 of whom (n = 48) underwent 22 operations. Median survival for the overall group was 47 years. Survival was similar in

patients who presented during the first 3 days of life but survived to 6 months of age, and those who presented after 3 months of age. All four patients in whom permanent atrial fibrillation developed died within 5 years.

Late deaths are uncommon after tricuspid valve repair (or replacement) and ASD closure, with about 80% of patients surviving long term. However, among 52 children undergoing repair, 15-year survival was 90%. Deaths are often sudden and attributable to rhythm disturbances. Although it seems that late survival and freedom from reoperation would be better after successful valve repair than replacement, the Mayo Clinic analysis indicates no difference in late reoperation-free survival between patients receiving tricuspid valve repair vs. replacement among patients 12 years of age or older. However, among patients under age 12, reoperation-free survival is superior for those undergoing valve repair.

Preoperative risk factors for late mortality include higher hematocrit (worse cyanosis), severe mitral valve regurgitation, prior cardiac operations, and moderate to severe reduction in RV systolic function. Left ventricular dysfunction is also a risk factor for early and late mortality, despite the finding of improved left ventricular systolic function in most such patients following Ebstein anomaly repair.

**Right Ventricular Function**

Little is known about the long-term fate of RV function after neonatal surgery for Ebstein anomaly. However, Reemtsen and colleagues compared echocardiographic findings at 6 to 204 months (median 30 months) with those immediately prior to the Starnes procedure performed in the neonatal period. The Great Ormond Street ratio (see Table 42.2) and RV size decreased prior to the bidirectional Glenn, indicating RV regression. Left ventricular septal impingement on left ventricular cavity dimensions decreased an average of 38%, with normalization of left ventricular morphology and systolic function. These findings have important implications in predicting favorable outcomes after the Fontan operation if a single-ventricle strategy is selected in the neonatal period.

**Functional Status**

Most patients (about 85%) achieve good functional status (NYHA class I or II) and improved performance during objective exercise testing postoperatively, although many are severely limited preoperatively. Residual symptoms, when present, are usually related to troublesome, non-WPW supraventricular arrhythmias. Failure to eliminate the atrialized portion of the RV has not been shown to decrease the probability of a good functional result. The effect of a bidirectional cavopulmonary shunt on late functional status has been incompletely studied, but favorable midterm functional status has been reported.

**Tricuspid Valve Function after Repair and Freedom from Reoperation**

Although many reports indicate absent or mild tricuspid regurgitation early and midterm after repair, concerns remain about the important occurrence of late tricuspid valve replacement. Several areas of controversy relate to the optimal methods to prevent late, progressive tricuspid regurgitation. The Danielson and Carpentier techniques (see Technique of Operation) rely on creating essentially a monoleaflet valve that coapts against the RV septum in the area of the septal leaflet. This area has been observed as the site of recurrent tricuspid regurgitation, which theoretically may be obviated by direct leaflet coaptation in the septal area, as is achieved with the cone procedure (see Technique of Operation).

da Silva and colleagues reported no reoperations for tricuspid valve replacement, but one for re-repair and a 9% occurrence of moderately severe early tricuspid regurgitation among 40 patients who underwent the cone procedure. Freedom from further tricuspid regurgitation has been maintained in the intermediate term. Whether this technique and repair principles provide an important improvement in late valve function will require further long-term studies.

**Postrepair Rhythm Disturbances**

Complete heart block is uncommon after repair, despite the distorted morphology in the region of the bundle of His. WPW has mostly been cured by concomitant sectioning of the accessory pathways (see Chapter 16), which can be accomplished without increasing operative risk. However, episodic non-WPW supraventricular tachycardia continues late postoperatively in about 20% of patients. Uncommonly, even after successful surgical relief of WPW syndrome, late sudden death occurs. The substrate for atrial arrhythmias is enhanced by the large right atrium, RV dysfunction, and tricuspid regurgitation that frequently accompany Ebstein anomaly late after operation. Stulak and colleagues at the Mayo Clinic reported greater than 90% freedom from late recurrence of atrial fibrillation or flutter with a right-sided maze procedure plus isthmus ablation. An ongoing area of controversy relates to the possible benefit of a prophylactic right-sided maze procedure at the time of Ebstein anomaly repair.

**RESULTS OF OTHER PROCEDURES**

Repair of Atrial Septal Defect Alone

The risk associated with simple ASD closure is low in properly selected patients. In the combined UAB-GLH experience, nine patients with either left-to-right or right-to-left shunts and competent but abnormal tricuspid valves underwent simple ASD closure, with no hospital deaths (CL 0%-19%; Table 42.4). It is surprising that closure of the ASD was well tolerated in the face of preoperative right-to-left shunting, but this was also the experience at the Mayo Clinic and has been the case in pulmonary stenosis with intact ventricular septum (see Chapter 39).

When a left-to-right shunt is present preoperatively, late results are good (see Table 42.4). Thus, in the combined UAB-GLH experience, three patients in this category were hospital survivors; two had excellent long-term results, and one had WPW syndrome with episodic arrhythmias.

If the indication is appropriate, late results of simple ASD closure are also good in patients with right-to-left shunting preoperatively and important cyanosis. At late postoperative...

Data from combined UAB-GLH experience.

*ASD repair alone was performed in eight; ASD and VSD repair in one; ASD repair and pulmonary valvotomy in one; ASD repair in patient with suspected myxoma in one. One patient with ASD repair and tricuspid valvotomy, not included in this table, died 2 weeks after hospital discharge.

†Bidirectional, but dominantly R → L.

follow-up, four of five such patients in the UAB-GLH experience were alive and acyanotic, but all had episodic arrhythmias, severe in three cases. Two patients considered themselves functionally normal (NYHA class I), whereas two were in NYHA class II (see Table 42-4). One patient had an initially good result, and then cyanosis and severe disability recurred. Three years after his initial operation, he died after reoperation for reclosure of the septal defect and tricuspid valve replacement.

Tricuspid Valvotomy

The rare occurrence of tricuspid stenosis invites tricuspid valvotomy, but severe regurgitation may result. If the Carpenter technique of fenestration to restore or substitute for interchordal spaces is not satisfactory, valve replacement is indicated.

Pulmonary Valvotomy

Pulmonary valvotomy can have low hospital mortality in patients with Ebstein anomaly when indications are appropriate. This procedure may be life saving in neonates, because it decreases the degree of tricuspid regurgitation.

**INDICATIONS FOR OPERATION**

Neonates presenting in extremis, usually in the first week of life, are immediately intubated and begun on prostaglandin E₁, appropriate catecholamine support, aggressive treatment of metabolic acidosis, and other intensive therapy (see Special Situations and Controversies). Once stabilized, a Starnes procedure is performed, particularly if the patient has a Celermajer grade of 3 or 4 (see Special Situations and Controversies). If the patient’s condition does not stabilize, operation is performed at an exceptionally high risk.

Extracorporeal membrane oxygenation (ECMO) should be considered in such circumstances, either before or following emergency operation.

In the absence of severe cyanosis or symptoms of heart failure, medical management is advisable. Surgical intervention should be considered with the development of heart failure symptoms, worsening cyanosis, progressive increase in heart size, reduction in ventricular systolic function, or the appearance of atrial or ventricular tachyarrhythmias. The presence of severe tricuspid regurgitation and moderate cyanosis secondary to right-to-left shunting through the ASD should prompt earlier surgical intervention. Severe limitations and severe hypoxia are not contraindications to repair, although increased hospital mortality in patients in functional NYHA class IV argues strongly in favor of advising operation before disability is this advanced. The correlation between sudden death and cardiomegaly argues for operation when the cardiothoracic ratio reaches 0.60 or greater, regardless of symptoms.

Among patients under about 12 to 14 years of age, valve repair is greatly preferable to replacement. In older teenagers and adults, tricuspid valve replacement is a suitable option if repair appears unlikely to succeed.

Simple repair of the ASD is indicated when there is a large left-to-right shunt (Qp/Qs > 2), with or without symptoms of heart failure, and little or no tricuspid regurgitation. Simple repair of the ASD, without repair (or replacement if needed) of the tricuspid valve, is otherwise rarely advisable.

In patients with WPW syndrome that is producing life-threatening arrhythmia, the accessory conduction pathways should be divided or ablated, and the valve defect should be treated concomitantly on its merits. Atrial communications should be closed at the time of accessory pathways division. Other arrhythmias are not an indication for operation, because their occurrence is not altered by correction of the valve defect. However, they are undoubtedly less well tolerated in the presence of severe tricuspid regurgitation,
cardiomegaly, and cyanosis, and can then be an added indication for operation on the valve.

**SPECIAL SITUATIONS AND CONTROVERSIES**

**Morphology**

Confusion as to morphologic classification has arisen in some infants who have pulmonary atresia and minor downward displacement (or adherence) of the septal tricuspid leaflet origin (see Chapter 40). When this is the only Ebstein-like leaflet abnormality present, the defect is not classified or treated as Ebstein anomaly. In a number of infants with pulmonary atresia, however, the tricuspid valve shows additional typical and often florid features of Ebstein anomaly in association with severe regurgitation. Such patients form one variety of complex Ebstein anomaly.

**Management of Critically Ill Neonates with Ebstein Anomaly**

When neonates with Ebstein anomaly present with severe cyanosis, prostaglandin infusion is initiated to maintain or restore ductal patency. Urgent echocardiographic evaluation is performed to establish the diagnosis and evaluate the RV outflow tract. If antegrade flow through the pulmonary valve is absent, the pulmonary atresia may be functional (elevated pulmonary vascular resistance coupled with severe tricuspid regurgitation and RV dysfunction) or anatomic. A trial of inhaled nitric oxide is warranted to lower pulmonary vascular resistance and promote antegrade flow through the pulmonary valve if it is patent. If nitric oxide is helpful in bridging a marginal patient through the neonatal period, the addition of oral sildenafil may be useful. Other standard measures for critical ill neonates with Ebstein anomaly include placement of umbilical arterial and venous catheters and mechanical ventilation with the minimum effective airway pressure and tidal volumes of 10 to 15 mL · kg⁻¹ to recruit areas of atelectasis. If the RV outflow tract is functional, a trial of prostaglandin weaning is indicated. If SaO₂ is maintained at 70% or greater without heart failure, surgical intervention may not be necessary.

If prostaglandin weaning is not successful, two situations may occur. If the circulation is stable without evidence of heart failure and the only problem is unacceptable cyanosis, a systemic-to-pulmonary shunt may be the only necessary procedure. However, if heart failure and circulatory compromise persist, the tricuspid valve itself must be addressed, either through the Starnes procedure or valve reconstruction (see Technique of Operation).

In planning for continued medical therapy vs. the likelihood of needing surgical intervention, calculation of the Celerier score is useful in predicting risk of death (see Table 42-2).

**Type of Prosthesis for Tricuspid Valve Replacement**

A stent-mounted glutaraldehyde-preserved porcine bioprosthesis or bovine pericardial bioprosthesis may be considered optimal in most patients with Ebstein anomaly, but both are subject to the usual problems of a bioprosthesis. Mechanical prostheses may also be used to achieve long-term durability, but anticoagulant therapy is required. An analysis of the Mayo Clinic experience identified use of a bioprosthetic valve (vs. mechanical prosthetic valve) as an independent predictor of long-term survival. An allograft, either a stent-mounted pulmonary or aortic valve, or a directly attached mitral allograft supported by an anuloplasty ring, could also be considered.

**Indications for Plication (or Resection) of Atrialized Ventricle**

Indications for plication of an atrialized ventricle at the time of tricuspid valve replacement are controversial. Potential advantages of plication (or resection) include (1) reducing the size of the nonfunctional RV, potentially increasing transit of blood by improved systolic function; (2) improving left ventricular function by alleviating left ventricular compression and septal bowing; (3) moving the anterior leaflet closer to the septum by elevating the papillary muscles; and (4) providing more space for lung expansion, especially in neonates. The major potential disadvantage relates to possible distortion of or injury to the right coronary artery and its branches, which could worsen RV function and contribute to ventricular arrhythmias. Some suggest that omitting routine plication compromises RV function postoperatively; others believe that plication is indicated only when the atrialized portion of the RV is very thin walled and aneurysmal (probably about 10% to 15% of cases). Excision or plication of the atrialized portion of the repair, without need to plicate the remainder of the atrialized portion.

**Excision or Plication of Right Atrial Wall**

Excision or plication of the right atrial wall was suggested by Timmis and colleagues, who considered it important “to promote atrial emptying and lessen the likelihood of clot formation” when a mechanical prosthesis was used. Danielson and colleagues incorporate excision of the right atrial wall in their repair. The simplicity of this maneuver during valve replacement or repair makes it an attractive step when the right atrium is markedly enlarged.

**Role of Bidirectional Cavopulmonary Shunt and One-and-a-Half Ventricle Repair**

The vast majority of patients with Ebstein anomaly can undergo successful biventricular repair. However, creating a “one-and-a-half” ventricle repair can be an effective strategy if reducing the tricuspid anulus to a z value of less than −2 (or about 2.5 cm in the adult) is necessary to eliminate important tricuspid regurgitation in an infant or child with normal pulmonary vascular resistance. In this instance, functional tricuspid stenosis is managed by constructing a bidirectional cavopulmonary shunt with division of the superior vena cava at its junction with the right atrium (see Chapter 41). This strategy may also be useful when the RV is severely dysfunctional, as long as the left atrial and
pulmonary artery pressures are low. By reducing the RV stroke volume required to maintain effective cardiac output, RV work requirement is reduced and preload of the left ventricle optimized. Furthermore, the adverse effect on left ventricular function by a massively enlarged RV can be ameliorated. Bidirectional cavopulmonary shunt may also reduce residual tricuspid regurgitation. Dearani and colleagues have recommended the following criteria for constructing a bidirectional cavopulmonary shunt: left ventricular end-diastolic pressure less than 15 mmHg, transpulmonary gradient less than 10 mmHg, and mean pulmonary artery pressure less than 18 to 20 mmHg. Malhotra and colleagues recommend performing a bidirectional cavopulmonary shunt if, at the end of the repair, right atrial pressure is more than 1.5 times left atrial pressure.

The potential disadvantages of this approach include possible facial suffusion secondary to elevated jugular venous pressure and pulsations in the head and neck veins, development of collateral veins and pulmonary arteriovenous fistulas, and compromise of access for pacemaker leads.

Malhotra and colleagues reported an experience of valve repair in 54 of 57 patients with Ebstein anomaly, of whom 55% received a bidirectional cavopulmonary shunt (half of these in adults). Freedom from subsequent valve replacement was 92% at 4 years, with 95% of patients in NYHA class I. Van Arsdell and colleagues reported 90% 10-year survival following one-and-a-half ventricle repair.

**Indications for Single-Ventricle Pathway**

The potential advantages of RV exclusion (Starnes procedure) for severely ill neonates with Ebstein anomaly are discussed under “Survival” in Results after Repair. Such patients, if they survive the initial neonatal procedure, have a high likelihood of survival through the bidirectional Glenn stage.

A particularly high-risk morphologic subset of Ebstein anomaly is hearts with the combination of severe tricuspid regurgitation and anatomic pulmonary atresia. Symptomatic infants and children with this combination are likely best treated with a single-ventricle strategy. Polimenakos and colleagues have also applied this strategy successfully in an adult Ebstein’s treated with a single-ventricle strategy. Polimenakos and colleagues have recommended the following criteria for constructing a bidirectional cavopulmonary shunt: left ventricular end-diastolic pressure less than 15 mmHg, transpulmonary gradient less than 10 mmHg, and mean pulmonary artery pressure less than 18 to 20 mmHg.

Malhotra and colleagues reported an experience of valve repair in 54 of 57 patients with Ebstein anomaly, of whom 55% received a bidirectional cavopulmonary shunt (half of these in adults). Freedom from subsequent valve replacement was 92% at 4 years, with 95% of patients in NYHA class I. Van Arsdell and colleagues reported 90% 10-year survival following one-and-a-half ventricle repair.

Q
Truncus arteriosus (persistent truncus arteriosus, truncus arteriosus communis, common aorticopulmonary trunk) is a congenital cardiovascular malformation in which one great artery arising from the base of the heart by way of a single semilunar (truncal) valve gives origin to the coronary, systemic, and one or two pulmonary arteries proximal to the origin of the brachiocephalic branches. It is one of several diagnoses within the phylum of common ventriculoatrial junction (see http://www.ipcc.net/). A ventricular septal defect (VSD) is almost always present beneath the truncal valve.

This definition excludes those hearts in which there are no true pulmonary arteries and in which the lungs are supplied only by large aortopulmonary arteries (Collett and Edwards type IV), characteristic of tetralogy of Fallot and pulmonary atresia with absence of the pulmonary trunk and the central and hilar portions of the right and left pulmonary arteries (see “Morphology” under Tetralogy of Fallot with Pulmonary Atresia in Section II of Chapter 38). Excluded also from discussion in this chapter are hearts with a common arterial trunk but an intact ventricular septum. Whether hearts in which there is a VSD but no interventricular communication during diastole (because the semilunar cusps close against the crest of the ventricular septum) should be considered to have an intact septum is controversial.

HISTORICAL NOTE

The first well-documented case of truncus arteriosus was reported by Wilson in 1798, and existence of the entity was confirmed by accurate clinical and autopsy reports of a 6-month-old infant by Buchanan in 1864. In the early literature, there was frequent confusion with a single arterial trunk and, although Vievordt clarified this aspect in 1898...
(quoted by Victoria and colleagues\textsuperscript{17,23}), confusion existed as late as 1930 when Shapiro\textsuperscript{55} distinguished it from hearts with aortic and pulmonary atresia. Lev and Saphir proposed the basic morphologic criteria defining the anomaly in 1942,\textsuperscript{1,5} and in 1949 Collett and Edwards\textsuperscript{17} reviewed previously published cases and proposed a classification. An alternative classification was suggested by the Van Praagh in 1965.\textsuperscript{12}

Surgical treatment was initially confined to banding of one or both pulmonary arteries.\textsuperscript{19,16,89} Intracardiac repair was first successfully accomplished in 1962 at the University of Michigan using a nonvalved polytetrafluoroethylene (PTFE) conduit; the patient was alive and well 11 years later.\textsuperscript{23} Experimental work using ascending aortic allografts including the aortic valve was reported from Japan by Arai and colleagues in 1965,\textsuperscript{88} and by Rastelli and colleagues at the Mayo Clinic in 1967.\textsuperscript{2,34} Before this, in 1966, Ross and Somerville had successfully used an ascending aortic allograft in reconstructing tetralogy of Fallot with pulmonary atresia.\textsuperscript{83}

McGoon and colleagues were the first to successfully repair truncus arteriosus using an ascending aortic allograft and valve conduit (cylinder) in September 1967.\textsuperscript{89,90} Weldon and Cameron reported a successful repair in 1967.\textsuperscript{92} Binet used a xenograft valve incorporated within a polyester cylinder in 1971 (see discussion of paper by Moore and colleagues\textsuperscript{1415}), and Bowman and colleagues reported use of a glutaraldehyde-treated porcine aortic valve in a polyester cylinder in 1973.\textsuperscript{88}

The first successful conduit repair in infancy was carried out in a 6-week-old infant by Barratt-Boyes in 1971, as reported by Girinath.\textsuperscript{83}

**MORPHOGENESIS AND MORPHOLOGY**

**Morphogenesis**

Deletion of chromosome 22q11 is present in a substantial number of patients with conotruncal abnormalities. About one third of subjects with truncus arteriosus have been found to have 22q11 deletion,\textsuperscript{84,112} and many of these have additional characteristic features of DiGeorge syndrome, velocardiofacial syndrome, or conotruncal face syndrome. As such, their natural history and also their course following operation may be complicated by hypocalcemia, palatal abnormalities, learning disability, and other noncardiac problems.

**Morphology**

Truncus arteriosus is classified based on origins of the pulmonary arteries from the truncal artery (Collett and Edwards\textsuperscript{17}) and also on degree of development of the ascending aorta and ductus arteriosus in cases with a single pulmonary artery (Van Praagh and Van Praagh\textsuperscript{12}).

**Truncal Artery**

The arterial trunk (truncal artery) is larger than a normal aorta and is the only vessel arising from the base of the heart. It originates in part from both ventricles, but usually is more over the right than left ventricle.\textsuperscript{85,88,12} In an autopsy series of 56 cases, the trunk was equally balanced over both ventricles in 50%. In the remainder, it was either exclusively or predominantly over the right ventricle in 40% and over the left ventricle in 10%.\textsuperscript{41} In the unbalanced cases, the VSD was much more likely to be smaller (both shallower and narrower). From the truncal artery arise the coronary arteries and one or both pulmonary arteries.

**Pulmonary Arteries**

The pulmonary arteries usually originate just downstream from the truncal valve on the left posterolateral aspect of the truncus artery, although their origin may lie truly laterally, truly posteriorly,\textsuperscript{60} or (rarely) anterolaterally (Table 43-1).\textsuperscript{83} There is frequently a single orifice leading into a short pulmonary trunk (type I of Collett and Edwards), which then divides into left and right pulmonary arteries that follow a normal course (Figs. 43-1 and 43-2). Alternatively and less commonly, the orifice is double, the left and right branches arising separately side by side (Fig. 43-3) or occasionally with the orifice of the left pulmonary artery superior (anterior) to the right rather than to the left of it (type II of Collett and Edwards). Types I and II merge into each other and are best considered together. They comprise the majority of cases\textsuperscript{85,17,7,18} (89% of the Toronto surgical series).\textsuperscript{83}

Rarely, ostia of left and right pulmonary arteries may be widely separated and arise from opposite lateral walls of the truncal artery at either the same or different levels above the valve (type III of Collett and Edwards). This arrangement poses special problems for repair.\textsuperscript{841}

Occasionally, only one pulmonary artery originates from the truncal artery. The arterial vascular supply to the opposite lung arises either from a patent ductus arteriosus as a complete branch pulmonary artery or from large aortopulmonary collateral arteries, as in tetralogy of Fallot with pulmonary atresia.\textsuperscript{88,12} When the left pulmonary artery is the one that does not originate from the truncus (or is absent), the right often continues to arise from the left posterolateral surface of the proximal truncal artery.\textsuperscript{17,12} The term hemitrunicus has been used to describe the condition of the common arterial trunk giving rise to only one branch pulmonary artery,\textsuperscript{87} but the term is more commonly used to describe the slightly more common “origin of right (or left) pulmonary artery from the aorta.” In the latter, of course, there are two separate semilunar valves (see Chapter 45).

Stenosis of the origin of one or both branch pulmonary arteries is more frequent than absence of the origin; it is probably underestimated in autopsy compared with cineangiographic studies. It was noted in five clinical cases (10%) in one series.\textsuperscript{17}
Figure 43-1  Autopsy specimen from 12-day-old neonate with type I truncus arteriosus. A distinct short pulmonary trunk arises from the left lateral aspect of truncal artery. Right ventricle (RV) has been opened, revealing its thick wall. Ventricular septal defect (VSD) lies immediately beneath truncal valve. Note that defect's lower margin is separated from the tricuspid valve (TV) by a prominent right posterior division of the septal band (trabecula septomarginalis). Infundibular septum is absent. Key: LPA, Left pulmonary artery; RPA, right pulmonary artery; RPD, right posterior division of septal band; TrV, truncal valve.

Figure 43-2  Autopsy specimen from 6-week-old infant with type I truncus arteriosus viewed from opened right ventricle and truncal artery. Truncal valve has three cusps of normal appearance. Orifice of pulmonary trunk arises from truncal artery close to the commissure between right and left cusps of truncal valve. There is lack of continuity between the right posterior division of septal band (trabecula septomarginalis) and ventriculoinfundibular fold, allowing tricuspid–truncal valve fibrous continuity at posteroinferior margin of ventricular septal defect (VSD). Bundle of His therefore lies along this edge of VSD. Key: L, Left cusp of truncal valve; LAD, left anterior division of septal band; PA, pulmonary artery; R, right cusp of truncal valve; RPD, right posterior division of septal band; S, septal band; TV, tricuspid valve; VIF, ventriculoinfundibular fold.

Figure 43-3  Autopsy specimen from a 4-week-old infant with type II truncus arteriosus. Proximal carina between left and right pulmonary arteries is well seen lying flush with posterolateral wall of widely opened truncal artery. Truncal valve (TrV) is quadricuspid with moderately abnormal leaflets, which clinically were considered to be both stenotic and regurgitant. Key: LPA, Left pulmonary artery; RPA, right pulmonary artery.
Chapter 43  Truncus Arteriosus

“Types” under Morphology in Section II of Chapter 48), or there is severe coarctation including tubular hypoplasia of the aortic isthmus and arch (see Fig. 43-4). This arrangement (Van Praagh type A4) was present in 12% of the cases of Van Praagh and colleagues and 14% (28 of 303) of the Toronto surgical series.

Coronary Arteries

Orifices of the coronary arteries have a variable relationship to the sinuses of Valsalva above the truncal cusps (Fig. 43-5). A minority (≈20%) arise centrally (more or less normally) within the sinuses; about 80% (whether the usual two or a single orifice) are at the margin of the sinus or at the upper margin of a commissure. In at least a third of cases, one coronary orifice (usually the left) is displaced cephalad above the sinutubular ridge and must be differentiated from the pulmonary artery orifices at the time of repair. In about two thirds of cases, the left coronary artery arises from the left posterior aspect of the truncal artery, and the right coronary artery from the right anterior aspect in a position similar to normal. Deviations from this pattern occur in the remainder of cases and include a single ostium (found in 18% of hearts reported by de la Cruz and colleagues), closely approximated right and left ostia, and small, slitlike, or stenotic and kinked proximal left coronary artery.

Rarely, a coronary artery may arise from a pulmonary artery rather than the truncal artery; Daskalopoulos and colleagues report the circumflex artery’s origin from the right pulmonary artery in a patient in whom pulmonary artery banding was not tolerated. The proximal part of the left anterior descending coronary artery is frequently displaced to the left of the interventricular sulcus and does not reach it until about halfway down the front of the heart. It tends to be small. Larger-than-normal diagonal branches from the

Ascending Aorta and Ductus Arteriosus

In truncus arteriosus, there is reciprocal development between ascending and transverse aortic arches (arising from fourth aortic arch) and ductus arteriosus (arising from sixth aortic arch). Thus, in the majority of cases the ascending aorta is a direct continuation of the truncus artery and of about the same diameter (see Fig. 43-1), whereas the ductus arteriosus is usually entirely absent. Rarely a ductus is present with a well-developed arch.

By contrast, when the ductus arteriosus is present, the transverse arch is usually absent (interrupted aortic arch) and the ascending aorta is underdeveloped. The ductus is a direct continuation of the truncus artery, arching leftward to join the descending aorta (Fig. 43-4). In this situation, left and right pulmonary artery branches usually arise separately from superior and inferior (leftward and rightward) walls of the truncal artery (type III of Collett and Edwards). The ascending aorta now arises from the superior rightward aspect of the truncus artery as the relatively smaller branch. Usually the transverse aorta is interrupted beyond the origin of the left common carotid artery (type B interrupted aortic arch; see

Figure 43-4  Autopsy specimen from 7-day-old neonate with truncus arteriosus (Van Praagh type 4). A large patent ductus arteriosus is similar in diameter to the descending aorta. There is also severe coarctation of the aorta consisting of a short, nearly atretic segment and a hypoplastic arch between left common carotid (LCC) and left subclavian (LSC) arteries. Truncal artery (opened anteriorly) is wider than usual with this arrangement. Origins of left and right pulmonary arteries (not visible in photograph) are widely separated. Key: AsA, Ascending aorta; Brach, brachiocephalic artery; D, patent ductus arteriosus; Desc Ao, descending aorta; LPA, left pulmonary artery; RPA, right pulmonary artery; Tr, truncal artery.

Figure 43-5  A volume-rendered image from a computed tomography angiogram of a 2-week-old neonate with truncus arteriosus, type II of Collette and Edwards. It shows that left and right branch pulmonary arteries (arrow) arise separately from the truncus arteriosus. Aorta is normal in appearance. Key: Ao, Aorta; LPA, left pulmonary artery; T, truncus.
right coronary artery cross the anterior right ventricle inferior to conal branches, contributing to the blood supply of the upper interventricular septum and occasionally part of the left ventricle. In autopsy material, obvious severe myxomatous thickening of the cusps is present in a third of cases and is much more common in those dying as neonates (Fig. 43-7). Less severe myxomatous changes are present in two thirds of older infants (Fig. 43-8), and microscopic increase in thickness of the distal portions of the cusps is apparent in many more. In autopsy material, obvious severe myxomatous thickening of the cusps is present in a third of cases and is much more common in those dying as neonates (Fig. 43-7). Less severe myxomatous changes are present in two thirds of older infants (Fig. 43-8), and microscopic increase in thickness of the distal portions of the cusps is apparent in many more. Rarely stenosis is contributed to right coronary artery cross the anterior right ventricle inferior to conal branches, contributing to the blood supply of the upper interventricular septum and occasionally part of the left ventricle. In autopsy material, obvious severe myxomatous thicken-
by commissural fusion. A redundant truncal valve leaflet may obstruct the pulmonary trunk ostium during ventricular ejection when the ostium is proximally placed.

Ventricular Septal Defect
The VSD is high, anterior, usually large, and juxatruncal in position. It is typically stated that the truncal valve forms its superior margin (see Figs. 43-2 and 43-6). Consistent with this observation is the fact that the infundibular septum is absent in truncus arteriosus, so there is no infundibular structure to form the superior margin of the VSD, leaving the superior margin to be formed by the valve itself. Another way to characterize the VSD is to describe it as U shaped—that is, with no superior margin. This perspective can be best appreciated if one examines a specimen with the truncal valve leaflets opened to the position they occupy during systole. Inferiorly and anteriorly, the VSD is bounded by the two divisions of the septal band (trabecula septomarginalis [TSM]) and posteriorly by the free wall muscle band that separates the semilunar from the tricuspid valve (the ventriculo-infundibular fold) (see Fig. 43-2).

Usually the junction of the right posterior division of the TSM and ventriculo-infundibular fold forms a muscle bridge that separates the defect from the tricuspid valve and right trigone (see Fig. 43-1) and therefore from the bundle of His. Occasionally, this muscle bridge is absent (see Fig. 43-2) or poorly formed (see Fig. 43-8); the lower margin of the defect then approaches the tricuspid anulus, or the VSD becomes juxatruncal in position, in which case the His bundle is at risk of damage during repair. In these hearts, there may be fibrous truncal-tricuspid-mitral valve continuity. Part of the membranous ventricular septum may still be present at the postero-inferior margin of the VSD.

Right Ventricle
The infundibular (conal) septum is absent from the right ventricular outflow tract. Contrariwise, it has been asserted that the infundibular septum can be recognized fused to the distal anterior (free) right ventricular wall; rarely, there is a persistent blind right ventricular outflow pouch in front of it. The right ventricle is nearly always hypotrophied and enlarged.

Left Ventricle
In contrast to the right ventricular outflow tract, the left ventricular outflow tract is relatively normal in hearts with truncus arteriosus (see Fig. 43-6), and flow from this chamber into the truncal artery is restricted only in the unusual situation when the truncal artery originates mainly from the right ventricle and the VSD is small. A pressure gradient demonstrable on catheter withdrawal from left ventricle to aorta in such rare instances will lie at the VSD level rather than at the truncal valve. Although a moderate-sized VSD is not restrictive before surgical repair, it may prove so afterward and thus may need to be enlarged at operation (see Technique of Operation later).

Associated Anomalies
The most common associated cardiac and noncardiac anomalies are shown in Tables 43-2 and 43-3. About 10% to 20% of patients with truncus arteriosus have coexisting interrupted aortic arch or coarctation with patency of the ductus arteriosus. Truncus arteriosus is rarely associated with atrioventricular discordant connection, situs inversus, asplenia or polysplenia, or dextrocardia. Double inlet ventricle is also rare, although mitral stenosis or atresia with left ventricular hypoplasia occurs.

Frequent total absence of the ductus arteriosus has already been mentioned together with association of a widely patent ductus arteriosus in patients in whom there is also aortic arch interruption or, less often, aortic coarctation or atresia. When hearts with aortic arch interruption are excluded, right aortic arch is as common in truncus arteriosus as in tetralogy of Fallot (25%-35%). Anomalous aortic branch origins occur frequently, usually of the subclavian arteries (10%). A persistent left superior vena cava drains to the coronary sinus in about 10% of patients, and occasionally there is partial anomalous pulmonary venous connection. Patent foramen ovale is

common, and atrial septal defect of moderate or large size is found in about 10% of patients. Mitral valve anomalies of various types are present with similar frequency. Other rare lesions include atroventricular septal defect, double aortic arch, and according to Bharati and colleagues, tricuspid stenosis and (rarely) atresia.

Extracardiac congenital defects are not uncommon and may occasionally contribute to death. DiGeorge syndrome (thymic and parathyroid aplasia or hypoplasia) is known to be associated with truncus arteriosus.²²

### CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

#### Symptoms

Presenting symptoms are almost always tachypnea, tachycardia, irritability, and unwillingness to take either breast or bottle feedings during the early weeks of life, all manifestations of heart failure.⁴ Rarely, respiratory distress is aggravated by compression of the left upper lobe bronchus between an anteriorly placed left pulmonary artery and the posterior aortic arch.⁵ Even more rarely, an aneurysmal truncal valve associated with interrupted aortic arch may severely compress the right main bronchus and produce total right lung collapse. Mild cyanosis accompanies these symptoms in about one third of cases but rarely is the presenting feature. By contrast, in those infants who survive for longer periods, recurrent respiratory infections, dyspnea, and failure to thrive are usually present, and cyanosis is more apparent secondary to rising pulmonary vascular resistance. Older children may occasionally present with increasing cyanosis (Eisenmenger syndrome) and fail to give a history of heart failure in infancy.

#### Physical Examination

On examination, signs of heart failure are accompanied by a jerky to collapsing arterial pulse produced by rapid runoff from the truncal artery into the pulmonary arteries. The heart is overactive, and a prominent left parasternal systolic ejection murmur and thrill are appreciated. There is frequently an ejection click coinciding with full opening of the truncal valve, and an apical gallop rhythm may be present, although it is surprisingly rare in neonates. An aortic early diastolic murmur (from truncal valve regurgitation) is highly suggestive of truncus arteriosus, particularly when it is accompanied by pulmonary plethora on chest radiograph and right aortic arch. The second heart sound is usually single but split in about one third of cases. A continuous murmur is noted occasionally and is most often due to stenosis at the origin of one or both pulmonary arteries. Important truncal valve stenosis is a confusing feature and usually results in diminished peripheral pulses accompanied by a harsh ejection systolic murmur and thrill, maximal in the right upper intercostal spaces.

#### Chest Radiography

Chest radiography shows marked cardiomegaly as well as plethoric lung fields in neonates and infants. The pulmonary trunk segment is deficient (as in transposition), but a high origin or arching of the left pulmonary artery may be evident in older children as a “comma” sign on the left upper mediastinal border. A solitary right pulmonary artery arising from the left side of the truncus artery may give a similar appearance. The hemithorax may be smaller and vascularity
less on the side of the “absent” branch pulmonary artery (when this lung is supplied by bronchial collaterals or by a relatively small patent ductus arteriosus). In truncus arteriosus with aortic arch interruption, the descending aorta is often prominent in the chest radiograph. In those few infants who survive without treatment, pulmonary plethora subsides, as does cardiomegaly, from increasing pulmonary vascular disease.

**Electrocardiography**

Electrocardiography (ECG) usually shows combined ventricular hypertrophy and a normal or slightly rightward axis, although left ventricular hypertrophy is usually dominant in the tracing (occasionally it is absent). 

**Echocardiography**

Two-dimensional echocardiography can be diagnostic and is usually definitive, with infrequent occurrence of only minor errors. It demonstrates a single vessel overriding the ventricular septum and reveals abnormalities in the truncal valve cusps. In addition, origins of pulmonary arteries can be predicted with some accuracy, and presence of major associated abnormalities, particularly interrupted aortic arch, can be determined.

**Cardiac Catheterization and Angiography**

Cardiac catheterization and angiography may still be performed in the occasional neonate or young infant to define the pulmonary arteries, and hemodynamic state when there is an atypical physiologic presentation, such as severe cyanosis, or when there is suspicion on echocardiography that the pulmonary artery morphology is complex (e.g., unilateral aortopulmonary collaterals). Magnetic resonance imaging (MRI) and computed tomography (CT) compete with traditional angiography when structural details and some physiologic details require definition (see "Computed Tomography Angiography and Magnetic Resonance Imaging" later). There is an absolute indication for catheterization in patients who present after 6 months of life to define the status of the pulmonary microvasculature.

In neonates and young infants with typical physiology, there is left-to-right shunting at the ventricular level with a high pulmonary-to-systemic blood flow ratio (Qp/Qs) and systemic pressures in the right ventricle and pulmonary artery. The high pulmonary blood flow keeps aortic oxygen saturation at 85% or more. Pulmonary vascular resistance is mildly raised (2-4 units · m²). Atypical physiology may occur. Rarely, when the VSD is restrictive and the truncal origin is mainly from the right ventricle, left ventricular pressure may exceed that in the right. When there is truncal valve stenosis, there is a withdrawal gradient across it. The site of stenosis may be difficult to identify preoperatively. Pulmonary artery pressure is often slightly below systemic pressure, but it is importantly reduced when there is stenosis at the origin of one or the other artery.

The progressive rise in pulmonary vascular resistance that occurs in virtually all children who survive infancy is associated with a fall in arterial oxygen saturation. Arterial oxygen saturations less than 80% are usually an indication that pulmonary vascular resistance is beyond the operable range.

Cineangiography with contrast injections into both ventricles and ascending aorta demonstrates the exact site of origin of the pulmonary arteries and differentiates this lesion from patent ductus arteriosus. Special views are required to demonstrate the origin of right and left pulmonary artery branches to assess any proximal stenosis. Should one pulmonary artery fail to outline after routine contrast injections, the origin and distribution of the blood supply to the other lung must be identified. This is usually possible by injections into the upper descending thoracic aorta and its branches, defining either a ductus or large collaterals. In addition, a pulmonary vein wedge injection can be used to retrogradely fill true pulmonary arteries that fill either inadequately or not at all from an aortic injection.

These studies also provide information on alignment of the truncal artery and truncal valve with the two ventricles, truncal valve cusp thickening, and truncal valve stenosis or regurgitation. A bicuspid or quadricuspid valve may show doming in systole without stenosis being present. Site of the VSD is demonstrated, as are the two ventricles.

**Computed Tomography Angiography and Magnetic Resonance Imaging**

CT angiography (CTA) and MRI are not routinely indicated, but these imaging modalities may be indicated in specific circumstances in both neonates and older children. CTA provides excellent spatial resolution (Fig. 43-10). When echocardiography suggests complex pulmonary artery problems such as stenosis or discontinuity, but there is no concern about pulmonary vascular resistance, CTA can...
define the morphologic details, and cardiac catheterization can be avoided (Fig. 43-11). MRI can quantify the regurgitant fraction of an abnormal truncal valve, providing objective data for longitudinal follow-up and decision making (Fig. 43-12).

NATURAL HISTORY

Truncus arteriosus is rare, occurring in 2.8% of cases of congenital heart disease in the cardiac registry report by Calder and colleagues and in 1.7% of the autopsy series of Tandon and colleagues. The natural history of patients with truncus arteriosus is unfavorable. No series follow a cohort of patients from birth, so exact data are not available. However, several studies when taken in aggregate provide an accurate estimate of survival without surgical treatment. Marcelletti and colleagues report on 23 cases prior to the era of intervention. Ten patients presented in the neonatal or infancy period (Table 43-4). Additional reports of autopsy cases by Calder and the Van Praaghes, Collett, Edwards, and colleagues, and Bharati, Lev, and colleagues imply similar mortality to the Marcelletti report. In two reports, the median age of death was 5 weeks, and in another, two thirds were dead before reaching age 6 months. Similar statistics are available from the review of 357 cases by Fontana and Edwards. Bharati and colleagues report a
Figure 43-12  Parasternal long-axis echocardiographic view showing important morphologic characteristics of truncus arteriosus. Small arrows show thickened truncal valve overriding crest of intraventricular septum (s), with the ventricular septal defect evident above septal crest and below truncal valve. Left pulmonary artery (LPA) is seen exiting from left and posterior aspect of common trunk (TR). Large arrows identify arch branches. Coronary arteries are not well visualized in this view. Right pulmonary artery is out of the plane of this view. Key: A Ao, Ascending aorta; ARCH, aortic arch; LA, left atrium; LV, left ventricle; RV, right ventricle.

*Where no value is given, the pulmonary artery pressure was unknown.

†Autopsy performed at Mayo Clinic; specimen available.

Key: ARI, Acute respiratory infection; ASD, atrial septal defect; Asymp., asymptomatic; C, cyanosis; HF, heart failure; LPA, left pulmonary artery; PDA, patent ductus arteriosus; Rp, pulmonary resistance; Sat., saturation; TVR, truncal valve regurgitation.
mean age of death of 6 months in 177 cases. Other isolated case reports confirm that some subjects, perhaps 10%, survive into adolescence or young adult life, but usually with severe pulmonary vascular disease.

Based on all these reports, about 50% of those born with this condition survive beyond the first month of life, 30% beyond 3 months, 15% beyond 6 months, and 10% beyond 1 year. There is little further mortality beyond this age until pulmonary vascular disease becomes severe and death occurs with Eisenmenger syndrome in about the third decade of life. Death in infancy is invariably due to heart failure, and when it occurs in the neonatal period, severe truncal valve regurgitation and large left-to-right shunt play contributing roles. The situation may be compounded by severe respiratory infection, as in other malformations with large left-to-right shunts in early life.

Longer-term survivors may occasionally succumb from infective endocarditis or cerebral abscess, but most eventually die from consequences of severe pulmonary vascular disease (see “Pulmonary Vascular Disease” under Natural History in Section I of Chapter 35). When pulmonary vascular disease develops during the first year of life or later (and it typically develops more rapidly than in patients with isolated VSD), the patient has a good chance of surviving at least into the teens, as is usually the case with Eisenmenger syndrome. Thus 7 of 10 Mayo Clinic patients with pulmonary vascular resistance greater than 8 units · m⁻² at diagnosis before 1 year of age were alive (without treatment) 1 to 15 years (average 8.3 years) later.

Rather remarkably, a few patients survive infancy and early childhood without developing severe pulmonary vascular disease despite large left-to-right shunts. These patients probably represent less than half of those surviving beyond 1 year of age and less than 5% of all those born with truncus arteriosus.

Survival is adversely affected by severe truncal valve regurgitation, as noted earlier, or by truncal valve stenosis. Even in older patients, truncal valve regurgitation is present in 60% to 70% of cases. Regurgitation may be predominantly into the right ventricle. Survival is also adversely affected by coexisting interrupted aortic arch or coarctation. Survival is also less favorable when there are other associated severe lesions such as left ventricular hypoplasia and a small or atretic mitral valve, complete atrioventricular septal defect, or serious extracardiac anomalies.

Survival is favorably affected by pulmonary stenosis (narrowing at the origins of the pulmonary trunk or right or left pulmonary arteries). Four of the first 28 (14%) truncus patients repaired beyond infancy at the Mayo Clinic had naturally occurring pulmonary artery stenosis.

The TECHNIQUE OF OPERATION

Repair by whatever technique chosen is usually performed during mildly to moderately hypothermic cardiopulmonary bypass (CPB) using a distally placed aortic cannula, one right atrial or two vena caval cannulae, and a left-sided vent placed through the right upper pulmonary vein. Although there is no technical reason to use deep hypothermia with either lowflow CPB or circulatory arrest, some surgeons prefer it. The branch pulmonary arteries are exposed and temporarily occluded with either nontraumatic microvascular clips or snares immediately after CPB is established.

Ideally, myocardial management is accomplished with cold blood cardioplegia using antegrade cardioplegia infused directly into the truncal root (also while the branch pulmonary arteries are occluded). When moderate or severe truncal regurgitation is present, the patient is cooled on CPB to the target temperature (or until ventricular fibrillation occurs spontaneously), the truncal root is clamped and opened, and cardioplegia is delivered directly into the coronary ostia (see “Methods of Myocardial Management during Cardiac Surgery” in Chapter 3). However, surgeon preference and morphologic findings may dictate other combinations.

Repair with Allograft Aortic or Pulmonary Valved Conduit

Following primary median sternotomy, a piece of pericardium may be taken and laid aside in a moist sponge. The proper-sized allograft aortic or pulmonary valved conduit (10-12 mm for a neonate, 12-14 mm for an infant) is selected, and its processing for insertion is begun (see Appendix 12A in Chapter 12 and Technique of Repair in Section II of Chapter 38).

Left and right pulmonary arteries are dissected in preparation for immediate temporary occlusion at the institution of CPB, as described earlier. The usual purse-string sutures are placed (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2), positioning the one for aortic cannulation as far downstream as possible so that the aortic clamp (placed proximal, or upstream, to the cannula) will be as far distal as possible on the ascending aorta.

Once CPB has been established and the pulmonary arteries controlled, cooling to the target core temperature is accomplished. The aorta is clamped and cardioplegia delivered. Snare on the pulmonary arteries are released, and repair is begun. The pulmonary trunk origin is detached from the truncal artery (Fig. 43-13, A-B); in truncus type II, an appropriate ellipse of truncal wall is included in the excision. The incision for detachment is begun on the left side, typically only several millimeters distal to the sinutubular junction of the truncal valve. The incision is initially made only large enough so that the interior of the truncal artery and valve, ostia of the coronary arteries, and orifices of right and left pulmonary arteries can be directly visualized. High origin of the left coronary artery should be distinguished from a pulmonary artery orifice. Detachment is then completed while viewing all these structures from within. The resulting orifice in the truncal root is closed with two rows of continuous 4-0 or 5-0 polypropylene sutures, using the second row to bring adventitia over the first row. This is done carefully to avoid distorting the coronary arteries or the truncal valve; a patch is often used for closure if direct repair risks distortion.

Alternatively, in some cases of truncus type I, the main pulmonary trunk may have enough length before it bifurcates into the two pulmonary branches such that it can be controlled directly rather than controlling the two branch pulmonary arteries individually. When this is possible, a vascular clamp can be placed across the base of the pulmonary trunk flush against the truncal root immediately upon the institution of CPB. When this is possible, the pulmonary trunk can then be separated from the truncal root, and the truncal root sutured at the clamp while the core cooling is taking place.
place prior to aortic clamping and cardioplegia. Thus, the subsequent period of aortic clamping can be substantially shortened.

When the pulmonary trunk or separately arising (but closely related) left and right pulmonary arteries arise from the posterior aspect of the truncal artery, they are excised as part of a large button of truncal wall. The opening into the truncus is closed with a patch. The distal end of the allograft valve cylinder is then anastomosed to the large button. Similarly, when widely separated right and left pulmonary arteries come off the lateral truncal walls at the same level above the truncal valve, they are excised along with a strip of posterior truncal wall or with the entire circumference of that part of the truncal artery. Excised origins of the pulmonary arteries and adjacent aortic wall are converted into a tube, to which the distal end of the allograft valve cylinder is anastomosed.\textsuperscript{[50,51]} The transected truncal root is reconstituted by end-to-end anastomosis.

Complete mobilization of the distal portion of the ascending aorta, arch, and brachiocephalic arteries should nearly always

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure43-13.png}
\caption{Repair of truncus arteriosus I, II with allograft valve cylinder. A, After establishing cardiopulmonary bypass and clamping the aorta, pulmonary arteries are temporarily occluded while cardioplegic solution is infused, and incision for separation of pulmonary trunk from truncus artery is begun. After looking through the incision and determining the precise origin of coronary and pulmonary arteries, excision of pulmonary trunk is completed. Dashed line represents proposed vertical right ventriculotomy. B, Pulmonary trunk has been cut away from truncal artery, and suture line in the latter is near completion. Distal end of pulmonary trunk is prepared for conduit. Longitudinal ventriculotomy has been made. Ventricular septal defect (VSD) illustrated is typical, with a band of muscle (see Fig. 43-1) separating it from tricuspid anulus. C, VSD is closed by suturing patch to edges of VSD, the atrioventricular node and bundle of His being away from this edge. Key: IVC, inferior vena cava; LPA, left pulmonary artery; RPA, right pulmonary artery; RV, right ventricle; SVC, superior vena cava.}
\end{figure}
allow direct anastomosis. The alternative of interposing a short segment of polyester graft is undesirable.

When widely spaced left and right pulmonary arteries arise from the lateral truncal wall at different levels above the truncal valve, pulmonary arteries are removed separately from the truncal root, each with a segment of surrounding truncal tissue. The branch pulmonary arteries are sewn together behind the truncal root to create continuity, using the extra truncal tissue to create a short tunnel that will be used to accept the distal aspect of the right ventricle to pulmonary conduit. The two separate defects in the truncal root are repaired with patches. A longitudinal right ventriculotomy is made just proximal to the truncal valve, essentially parallel to and to the right of the left anterior coronary artery; stay sutures may be placed for exposure. Alternatively, the opening may be enlarged to an oval shape by excising muscle from the anterior wall, leaving adequate tissue along the right and left sides so that neither the left anterior descending nor right coronary arteries will be compromised during subsequent suturing.

The VSD is repaired through the right ventriculotomy as described for tetralogy of Fallot (see “Repair of Uncomplicated Tetralogy of Fallot with Pulmonary Stenosis via Right Ventricle” under Technique of Operation in Section I of Chapter 38). However, in most cases of truncus arteriosus, there is a rim of muscle between the VSD and tricuspid anulus (ventriculoinfundibular fold; see Morphology earlier); this facilitates repair of the VSD, because sutures may be placed in this muscular rim postero-inferiorly without producing heart block or tethering the septal leaflet of the tricuspid valve (Fig. 43-13, C). If the VSD extends far posteriorly and is juxtratricuspid as well as juxtatruncal, the appropriate suture technique must be used (away from the rim of the VSD) (see Technique of Operation in Section I of Chapters 35 and 38). As in repair of tetralogy of Fallot with pulmonary atresia (see Section II of Chapter 38), the superior sutures may pass into the anterior right ventricular wall where it forms the distal margin of the circular VSD opening. If the lower margin of the VSD lies so close to the truncal valve that the left ventricular outflow tract would be narrowed following patch closure, the VSD is enlarged by excising a wedge of muscle from its anteroinferior margin. The defect is then closed with a polyester, PTFE, or pericardial patch in a manner similar to that used in repair of double-outlet right ventricle (see Fig. 53-13 in Chapter 53).
While the heart is still under cardioplegic arrest, the atrial septum is addressed if necessary. In most circumstances when a valved right ventricular outflow tract conduit is used, both secundum atrial septal defects and patent foramen ovales should be closed. If two caval cannulae are used for CPB, the cavae are snared at this point. If a single right atrial cannula is used, it is positioned into the inferior vena cava at this point. A right atriotomy is made. In the case of a single right atrial cannula, a cardiotomy suction device is positioned into the superior vena cava orifice. The atrial defect is then closed either primarily or with an autologous pericardial patch, as appropriate, using a continuous 5-0 or 6-0 polypropylene suture. The atriotomy incision is then closed.

Before placing the right ventricular outflow tract conduit, the aortic clamp is removed and core rewarming started. The allograft valve cylinder is then trimmed to an appropriate length. A conduit that is too long tends to kink the pulmonary trunk bifurcation or the back wall of the conduit itself. Either an aortic or pulmonary allograft valved conduit can be used; however, pulmonary is preferred in those requiring augmentation of the native pulmonary trunk bifurcation or stenotic pulmonary artery orifice.  

If there is narrowing at the origins of the right or left pulmonary artery, the offending artery is opened longitudinally across the stenosis, and a tongue of allograft is left on the distal end of the conduit, widening this point. The distal conduit–to–pulmonary artery end-to-end anastomosis is constructed with continuous 6-0 or 7-0 polypropylene. The proximal end of the conduit may be anastomosed directly to the right ventriculotomy (Fig. 43-13, D). The posterior portion of the conduit suture line may also pick up adjacent edges of the VSD patch and right ventricular wall. A hood of pericardial or allograft arterial wall patch is usually needed to complete the anterior portion of the proximal attachment of the allograft to the ventriculotomy (Fig. 43-13, E). To avoid conduit valve compression or distortion and valvar regurgitation, the valve should be placed distal to its usual anatomic position, away from the back of the closed sternum. As this anastomosis is being made, rewarming is accomplished, and the remainder of the operation is completed in the usual manner (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2).

In neonates with typical preoperative physiology and in whom a post-CPB transesophageal echocardiogram shows normal left ventricular and right ventricular function, a right atrial volume and pressure monitoring polyvinyl catheter should be placed if one has not been placed preoperatively by the anesthesiology team. Pulmonary artery and left atrial catheters are not needed.

In older patients in whom pulmonary hypertensive episodes can be expected with a high likelihood, in patients with atypical preoperative physiology, and in those with reduced ventricular function by echocardiography post-CPB, a very important step is placing fine polyvinyl catheters in the left atrium, right atrium, and pulmonary artery by way of the right ventricle so that postoperative care may be rational, with particular regard for paroxysmal pulmonary hypertensive crisis. As for other repairs using right ventricular–to–pulmonary artery conduits, conduit reoperation may be expected in the future. Therefore, some form of pericardial closure should be considered, usually using PTFE pericardial membrane to protect the anteriorly placed conduit from injury during resternotomy.

Repair of Truncus I, II with Autologous Tissue for Right Ventricular Outflow Tract

Preliminary steps in the operation are the same as those already described, and mildly or moderately hypothermic CPB is established in a similar fashion. The snares previously placed around left and right pulmonary arteries are snugged down, cooling of the patient is begun, the aorta is clamped and cold cardioplegia given, the left side of the heart is vented via the right upper pulmonary vein, and the snares are removed.

A longitudinal incision is made into the anterosuperior aspect of the left pulmonary artery and extended inferiorly into the truncal root toward the left sinus of Valsalva (Fig. 43-14, A). The interior of the truncal root is inspected through the incision, and orifices of left and right pulmonary arteries, coronary ostia (particularly that of the left coronary artery), and truncal valve cusps are identified. A woven polyester, PTFE, or pericardial patch (with or without immersion in glutaraldehyde) is then sewn into place to partition the truncal root into aortic and pulmonary trunks (Fig. 43-14, B).

A vertical incision is made into the right ventricle, extending it nearly to the truncal wall over the left-sided sinus of Valsalva. The VSD is repaired. The posterior wall of the right ventricular–pulmonary trunk pathway is created by suturing the inferior flap of the initial left pulmonary artery/trunkal root incision to the superior aspect of the right ventricular borders of the ventriculotomy (Fig. 43-14, C). The anterior wall is created by suturing into place a patch of autologous or bovine pericardium or synthetic material (Fig. 43-14, D). Barbero-Marical, the innovator of this method, uses a bovine pericardial patch, to the undersurface of which has been attached a bovine pericardial monocuspid valve. The remainder of operation is completed in the usual manner.

When the pulmonary trunk or separate but closely related left and right pulmonary arteries arise from the posterior aspect of the truncal artery, excision is as described in the previous section. A modification of the technique may then be necessary because of the distance between the opening into the pulmonary arteries and right ventriculotomy. In this modification, the left atrial appendage is interposed to create the posterior wall of the right ventricular–pulmonary arterial pathway (Fig. 43-15).

Repair of Truncus with Single Branch Pulmonary Artery Arising from Truncal Root

Morphology of this lesion is highly variable, and experience with each type is limited. If the lung that does not have an arterial connection to the truncal root is supplied by a true branch pulmonary artery connected to a ductus arteriosus, single-stage neonatal repair is recommended. The technique of creating pulmonary artery continuity is similar to that described previously for widely separated branch pulmonary arteries that arise at different levels above the truncal valve. Care must be taken to eliminate the ductal tissue from the anastomosis.

If the lung that does not have an arterial connection to the truncal root is supplied by aortopulmonary collaterals, several options are available. If the collaterals are few and
At a second-stage procedure through a median sternotomy—which can be performed days to weeks later—vascular continuity of the two lungs is created and intracardiac repair performed. After taking down the previously created shunt and removing the pulmonary artery from the truncal root, the right and left pulmonary arteries are made confluent with each other behind the truncal artery, either by direct anastomosis or with interposition of an autologous pericardial tube. After the VSD has been repaired, a valved conduit is interposed between the confluent pulmonary and right ventriculotomy.

Figure 43-14  Repair of truncus arteriosus I, II with autologous tissue (Barbero-Marcial and colleagues). A, Incision is made into pulmonary trunk and adjacent portion of truncal artery. Proposed right ventriculotomy (dashed line) begins just beneath left side of sinuses of Valsalva and extends downward and slightly leftward, avoiding (inasmuch as possible) large diagonal branches of right coronary artery. Usually the incision opens widely after stay sutures are placed, but if it does not, some free right ventricular wall may be excised. B, Patch is placed to separate completely neoaorta from neopulmonary trunk. Illustration shows that the patch is placed clearly on the pulmonary trunk side of cusps of neoaortic valve and coronary ostia (i.e., anteriorly). After separating neopulmonary artery from truncus (now neoaorta) the ventricular septal defect (VSD) is closed with a patch. C, Inferior aspect of original “truncal” incision is attached to upper portion of right ventriculotomy using fine polypropylene suture. D, A roof is placed on the opening with essentially the same technique and materials used for inserting a transanular patch in repair of tetralogy of Fallot (see “Decision and Technique for Transanular Patching” under Technique of Operation in Section I of Chapter 38). Note: Barbero-Marcial places a monocusp valve in the outflow patch that closes against the posterior suture line between pulmonary trunk and right ventricle.

large, unifocalization and complete repair in one stage is preferred. The technique of unifocalization is similar to that described for single-stage unifocalization using a median sternotomy (see Chapter 38). The unifocalized lung arterial supply is then made continuous with the “normal” pulmonary artery from the opposite lung, and intracardiac repair is accomplished. If the collaterals are multiple and complex, an initial thoracotomy is performed to unifocalize the arterial supply and create a vascular hilar confluence in the affected lung. The unifocalized vessel is then connected to a systemic-to-pulmonary artery shunt.
Repair of Truncus Arteriosus with Interrupted Arch

One-stage repair from the anterior approach is the preferred procedure.\cite{33,57,33,55,31,53,55} We recommend using extracorporeal circulatory management without circulatory arrest. After standard exposure through a median sternotomy, the thymus gland is subtotally resected and the pericardium opened. The great vessels are dissected above the brachiocephalic vein into the base of the neck, providing full exposure of the brachiocephalic artery. A purse-string suture is placed in the midportion of the brachiocephalic artery in preparation for arterial cannulation (Fig. 43-16, A-B). Purse-string sutures are placed in the superior and inferior venae cavae for venous cannulation and in the right upper pulmonary vein in preparation for left-sided venting. Depending on patient size, either a 6F or 8F arterial cannula is used to perfuse the systemic circulation through the brachiocephalic artery. Bivacal cannulation with appropriately sized right-angled venous cannulae is also performed.

Once CPB is initiated, the two branch pulmonary arteries are temporarily occluded with either snares or vascular clamps, allowing perfusion of the lower body through the ductus arteriosus. After a core body temperature of 25°C is achieved, the ductus arteriosus is ligated and divided just distal to the left branch pulmonary artery origin, and perfusion flow is reduced to 30 to 40 mL · kg⁻¹ · min⁻¹, effectively establishing antegrade selective cerebral perfusion. The aorta is clamped and cardioplegia introduced into the aortic root. Cavai snares are tightened to provide occlusive venous return, and a vent is placed through the right upper pulmonary vein purse string, across the mitral valve, and into the left ventricle.

The distal ductus arteriosus and proximal descending aorta are dissected to the second set of intercostal vessels, and a curved vascular clamp is placed on the descending aorta to prevent backbleeding. All ductal tissue is resected from the descending aorta. The aortic clamp is then adjusted by moving it superiorly to allow arterial perfusion to the brachiocephalic and left carotid arteries while leaving the ascending aorta available for aortic arch reconstruction. This is achieved by placing the aortic clamp in a slightly oblique position as shown in Fig. 43-16, C.

Arch reconstruction as shown in Fig. 43-16, C and D is performed, using the left subclavian artery to establish arch continuity. The pulmonary trunk confluence is removed from the side of the common trunk in standard fashion. The ascending aorta is then incised from the opening in the truncal root that resulted from removing the pulmonary arteries, up to the arch. The ascending aorta, arch, and proximal descending aorta are augmented with a patch similar in length and shape to the patch used in stage-one reconstruction for patients with hypoplastic left heart physiology (see Chapter 49).

Alternatively, a direct descending-to-ascending aortic anastomosis can be performed. In this case, an appropriately sized incision is made in the left posterolateral aspect of the ascending aorta to accommodate the diameter of the descending aorta. A primary end-to-side anastomosis of the descending aorta to the ascending aorta is done (Fig. 43-16, F) using a nonabsorbable monofilament suture.

Once the arch repair is completed, the aortic clamp is repositioned at the mid–ascending aorta, reestablishing total body perfusion, and perfusion flow rate is increased appropriately. Additional doses of cardioplegia are given through the aortic root as appropriate every 20 to 25 minutes.

The cardiac portion of the repair is performed in standard fashion through a right ventriculotomy infundibular incision, with patch closure of the VSD, assessment of the atrial septum with maintenance of a competent foramen ovale, and placement of a right ventricle–to–pulmonary trunk valved allograft conduit (Fig. 43-16, E). Rewarming and separation from CPB are performed in standard fashion (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2).

An alternative approach is to use hypothermic circulatory arrest. The aortic cannula is placed distally into the ascending aorta, and a single venous cannula is placed into the right atrium at its junction with the inferior vena cava. Two periods of hypothermic circulatory arrest are used: to reconstruct the aortic arch and again to close the VSD (although the second period of arrest is not uniformly necessary).

Using either technique just described, it is imperative to achieve adequate resection of ductal tissue so that later anastomotic stenosis in the arch does not occur. When primary descending-to-ascending aortic anastomosis is used, the connection is made as distally on the arch as possible to prevent compression of the left bronchus.
Figure 43-16  Repair of truncus arteriosus with interrupted aortic arch. A, The malformation characteristically has a vertically oriented ascending aorta originating from a broad truncus. Proposed incisions to isolate the pulmonary artery branches and bifurcation are indicated by dashed line. Incision to open ascending aorta is indicated by dot-dashed line. B, Two venous cannulae are positioned, and arterial return is via brachiocephalic artery, which has been fully mobilized to accommodate anticipated leftward displacement of ascending aorta. Pulmonary artery branches are temporarily occluded while delivering cold cardioplegia. C, Diminutive aortic arch and descending aorta are thoroughly mobilized and all ductal tissue resected (see Technique of Operation in Section II of Chapter 48). Transection of left subclavian artery enhances mobilizing the ascending aorta, which has been opened in preparation for augmentation. Augmentation is by a segment of cryopreserved pulmonary allograft fashioned by confluence of donor pulmonary trunk and left pulmonary artery (LPA) to produce a curvilinear gusset, and amplified by spatulation of proximal left subclavian artery. Key: LAA, Left atrial appendage; SVC, superior vena cava.
Figure 43-16, cont’d  D, Descending aorta has been attached to ascending aorta and neoaorta augmented by the allograft gusset.  
E, Operation is completed as usual for truncus arteriosus by closing ventricular septal defect through a right ventriculotomy and connecting the isolated pulmonary trunk to the right ventricle using a valved allograft conduit.  
F, Alternative traditional repair. Ascending and descending aortae are fully mobilized. All ductal tissue is resected. Pulmonary trunk is isolated from truncus arteriosus and the latter closed with a small patch. Descending aorta is anastomosed directly to low ascending aorta. After closure of ventricular septal defect, right ventricle is connected to pulmonary trunk with a valved conduit.
If bronchial compression is still of concern, alternative arch reconstructive techniques, such as that shown in Fig. 43-16, A to E or the technique described by McKay and colleagues, can be used. The McKay technique involves placing the distal aortic segment beneath (posterior to) the pulmonary arteries and anastomosing it to the defect left in the truncal artery by excision of the pulmonary trunk. The ascending aortic valved allograft from the right ventricle to pulmonary trunk is placed anterior to the reconstructed aortic pathway.

Other techniques are described for bringing the pulmonary arteries anterior to the aorta. It has also been reported that success has been achieved by leaving the duc tus arteriosus open to serve as a permanent pathway to the descending aorta and performing the usual operation for truncus arteriosus. However, in most patients who are under consideration for surgery in the neonatal period, the ductus is not a reliable long-term pathway, because it will narrow and close.

SPECIAL FEATURES OF POSTOPERATIVE CARE

Neonates and infants who have undergone repair of truncus arteriosus require the same standard intensive care required for all patients undergoing complex cardiac repair. If repair is undertaken after 12 weeks of age, a right ventricular or pulmonary artery pressure catheter is required because these patients are particularly susceptible to pulmonary hypertensive crises, the prevention and management of which are described under “General Care of Neonates and Infants” in Section IV of Chapter 5.

RESULTS

Survival

Early (Hospital) Death

Non–risk-adjusted hospital mortality of 17% (CL 12%-24%) was reported by Hanley and colleagues in 63 neonates and infants operated on between 1986 and 1991. Patients included those with interrupted aortic arch, severe coronary anomalies, and severe truncal valve regurgitation. In patients without these risk factors, there was no early mortality. Similarly, hospital mortality of 11% (CL 7%-17%) was reported in 46 neonates and infants operated on during the same period by Bove and colleagues. Kalavrouziotis and colleagues reported a 3.4% early mortality in 29 patients operated on between 1992 and 2005, and Thompson and colleagues reported a 5% mortality in 65 consecutive neonates operated on between 1992 and 1999. These studies are representative of what can be accomplished in the current era in institutions properly experienced to perform this type of surgery in neonates and young infants.

With the exception of the 1984 study by Ebert and colleagues that reported a mortality of 11%, most earlier studies reported much higher early mortality. No deaths (0%; CL 0%-24%) were reported by Sano and colleagues among 7 neonates and infants undergoing repair of truncus arteriosus and interrupted aortic arch, and Tlaskal and colleagues reported 1 death (12%) in 8 patients. In marked contrast to these single-institution studies, the multinstitutional Congenital Heart Surgeons Society report of 50 patients with truncus arteriosus with interrupted aortic arch operated on from 1987 to 1997 showed an early mortality of about 50%.

Incremental Risk Factors for Premature Death after Repair

Hanley and colleagues performed a multivariable analysis of 63 patients; interrupted aortic arch, severe truncal valve regurgitation, severe coronary artery abnormalities, and age older than 100 days at operation were identified as risk factors for early death. The multivariable analysis by Brown and colleagues indicated that earlier year of operation and coexisting interrupted aortic arch were risk factors. More recent studies, not surprisingly, suggest that morphologic factors such as interrupted aortic arch and truncal valve regurgitation may no longer be risk factors. Thompson and colleagues, however, show that some of these previously identified risk factors continue to be of clinical concern but fall just short of reaching statistical significance as risk factors (Table 43-5). Other variables have not been clearly identified as risk factors, but they have not been rigorously studied. They are discussed briefly in the text that follows.

From Thompson and colleagues.74

*Numbers in parentheses are 95% confidence intervals.

*An odds ratio >1 indicates shorter freedom from reintervention.

*Repair of interrupted aortic arch is not listed, because all patients with an interrupted arch underwent concurrent repair, and the odds ratio and P value were identical.

Age at Repair
Young age has been neutralized in institutions properly prepared for neonatal cardiac surgery, where risk after neonatal repair has been reduced to about 10%,87,144 In fact, many recent series involve only neonates.74 Older age at may be a risk factor for premature death after repair, both early and late. However, age is probably a surrogate for severity of pulmonary vascular disease144 (see later).

Low Birth Weight
Low birth weight has been identified as a risk factor for early death in two single-institution studies, one of 65 consecutive neonatal repairs and the other of 61 patients younger than 6 months of age at repair.13,74

Type of Truncus Arteriosus
Types I and II truncus arteriosus are so similar that no difference in risk of death after operation has been identified.56 Relatively few patients with truncus arteriosus type III have undergone repair, but increased complexity of operation is expected to increase risk of death to some extent.

Size of Ventricular Septal Defect
Closure of relatively small VSDs may result in some degree of left ventricular outflow obstruction; surgical enlargement of such defects risks interference with septal coronary arteries. Thus, small size of the VSD may be a risk factor.

Predominance of Origin of the Truncal Artery
The more the truncal artery lies over the right ventricle, the greater the probability that VSD closure will narrow the left ventricular outflow tract (particularly when the VSD is small and has not been surgically enlarged), potentially increasing the risk of death early after operation. Possibly this risk factor and that of small VSD size can be neutralized by appropriate VSD enlargement and proper contouring of the VSD patch.

Small Size of Right and Left Pulmonary Arteries
Small branch pulmonary arteries may present risk, especially if proximal obstruction is not addressed at surgical reconstruction.

Truncal Valve Abnormalities
Narrowing of the truncal valve may be difficult to identify and evaluate because flow through it, comprising both systemic and pulmonary flow, is large. Preoperative evaluation typically indicates obstruction across the truncal valve because of the high flow; however, true stenosis is rare and has not been specifically identified as a risk factor. Severe truncal valve regurgitation itself is a well-identified risk factor for death after repair.82,36 This is probably related to both its unfavorable effect postoperatively and its interference with myocardial management intraoperatively.35 Treatment of truncal valve regurgitation, either by valvuloplasty or by using an allograft valve conduit placed by the “mini” root-replacement technique (see “Allograft Aortic Valve Cylinder” under Technique of Operation in Chapter 12) is the most important modification of the operation for neutralizing incremental risk of truncal regurgitation (see Appendix 6C in Chapter 6).87

Truncus with Only One Branch Pulmonary Artery Connected to the Truncal Root
Neonates and infants undergoing repair of truncus with only one branch pulmonary artery connected to the truncal root undergo a complex single- or two-stage operation, increasing risk. Nonetheless, repair has been accomplished in 10 infants by Mee, with a 20% (CL 7%-41%) hospital mortality and no post-discharge deaths in a follow-up of nearly 5 years.88

In patients who do not undergo repair during the first 6 months of life, pulmonary vascular disease develops rapidly in the lung supplied from the truncus arteriosus, increasing both early and late risks of repair.541

Major Associated Cardiac Anomalies
Major associated cardiac anomalies increase overall risks. Repair of truncus arteriosus and interrupted arch has been associated with risk of early death in up to 50% of patients58,314 but more recent studies bring this association into question.13

Pulmonary Vascular Disease
Irreversible pulmonary vascular disease is rarely an issue when repair is performed during the first 3 months of life. The likelihood of postoperative pulmonary hypertensive episodes, however, increases in infants who are repaired after the first 3 weeks of age.144 These episodes are a manifestation of a damaged pulmonary vasculature, but the vasculature can remodel and become normal when hemodynamics are normalized with early repair. Progressive damage to the pulmonary vasculature may play an important role in the increased risk of death observed in patients operated on later than 3 months of age.144
Progressing Truncal Valve Regurgitation

Rajasinghe and colleagues show that pre-repair truncal valve regurgitation portends only a 20% freedom from eventual truncal valve replacement, and also that a few valves with no pre-repair truncal regurgitation will have to be replaced (Fig. 43-18).\textsuperscript{M4,R1} Henaine and colleagues showed the same associations.\textsuperscript{H7} Most patients have mild regurgitation 1 to 2 years after repair, and occasionally moderate regurgitation is observed at that time. Mortality for truncal valve replacement can be high when performed in children early after initial truncus repair, but mortality for late truncal valve replacement is low.\textsuperscript{M4}

Conduit Replacement

Conduit replacement or revision is almost inevitable (Fig. 43-19). Mean time to conduit replacement was 5.5 years in the study by Rajasinghe and colleagues.\textsuperscript{R1} The only factor associated with shorter time to replacement is smaller conduit size at initial repair.\textsuperscript{C3,R1} Type of conduit (aortic allograft, pulmonary allograft, or xenograft) does not seem to affect the interval between initial repair and need for reoperation.\textsuperscript{C3,R1} Avoidance of a conduit and use of the direct right ventricle-pulmonary artery connection at the initial operation may reduce the need for reoperation on the right ventricular outflow tract,\textsuperscript{C3} but the need for catheter-based intervention for obstruction is higher using the direct connection. Thus, the requirement for intervention of any kind (surgical and catheter-based combined) is the same for both conduit and direct connection techniques.\textsuperscript{C3} In the series by Honjo and colleagues, freedom from intervention for right ventricular outflow tract obstruction was only 50% at 5 years.\textsuperscript{H10} The jugular venous valved conduit has been evaluated in a prospective multicentered study and appears to be equivalent to allograft conduits in most respects.\textsuperscript{H9} Time to conduit replacement was similar, and both right ventricular outflow tract gradient and valve regurgitation showed similar progression in the two conduit types. Progression of stenosis after catheter intervention for stenosis was significantly slower in the jugular vein conduit.

INDICATIONS FOR OPERATION

Diagnosis of truncus arteriosus is an indication for repair. Because about 50% of surgically untreated patients die during the first month of life, repair should be recommended as early as possible, rather than deferring it to some predetermined age.\textsuperscript{A7,B6,B7,S12} This is true whether or not important cardiac anomalies coexist. In children older than 6 months at presentation, operation may be complicated, or even contraindicated, by presence of important elevation of pulmonary vascular resistance. Cardiac catheterization with assessment of pulmonary vascular resistance will determine operability. Criteria for inoperability are the same as for patients with VSD (see Indications for Operation in Section I of Chapter 35).

SPECIAL SITUATIONS AND CONTROVERSIES

Importance of a Valve in Repair

An unsettled matter is the importance of a right ventricular outflow valve. Several groups have reported success with use of valveless conduits.\textsuperscript{B5,B7,S10} Although there are no randomized trials comparing the valveless direct connection technique and the valved conduit technique, two studies that use both techniques retrospectively evaluated outcomes.\textsuperscript{C3,D1} Fewer total reinterventions were needed in the direct connection patients in one study\textsuperscript{D1} but not in the other.\textsuperscript{C3} Early mortality did not differ in one study.\textsuperscript{C3} In the other,\textsuperscript{D1} it was significantly higher in the direct connection group (22% vs. 8%) by univariable analysis; however, multivariable analysis did not confirm the univariable finding. The study authors believe that the validity of the multivariable analysis may be questionable because of the small number of patients and events. To further confuse matters, biases may exist in these retrospective studies that make inferences difficult. For example, in the study by Danton and colleagues,\textsuperscript{D3} neonates
and young infants (patients not likely to have pulmonary hypertension) predominantly received the valveless direct connection, and older patients (with higher risk for pulmonary hypertension) received valved conduits. These biases may affect timing and prevalence of right ventricular outflow tract reintervention and mortality.

Aortopulmonary window (APW) is a round, oval, or sometimes spiral opening between the ascending aorta and pulmonary trunk, occurring as a congenital anomaly in hearts with separate aortic and pulmonary valves. This malformation has also been termed aortic septal defect; aortopulmonary fistula, fenestration, or septal defect; and aortopulmonary window, fistula, fenestration, or septal defect.\(^{\text{R1}}\)

**HISTORICAL NOTE**

The first report of an APW was by Elliotson in 1830, and in the American literature by Cotton about 70 years later.\(^{\text{C6,R1}}\)

The first reported correct clinical diagnose are attributed to Dodds and Hoyle in 1949 and to Gasul and colleagues in 1951.\(^{\text{D5,G2}}\)

In 1952, Gross reported successful ligation of an APW using a closed technique.\(^{\text{G1}}\) Scott and Sabiston in 1953 and Fletcher and colleagues in 1954 reported successful division of an APW by a closed technique.\(^{\text{F2,F3}}\) The operation was difficult and hazardous, however.

The advent of open operation with cardiopulmonary bypass (CPB) in 1954 to 1955 made it easier to correct this malformation. Division of the connection between aorta and pulmonary trunk was used in early cases at the Mayo Clinic. In 1957, Cooley and colleagues reported the transaortic approach, but with polyester patch closure.\(^{\text{C9}}\)

In 1958, Gross reported successful ligation of an APW using a vascular clip in an infant weighing 758 g.\(^{\text{K1}}\)

**DEFINITION**

An APW is usually a large defect between the aorta and pulmonary trunk, although in about 10% of patients the defect is small. The pulmonary arteries are normally related to the pulmonary trunk. As the term window implies, there is little or no length to the communication in most patients. It is nearly always a single orifice, although it may be fenestrated.

Several classifications have been proposed to describe the location of the anomalous “window” on the ascending aorta and its relationship to the branch pulmonary arteries. Mori and colleagues proposed the terms proximal, distal, and total to describe the location within the ascending aorta.\(^{\text{M5}}\) Richardson and colleagues used the term type I to describe proximal defects and type II to indicate defects in the distal ascending aorta.\(^{\text{R1}}\) Ho and colleagues added the term intermediate to describe defects with upper and lower edges suitable for percutaneous closure.\(^{\text{H2}}\) Jacobs and colleagues from the Society of Thoracic Surgeons' Congenital Heart Surgery Database Committee recommended the terms type I–proximal defect, type II–distal defect, type III–total defect, and intermediate defect (Fig. 44-1).

Proximal (type I) APWs are located in the proximal ascending aorta (see Fig. 44-1). The window is in the left lateral wall of the ascending aorta, usually close to the orifice of the left coronary artery, and in the contiguous right wall of the pulmonary trunk inferior to the origin of the right pulmonary artery.\(^{\text{N1}}\) It is not surprising, therefore, that occasionally the right coronary artery, and rarely the left, may be transposed onto the pulmonary trunk close to the edge of the defect.\(^{\text{B4,B7,D6,D7,L2}}\) This must always be considered in the surgical treatment of APW.\(^{\text{K4}}\) When viewed from within the pulmonary trunk, the APW can be confused with the orifice of the right pulmonary artery. The proximal type occurs in about 90% of APW cases.\(^{\text{B6,F3,T4}}\)
APW is accompanied by other cardiac anomalies in about 50% of cases\textsuperscript{53,54}, of which interrupted aortic arch (IAA) (about 90% of which are type A and the rest type B) is the most frequently observed major associated lesion\textsuperscript{54,55} (although this combination is rare among all patients with congenital heart disease). Other major associated lesions include ventricular septal defect (VSD), tetralogy of Fallot, transposition of the great arteries (Vannini V: personal communication, 1980), anomalous origin of a coronary artery, aortic isthmic hypoplasia, and subaortic stenosis\textsuperscript{51,53,54,56,72}

Rarely, there is a complex syndrome of the APW, usually in the downstream portion of the ascending aorta, with aortic origin of the right pulmonary artery, intact ventricular septum, patent ductus arteriosus, and interrupted aortic arch or severe coarctation (Berry syndrome).\textsuperscript{A1,B2,F2,D1,T1} This is a particularly lethal combination; most affected infants die shortly after birth.

From 5% to 10% of patients with the malformation have less severe associated cardiac anomalies such as right aortic arch (7%), ostium secundum atrial septal defects, or patent ductus arteriosus.\textsuperscript{54,56,57,71}

The rarity of IAA with APW is such that among 472 neonatal patients with IAA reported in a Congenital Heart Surgeon’s Society study, 20 (4%) had IAA with APW\textsuperscript{53} (Fig. 44-2).

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

In infants with isolated APW, symptoms and signs of heart failure usually develop early in life, and their presentation is similar to that of infants with a large VSD. These infants are generally small, underdeveloped, and tachypneic, and they tend to have repeated respiratory infections.\textsuperscript{73}

On examination, the left precordium is prominent because of marked cardiomegaly. The second heart sound at the base is usually accentuated. The murmur is usually only systolic and of variable intensity.\textsuperscript{D2,M5,N1} In about 15% of patients, it is continuous because the APW is smaller and pulmonary hypertension less than usual.\textsuperscript{M5,N1} When the left-to-right shunt through the defect is large, there are peripheral signs of rapid aortic runoff (e.g., jerky or collapsing peripheral pulses), but these signs are not evident when heart failure is marked or pulmonary vascular resistance is severely elevated.

Chest radiograph and electrocardiogram (ECG) findings are similar to those of infants and young children with VSD or large patent ductus arteriosus, giving evidence of left and right ventricular enlargement and large pulmonary blood flow.\textsuperscript{B4} Left atrial enlargement (a result of large pulmonary blood flow) is usually prominent.

Differential diagnoses before special study include large patent ductus arteriosus (see Chapter 37), truncus arteriosus (see Chapter 43), and, in patients beyond the infant age group, VSD with aortic regurgitation (see Section II of Chapter 35) and ruptured sinus of Valsalva aneurysm (see Chapter 36).

Since the early 1990s, diagnosis has relied exclusively on two-dimensional (2D) echocardiography.\textsuperscript{M1,P1,S1,T4} Nevertheless, other imaging techniques are useful. Garver and colleagues correlated echocardiography, angiography, and magnetic resonance imaging (MRI) to achieve accurate diagnosis in APW.\textsuperscript{G1} Prior to the advent of 2D echocardiography,
cardiac catheterization and cineangiography were used to provide the definitive diagnosis and identify associated cardiac anomalies. Cardiac catheterization shows blood oxygen saturation in the pulmonary artery is elevated over that in the right ventricle and right atrium in most cases. Occasionally, oxygen saturation in the right ventricle is increased over that in the right atrium, which may suggest VSD or truncus arteriosus until cineangiography shows this to be from pulmonary valve regurgitation associated with APW. Ascending aortic angiography shows rapid filling of the pulmonary trunk through the APW, as well as separate aortic and pulmonary valves. Because location of the APW varies and coronary arteries may arise from the pulmonary trunk, visualization of all anomalies must be accurate.

**NATURAL HISTORY**

APW is a rare malformation, occurring in about 0.2% of cases of congenital heart disease. There is no known tendency for APWs to close spontaneously. The natural history of infants with large APWs is at least as unfavorable as that of infants with persistently large VSD (see Natural History in Section I of Chapter 35). In the absence of surgical correction, mortality in the first year of life has been estimated at 40%. In fact, patients with large APWs are rarely seen in childhood or adult life, and those who survive beyond early life have important pulmonary vascular disease. This natural history is, therefore, similar to that of surgically untreated older patients with large VSD.

**TECHNIQUE OF OPERATION**

Because APW often coexists with other important cardiac anomalies, the basic technique of repair must be modified and adapted to the individual situation. However, every effort should be made to accomplish a one-stage repair. A special combination is APW and anomalous origin of the right pulmonary artery from the ascending aorta, in which the APW may be left open anatomically but functionally closed by connecting it to the orifice of the right pulmonary artery by one of several techniques.

The discussion that follows pertains specifically to isolated APWs. Cardiac catheterization and cineangiography were used to provide the definitive diagnosis and identify associated cardiac anomalies. Cardiac catheterization shows blood oxygen saturation in the pulmonary artery is elevated over that in the right ventricle and right atrium in most cases. Occasionally, oxygen saturation in the right ventricle is increased over that in the right atrium, which may suggest VSD or truncus arteriosus until cineangiography shows this to be from pulmonary valve regurgitation associated with APW. Ascending aortic angiography shows rapid filling of the pulmonary trunk through the APW, as well as separate aortic and pulmonary valves. Because location of the APW varies and coronary arteries may arise from the pulmonary trunk, visualization of all anomalies must be accurate.

**NATURAL HISTORY**

APW is a rare malformation, occurring in about 0.2% of cases of congenital heart disease. There is no known tendency for APWs to close spontaneously. The natural history of infants with large APWs is at least as unfavorable as that of infants with persistently large VSD (see Natural History in Section I of Chapter 35). In the absence of surgical correction, mortality in the first year of life has been estimated at 40%. This natural history is, therefore, similar to that of surgically untreated older patients with large VSD.
Chapter 44 Aortopulmonary Window

![Figure 44-3](image)

**Figure 44-3** Repair of type I aortopulmonary window (APW). **A,** Operation is performed on cardiopulmonary bypass with aorta occluded. APW is exposed through a transverse aortotomy. It is located just above sinotubular junction. Origin of left coronary artery is identified because it may have a close relationship with inferior margin of APW. **B,** APW is closed with a polyester, polytetrafluoroethylene, or pericardial patch to create a partition between aorta and pulmonary trunk. Left coronary artery is protected from inclusion in suture line.

cannulation site. Care is taken to identify and protect the right pulmonary artery during this dissection and while placing the aortic clamp. A single venous cannula may be used, or the cavae may be cannulated directly. The right atrium is opened and a pump-oxygenator sump sucker placed across the foramen ovale into the left atrium.

As soon as CPB has been initiated and core cooling begun, a side-biting clamp (e.g., small Cooley clamp) is placed across the window from the pulmonary trunk side to occlude the window; alternatively, separate tourniquets may be placed on left and right pulmonary arteries. The aortic occlusion clamp is positioned exactly at the place provided by the prior dissection. Cold cardioplegic solution is injected into the ascending aorta or retrogradely via the coronary sinus (see “Methods of Myocardial Management during Cardiac Surgery” in Chapter 3).

Repair can be done through either the aorta or pulmonary trunk, and even the older technique of complete division has given good results. However, an initial approach through the aorta is generally recommended to facilitate clear identification of the aortic valve and right and left coronary orifices in relation to the defect. The aorta is opened transversely at the level of the APW (Fig. 44-3, **A**). Both coronary arteries must be identified. If one is anomalously positioned in the pulmonary trunk, the patch for closure of the window must be positioned so that both coronary ostia are on the aortic side of the patch. Small or moderate-sized APWs may be closed by direct suture, using one or two rows of continuous 4-0 polypropylene sutures. A large window is closed with a polyester, polytetrafluoroethylene (PTFE), or pericardial patch sewn into place with continuous 4-0 or 5-0 polypropylene sutures (Fig. 44-3, **B**). The aortotomy incision is then closed with one row of continuous polypropylene sutures. The remainder of the operation, including the de-airing procedure, is carried out as usual (see “De-airing the Heart” in Section III of Chapter 2).
PART VII  Congenital Heart Disease

This technique allows visualization of the left coronary ostium and orifice of the right pulmonary artery and provides a secure partitioning of the ascending aorta from the pulmonary trunk. Unless there is aneurysmal thinning around the window, this technique seems useful.

A modification of this technique is required when the right coronary artery arises from the pulmonary trunk just to the left of the anterior wall of the APW. Then the anterior incision into the window curves to the left into the pulmonary trunk to create a flap of anterior pulmonary trunk wall. The flap should be large enough to cover the entire window. It is sewn into position over the window with a continuous stitch passing through the aortic wall, the patch, and the pulmonary trunk wall. This technique allows visualization of the left coronary ostium and orifice of the right pulmonary artery and provides a secure partitioning of the ascending aorta from the pulmonary trunk. Unless there is aneurysmal thinning around the window, this technique seems useful.

Alternatively, a vertical incision may be made in the anterior wall of the APW itself, more or less transecting its anterior half. After carefully identifying orifices of the right pulmonary artery and left coronary artery, the patch for closure is sutured to the posterior, superior, and inferior walls of the window. The incision into the window is then closed by incorporating the front edge of the patch, with each stitch passing through the aortic wall, the patch, and the pulmonary trunk wall. This technique allows visualization of the left coronary ostium and orifice of the right pulmonary artery and provides a secure partitioning of the ascending aorta from the pulmonary trunk. Unless there is aneurysmal thinning around the window, this technique seems useful.

polypropylene stitch. Repair is completed by closing the defect in the pulmonary trunk with a pericardial patch. Rarely, the right coronary artery arises from the anterior aspect of the pulmonary trunk at some distance from the APW. In that situation, the right coronary artery can be taken as a button from the pulmonary trunk, mobilized, and reimplanted into the aorta at a site distinct from the APW, which is closed with a separate patch. Similar methods (flap reconstruction or reimplantation) can be used to repair APW with an anomalous origin of the left coronary artery from the posterior wall of the pulmonary trunk.

SPECIAL FEATURES OF POSTOPERATIVE CARE

Postoperative care is as usual (see Chapter 5). The hemodynamic state is generally excellent because the left ventricle is large, no ventriculotomy has been made, and duration of myocardial ischemia is less than 1 hour. When repair has been performed in a neonate or infant, care appropriate to this age group is used (see Section IV, Chapter 5).

RESULTS

Early (Hospital) Death

Hospital mortality is low after repair of APW unless unusual circumstances are present; no deaths occurred among 18 patients undergoing primary repair at UAB and the University of California at San Francisco (Table 44-1), and one death occurred among 11 infants reported by Tiraboschi and colleagues. Even with coexisting major anomalies or low birth weight, risk of total repair may also be low.

Time-Related Survival

Time-related survival is excellent when the operation is performed in infancy. McElhinney and colleagues followed patients for up to 25 years after operation. Eighteen patients with Richardson type I or II were operated on at age 6 months or less. Eleven were categorized as complex because of operability described for patients with VSD are applicable to those with large APWs (see Indications for Operation in Section I of Chapter 35).

### Definition

Anomalous origin of a pulmonary artery from the ascending aorta is a condition in which the right pulmonary artery (RPA) or rarely, the left pulmonary artery (LPA), arises from the ascending aorta in the presence of separate aortic and pulmonary valves and without interposition of ductal tissue. This condition is sometimes referred to as hemitrunicus. Hemitrunicus is also used to describe a subset of truncus arteriosus (see Chapter 43). Rarely, both right and left pulmonary arteries arise from the ascending aorta in the presence of two separate semilunar valves.

Origins of one or both pulmonary arteries from the transverse aortic arch via a ductus arteriosus or collateral arteries and from the descending thoracic aorta via collateral arteries are not discussed; these conditions are most commonly part of tetralogy of Fallot, but they can occur in the presence of other intracardiac defects or even with normal intracardiac morphology (see Chapter 38). When both the RPA and LPA or only one pulmonary artery arise from the ascending aorta with a common semilunar valve, the condition is a subset of truncus arteriosus (see Chapter 43).

### Historical Note

The first description of this entity was by Frantzel, who in 1868 reported the case of a 25-year-old woman dying in heart failure, with the RPA arising from the ascending aorta and an aortopulmonary window. In 1914, Doering reported aortic origin of the RPA in an infant dying at age 8 months whose only associated anomaly was a patent ductus arteriosus. Bopp, in 1949, gave a detailed report of this condition; since then, and with development of cardiac catheterization and angiography, other cases have been reported.

In 1957, Caro and colleagues corrected the malformation by disconnecting the RPA from the ascending aorta and connecting it with an interposition graft to the pulmonary trunk. The patient, a 23-year-old man, died a short time after operation. The first successful repair, which was in a 12-month-old infant, was reported in 1961 by Armer and colleagues. They interposed a graft between the pulmonary trunk and distal end of the divided RPA and closed a coexisting patent ductus arteriosus. In 1967, Kirkpatrick and colleagues reported the first successful cases of retroaortic direct anastomosis of the divided RPA to the pulmonary trunk. The first report of successful surgical treatment of aortic origin of the LPA, in a 6-week-old infant, was by Herbert and colleagues in 1973.

### Morphogenesis and Morphology

#### Morphogenesis

Anomalous origin of the RPA from the ascending aorta is related to development of the aortopulmonary septum by fusion of the right and left conotruncal ridges. As such, this defect has developmental morphogenesis similar to aortopulmonary window (see Chapter 44). Severe unequal partitioning of the aortopulmonary trunk by conotruncal ridges results in more dorsal development of the aorta. In this situation, the right sixth aortic arch originates solely from the ascending aorta and is not related to the pulmonary trunk. The result of severe conotruncal ridge malalignment is anomalous origin of the RPA from the ascending aorta, which has been classified by Richardson and colleagues as aortopulmonary septal defect type III.

#### Morphology

**Anomalous Origin of Right Pulmonary Artery**

The RPA usually arises from the right or posterior aspect of the ascending aorta (Fig. 45-1) in this condition, but occasionally it arises from the leftward posterior aspect. Its origin is usually within 1 to 3 cm of the aortic valve. Uncommonly, it arises from the distal portion of the ascending aorta just proximal to the origin of the brachiocephalic
When the RPA arises anomalously from the ascending aorta and no other anomalies are present, pulmonary vascular beds of the two lungs may be similar despite differences in origin of the pulmonary arteries. Occasionally, pulmonary and tricuspid valves are dilated as a result of right heart failure, and the tricuspid leaflets may be thickened and edges rolled. Origin of the RPA from the ascending aorta is an isolated lesion in about 20% of cases. In the remainder, the most common coexisting lesion is patent ducus arteriosus, present in about 50% of cases.

Other less common associations are with tetralogy of Fallot, ventricular septal defect, aortopulmonary window, coarctation of the aorta, interrupted aortic arch, and atrial septal defect. Severe contralateral (left) pulmonary vein stenosis may coexist. The vein stenoses are typically tubular, with dilatation of the left pulmonary veins proximal to the stenoses. Also, Sievers and colleagues report coexisting subtotal obstruction of the left pulmonary vein orifices by a membrane that was excised at operation.

**Anomalous Origin of Left Pulmonary Artery**

Origin of the LPA from the ascending aorta is rare. It occurs as an isolated lesion in about 40% of cases, usually coexisting with right aortic arch. In contrast to origin of the RPA from the ascending aorta, the most common associated anomaly is tetralogy of Fallot. Then, the aortic arch may be left sided. Tetralogy of Fallot with absent pulmonary valve syndrome is also observed (Fig. 45-2).

**Anomalous Origin of Both Pulmonary Arteries**

Origin of both RPA and LPA from the ascending aorta has been reported in one patient who had no other cardiac anomaly. The origin was by way of a short single trunk coming off the posterior aspect of the ascending aorta, with the pulmonary trunk arising normally from the right ventricle and connected only to a patent ductus arteriosus. Repair was attempted unsuccessfully at age 11 days.

**CLINICAL FEATURES AND DIAGNOSTIC CRITERIA**

When the condition is isolated except for a patent ductus arteriosus, the patient characteristically presents early in infancy with respiratory distress and heart failure. Frequently the infant is acutely ill. There may be cyanosis from (1) venous admixture in the lungs or (2) reversed shunting through a patent ductus arteriosus or a patent foramen ovale resulting from right heart failure.

There are no typical auscultatory findings, and murmurs may or may not be present. When present, the murmur is usually systolic and heard along the left sternal border. Rarely, it may be continuous as a result of kinking or stenosis of the artery. The peripheral pulses are jerky or bounding because of rapid runoff from the aorta into the lung and consequent left-to-right shunting. Electrocardiographic findings are not diagnostic and usually indicate biventricular and right atrial enlargement. Cardiomegaly is usually severe on the chest radiograph, with the heart assuming a globular shape. Pulmonary plethora is usually of similar degree bilaterally.

When tetralogy of Fallot is present with severe pulmonary stenosis, clinical features are dominated by the tetralogy. The condition may be suspected, however, because the lung supplied by the anomalously arising artery is usually plethoric, whereas the other lung is oligemic. Since the early 1990s, correct diagnosis and assessment have been adequately made with two-dimensional echocardiography alone, making cardiac catheterization unnecessary.

![Figure 45-1](image1.png) Origin of right pulmonary artery (RPA) from ascending aorta, also referred to as aortopulmonary septal defect type III (see Chapter 44). RPA takes its origin from right lateral aspect of ascending aorta. There is a large blood flow shunt from aorta to RPA.

![Figure 45-2](image2.png) Heart specimen from 1-month-old infant viewed from in front. The left pulmonary artery arises from ascending aorta and crosses in front of the dilated right pulmonary artery that arises normally from the pulmonary trunk. This infant had tetralogy of Fallot with absent pulmonary valve. Key: Ao, Aorta; LAA, left atrial appendage; LPA, left pulmonary artery; LV, left ventricle; RAA, right atrial appendage; RPA, right pulmonary artery; RV, right ventricle; Tr, trachea. (From Calder and colleagues.)
lethal condition. About 70% of surgically untreated patients are dead by age 6 months and 80% by age 1 year (Fig. 45-6). Intractable heart failure is the usual mode of death.

Pulmonary hypertension in the anomalous pulmonary artery is uniformly present, and commonly it is also present in the normally connected pulmonary artery. This finding is supported by Pool and colleagues’ observation that provide additional information. Pressure in the pulmonary artery arising from the aorta is systemic in almost all cases, because ostial stenosis is rare. As already noted, pressure in the pulmonary artery that arises normally is usually also elevated to systemic or suprasystemic levels. Accurate measurement of pulmonary and systemic blood flows is difficult in this situation but not critical, because the infants usually present with clear clinical evidence of increased pulmonary blood flow. Pulmonary vascular resistance in the normally connected lung can be calculated and is a useful guide to operability—and an essential guide in older patients.

Cineangiography is diagnostic, and a right ventriculogram or pulmonary angiogram opacifies only the normally connected pulmonary arteries. Antegrade or retrograde aortography shows the pulmonary artery that arises from the ascending aorta (Fig. 45-4). Cineangiography is also used to define other cardiac anomalies that may be present.

In neonates and infants in whom catheterization is not critical, computed tomography angiography can confirm morphologic details suspected by echocardiography (Fig. 45-5).

**NATURAL HISTORY**

Anomalous origin of a branch pulmonary artery from the ascending aorta is rare, reportedly accounting for 0.12% of all congenital heart defects. Nearly all cases involve the RPA. As of 2004, 136 cases of RPA from the aorta had been reported, and from 2004 to 2010, at least 35 additional cases appeared in the literature. In 2003, Prifti and colleagues reviewed the reported experience with LPA from the aorta and found 77 cases; however, many of these appear to have had LPA origins from the descending thoracic aorta or from a ductus, with a high association with tetralogy of Fallot, and thus likely represent a different lesion. It is a lethal condition. About 70% of surgically untreated patients are dead by age 6 months and 80% by age 1 year (Fig. 45-6). Intractable heart failure is the usual mode of death.

Pulmonary hypertension in the anomalous pulmonary artery is uniformly present, and commonly it is also present in the normally connected pulmonary artery. This finding is supported by Pool and colleagues’ observation that
pulmonary hypertension develops in 19% of infants born with unilateral absence of a pulmonary artery and no associated malformations, and that ligation of one pulmonary artery within 24 hours of birth in five calves resulted in severe pulmonary hypertension in the opposite lung within 2 months. Surprisingly, Keane and colleagues report no important obstructive vascular changes in either lung in most patients dying in the first 6 months of life. This does not mean that pulmonary hypertension was not present, just that pathologic changes were not evident.

Among older patients, pathologic evidence of hypertensive pulmonary vascular disease is usually present, often to a similar extent in the two lungs, sometimes greater in the right and sometimes greater in the left. It is likely that the natural history of isolated origin of the LPA from the ascending aorta is similar, but too few patients have been observed to establish this.

**TECHNIQUE OF OPERATION**

Preparations for operation, median sternotomy, and cardiopulmonary bypass (CPB) are those normally used (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2), as are the techniques for myocardial management (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion,” and “When Needed] Warm Cardioplegic Induction” in Chapter 3). The technique is described for anomalously arising RPA; it is similar when the LPA is affected.

Once the pericardium has been opened, the anomalously originating RPA is visualized coming from either the posterior or right lateral aspect of the ascending aorta (Fig. 45-7, A). It passes into the right hemithorax behind the superior vena cava. The aorta is completely dissected from the pulmonary trunk, and the ductus arteriosus is dissected out at this point.

The purse-string sutures and preparation for CPB are made as usual, except that care is taken to place the aortic cannula far enough downstream so that the aorta may be occluded distal to the aortic origin of the RPA (see Fig. 45-7, A). A single venous cannula is placed into the right atrium. CPB is established as usual, and as soon as it has begun, a temporary arterial clamp is placed across the RPA.

The ligamentum arteriosum or ductus arteriosus is ligated and specifically divided. Division allows improved mobility of the pulmonary trunk so that the connection to the RPA can be performed with minimal tension. A vent catheter is placed in the left atrium through a purse-string in the right upper pulmonary vein. After the aorta is occluded well distal to the RPA, cold cardioplegia is administered. The clamp is removed from the RPA, which is then thoroughly mobilized beneath the superior vena cava out to the lobar branches.

The pulmonary artery is then disconnected from the ascending aorta (see Fig. 45-7, A). The defect left in the ascending aorta is closed by a pericardial patch or other patch material (Fig. 45-7, B). In some cases, it may be possible to close the aorta transversely by direct suture. The aorta is rotated anteriorly and leftward. The right side of the pulmonary trunk is pulled out from beneath the aorta (see Fig. 45-7, B), and a longitudinal incision is made in it. An anastomosis is made between the end of the well-mobilized RPA and the side of the pulmonary trunk (Fig. 45-7, C). A 7-0 polypropylene suture is used, sewing from within the vessels posteriorly and working external to the vessels anteriorly. The completed repair establishes continuity between the RPA and pulmonary trunk, eliminating the shunt (Fig. 45-7, inset).

An alternative technique that achieves greater length on the RPA was described by van Son and Hanley (Fig. 45-8, A). After the aorta is occluded, it is incised transversely at the level of RPA origin. The aortic incision is continued posteriorly, leaving a generous cuff of posterior wall around the origin of the RPA. Position of the left coronary artery is noted and its ostium protected from injury. An incision is made in the right lateral wall of the pulmonary trunk so as to create an anteriorly based flap (Fig. 45-8, B). An anastomosis of the RPA to the pulmonary trunk is created with the two flaps forming the proximal segment of the RPA (Fig. 45-8, C). The ascending aorta is reconstructed by end-to-end anastomosis (Fig. 45-8, D).
Figure 45-7 Repair of anomalous origin of right pulmonary artery (RPA) from ascending aorta. A, Aorta is occluded near origin of brachiocephalic artery above anomalous origin of RPA. This requires cannulating the distal ascending aorta or aortic arch. RPA is removed from aorta (dashed line). B, Opening in ascending aorta is repaired by prosthetic patch. Right lateral aspect of pulmonary trunk is mobilized and delivered to the right. An opening is made into the pulmonary trunk. C, An end-to-end anastomosis of RPA to pulmonary trunk is constructed using continuous stitches of 6-0 or 7-0 polypropylene or polydioxanone suture. Inset, Repair restores normal continuity of pulmonary arteries and eliminates shunting from aorta to RPA.
Chapter 45  Origin of the Right or Left Pulmonary Artery from the Ascending Aorta

RESULTS

When origin of the RPA or LPA from the ascending aorta is an isolated condition (apart from patent ductus arteriosus), operation can be a low-risk procedure even in critically ill small infants (Table 45-1). This has been confirmed in other small individual institutional experiences, each ranging from 1 to 16 cases, with little or no early mortality.

SPECIAL FEATURES OF POSTOPERATIVE CARE

Management usually given to infants after intracardiac surgery is used (see Chapter 5). Pulmonary hypertensive crises can be expected early postoperatively, and the infant is treated accordingly (see “Pulmonary Hypertensive Crises” under Pulmonary Subsystem in Chapter 5).

**Figure 45-8**  Repair of anomalous origin of right pulmonary artery (RPA) from aorta using autogenous flaps of aorta and pulmonary trunk.  

A, Ductus arteriosus is doubly ligated and divided. Aorta is transected at level of anomalous origin of RPA. Posteriorly, as indicated by dotted line, the transection incision separates at midpoint of aorta to encompass origin of RPA, thereby creating a flap of aorta attached to the RPA. Two parallel incisions (dashed lines) are made on the pulmonary trunk at proposed site of anastomosis of RPA. Incisions are joined posteriorly (dotted line) to create an anteriorly based flap on the pulmonary trunk.  

B, Aortic and pulmonary artery flaps are shown. Sufficient length is created to allow tension-free anastomosis of RPA to pulmonary trunk.  

C, Tissue flaps are anastomosed with continuous stitches of 6-0 polyglyconate suture, creating a proximal extension from pulmonary trunk to RPA.  

D, Aorta is reanastomosed in end-to-end fashion anterior to RPA to complete the repair.
tetralogy of Fallot with absence of the pulmonary valve or pulmonary vein stenosis, risk of death increases. Survivors of repair in infancy, with or without patent ductus arteriosus, have generally done well and have normal pulmonary artery pressure late postoperatively and presumably a normal life expectancy.\textsuperscript{6,8,11,23} Stenosis can occur at the anastomotic site of the RPA.\textsuperscript{7,14} It can be effectively treated by surgical revision or catheter angioplasty.\textsuperscript{2,12,21} Ascending aortic stenosis has been reported at the site of pulmonary artery removal.\textsuperscript{2,12,21} Ventilation and perfusion are usually normal in both lungs late postoperatively.\textsuperscript{21}

At least an intermediate-term good result can be obtained in some older patients. Juca and colleagues reported a satisfactory decrease in RPA and LPA pressure in a patient who was 20 years old at operation.\textsuperscript{11,12} Long and colleagues reported normalization of pulmonary vascular resistance in both lungs in a patient repaired at age 23 years with stenosis of the anomalous pulmonary artery but severe LPA hypertension due to a ductus arteriosus.\textsuperscript{11}

**INDICATIONS FOR OPERATION**

Diagnosis of origin of RPA or LPA from ascending aorta in infancy is an indication for urgent operation. This is true regardless of pulmonary vascular resistance in the two lungs, because these changes are usually reversible, at least in infants operated on before age 6 to 12 months. In rare cases of presentation beyond infancy, excessive elevation of pulmonary vascular resistance in the normally connected lung is a contraindication to operation.\textsuperscript{72} However, experience is insufficient to state the exact level of pulmonary vascular resistance in the normally connected lung that makes patients inoperable.

If the resistance is normal in the normally connected lung, repair is indicated. The anomalously connected lung will never have infinite resistance, so connecting it to the pulmonary circuit will always lower pulmonary vascular resistance. The difficulty lies in assessing resistance in the anomalously connected lung prior to repair. Pressure and flow to the normally connected lung can be easily measured at catheterization, and thus resistance in that lung can be calculated. Pressure, but not flow, to the anomalously connected lung can be easily measured, thus resistance cannot be calculated. A nuclear medicine lung perfusion scan can be used to estimate the flow ratio to each lung, and when this is combined with other pressure and flow data from catheterization, resistance can be calculated independently in each lung, helping to determine operability.

INTRODUCTION

Congenital anomalies of the coronary arteries represent a varied group of lesions. Taken together, they are relatively common, seen in 1% to 5% of the population, depending on the method of detection. Many lesions are incidental findings with little or no consequences, but approximately 20% have the potential to cause coronary ischemia and its sequelae.

Box 46-1 presents a useful classification of all congenital coronary artery lesions. Some of these—an anomalous or eccentric location of a coronary artery ostium, multiple ostia, and duplication of coronary arteries—have no physiologic importance but may be important if other cardiac procedures are required. Others lesions such as myocardial bridging, ectasia or aneurysm, and small fistulas may or may not have to be surgically repaired, depending on whether or not they have physiologic consequences.

The most important lesions include large coronary arteriovenous fistula, anomalous connection of a coronary artery to the pulmonary trunk, and anomalous connection of a coronary artery to the wrong aortic sinus. All require surgical correction, or occasionally other intervention. This chapter focuses on these three lesions. A discussion of the more minor and incidental lesions outlined in Box 46-1 can be found in the review by Kayalar and colleagues.65

Section I  Coronary Arteriovenous Fistula

DEFINITION

A congenital coronary arteriovenous (AV) fistula is a direct communication between a coronary artery and the lumen of any one of the four cardiac chambers, the coronary sinus or its tributary veins, or the superior vena cava, pulmonary artery, or pulmonary veins close to the heart. Fistulous coronary connections that occur in congenital pulmonary and aortic atresia (see “Right Ventricular Coronary Artery Fistulae” under Morphology in Chapter 40 and “Other Associated Cardiac Anomalies” under Morphology in Chapter 49) are excluded from this chapter.

HISTORICAL NOTE

A congenital coronary AV fistula was first described by Krause in 1865.61 The first report in the English literature was that of Trevor in 1912, who described autopsy findings in a case with a fistula from the right coronary artery into the right ventricle. The patient died from associated endocarditis.73 Autopsy reports from Blakeway89 and from Halpert32 followed. The first report of surgical correction was in 1947 by Biorck and Crafoord,87 who discovered a fistulous connection to the pulmonary trunk at thoracotomy in a patient presumed to have a patent ductus arteriosus. It was closed with sutures. Probably the first reported case of a fistula that was correctly diagnosed preoperatively was that of Fell and colleagues in 1958,82 and the first report of repair using cardiopulmonary bypass (CPB) was that of Swan and colleagues in 1959.61,63 Currarino and colleagues described the use of angiography in diagnosis in 1959.515

MORPHOLOGY

Coronary Artery Site

The right coronary artery or its branches are the site of the fistula in 50% to 55% of cases.12,112 The left coronary artery is involved in about 35%, and both coronary arteries in 5%.82 The fistulous artery is almost invariably part of a normally distributed coronary artery with a normal branching pattern. The fistula occurs either in the main vessel that continues beyond the fistula (a side-to-side pattern) or at the termination of the main vessel itself, or at a branch (an end artery).55 Rarely, the involved artery is anomalous.11 The coronary artery proximal to the fistula is always dilated and elongated and may be serpiginous, and the degree of these changes is roughly proportional to the size of shunt through the fistula. Usually, dilatation is uniform throughout, but it may become aneurysmal anywhere along its course. Rarely, a giant aneurysm occurs involving the whole artery. This is particularly prone to occur in fistulae from the right coronary artery entering either the posterior wall of the left ventricle11,10,03 or right ventricle17 (Fig. 46-1). Although such aneurysms enlarge progressively,11,18 rupture is rare. Should the artery continue beyond the fistula, it reduces abruptly to a diameter smaller than expected. It is probable that in such cases a
coronary steal phenomenon occurs. There is no convincing evidence that these “feeding arteries” are unusually susceptible to developing arteriosclerosis.

Site of Fistulous Connection

Fistulous connections between the coronary artery and heart may enter any of the four cardiac chambers, the coronary sinus or its tributary veins, or the great arteries or veins adjacent to the heart (pulmonary trunk, proximal pulmonary veins or proximal superior vena cava, or left superior vena cava). There are, however, certain predilections. More than 90% of fistulae open into right heart chambers or their connecting vessels. True AV fistulae to the veins themselves (coronary sinus or its major branches or venae cavae) are uncommon. Thus, about 40% connect to the right ventricle, 25% to right atrium, 15% to 20% to pulmonary artery, 7% to coronary sinus, and only 1% to superior vena cava.

Fistulae entering the right side of the circulation cause rapid systolic and diastolic runoff from the aorta and a left-to-right shunt. The Qp/Qs is seldom larger than 1.8 and is often less, and arterial pulse pressure is seldom greatly widened. About 8% of fistulae drain into left heart chambers or their tributaries, usually the left atrium, less often the left ventricle (about 3%), and rarely the proximal pulmonary veins. Left heart fistulae are not, of course, AV fistulae but arterioarterial (arteriocameral, arteriosystemic) and therefore do not produce a left-to-right shunt. There may be important runoff from the aorta during both systole and diastole when fistulae enter the left atrium, or only during diastole when they enter the left ventricle, because fistulae usually close off during systole, and because there is no pressure gradient. Volume overload on the left ventricle is therefore similar to that produced by aortic regurgitation.

Information on sites of fistulous connections comes in large part from numerous collective reviews of this subject, and most patients were surgically treated.

The right atrium and right ventricle are the most frequent sites of connection for cases requiring surgery. In angiographic series, the most frequent site of connection of small coronary fistulae not requiring surgical therapy was the pulmonary trunk. Fistulae (localized and diffuse) to the left heart are more common in coronary angiographic series than in surgical series.

Size and Multiplicity of Fistulae

In surgically treated cases, the fistulous opening, when single, is seldom larger than 2 to 5 mm (Fig. 46-2) and usually has fibrous margins, although uncommonly it may itself be aneurysmal as in the first reported case. Occasionally there may be several openings or a localized angiomatous network of vessels. Among the 58 patients reported from the Texas Heart Institute, multiple fistulae were identified in 16% and an angiomatous lesion in 10%; the fistula was aneurysmal in 19%. In a number of instances (no doubt many times the number reported in surgical series), the fistula is small and is recognized only because of high-quality cineangiography. As in other sites, most fistulae to the left ventricle are single. In a small group of patients, however, there is a diffuse sponge-work of tiny connections from a number of, if not most, branches of the left coronary and sometimes also the right coronary artery (Fig. 46-3). These presumably represent persistence of embryonic trabecular spaces.

Cardiac Chambers

The chamber or vessel into which the fistula connects is variably affected. When the right atrium receives the fistula, it tends to become considerably dilated, whereas the right ventricle and pulmonary trunk show less change (apart from that to be expected from an increase in pulmonary blood flow) until heart failure occurs and they participate in cardiomegaly. Similarly, the left ventricle tends to remain normal in size despite a fistulous connection to it, probably because runoff occurring only in diastole is seldom large and seldom comparable with that occurring in severe aortic regurgitation. Left ventricular hypertrophy may be present. Rarely the left atrium becomes aneurysmally dilated.

The coronary sinus may also become aneurysmal and may rupture; this is the only reported site of preoperative rupture in this condition. It is possible that runoff through the coronary sinus is limited by the coronary sinus ostium. Arterialization of the coronary sinus occurs, and possibly in relation to this, there is an unusually high prevalence of heart failure in such patients.

Infective Endocarditis

The fistula is the site of endocarditis in about 5% of cases and is attributed to turbulence.

Associated Lesions

Most coronary AV fistulae occur as isolated lesions, but there may be coincidental congenital or acquired lesions of almost any type. In the series reported by Urrutia-S and colleagues, 21 of 58 patients had associated lesions such as atrial septal defect, ventricular septal defect, and acquired valve or coronary disease.
Figure 46-2  Cineangiogram frames in right anterior oblique projection in two patients with coronary arteriovenous fistulae from main right coronary artery (RCA) to right ventricle (RV).  

A, Dilated RCA runs in its usual position in atrioventricular groove, and beyond fistula (arrow) it continues around acute margin to divide into posterior descending and inferior left ventricular (posterolateral segment) branches (not seen).  

B, RCA is again shown to be normally positioned and very dilated and tortuous. Fistula (arrow) arises from posterior descending branch about halfway along posterior interventricular groove and lies therefore at termination of this vessel.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Age at Presentation
Most patients present late in life, occasionally in childhood, rarely in infancy.

Symptoms
Most patients considered for operation are asymptomatic and present either because of a continuous murmur or mild cardiomegaly and plethora on chest radiograph. Some 80% of patients under age 20 years are asymptomatic, whereas only 40% of those older are without symptoms. Patients with small fistulae are being detected because of coronary angiography for other conditions. They are typically asymptomatic and presumably will continue to be so.

The most common symptoms are effort dyspnea and fatigue from the left-to-right shunt. Angina is uncommon (about 7%) and myocardial infarction rare (about 3%). It is postulated that these ischemic symptoms are due to coronary artery steal.

Heart failure occurs in 12% to 15% of patients presenting for operation but is much more common in older patients, as is angina. Thus, in the review by Libethson and colleagues, only 6% of patients under 20 years of age had heart failure, but 39% of those 20 years or older did. Heart failure can occur in infants with large shunts and in the occasional child with a large right coronary–left ventricular fistula comparable with an aortico–left ventricular tunnel. The likelihood of older patients having heart failure is not directly related to shunt size; rather, it is presumably related to a long-standing modest left-to-right shunt, as in the case of atrial septal defect. Heart failure is more common in patients with fistulous connection to the coronary sinus (50% vs. 14% in the overall group as reported by Ogden and Stansel). It may also be more common with onset of atrial fibrillation, which occurs more often when the connection is to the right atrium.

When infective endocarditis occurs, presentation may be with chills and fever.

Diagnosis
Diagnosis is often strongly suspected from physical signs, but it may be difficult to distinguish coronary AV fistula from other lesions with rapid aortic runoff and continuous murmurs such as patent ductus arteriosus, ventricular septal defect with aortic regurgitation, ruptured sinus of Valsalva aneurysm, and in infancy, aortico–left ventricular tunnel. In coronary AV fistula, there is usually a continuous murmur that is maximal to the right of the sternum when the fistula enters the right atrium, and usually at the lower left sternal edge when it enters the right ventricle or left ventricle. However, when the pulmonary trunk is involved, the murmur is situated as in a patent ductus arteriosus. When the fistula enters the left ventricle, the murmur is usually only diastolic.

A systolic thrill is occasionally palpable when the fistula lies anteriorly (entry into right atrium or right ventricle). When the shunt and aortic diastolic runoff are large, pulse pressure...
is wide and the pulse jerky.Rarely, infants with a connection to the left ventricle may present with full-blown signs of severe aortic regurgitation.

The electrocardiogram (ECG) is entirely normal in about half of surgical patients and shows evidence of right or left ventricular overload in the remainder. The chest radiograph may also be normal or may show mild cardiomegaly and plethora. Cardiomegaly is more marked when heart failure appears. There may be evidence of right or left atrial enlargement, and occasionally the dilated and tortuous or aneurysmal coronary artery or fistulous site may distort the cardiac silhouette. This is most obvious when a giant aneurysm of the right coronary artery drains to the left ventricle, although this is rare.

Two-dimensional (2D) echocardiography can detect importantly enlarged coronary arteries and may also confirm specific chamber enlargement. Thus, diagnosis of a coronary AV fistula can be made by 2D and Doppler echocardiography if the fistula is large enough (Fig. 46-4). Echocardiography, however, is not definitive.

Cardiac catheterization, aortography, and selective coronary angiography have long been the gold standard for definitive diagnosis and planning of either surgical repair or coil occlusion by interventional catheterization (Figs. 46-5 and 46-6; also see Figs. 46-2 and 46-3). Left-to-right shunts are calculated, and right heart pressures are measured.

Computed tomography angiography (CTA) can accurately define the morphology of the fistula in both adults and young children, in cases that will not require hemodynamic measurements to make management decisions, it may be the diagnostic procedure of choice.

NATURAL HISTORY

The natural history of coronary AV fistula is not known precisely, but its general outlines are clear. The fistula, if not present at birth, develops early in life. Likely, small fistulae remain small, and moderate fistulae slowly increase in size, although there may be little change over 10 to 15 years. Onset of dyspnea, heart failure, and angina can occur in young patients with large fistulae. However, because the shunt is usually only moderate, symptoms often do not appear until later in life consequent to long-standing moderate left ventricular volume overload. Daniel and colleagues found from a review of the literature that if heart failure did not occur early in infancy, it would be virtually unknown until age 20. The maximum prevalence of heart failure occurs in the fifth and sixth decades.
The other event that may precipitate symptoms and cause premature death is infective endocarditis, which occurs in about 5% of patients and may develop at any age.\textsuperscript{19,25,52} Aneurysm formation develops with increasing frequency over time, occurring in 9% of children and 14% to 29% of adults.\textsuperscript{52,54} Spontaneous rupture is rare,\textsuperscript{11} even though the feeding coronary artery or the fistula itself may become aneurysmal, and as with other aneurysms, there is progressive dilatation of the sac.\textsuperscript{1,10} Rupture has not been reported in children.\textsuperscript{52} Libethson and colleagues found that among 173 reported patients with mean age 24 years, fistula-related death occurred in 6%: 1% in those presenting younger than age 20, and 14% in those presenting later (mean age 45 years).\textsuperscript{19} Spontaneous closure of a fistula has been recorded\textsuperscript{25,31,52,59} but is rare.

**Figure 46-4** Two-dimensional echocardiogram and color-flow Doppler interrogation of coronary artery fistula. A, Right coronary artery (RCA) to right ventricular (RV) fistula is demonstrated. Note increased diameter of coronary artery. B, Color-flow Doppler signal showing turbulence at fistulous site entering right ventricle. Key: Ao, Aorta; CF, coronary fistula.

**Figure 46-5** Cineangiograms in two patients with small fistulae to pulmonary trunk. A, Right anterior oblique projection. Fistula (arrowhead) is supplied by small branches from second diagonal and proximal left anterior descending coronary arteries (LAD). Pulmonary trunk (PT) opacifies faintly during part of each cardiac cycle. Operation is not indicated. B, Left anterior oblique projection. Fistula (arrow) is supplied by two branches from proximal LAD (origin of superior one is overlapped by shadow of cardiac catheter). PT opacified faintly. This lesion was closed at time of atrial septal defect repair. Key: Ao, Aorta; Cx, circumflex artery.

**TECHNIQUE OF OPERATION**

Approach in all patients is through a median sternotomy, with preparation made for use of CPB (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2). After opening the pericardium, site of the fistula and location, size, and pathology of the coronary artery leading to it are noted. CPB is indicated:

1. When the artery is dilated and tortuous, to prevent catastrophic hemorrhage during closure of the fistula
2. When the fistula is relatively inaccessible, such as when it is in the left atrioventricular groove or distribution of the circumflex or distal right coronary artery
3. When the fistula is in the course of the coronary artery rather than at its termination, so that the fistula itself can be closed without ligation of the coronary artery
4. When an aneurysm requires excision
Precise location of the coronary AV fistula is determined and marked with a stitch before establishing CPB, because this is difficult to do later. After establishing CPB, the aorta is clamped. While the fistula is digitally closed, cold cardioplegic solution is administered. When the chamber into which the fistula opens is an atrium or the pulmonary trunk, the chamber is opened and the fistula closed from within with over-and-over sutures supplemented with a pledgeted mattress suture.

Cold cardioplegic solution can be infused both to identify the entry point of the fistula in the opened chamber and to test security of closure. When the fistula enters a ventricle or when the coronary artery is large and continues beyond the fistula, the coronary artery itself is opened and the fistula closed with a running suture, followed by closure of the arteriotomy with 6-0 or 7-0 polypropylene sutures. Use of a running mattress suture beneath the artery through the fistulous site is not recommended because this may lead to fistula recurrence.

Alternatively, if the fistula enters the right ventricle, right atrium, or pulmonary trunk, once CPB is established, the pulmonary trunk or right atrium, as appropriate, is opened without clamping the aorta. A pressurized blood stream emitted from the fistula makes its identification easy. This technique is especially helpful if the fistula enters the trabeculations of the right atrium or right ventricle. Closure from within the chamber is performed, and elimination of the blood stream confirms efficacy of closure.

When a large aneurysm is present (see Fig. 46-1), it should be excised. If the aneurysm is localized over the fistula site, excision entails trimming away the edges of the dilated vessel and resutting its walls to create an artery of near-normal size. This is possible because the posterior wall invariably consists of strong tissue. This is necessary only when the artery continues beyond the site of the fistula. When it is an end artery, the aneurysm is completely excised and the vessel remnants oversewn. When the aneurysm involves most of the feeding coronary artery (see Fig. 46-1), there is usually no option but to unroof it completely and close the coronary artery proximal and distal to the sac, the latter closure including the fistula site. In such circumstances, it is always appropriate to consider use of coronary artery bypass grafting (CABG) using either a saphenous vein or internal thoracic artery to the vessel beyond the fistula, but this may not be possible when the coronary artery is too small.

After completing the repair, if a left-sided chamber has been opened, it is aspirated for air. The remainder of the operation is completed as usual (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2). Fistulous connection may be safely closed without CPB when it represents the termination of a major coronary artery branch into an easily accessible site and indicators for CPB are absent. In such instances, a suture ligature is placed around the “feeding” coronary artery very close to the fistulous connection. The fistula is then temporarily completely closed (verified by complete ablation of the thrill), and the ECG is monitored for several minutes. If there are no ECG changes, the ligature is tied down and another suture ligature placed for additional security. When the fistula is less clearly localized and consists of multiple vessels, secure closure requires a running suture that encompasses all involved vessels and the underlying wall.

**SPECIAL FEATURES OF POSTOPERATIVE CARE**

Patients are managed as described in Chapter 5.

**RESULTS**

**Survival**

**Early (Hospital) Death**

Hospital mortality for repair of coronary AV fistula in the absence of giant aneurysm formation approaches zero. A literature review by Liberthson and colleagues indicates a mortality of 4% (CL 2.5%-6.2%) in 173 patients. Giant aneurysms almost always involve the right coronary artery, necessitating complete aneurysm excision and usually regrafting of the remaining right coronary system; risk of ischemia and arrhythmia increases in this situation. Of 10 reported patients with right coronary artery–left ventricular fistula, 3 (30%; CL 14%-51%) died postoperatively. Operative complications are rare. Myocardial ischemia, either temporary or with infarction, has been reported in 5% of cases, and fistula recurrence in 4%. With use of the techniques described here, these complications have become uncommon.

**Time-Related Outcomes**

Late results of repair are excellent. Edis and colleagues report that essentially all patients in whom the fistula was eradicated remain in New York Heart Association (NYHA) class I. Lowe and colleagues found no late deaths and no recurrent fistulas among 22 survivors of repair, with a mean follow-up of 10 years. Although involvment of the greatly dilated leading artery can occur when repair is performed in early life, this is not the case in adults.
INDICATIONS FOR OPERATION

Some believe that prognosis of a surgically untreated coronary AV fistula is excellent, and operation is indicated only if symptoms are present. However, in view of the probability that at least some of these fistulae will increase in size and therefore eventually produce symptoms and heart failure, the tendency for development of infective endocarditis, the low probability of spontaneous closure, and the safety and efficacy of operation, it is recommended that diagnosis of a coronary AV fistula is an indication for operation unless the shunt is small ($Q_p/Q_s < 1.3$).

SPECIAL SITUATIONS AND CONTROVERSIES

Use of various interventional catheter-delivered occluding devices and coils has been reported to treat coronary AV fistulae successfully. These techniques are increasingly being considered the therapy of choice for appropriately selected patients. In a nationwide survey conducted between 1996 and 2003, 85% of treated patients were managed surgically and 15% with interventional techniques.

Section II  Anomalous Connection of Left Coronary Artery to Pulmonary Trunk

DEFINITION

In anomalous connection of left coronary artery to pulmonary trunk, the whole of the left main coronary artery or only the left anterior descending or circumflex branch connects anomalously to the proximal pulmonary trunk or very rarely to the proximal right pulmonary artery. Branching pattern of the anomalously connecting left coronary artery remains normal. The right coronary artery arises normally from the aorta and has a normal branching pattern. Collaterals from the right coronary artery feed the left coronary artery, in which flow is reversed, so that the left coronary artery drains into the pulmonary artery. Very rarely, both coronary arteries connect to the pulmonary artery by a single trunk.

HISTORICAL NOTE

In 1886, Brooks in Dublin described, apparently for the first time, anomalous connection of a coronary artery to the pulmonary trunk, and in 1908, Abbott described anomalous connection of left coronary artery to pulmonary trunk. Bland, White, and Garland in 1933 described the clinical syndrome associated with the anomaly, based on their experience with a 3-month-old infant who died from it. The pathophysiology, as suggested by Brooks in his original paper, is impoverished left ventricular myocardial blood flow—despite good collaterals between right and left coronary arteries—because of retrograde flow from left coronary artery to pulmonary trunk. Edwards supported this hypothesis, as did Case and colleagues in 1958. The latter also reported the postmortem observation that radiopaque dye injected into the ascending aorta passed out through the normal right coronary artery and, by collaterals, filled the left coronary artery in retrograde fashion.

Sabiston and colleagues verified retrograde flow at the first successful operation for the anomaly in 1959 by measuring a striking increase in left coronary artery pressure when its anomalous connection to the pulmonary trunk was occluded. Actual demonstration of left-to-right shunt into the pulmonary trunk was by Augustsson and colleagues in 1962 and by Rudolph and colleagues in 1963.

Earliest surgical attempts to ameliorate the condition were indirect. The first attempt was apparently by W.J. Potts, who created an aortopulmonary (AP) fistula to increase saturation in the pulmonary trunk (personal communication, 1955). Kittle and colleagues banded the pulmonary artery, and Paul and Robbins used pericardial poudrage. These procedures are obsolete.

Successful ligation of the anomalous left coronary artery connection by Sabiston and colleagues in 1959 was followed by a similar report from Rowe and Young in 1960. As early as 1953, Mustard reported attempts to anastomose the turned-down left common carotid artery to the anomalous left coronary artery that he detached from the pulmonary trunk together with a button of pulmonary trunk wall. Apley and colleagues attempted a similar procedure using the subclavian artery in 1957. Meyer and colleagues first used this latter procedure successfully to create a two-artery coronary system in 1968, and others including Pinsky and colleagues reported such a repair.

In 1966, Cooley and colleagues reported use of coronary artery bypass vein grafting from the aorta to the left main or proximal left anterior descending artery, after closing the left coronary ostium from within the pulmonary trunk. The next procedure to evolve was translocation of the anomalous coronary artery from pulmonary trunk to ascending aorta. Such a procedure was performed unsuccessfully in 1972 using hypothermic circulatory arrest. This was first performed successfully for the rare condition of anomalous connection of the right coronary artery to pulmonary trunk (where the artery lies anteriorly and is more readily translocated) by Tingelstad and colleagues in 1971, and for the left coronary artery by Neches and colleagues in 1974. The latter also described successful interposition of a free left subclavian artery segment between the left coronary artery and the back of the ascending aorta.

In 1979, use of a tunnel within the pulmonary trunk to connect the ostium of the anomalous coronary artery to the aorta via an AP window was introduced. It was created either of pericardium, as described by Hamilton and colleagues, or of pulmonary artery wall, as described by Takeuchi and colleagues. Arciniegas and colleagues modified this concept by placing a free subclavian artery graft inside the pulmonary trunk. Reconstructive techniques have been devised to permit implanting coronary arteries that are remote from the aorta. Use of temporary ventricular assistance in infants has been an important adjunct to postoperative management. The aneurysmal left ventricular wall was excised unsuccessfully in 1960. This procedure, combined with ligation of the left coronary artery, was subsequently performed successfully by Turina and colleagues in 1973 and Fleming and colleagues in 1975.
MORPHOGENESIS AND MORPHOLOGY

Morphogenesis

Embryologic information indicates that the proximal coronary arteries grow from the peritruncal area into the aorta, with formation (normally) of single orifices for both left and right coronary arteries. Therefore, the phrase “the anomalous artery arises from” is inappropriate. For that reason, the former term, anomalous origin, has been abandoned in this text for anomalous connection.

Morphology

The anomalous left main coronary artery connects most often to the sinus of Valsalva immediately above the left or posterior cusp of the pulmonary trunk and rarely from that above the right cusp. The left main coronary artery is of variable length, but usually divides into anterior descending and circumflex branches within 5 or 6 mm of its origin. Collateral communications between right and left coronary arteries are always present, but vary in extent and are grossly visible in only a few cases, mainly in adults. Uncommonly, only the circumflex branch connects anomalously to the pulmonary trunk, and rarely only the anterior descending branch.

Very rarely, the left main coronary artery or only the circumflex artery connects to the right pulmonary artery near its origin rather than to the pulmonary trunk. Even more rarely, both the left and right coronary arteries connect to the pulmonary trunk (see “Total Anomalous Connection of Coronary Arteries to Pulmonary Trunk” under Special Situations and Controversies later in this section).

The left ventricle is always hypertrophied and usually greatly dilated, with dilatation often involving primarily the left ventricular apex. Diffuse left ventricular fibrosis is virtually always present, and patients dying in infancy usually have evidence of recent and old anterolateral myocardial infarction. Fibrosis is most marked in the subendocardial layer. Focal calcification may be present in fibrotic areas. Secondary subendocardial fibroelastosis of variable degree is usually present. However, a considerable amount of left ventricular dysfunction, in infants at least, must be ischemic in origin, in view of the dramatic improvement in left ventricular function that can result from an operation that creates a two-artery coronary system. Improvement in left ventricular function in a patient with coronary artery disease is difficult to distinguish from that of myocardial ischemia.

The chronic ischemia accompanying this lesion results in devitalization (or adaptive response) of the myocardium at a cellular and biochemical level. The devitalized myocardium has been termed hibernating myocardium (see “Myocardial Cell Stun ning” under Damage from Global Myocardial Ischemia in Chapter 3). The devitalized muscle slowly recovers over the time described once adequate blood flow and oxygen delivery are established.

Several pathologic features may result in mitral valve regurgitation. There may be extensive fibrosis and sometimes calcification in the papillary muscles, leading to papillary muscle dysfunction. Endocardial fibroelastosis may involve the mitral apparatus, with fusion and shortening of chordae tendineae. Also, papillary muscles may be abnormally positioned, which may lead to mitral regurgitation. Extensive left ventricular fibrosis can produce left ventricular and mitral anular dilatation and mitral regurgitation. Reversible left ventricular ischemia must, to some degree, contribute to the mitral valve regurgitation in infants, because in many cases regurgitation has been observed to decrease to an important extent after surgical treatment and creation of a two-artery coronary system.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Infant Presentation

Symptoms may be recognized within a week or so of birth. When there are no other anomalies, these are seldom severe enough to warrant referral before age 2 months. Presumably, high postnatal pulmonary artery pressure limits runoff into the pulmonary trunk, so there is less coronary steal, and myocardial dysfunction is gradual in onset rather than sudden. Circumural pallor and blueness are often present. The cardiac symptom is poor feeding. The baby takes the first 2 to 3 ounces well but then stops; there is breathlessness and sweating, and the baby may draw up the knees, arch the back, and uncommonly, cry or scream. The presumed cause is angina. As a result of the feeding problem, weight gain is poor. Few infants with these symptoms improve spontaneously. Usually by age 2 to 3 months, there is overt heart failure with persistent tachypnea and tachycardia. The infant by then is seriously ill and occasionally moribund.

Clinical signs are difficult to distinguish from those of cardiomyopathy or endocardial fibroelastosis. There may be a nonspecific systolic murmur at the base, or a more definite apical pansystolic murmur caused by mitral regurgitation and an apical gallop rhythm. A continuous murmur is not audible in infants. A precordial lift is common in association with marked and frequently gross cardiomegaly. Hepatomegaly also is present, and rales are heard throughout the lungs. The ECG is frequently helpful in diagnosis, because it usually shows anterolateral infarction with Q waves and ST-segment elevation in lateral chest leads and evidence of left ventricular hypertrophy. However, left ventricular hypertrophy alone may be reflected in the ECG. Myocardial enzymes may be elevated. In addition to cardiomegaly, interstitial pulmonary edema is evident on the chest radiograph.

Echocardiography shows a dilated, poorly contracting left ventricle (with ejection fraction typically <20%) and reveals the functional status and morphology of the mitral valve. In infants otherwise thought to have dilated cardiomyopathy, 2D and pulsed Doppler echocardiography may detect an abnormally large right coronary artery and anomalous connection of the left coronary artery to the pulmonary trunk, with retrograde flow in it (Fig. 46-7). This technique can also be used to identify an anomalously connecting right coronary artery.

Although definitive diagnosis is often made by echocardiography, current practice requires cardiac catheterization and cineangiography. An aortogram demonstrates the single right coronary artery arising from the aorta, and retrograde filling of the left coronary artery that produces a varying degree of opacification of the pulmonary trunk (Fig. 46-8). A left ventriculogram can be used to assess left ventricular function and degree of mitral regurgitation. It may also demonstrate coronary anatomy, making an aortogram unnecessary. Left ventricular end-dia stolic pressure is always elevated but may be lower than anticipated from viewing the typically very poor ejection fraction on echocardiography. Right heart
catheterization may show an increase in blood oxygen content at pulmonary artery level.

**Adult Presentation**

Collateral circulation from the right coronary artery is apparently adequate to prevent massive infarction, because few patients presenting later in life report a history of hospitalization in infancy, although there may have been feeding difficulties. When severe symptoms do not occur in infancy, presentation is often delayed to beyond age 20 years. Some adults remain asymptomatic or complain only of fatigue, dyspnea, or palpitations. About half have effort angina. There usually is a nonspecific systolic murmur, sometimes an apical pansystolic murmur from mitral regurgitation, and occasionally a continuous murmur over the upper left sternal edge due to retrograde flow from the coronary artery into the pulmonary trunk. Occasionally, mitral regurgitation dominates the clinical picture, producing heart failure. In an earlier era, some of these patients were operated on for mitral regurgitation or died without diagnosis of anomalous connection of left coronary artery to pulmonary trunk having been made.

The resting ECG is virtually always abnormal, with ST-T segment changes or evidence of old anterolateral infarction. Exercise ECG usually shows an abnormal ischemic response, and stress thallium myocardial imaging is usually abnormal. The chest radiograph may be normal or may show cardiac enlargement. Cineangiography shows more prominent collaterals from the right coronary artery in adults than in infants and usually a near-normal left ventricular ejection fraction, but with anterolateral hypokinesia. Mitral regurgitation occasionally is severe.

Individuals with anomalous left anterior descending or anomalous circumflex coronary artery typically present in adulthood rather than infancy. In the rare case that all coronary arteries arise from the pulmonary artery, death early in life is almost a certainty.

**NATURAL HISTORY**

Anomalous connection of the left coronary artery to the pulmonary trunk is rare, occurring in 0.26% of patients with congenital heart disease undergoing cardiac catheterization. About 65% of infants born with it die during the first year from intractable left ventricular failure (Fig. 46-9). However, they uncommonly do so in the first 2 months. Explanation for this symptom-free interval is not entirely clear, because extensive left ventricular scarring, particularly of the subendocardium, and evidence of old and recent infarction are usually present by then. It likely results, however, from a combination of initially elevated pulmonary...
Figure 46-8  Biplane cineangiographic frames in 3-month-old infant with anomalous connection of left coronary artery to pulmonary trunk.  
A-B, In right anterior oblique projection.  
C-D, In left anterior oblique projection. In A and C, right coronary artery (RCA) fills directly from aorta, and prominent conal branch collaterals are visible. In B and D, there is delayed retrograde filling of left anterior descending (double arrowheads) and circumflex arteries (single arrow). Whiff of contrast can be seen in the pulmonary trunk (x) in D.

Figure 46-9  Freehand depiction of survival without surgical treatment of patients with anomalous connection of left coronary artery to pulmonary trunk. (Figure is based primarily on collective review of 140 cases by Wesselhoeft and colleagues.)*

artery pressure, which limits the runoff, and gradual accumulation of myocyte dysfunction and loss.

If death does not occur during the first year, the hazard lessens considerably and the chronic phase of natural history is reached. Survival to this stage may be related to presence of rich interarterial collaterals, possibly associated with a slightly restrictive opening between left coronary artery and pulmonary trunk. Supporting this is the continuous murmur heard in about 5% of patients. Many such patients are in good health, and a few have normal ECGs.* Survival beyond the first year may also be related to marked right coronary dominance, with this vessel supplying not only the diaphragmatic portion of the left ventricle but also much of the septum and lateral wall.* Patients with this arrangement may occasionally only have papillary muscle ischemia and fibrosis, and mitral regurgitation may dominate the clinical picture.

Most patients who survive infancy continue to be at risk of death from chronic heart failure secondary to ischemic left ventricular cardiomyopathy. Those who survive until the
fourth decade are at less risk of death from heart failure (see Fig. 46-9), and those few patients who live to the fifth and sixth decades occasionally die suddenly, as do older patients with long-standing ischemic heart disease (see “Death” under Natural History in Chapter 7). In adult patients, myocardial ischemia and fibrosis are prominent, and occasionally, extensive myocardial calcification develops. However, left ventricular ejection fraction is only moderately depressed or normal in most of these patients.\(^{510}\)

**TECHNIQUE OF OPERATION**

**Constructing a Two-Artery Coronary System**

Optimally, operation is undertaken with the idea of constructing a two-artery coronary system in all patients. Translocation of the anomalous coronary artery into the aortic root appears to be the most direct and therefore advisable procedure, but it is not always possible. Smith and colleagues found the distance between the midpoint of the empty left aortic sinus and posterior aspect of the anomalously connected coronary artery to vary between 2 and 18 mm.\(^{312}\) The longer of these distances probably precludes direct implantation and makes the tunnel (Takeuchi) repair necessary.\(^{51}\)

Other methods of creating a two-artery coronary system may be less desirable. In critically ill infants, a case may still be made for use of simple ligation of the anomalously connected coronary artery, especially if used as a temporary maneuver to resuscitate a patient presenting in cardiac arrest. However, this seems less desirable in an era when mechanical assist devices are available even for the smallest infants. In seriously ill infants, ventricular fibrillation is likely to develop before the heart can be cannulated and CPB commenced. Therefore, vigilance is required to maintain an optimal hemodynamic state during preparations for operation and cannula for CPB.

Operation is best done with CPB at 18°C to 28°C (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2), although left coronary artery translocation has recently been reported using normothermic CPB and a continuously beating heart.\(^{54}\) After sternotomy, the pericardium is opened without touching the heart, because even the slightest trauma can induce ventricular fibrillation. Preferably, arterial cannulation of both the aorta and pulmonary trunk is used with a bifurcated system to maximize myocardial perfusion once CPB is started. Single venous cannulation is used. Immediately before commencing CPB, tourniquets are placed around the left and right pulmonary arteries. The tourniquets are tightened as CPB is initiated to prevent perfusion steal into the pulmonary bed from the pulmonary trunk arterial cannula. A left-sided vent is placed through a purse-string in the right upper pulmonary vein.

Myocardial protection during aortic clamping is particularly important for two reasons: the existing compromised state of the myocardium, and the potential for inadequate delivery of cardioplegic solution to the left ventricle. Preferably, cardioplegic solution is delivered simultaneously into the aortic root and pulmonary trunk using a bifurcated cardioplegia delivery system to maximize protection of the left ventricle.

Alternatively, some surgeons use only one arterial cannula (in the aorta) and deliver cardioplegia only into the aortic root. It is critically important to occlude the branch pulmonary arteries at the initiation of CPB and through cardioplegia delivery using this technique.

After completing cardioplegia, the pulmonary trunk cannula and branch pulmonary artery tourniquets are removed. A transverse incision is made in the pulmonary trunk just downstream to the commissure of the pulmonary valve. When the opening of the anomalously connecting left coronary artery is posterior or right-sided, the coronary artery translocation technique is used. When the opening is on the left-sided aspect of the pulmonary trunk, the tunnel operation\(^{71}\) should be considered.

**Tunnel Operation (Takeuchi Repair)**

Taking care to avoid injury to the aortic valve, a button of aortic wall about 5 to 6 mm in diameter is excised at a point at which the left wall of the aorta is in contact with the right side of the pulmonary trunk (Fig. 46-10, A). Directly opposite this, a button is excised from the right wall of the pulmonary trunk (Fig. 46-10, B [also see A]). These openings are sewn together with continuous 7-0 polypropylene to create an aortopulmonary window.

Using a flap of anterior pulmonary trunk wall hinged on the right, the anterior wall of the tunnel is created, completing the tunnel conveying blood from the aortopulmonary window across the back of the pulmonary trunk to the anomalously connecting left coronary artery (Fig. 46-10, C [also see B]). The large defect in the anterior wall of the pulmonary trunk is reconstructed with a patch of pericardium, pulmonary artery allograft, or polytetrafluoroethylene (PTFE) (Fig. 46-10, D). Occasionally, this operation narrows the immediately supravalvar portion of the pulmonary trunk sufficiently to require a transanular patch.

The remainder of the operation is completed in the usual fashion (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2). Weaning the patient from CPB may require patience, intravenous nitroglycerin, and monitoring left and right atrial pressures.

**Left Coronary Artery Translocation**

When the left coronary artery connects to the posterior or right-sided aspect of the pulmonary trunk (Fig. 46-11, A), the transverse pulmonary trunk incision is continued until the trunk is transected (Fig. 46-11, B).\(^{64,118,52,51}\) The incision is arranged so that a sizable button of pulmonary artery wall around the coronary ostium is excised (see Fig. 46-11, B). The left coronary artery is carefully mobilized for a short distance. An opening is made in the adjacent left posterolateral portion of the aorta (Fig. 46-11, C). The button around the coronary ostium is anastomosed to the aorta with 7-0 monofilament absorbable sutures, the pulmonary trunk is reconstructed by end-to-end anastomosis, and the coronary artery explant site is patched (see Fig. 46-11, C).

**Subclavian–Left Coronary Artery Anastomosis**

This procedure may be indicated when the anomalous coronary ostium within the pulmonary trunk is remote from adjacent aorta, making direct coronary translocation impossible and Takeuchi repair difficult. Initial CPB management uses a single aortic cannula, with attention to myocardial perfusion similar to that already described, but because the aortic root is not opened or manipulated, aortic clamping and cardioplegia are not necessary.
Figure 46-10  Tunnel operation (Takeuchi repair).  

A, After instituting cardiopulmonary bypass using techniques to maximize myocardial preservation, the initially small transverse pulmonary arteriotomy, made to confirm the unfavorable position of the anomalous coronary ostium for direct translocation, is extended to develop an anterior pulmonary arterial wall flap. It is based on the right lateral aspect of the pulmonary trunk. Dotted lines indicate (1) positions of buttons on adjacent aortic and pulmonary arterial wall that are to be removed, and (2) extent of incisions used for anterior pulmonary arterial flap.  

B, Anterior pulmonary arterial wall flap has been fully developed, and aortopulmonary window anastomosis is created using a running 7-0 monofilament absorbable suture. During creation of the aortopulmonary window, care should be taken to avoid direct injury or distortion of the semilunar valve cusps and commissures.  

C, Aortopulmonary window suture line has been completed, and the anterior pulmonary arterial wall flap has been used to create the tunnel connecting aortopulmonary window and remote ostium of anomalous coronary artery. This anastomosis is also performed with a running 7-0 monofilament absorbable suture. Great care should be taken as the suture line approaches the ostium of the coronary artery to avoid distorting the proximal coronary artery.  

D, Remaining defect in the anterior wall of the pulmonary trunk is now reconstructed with an appropriately shaped patch of either glutaraldehyde-treated autologous pericardium, pulmonary artery allograft arterial wall tissue, or polytetrafluoroethylene. A running monofilament nonabsorbable suture is used. Size of patch should be generous to avoid supravalvar pulmonary stenosis.
The left subclavian artery is dissected as far distally as possible and then ligated and divided at this level (Fig. 46-12). It is important that adequate length of left subclavian artery is achieved; otherwise, kinking at the subclavian origin is possible following anastomosis. The connection of the coronary artery to the pulmonary trunk is identified and the coronary mobilized on a generous button of pulmonary sinus tissue. The coronary artery is mobilized appropriately to allow the anastomosis to be performed without tension or kinking. The preferred method of anastomosis is end-to-end connection of subclavian artery to coronary button using a running 7-0 monofilament absorbable suture.

After completing the anastomosis and establishing flow through the reconstructed area, the proximal aspect of the subclavian artery should be examined carefully to ensure that no tension or kinking is present. The coronary explantation site on the pulmonary trunk can be closed primarily or, if preferred, with a small patch of autologous pericardium, pulmonary artery allograft, or PTFE, using a running monofilament nonabsorbable suture. Alternatively, the left coronary
The coronary artery is mobilized over an appropriate length so that there is no tension as the artery is brought over to the aortotomy site. A running 7-0 monofilament absorbable suture is used to create the coronary to aortic anastomosis. Also shown is the pulmonary trunk end-to-end reconstruction and reconstruction of the coronary explantation site using a patch of glutaraldehyde-treated autologous pericardium, pulmonary artery allograft, or polytetrafluoroethylene.

The patient’s anatomy may not permit this operation to be performed without excessive tension or kinking of the subclavian artery, so the surgeon must always have an alternative procedure in mind.

Other Techniques for Assisting Translocation
A number of techniques have been described to increase the likelihood of translocation of the anomalous coronary into the aorta for coronary arteries remote from the aorta. The coronary artery can be extended by autologous flaps of aorta and pulmonary artery, or it can be excised with a button of pulmonary artery, mobilized to reach the aorta, and anastomosed within the aortic lumen, a technique attributed to Yacoub. One such technique is shown in Fig. 46-13.

Coronary Artery Bypass Grafting
Techniques for CABG are the same as those used for internal thoracic artery grafting in the surgical treatment of arteriosclerotic coronary artery disease (see under Indications for Operation later in this section; see also Technique of Operation in Chapter 7). Even in small patients, the left internal thoracic artery can be used.

Ligation of Left Coronary Artery
This procedure may be carried out in the simplest manner through a limited left anterolateral fourth interspace incision. The pericardium is opened in front of the phrenic nerve after mobilizing the thymus from its upper part. A ligature is tied around the tip of the left atrial appendage to retract it superiorly. The anomalous connection of the left coronary artery is immediately obvious, and is rapidly dissected and ligated close to the pulmonary trunk wall with a single transfixing suture or metal clip. Venous collaterals around the artery may require cautery control. The pericardium is loosely closed and chest closed with or without drainage. The entire procedure can be completed within 30 to 45 minutes.

In the current era, this procedure may be applicable as an interim measure to stabilize critically ill patients before more formal revascularization. CPB may be used, especially if the anomalous coronary artery connects to the pulmonary trunk posteriorly. Using a single venous cannula, perfusion at 37°C, and no aortic clamping, the pulmonary trunk is opened transversely and the origin of the left coronary artery oversewn with a few simple sutures reinforced with a pledgeted mattress suture. CPB time is approximately 15 minutes.

SPECIAL FEATURES OF POSTOPERATIVE CARE
Care of patients undergoing repair of anomalous connection of left coronary artery to pulmonary trunk is the same as that for other patients undergoing cardiac surgery (see Chapter 5). A left atrial pressure monitoring catheter should be used. In critically ill small infants, low cardiac output can be anticipated during the first few postoperative days, and appropriate measures applied (see “Cardiovascular Subsystem” in Section I of Chapter 5). These measures may include use of temporary left ventricular assistance (see “Temporary Ventricular Assistance” in Section I of Chapter 5).
RESULTS

Survival

Early (Hospital) Death

Early mortality reported for heterogeneous groups of patients is almost valueless because of the powerful effect of risk factors in this setting, the small number of patients in all reported series, and the effect of “patients too sick for operation” on mortality after surgery. These factors also make difficult an appropriate comparison of outcomes after various surgical procedures. There is a suggestion, supported by physiologic arguments, that outcome following simple ligation is not as good as with more formal revascularization (Tables 46-1 and 46-2). Mortality in various subsets from series reported from 1975 to 1980 ranged from 0% to 75%. Certain trends have emerged over time. Series reported since 1995 emphasize operations that result in a two-artery coronary system and also document excellent survival (mortality 0% to 14%). Improved postoperative support, including use of temporary ventricular assistance, may play an important role.

Time-Related Outcomes

Few appropriate studies of long-term survival have been conducted. In one study, no late deaths were recorded in 21 patients with a mean follow-up of 6.5 years (range 2 months to 18 years) and a total of 145 patient-years of follow-up. Similar midterm results have been reported by others, supporting the position that most patients survive long term after any of the described procedures.

Modes of Death

Most hospital deaths result from acute cardiac failure.

Incremental Risk Factors for Premature Death

No formal analysis provides information regarding incremental risk factors for premature death. Presumably, there is an early, rapidly declining hazard phase for death; a low constant phase of hazard follows, conditioned by status of the left ventricular myocardium.

Preoperative status of the left ventricle is also the important risk factor for death during or early after repair, with depressed shortening fraction identified in one analysis of 39 patients. This status determines functional state of the patient, which is also a powerful risk factor for death.

Important risk factors are also a risk factor for death early (and perhaps late) after repair, but this is correlated with status of the left ventricle. As with older studies (see Fig. 46-9), more recent reports seem to indicate that deaths are more frequent among infants.

Functional Status

Functional status is generally good late postoperatively. Of 21 patients assessed by Cochrane and colleagues, 18 were in NYHA class I and 3 in class II at midterm follow-up. Size of the left ventricle (including cardiothoracic ratio) is nearly always markedly reduced by operation, and signs of myocardial ischemia are reduced. Late postoperative functional status in patients operated on in infancy or in adult life appears to depend primarily on status of the left ventricle before operation, just as it does in arteriosclerotic ischemic heart disease (see “Left Ventricular Function” under Results in Chapter 7). Clearly, however, these patients are not normal. In 11 late survivors, myocardial flow reserve was reduced, and exercise tolerance was lower than normal.

Left Ventricular Function

Left ventricular function does not change immediately after operation, but it improves strikingly after several months in most surviving patients, as evidenced by reduction in cardiothoracic ratio (Fig. 46-14) and left ventricular end-diastolic and end-systolic volumes, return of left ventricular shape to normal in both diastole and systole, and increase in left
Figure 46-13  Technique for extending coronary artery. A, Pulmonary trunk is transected above level of pulmonary valve. A sleeve of pulmonary artery posterior wall is excised along with left coronary orifice. Inset, Partially excised pulmonary arterial wall in continuity with origin of left coronary artery (LCA). B, Upper and lower edges of this pulmonary flap are sewn together with a 7-0 or 6-0 monofilament suture in order to form a tube-shaped autologous graft 3 to 4 mm in internal diameter in continuity with origin of left coronary. C, Graft is sutured end to side into left posterior wall of ascending aorta with a 6-0 monofilament suture. Defect in pulmonary trunk is repaired with a fresh autologous pericardial patch. Key: RCA, right coronary artery. (From Wu and colleagues.)

ventricular ejection fraction and left ventricular shortening during systole.\textsuperscript{50,57,68,88,89,10,11,10,12,10,58} (Fig. 46-15). These findings indicate that in many patients, severe left ventricular dysfunction present preoperatively is due to reversible devitalization of the myocardium, or myocardial hibernation, as opposed to myocardial stunning (see “Myocardial Cell Stunning” under Damage from Global Myocardial Ischemia in Chapter 3).

**Mitral Regurgitation**

Mitral regurgitation frequently exists at presentation in patients with anomalous connection of left coronary artery to pulmonary trunk. It is argued by some that the basis for the regurgitation is ischemic and is reversible, and therefore the mitral valve should not be addressed routinely at initial operation for the anomalous coronary artery.\textsuperscript{1,12} Others routinely perform mitral anuloplasty when regurgitation is severe.\textsuperscript{12} When operation is performed in infancy, even important mitral regurgitation can regress postoperatively, no doubt related to improved left ventricular function.\textsuperscript{B21,C12,S8} However, when mitral regurgitation is severe, it may not regress, and reoperation is required for regurgitation a few months to a few years later.\textsuperscript{B14,B21,C12,S15} In one study that carefully tracked mitral valve function following surgery, regurgitation did not improve in 38% of cases but remained severe.\textsuperscript{65}

**Effect of One-Artery Coronary System**

Whether a two-artery coronary system after repair confers a better outcome than a one-artery system remains arguable. Speculatively, a two-artery system would seem to be advantageous, and results of exercise testing in a small number of patients support this view.\textsuperscript{142} Evidently, coronary blood flow is increased either by simple ligation of the anomalous left coronary artery or by creating an aortic origin of left coronary flow. However, coronary perfusion pressure in much of the left ventricle must be greater after the second type of repair, because it is not dependent on collateral flow. As a result,

early and long-term results should be better, although magnitude of the difference when all other risk factors are similar remains to be determined.

Conduit Patency after Two-Artery Repair

Conduit patency cannot be assumed because the patient is asymptomatic, as is obvious from the fact that many patients are asymptomatic after a one-artery coronary system repair. The Takeuchi tunnel conduit was found to be obstructed in one of three patients studied late postoperatively by Bunton and colleagues, while four PTFE tubes used in a similar fashion were all patent. Two of five young patients undergoing left subclavian–left coronary artery anastomosis were found to have occluded conduits 3 to 5 years postoperatively.

When saphenous vein bypass grafts are used in adults, graft patency may be higher than in arteriosclerotic coronary artery disease. Donaldson and colleagues reported four of five grafts were patent 14 years postoperatively. When the reports of Moodie and colleagues and Chiariello and colleagues are combined, 11 of 15 grafts were patent. However, concern remains about the potentially lethal effect of vein graft closure, particularly in view of demonstrated regression of right coronary artery collaterals following successful revascularization. Anthony and colleagues reported sudden death in a 9-year-old girl 5 months after saphenous vein bypass grafting; at autopsy the graft was occluded and had extensive intimal fibrous hyperplasia. Similar vein graft obliterative changes were observed by el-Said and colleagues.

Right Ventricular Outflow Obstruction after Tunnel Repair

Right ventricular outflow obstruction is a risk following Takeuchi tunnel repair, but use of a generous anterior pulmonary trunk patch apparently reduces risk of serious obstruction.

INDICATIONS FOR OPERATION

Diagnosis of anomalous connection of left coronary artery to pulmonary trunk in an infant, regardless of clinical status, is an indication for urgent operation. The recommendation that operation be delayed until an older age is no longer tenable. Diagnosis is an indication for operation in older patients. Creating a two-artery coronary system may be considered to be indicated in all situations, including critically ill infants, especially if the option of using left ventricular assistance is available. Proper myocardial management (as described under Technique of Operation in this section) is mandatory.

Translocation of the left coronary artery into the aorta is the optimal operation when anatomy is favorable, with the Takeuchi procedure as the second option in infants. In older patients, internal thoracic artery grafting is a reasonable second alternative when size of the graft permits (see “Internal Thoracic Artery” under Technique of Operation in Chapter 7). Some recommend leaving the mitral valve alone when operation is performed in young patients, even when it is severely regurgitant, because this usually regresses if operation is successful; however, others routinely perform mitral anuloplasty as part of the initial operation. In older patients, mitral repair or replacement may be required (see Technique of Operation in Section I of Chapter 11).

SPECIAL SITUATIONS AND CONTROVERSIES

Anomalous Connection of Right Coronary Artery, Circumflex Coronary Artery, or Left Anterior Descending Coronary Artery to Pulmonary Trunk

An anomaly rarer than anomalous connection of left coronary artery to pulmonary trunk is anomalous connection of right coronary artery to pulmonary trunk. As of 2006, 77 cases had been reported. Undoubtedly, this lesion occurs more frequently and is underdiagnosed because of the relatively benign nature of the lesion compared with anomalous connection of the left coronary artery to pulmonary trunk (Table 46-3). Diagnosis is usually made at autopsy or incidentally in asymptomatic adults. Occasionally the anomaly is associated with symptoms in an older child or adult or with sudden death. Surgical correction consists of excising the anomalous connection of the right coronary artery to the anterior aspect of the pulmonary trunk, along with a button of pulmonary arterial wall, and translocating it into the anterior aspect of the ascending aorta.

Anomalous connection of circumflex or left anterior descending coronary artery to pulmonary trunk is also less lethal than anomalous connection of left coronary artery to pulmonary trunk. Both are also rarer than right coronary anomalous connection. Indications for surgery and technique of operation are similar to those for anomalous connection of the right coronary artery. Operation is indicated at the time of diagnosis for all these variations.

Total Anomalous Connection of Coronary Arteries to Pulmonary Trunk

Rarely, all coronary blood flow originates from the pulmonary trunk, either with a single ostium and trunk from which all branches emerge or from two ostia close together, giving rise to left and right coronary systems. In less than half the cases reported, this has been an isolated anomaly. In such cases, mitral anuloplasty or replacement may be required. Operation is indicated at the time of diagnosis for all these variations.

Modified from Williams and colleagues. Key: ECG, Electrocardiogram.
Anomalous Connection of a Main Coronary Artery to Aorta

DEFINITION
This section focuses on a condition in which (1) either the left main coronary artery connects to the aorta in a site other than the left coronary sinus or sinutubular junction (identified by the ridge between the sinus and ascending aorta), or (2) the right coronary artery connects to a site other than the right coronary sinus or sinutubular junction. The anomalously connected artery frequently passes between the aorta and pulmonary trunk (interarterial course) before normally distributing to the myocardium, commonly has a proximal course running within the aortic wall (intramural course), and occasionally has an ostial stenosis.

All these morphologic variations have been associated with ischemia and clinical events. Whether the course between the great arteries plays a pathophysiologic role in all clinical events remains controversial. The anomalously connected artery does not always pass between the aorta and pulmonary trunk but may pass in a retroaortic, pre pulmonary, or transseptal course. Rarely the anomalous artery does not arise from the opposite coronary sinus, but rather from the posterior (“noncoronary” sinus). These variations are of concern only when there is ostial stenosis or an intramural course.

HISTORICAL NOTE
Chetlin and colleagues in 1974 described death from anomalous connection of left main coronary artery to right sinus of Valsalva, with the artery then passing posteriorly between aorta and pulmonary trunk and then behind the trunk before branching into left anterior descending and circumflex arteries. In 1984, Roberts and colleagues described anomalous connection of right coronary artery to left sinus of Valsalva, with the right coronary artery passing anteriorly between the aorta and pulmonary trunk before passing across the outflow portion of the right ventricle.

MORPHOLOGY
The morphology of anomalous connection of a main coronary artery to aorta is abnormal in a number of ways beyond connection to the wrong sinus. These abnormalities have important implications with respect to both the likelihood of ischemia-related clinical events and specific surgical management.

Anomalous Connection of Left Main Coronary Artery
Most commonly, two coronary ostia are close together side by side in more or less the center of the right sinus of Valsalva. The ostium of the anomalous left main coronary may be eccentrically placed, however, often high in the right sinus and close to the right-left commissure. Less commonly, there is a single enlarged ostium in the right sinus, giving rise to both the normal right coronary and the anomalous left main coronary arteries. The ostium may have other abnormal characteristics. It may be angulated as it arises from the aorta, its opening may be slitlike, or it may travel in an intramural course, running within the wall of the aorta for up to several centimeters.

The left main coronary artery almost always passes posteriorly in an interarterial course between the aorta and pulmonary trunk, and then behind the pulmonary trunk to branch at the usual site. Much more rarely, the anomalously connecting left main coronary artery passes forward and across the floor of the right ventricle (ventricular septum) to emerge and pass near to its usual point. Also rarely, it may also pass retroaortically, or anteriorly across the right ventricular free wall. Circulation may be left or right dominant. Finally, anomalous connection of left main coronary artery to non-facing aortic sinus occurs rarely and may be associated with abnormal angulation and slitlike orifice as well.

Anomalous Connection of Right Coronary Artery
Anomalous connection of right coronary artery to aorta appears to be considerably more common than anomalous aortic origin of left main coronary artery. It may connect to a separate ostium within the left sinus, to a separate ostium just above the commissure between left and right sinuses, or to one just above the sinutubular ridge over the left sinus. Less commonly, the right coronary artery may connect to a single ostium that also gives origin to the left main coronary artery, and this ostium may lie within the left sinus or over the commissure between left and right sinuses. The anomalously connecting right coronary artery may have all the other ostial abnormalities described for the anomalously connected left main coronary artery, and always passes forward in an interarterial course between the great arteries. Rarely, one or both coronary ostia may arise from the posterior (the normal noncoronary) sinus.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA
Anomalous connection of a coronary artery to the aorta results in no characteristic clinical or ECG features. A meta-analysis using a number of reasonable assumptions suggests that more than 99% are asymptomatic and will remain so (see Natural History). The true prevalence of this defect is unknown. The most accurate estimate probably comes from a prospective search for the defect in more than 2000 children with normal hearts, in which a prevalence of 0.17% was found, or in other words, about 1 to 2 per 1000 children. Studies based on cardiac catheterization typically show similar to higher prevalence, probably because of selection bias.
Patients who are symptomatic typically present in the second or third decade of life and may complain of angina or syncope, or they may present with sudden death. Rarely, patients present with symptoms as neonates, infants, or in the first decade of life. The anomalous connection is most commonly diagnosed by echocardiography. The ECG may be indicated for other reasons in asymptomatic patients, and the anomalous vessel is identified incidentally. In symptomatic patients, an ECG is typically the initial imaging study.

The purpose of imaging the vessel is to define several clinically relevant morphologic characteristics:

1. Presence of a single ostium or separate ostia
2. Exact position of the ostium within or near the sinus
3. Presence of an intramural course
4. Identification of a slitlike or angulated ostium
5. Identification of an interarterial course, and determination of whether the caliber of the artery is narrowed in this area

Echocardiography can accurately define the ostial position and interarterial course of the vessel. It can also sometimes reveal whether there are one or two ostia and whether there is an intramural course\(^6\) (Fig. 46-16). However, this modality may have difficulty demonstrating whether there are one or two ostia when these are closely spaced, and whether there is an intramural course when that course is a short segment. Because of these limitations, further imaging is indicated.

Magnetic resonance angiography, CT, and angio- 
graphy at cardiac catheterization all have been used to further characterize the morphology, but available data are insufficient to assess whether these imaging modalities are superior to echocardiography, particularly with respect to defining an intramural course (Fig. 46-17). One study compared the accuracy of catheter-based angiography and CTA in helping determine the origin and proximal course of the anomalous artery. CT was found to be more accurate in revealing the proximal course. Accurate CT images require gating, so this modality may be of less use in smaller patients because of their faster heart rates. A search is also made for objective evidence of reversible ischemia. Documentation of compression of the right coronary artery coursing between aorta and pulmonary artery, with the right coronary artery arising from the left main coronary artery, has been demonstrated angiographically in a patient with exertional angina.\(^1\)

**NATURAL HISTORY**

The natural history is controversial. A number of cases have been reported in which serious sequelae, including sudden death, have been ascribed to anomalous connection of coronary artery to left sinus of Valsalva (summarized by Berdoff and colleagues\(^6\) and Mustafa and colleagues\(^3\)). The relationship between sequelae and anomaly is not conclusive. Asymptomatic patients with the condition were observed by Berdoff and colleagues, with a mean age of 40 to 69 years and with normal segmental wall motion and a left ventricular ejection fraction of 60% to 80%\(^6\); no unfavorable events were experienced in a follow-up of 8 to 69 months. Sudden death in neonates may occur in the presence of this defect in rare cases, but causality is difficult to prove.

There are only rare cases of clinical events in individuals once out of the neonatal period, until the second decade is reached. The combined U.S. and Italian registries of sudden deaths in competitive athletes revealed 27 individuals dying with anomalous coronary arteries; all but one death occurred between ages 10 and 32 years. The other individual was 9 years old. In two thirds of the deaths, there were no previous events and no symptoms. The prevalence of sudden death in competitive athletes is about 1 : 100,000. About 20% of these are due to coronary anomalies; thus, the prevalence of sudden death due to a coronary anomaly is about 2 : 1,000,000 in competitive athletes.

Most clinical events, including sudden death, occur in the second and third decades of life, and more commonly in males. Events are likely to occur during or just after exertion. Sudden death may be the initial event. If an individual lives into the third decade, new onset clinical events are extremely rare.

**TECHNIQUE OF OPERATION**

Several operations have been developed to relieve ischemia or potential ischemia. The choice of operation depends on the specific morphologic details, emphasizing the importance of accurate preoperative imaging (Fig. 46-18). Translocation of the anomalously connected artery to the correct sinus is indicated in several circumstances. This operation can usually be accomplished and will be effective when there are two reasonably widely spaced ostia, and when there is not an intramural course or angulated or slitlike ostium. The operation effectively removes the vessel from its vulnerable interarterial position. The technique of operation requires standard CPB and cardioplegic arrest. The coronary artery is dissected, mobilized, and translocated using the exact principles outlined for coronary translocation in the arterial switch operation for transposition (see Chapter 52).

Unroofing the proximal coronary artery is indicated when an intramural course is present (Fig. 46-19). This maneuver may be all that is necessary if the unroofing moves the effective ostium into the appropriate sinus. This
accomplishes two things: It relieves any stenosis in the intramural segment, and it moves the coronary lumen away from the interarterial position. Unroofing can be accomplished whether or not there is a single coronary ostium or separate ostia. Modified unroofing can be performed in some cases to avoid disturbing the commissure of the aortic valve. In this case, as in the arterial switch operation, care must be taken to excise the ostium with a button of sinus tissue that fully encompasses the intramural component. Also, in certain cases with an angulated or slitlike ostium but no true intramural element, ostial patching should be performed along with translocation.

When the morphology is that of a single coronary ostium without an intramural element, neither translocation nor
unroofing is possible. The goal of surgery is to eliminate the risk of the interarterial component of the vessel. CABG using the internal thoracic artery or a saphenous vein graft to the anomalously connected artery has been described. This option, however, is not recommended for several reasons. First, the long-term efficacy of the graft is uncertain in young patients. Second, the graft will be in competition with essentially normal antegrade flow through the anomalously connected artery, raising concern about graft thrombosis or, at the very least, adequacy of the graft when it may be acutely needed during transient compression of the anomalously connected artery. Instead of bypass grafting in this situation, moving the pulmonary trunk away from the aortic root so that the interarterial component of the anomalously connected artery is no longer at risk of compression should be considered. This can be accomplished in two ways, either translocating the distal pulmonary trunk leftward into the left pulmonary artery (Fig. 46-21), or translocating the right
pulmonary artery branch anterior to the aorta (Fig. 46-22), similar to the Lecompte maneuver in the arterial switch operation for transposition (see Chapter 52).

RESULTS

Early and midterm outcomes are generally excellent regardless of the specific operation, with mortality approaching zero and relief of symptoms in patients who are symptomatic preoperatively. Romp and colleagues report no mortality and relief of symptoms in nine previously symptomatic patients, all of whom underwent unroofing of an intramural artery. Of concern, however, despite lack of postoperative symptoms in 24 repaired patients, Brothers and colleagues were able to demonstrate signs of ischemia in almost 40% of patients evaluated with stress echocardiography, exercise stress testing, and stress myocardial perfusion scanning at a mean follow-up of 15 months after surgery. This same group of investigators also report that exercise capacity and quality of life were normal following surgical repair.

Indications for operation remain arguable. Ischemia, whether reversible or not, in the distribution of the anomalously connecting coronary artery is an indication for operation. A syncopal event, angina, or an episode of sudden death with resuscitation is an indication for operation, even if ischemia cannot be demonstrated at evaluation. In fact, ischemia typically is not elicited with stress testing.

Concerning morphology, such as intramural course, slit-like ostium, or narrowed caliber of the interarterial course, is probably an indication for operation, even in the absence of demonstrable ischemia. Existence of the anomalous connection with an interarterial course, but without symptoms and without other concerning morphologic characteristics, may be an indication for operation in individuals diagnosed in the second and third decades of life but probably not in those diagnosed later. Presence of the anomalous connection without ischemia, symptoms, or concerning morphologic characteristics is probably not an indication for operation in the first decade of life. Effectiveness of operation can be proved by absence postoperatively of any evidence of reversible ischemia.

SPECIAL SITUATIONS AND CONTROVERSIES

Presence of an anomalously connected vessel without other concerning morphologic characteristics in an asymptomatic child under age 10 years is probably not an indication for operation, but it is unclear whether such a patient should undergo operation once the second decade is reached if no clinical events have occurred. A survey of the Congenital Heart Surgeons Society regarding management practices underscores the marked heterogeneity of opinion regarding management of anomalous coronary arteries. There was strong but not unanimous agreement that evidence of ischemia warranted surgery. Less than 80% recommend referral for surgery with symptoms but no objective evidence of ischemia.

There is no consensus regarding the pathophysiologic importance of the interarterial course, especially when no narrowing of the vessel can be demonstrated in this area during imaging. The concern is that this region of the vessel
is at risk of transient narrowing or stretching during the dynamic conditions of exercise, when the wall tension of both the aorta and pulmonary trunk may increase from pressure and diameter changes. Although not recommended in young patients, use of interventional catheter-based techniques, including coronary artery stenting, has been anecdotally described for various coronary artery anomalies. These procedures are typically performed in previously undiagnosed adults who present with evolving acute myocardial events at the time of diagnostic, and potentially therapeutic, cardiac catheterization. CABG is also not recommended in young patients; however, it becomes a more attractive surgical option in older patients, particularly those presenting with symptoms or with associated arteriosclerotic disease. Excellent outcomes can be achieved. Brothers and colleagues have shown that familial screening in patients with anomalous coronaries yielded positive findings not attributable to chance alone, suggesting a genetic component for this disease.

Congenital aortic stenosis is a cardiac anomaly in which narrowing at valvar, subvalvar, supravalvar, or combined (multiple) levels results in a systolic pressure gradient between the inflow portion of the left ventricle (LV) and the aorta beyond the obstruction. A spectrum of defects involves the aortic root, with some overlap of abnormalities. Congenital aortic stenosis in neonates and infants may be part of the constellation of hypoplastic left heart physiology (see “Coarctation as Part of Hypoplastic Left Heart Physiology” under Morphology in Section I of Chapter 48). This association is highly relevant to therapy.

Section I  Congenital Valvar Aortic Stenosis

DEFINITION

Congenital valvar aortic stenosis includes defects in which the major malformation involves the aortic valve cusps. An obstruction at valve level is caused by imperfect cusp development with cusp thickening and fusion. Cusp abnormalities can be severe in early life; when they are not, important obstruction may not develop until later in life when calcification occurs. This chapter discusses congenital valvar aortic stenosis only in the age range from birth to young adult life.

HISTORICAL NOTE

Congenital valvar aortic stenosis has been long recognized by morphologists. Initial efforts to find a surgical solution were made by Carrel and Jeger, who independently attempted experimentally to place conduits between left ventricular apex and aorta. In 1955, Marquis and Logan reported surgical treatment using dilators introduced through the LV apex, as did Downing in 1956. Also in 1956, valvotomy was performed by an open technique during inflow stasis with moderate hypothermia induced by surface cooling. The first report of its treatment by accurate valvotomy during cardiopulmonary bypass (CPB) was by Spencer and colleagues in 1958, although this had been performed at the Mayo Clinic in 1956 and was reported by Ellis and Kirklin in 1962.

MORPHOLOGY

Aortic Valve

The prevalences and precise nature of the various types of morphology of severely stenotic aortic valves and coexisting anomalies are incompletely understood for several reasons. First, it is difficult to obtain enough cases to constitute a reasonable sample of the spectrum of severe congenital valvar stenosis in neonates, infants, and children. Second, sources of data range from autopsy studies and surgical studies to echocardiographic and cineangiographic imaging in patients undergoing balloon valvotomy. Third, differing terminology contributes to incompleteness of morphologic data; ideally, not only should the morphologic nature of the cusps be defined, but also that of the sinuses of Valsalva, commissures (upper points of attachment of cusps to the aortic wall), and interleaflet triangles (fibrous or muscular tissue interposed between the sinuses in the subcusp LV outflow tract), as described by Angelini and colleagues for bicuspid valves.

In patients with stenosis severe enough to require operation in infancy or childhood, the valve is bicuspid in about 65% (Table 47-1). The valve usually consists of thickened...
stenosis can occur without fusion, resulting only from thickened cusps and a bicuspid configuration. If free edges of both thickened cusps are taut, they are then equal in length to the diameter of the aortic root and cannot open (Fig. 47-1, B). Most bicuspid valves will show three intercusp triangles on their ventricular side, indicating that three cusps were present in the developing valve. A bicuspid valve with only two definitive cusps is uncommon and usually is not stenotic early in life, rather presenting later in life with obstruction or regurgitation. A full discussion of the genetics, morphology, natural history, and therapeutic options for adult patients with a congenitally bicuspid aortic valve is found in Chapter 12.

In about 30% of patients the valve is tricuspid, with three thickened cusps of approximately equal size and three recognizable commissures that are fused peripherally to varying degrees, creating a dome with a central stenotic orifice. This type of valve is more favorable for valvotomy because all three commissures can usually be opened.

Less often (5%) the valve may have a unicuspid configuration with only one commissure (Fig. 47-2). This variety is more common in infants presenting with severe stenosis. Occasionally, however, the stenosis is not severe, and signs and symptoms develop in later life as the valve thickens and calcifies. A thickened unicuspid valve is inherently stenotic, whether the commissure is fused or not, unless the cusp is particularly redundant.

The cusps are approximately equal in size in only a small percentage of congenitally bicuspid or stenotic tricuspid valves. Likewise, the raphae are variable in thickness and length. Number of sinuses may not be the same number of cusps; most congenitally bicuspid and unicuspid (unicommissural) valves have three sinuses and three intercusp triangles.

Diffuse cusp thickening, most marked at the free cusp edges, contributes importantly to valvar stenosis. Thickening is more extreme in symptomatic neonates and infants, and cusps may be irregular and myxomatous or dysplastic in

Frequency may be underestimated because “bicuspid” valve with rudimentary commissures might better be termed unicuspid.

Table 47-1  Morphology of Congenital Valvar Aortic Stenosis in Surgical Patients Aged 1 Day to 26 Years
Shortness of breath and cyanosis may be present. In children and young adults, even important stenosis may be without symptoms. However, effort dyspnea, effort angina, or effort syncope, singly or in combination, usually indicates a severe lesion.

Dyspnea may be present with moderate stenosis.

**Signs**

In neonates and infants with severe valvar aortic stenosis, the most striking feature is small pulse volume with pallor, dyspnea, and at times cyanosis. Both the murmur and gradient across the valve may be unimpressive because of a low cardiac output. There also may be a hyperactive right ventricular impulse.
Clinical signs in children and young adults include an ejection systolic murmur (and thrill) at the base radiating to the carotid vessels, accompanied by a systolic ejection click. An aortic diastolic murmur is uncommon, particularly when compared with patients with discrete subvalvar stenosis. A severe lesion is characterized by palpable pulse of low volume and slow upstroke, single or reversed splitting of second heart sound, and sometimes third heart sound, and thrusting LV impulse.

Many investigators have concluded that physical signs are unreliable in assessing severity of valvar stenosis in children. However, physical signs can be used to differentiate among mild, moderate, and severe lesions in most patients, and severe lesions can always be distinguished from mild ones.

Electrocardiography

The electrocardiogram (ECG) usually shows severe LV hypertrophy but can be near normal. Right ventricular hypertrophy on the ECG may be associated with a left-to-right shunt at atrial level through a stretched patent foramen ovale and rarely a reversed shunt at ductus level.

Chest Radiography

The ascending aorta frequently is prominent in older children but is small in neonates and infants. Increased heart size is seldom seen except in neonates and infants in heart failure, in whom it may be marked. Radiologically demonstrable valvar calcification is rare in patients younger than age 25.

Noninvasive Studies

Two-dimensional echocardiography has become particularly important as a diagnostic tool. In neonates and infants, morphology and severity of narrowing of the valve and size, wall thickness, and contractility of the LV can be assessed. The congenitally stenotic aortic valve can be continuously reevaluated by Doppler ultrasound measurement of flow velocity across stenotic valves, which can be used to quantify transvalvar pressure gradient. Echocardiographic markers are useful for managing fetuses with important aortic stenosis. Serial measurements of fetal cardiac size and function may predict postnatal outcome.

Estimation of subendocardial oxygen requirements may be helpful in assessing severity of stenosis.

Cardiac Catheterization and Angiography

A systolic gradient across the aortic valve can be demonstrated at cardiac catheterization, usually through a retrograde aortic approach if possible or otherwise a transseptal approach. Cardiac output can also be measured so that valve area can be calculated. Systolic gradient greater than 75 mmHg or valve area less than 0.5 cm$^2$ is indicative of severe stenosis (see “Summary” in text that follows). Measuring gradient and valve area at cardiac catheterization has become less important as echocardiographic measurements have become more accurate. A raised LV end-diastolic pressure indicates LV failure or a fibrotic and noncompliant ventricle.

Angiography demonstrates thickened leaflets that form a dome in systole, with a localized jet of contrast entering the aorta (Fig. 47-6). Although this type of study is not reliable in assessing severity of stenosis, it can assess size of the aortic “anulus” and LV. An aortic root injection allows quantification of aortic regurgitation if present.

Summary

By a combination of clinical and hemodynamic assessments (echocardiography, cardiac catheterization), patients with congenital valvar aortic stenosis can be categorized as having mild, moderate, or severe obstruction. Mild implies that pulse volume and contour are normal, as is the second heart sound. Patients with these findings have an LV-aortic systolic pressure difference less than 40 mmHg at rest, with a mean of 20 mmHg. Patients with moderate stenosis have an

abnormally small pulse volume on palpation and abnormal contour, and narrow inspiratory splitting of the second heart sound may be present. Such patients generally have systolic gradients less than 75 mmHg, with a mean of 20 to 50 mmHg. Patients with severe stenosis have a systolic gradient in excess of 75 mmHg and an abnormal pulse volume and contour, as well as a single second heart sound or reverse splitting. These patients have a mean calculated aortic valve area index of less than 0.5 cm² · m⁻².¹¹³

NATURAL HISTORY

Congenital valvar aortic stenosis is three to four times more common in males than in females and occurs in about 5% of Caucasians with congenital heart disease.

¹Data from 142 patients, UAB experience 1967-1982.
²Patients were categorized into NYHA classes I to V, with class V indicating those undergoing emergency operation because of shock or metabolic acidosis. In the current era, isolated valvar aortic stenosis in newborns and infants is generally treated by percutaneous balloon valvotomy.

Presentation in Infancy

When neonates and infants present with valvar stenosis, the lesion is typically severe, with rapidly progressive heart failure and death within a few days to a few weeks of birth. Thus, most neonates and young infants come to intervention (currently with percutaneous balloon valvotomy) critically ill and in New York Heart Association (NYHA) class IV or V (Table 47-3). Many have other anomalies associated with the spectrum of the hypoplastic left heart physiology. Ten Harkel and colleagues noted a 5-year survival rate of 73% among patients presenting in infancy.⁷²

Presentation in Childhood

When symptoms are delayed beyond age 1 year, heart failure is rare, and survival without treatment generally is prolonged. Also, associated anomalies are less common. The Second Natural History Study of Congenital Heart Defects includes data on many patients treated for valvar aortic stenosis and followed for 25 years. Patients were 2 years or older at entry into the study, and 40% managed medically subsequently required surgical management. For patients presenting with LV-aortic pressure gradient greater than 50 mm Hg, 70% required surgical intervention. Almost 40% of patients required a second operation.

Survival is related to (1) sudden death in untreated children and (2) rate of progression of stenosis.

Sudden Death

Occurrence of sudden death varies between 1% and 19% of patients. Of 58 patients younger than 35 years old who died suddenly and were found to have congenital heart disease, three (5%) had aortic valve stenosis. Analysis of the literature and of a series of 218 patients with congenital valvar stenosis indicates that sudden death directly attributable to aortic stenosis is virtually confined to patients with a severe lesion. Sudden death in patients with no symptoms and normal physical findings except for the murmur of aortic stenosis has not been documented. Sudden death may occur...
in patients with a normal ECG, but this finding is not incompatible with severe stenosis. Thus, the true prevalence of sudden death in children and adolescents in whom surgery is deferred until the lesion is considered severe on clinical grounds is probably about 1%.

**Progression of Stenosis**

When congenital aortic valvar deformities are nonobstructive in infancy and childhood, less than 10% progress to mild obstruction within about 10 years. Leech, Mills, and colleagues obtained information on 26 patients aged 1 week to 29 years when first seen, and in whom diagnosis of nonobstructive aortic valve deformity was made based on an isolated aortic ejection sound. During a 5- to 16-year follow-up, two patients (7%; CI 2%-16%) developed signs of mild stenosis after 7 and 15 years. As more years pass, an undetermined time-related proportion of patients with deformed (usually congenitally bicuspid) aortic valves develop progressive thickening and calcification and ultimately important stenosis. Vollebergh and Becker suggest that minor inequality of size of tricuspid valves present from birth may lead to formation of senile or degenerative type of aortic valve stenosis presenting in the seventh or eighth decade of life.

When *mild* stenosis is present at first evaluation in childhood, progression is more rapid. Moderate or severe stenosis develops in about 20% of patients within 10 years and in 45% within about 20 years (Fig. 47-7). Even after this long interval, therefore, 55% of the mild lesions remain mild.

When *moderate* stenosis is present initially, the lesion becomes severe within 10 years in about 60% of patients (Fig. 47-8).

**Infective Endocarditis**

Spontaneously occurring infective endocarditis appears in less than 1% of patients. The reported incidence is 1.8 to 2.7 episodes per 1000 patient-years. Infective endocarditis may produce aortic regurgitation and may be a cause of death.

---

**Figure 47-7** Cumulative incidence curves (multiple decrement; see “Competing Risks” in Section IV of Chapter 6) for 153 patients presenting with originally mild congenital valvar aortic stenosis. Vertical bars represent 70% confidence limits. Mean age at presentation was 6.5 years (1 to 25 years) and mean follow-up 8.8 years (1 to 26 years). The one death was caused by infective endocarditis. Patients underwent operation when stenosis was considered severe. Percentages refer to distances between curves. Key: AS, Aortic stenosis. (From Hossack and colleagues.)

**Figure 47-8** Cumulative incidence curves for 54 patients presenting with originally moderate congenital valvar aortic stenosis (AS). Vertical bars represent 70% confidence limits. Mean age at presentation was 12 years (1–25 years) and mean follow-up 8.5 years (1–24 years). The two deaths were both sudden, in 4 and 9 years after presentation, in association with progression to severe stenosis. Percentages refer to distances between curves. (From Hossack and colleagues.)

**TECHNIQUE OF OPERATION**

**Percutaneous Balloon Valvotomy**

Percutaneous balloon valvotomy is often used for treating congenital valvar aortic stenosis, but a description of this technique is beyond the scope of this text. Its place in treating neonates is discussed under Special Situations and Controversies later in this section.

**Valvotomy in Neonates and Critically Ill Infants**

Closed techniques and surface cooling for hypothermic circulatory arrest have largely been replaced by aortic valvotomy on CPB using cold cardioplegic myocardial management.

Anesthetic and supportive management must be precise (see Section II of Chapter 4). Drifting downward of body temperature to 32°C to 34°C is probably advantageous. Preparation and median sternotomy are described under “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2. As the pericardium is being opened, care is taken to touch the heart as seldom as possible because ventricular fibrillation is easily provoked. The purse-string suture is placed for the aortic cannula, the patient heparinized, and the cannula inserted and connected to the arterial tubing. Only then is a purse-string suture placed around the right atrial appendage; if the heart fibrillates, CPB can be established in less than a minute. A single venous cannula is inserted, and CPB is begun with the perfusate at 34°C; the ductus arteriosus is ligated, perfusate taken to 20°C to 28°C, aorta clamped, cold cardioplegia administered, and the perfusate temperature is then taken to 34°C to 36°C. In the presence of aortic regurgitation to a degree that interferes with cardioplegia delivery, cardioplegia can be delivered via small olive tip catheters directly into the coronary ostia, or coronary sinus cardioplegia can be used.
A transverse aortotomy is made (Fig 47-9, A). Two stay sutures are placed on the upstream side of the aortotomy for exposure. The aortic valve is inspected to determine which of the commissures to incise. Only partially formed commissures should be incised; commissurotomy should not be performed where there is only a rudimentary raphe (Fig. 47-9, B).

Valvotomy is performed by dividing fused commissures with a knife to within 1 mm of the aortic wall; in neonates the cusps are often gelatinous, but every effort should be made to identify these commissures. It is important that even tension be placed on the two adjoining cusps so that incision is precise (Fig. 47-9, C). Only commissures with adequate cusp/commissural attachment to the aortic wall are opened, because division of rudimentary commissures produces regurgitation. Incisions are deepened in stages, and cusps on each side are evaluated for competence and lack of prolapse before each further incision. If further incising of the commissure might cause cusp prolapse, the incision is carried no further. Occasionally, myxomatous nodules can be excised from the cusp’s free edge, or fibrous thickening can be shaved off the ventricular aspect of one or more cusps. The aortotomy is then closed with a continuous suture. If there is any degree of aortic regurgitation by saline filling of the aortic root, a 6-0 polypropylene suture (Frater stitch) can be placed through the midpoint of each cusp and brought out through the closed aortotomy. The suture is removed when LV contraction begins.

The remainder of the procedure is completed as usual (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2). A left atrial catheter should be positioned before discontinuing CPB. If the neonate is of suitable size for placing a transesophageal echocardiography (TEE) probe, the repair is evaluated before and after discontinuing CPB. LV and aortic pressures are measured and recorded before closing the chest.

Valvotomy in Older Infants, Children, and Adults

Preparation for operation, the incision, and preparations for CPB are described under “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2. Using a single venous cannula or caval cannulation, CPB is established at 28°C. A left atrial or LV vent is used. External cardiac cooling may be applied. The aorta is clamped and cold cardioplegic solution infused. The transverse aortotomy is made, and stay sutures are applied to the edges of the incision for exposure. Commissurotomy is performed as described.

The aortotomy is closed by continuous stitches, and the rest of the operation is completed as usual (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2).
Cusp Reconstruction

Pericardial cusp extension valvuloplasty procedures (as described by Duran) to compensate for deficiency of valvar tissue and increase the coaptation surface area have been applied primarily to regurgitant aortic valves (see Chapter 12). More recently, encouraging midterm results with these techniques applied to congenital aortic stenosis support their inclusion as surgical options. Aortic cusp extension valvuloplasty may be considered as an adjunctive procedure to primary open valvotomy or in reoperative situations with recurrent aortic stenosis or regurgitation following previous valvotomy. Before proceeding with valve reconstruction, pre-operative echocardiographic studies should ascertain the absence of LV subaortic obstruction.

Following a median sternotomy, autologous pericardium is harvested, thoroughly cleaned of all fatty tissue and adhesions, treated with 0.625% glutaraldehyde solution for 3 to 5 minutes, and kept moist with normal saline. CPB, LV venting, and myocardial management are performed as described under “Valvotomy in Older Infants, Children, and Adults.”

An oblique aortotomy is made, and the aortic valve is evaluated for presence of complete but fused commissures and a raphe in congenitally bicuspid aortic valves. Each cusp is examined for thickness and mobility, free-edge irregularities, and tissue deficiency.

The valve is prepared for cusp extension by first thinning the thickened cusp edges. Fused commissures are incised out to the aortic wall, and subcommissural fusion or scar tissue is released to maximize cusp mobility. Bicuspid valves with a rudimentary raphe are tricupidized by incising through the fused cusp at the raphe all the way to the aortic wall (Fig. 47-10). The pericardial patches are each cut to a length determined by the diameter of the aorta, supplemented with an additional 15% to 20% to account for later pericardial shrinkage. Height of each patch is chosen to extend the line of coaptation of the repaired cusps about 5 mm higher than the highest cusp and to bring the extended cusps into a coaptation point in the center of the valve orifice. The pericardial extensions are sutured to each cusp with continuous 5-0 polypropylene, beginning in the center of the cusp and working toward the commissures. The extensions are attached to the aortic wall, creating neo-commissures at the level of the sinutubular junction. Ilbawi and colleagues recommend leaving a little excess pericardial patch at the commissural level, secured with a pledgeted mattress suture through the aortic wall. With all the patch extensions in place, the newly constructed extensions are trimmed to provide a uniform cusp height and symmetric coaptation surface (see Fig. 47-10).

Adequacy of the valve opening is examined, and initial valve competence is assessed by filling the aortic root with saline. Aortotomy closure and discontinuation of CPB are conducted as usual. Evaluation of valve function by TEE is performed before and following discontinuation of CPB. If aortic regurgitation is more than mild or if peak transvalvar gradient by TEE exceeds 30 mm Hg, consideration should be given to reestablishing CPB and revising the valve repair or, if improvement is not feasible, proceeding with valve replacement.

Aortic Valve Replacement in Children

When viewed at operation, the congenitally stenotic aortic valve may be too extensively deformed to be opened and remain reasonably competent. However, this situation is rare in primary operations in patients younger than age 10 and uncommon in those younger than 20. It is more common when multiple prior balloon valvotomies have been performed, and particularly when progressive or recurrent stenosis is accompanied by moderate or worse aortic regurgitation.

Aortic valve replacement in older children may be done in a standard fashion using a mechanical prosthesis (see “Isolated Aortic Valve Replacement” under Technique of Operation in Chapter 12). It may also be performed in the standard freehand manner using an aortic valve allograft (see “Allograft Aortic Valve” under Technique of Operation in Chapter 12) or a pulmonary valve autograft (see “Autograft Pulmonary Valve” under Technique of Operation in Chapter 12). Because the aortic root and LV-aortic junction may be quite small in young children who require aortic valve replacement, aortic root enlargement (see “Root-Enlarging Technique” under Technique of Operation in Chapter 12) or replacement (see “Replacement of Aortic Valve and Ascending Aorta, En Bloc” under Technique of Operation in Chapter 12) may be advantageous. An aortic allograft can be used as the replacement device, or a pulmonary autograft may be preferred. The autograft has the advantage of remaining unchanged and uncompromised by host reaction, and it also may grow.

SPECIAL FEATURES OF POSTOPERATIVE CARE

Postoperative care after aortic valvotomy or other procedures discussed in this section are conducted in the manner generally used after intracardiac operations (see Chapter 5).

Whenever valvotomy is performed for congenital valvar aortic stenosis, long-term follow-up is indicated because of possible recurrence of stenosis requiring reoperation.

RESULTS

Early (Hospital) Death

Hospital mortality for surgical treatment of congenital valvar aortic stenosis in heterogeneous groups of patients younger than 20 to 25 years of age is largely an unhelpful value because of the important role of incremental risk factors for death and the selection processes by which treatments (or no treatments) are chosen.
Mortality varies widely among patient subsets, with few or no deaths after valvotomy in children and young adults.\(^5,17,79\) Mortality is higher in neonates, but the potential safety of an open approach in neonates with severe congenital aortic stenosis has been demonstrated.\(^7,19\) Still, the current preference in most centers is initial percutaneous balloon valvotomy. Multiple centers have achieved hospital mortalities of 15% or less in neonates.\(^51,28,15,20,3,78\) Again, however, mortality figures in heterogeneous groups of patients, even if all are neonates, are difficult to interpret, as demonstrated by Gaynor and colleagues\(^15\) and a Congenital Heart Surgeons’ Society (CHSS) analysis.\(^14\) In contrast to many situations in cardiac surgery, nearly all deaths after operation for congenital valvar aortic stenosis occur early postoperatively, most within 48 hours.

Success in salvaging such patients with emergency temporary extracorporeal membrane oxygenator (ECMO) or left ventricular assist device (LVAD) support has not been fully evaluated, but such support is advisable in the face of progressive circulatory failure (see “Treatment of Low Cardiac Output” in Chapter 5).

Hospital mortality after operations for congenital valvar aortic stenosis in patients older than age 1 year approaches zero.

**Time-Related Survival**

Overall survival up to 40 years is good after the primary operation for congenital valvar aortic stenosis in older infants and children.\(^38,79\) In very ill neonates and young infants, however, survival is compromised, primarily by high early risks.\(^7\)

A CHSS study of 320 neonates with critical aortic stenosis noted 1- and 5-year survival of 72% and 70%, respectively, among those receiving an initial procedure aimed at biventricular repair (Fig. 47-11).

**Modes of Death**

Almost all early deaths are in acute cardiac failure,\(^15\) and theoretically most should be preventable by (1) stabilization of critically ill neonates and others (with ECMO or LVAD support if needed) so that operation is not performed in NYHA class V patients as it was in the past,\(^12\) and (2) proper myocardial management. In neonates and young infants, however, many deaths result from (1) failure to appreciate the importance of coexisting components of the spectrum of the hypoplastic left heart physiology (see “Coarctation as Part of Hypoplastic Left Heart Physiology” under Morphology in Section I of Chapter 48), and (2) nonoptimal selection, in particular of a biventricular pathway rather than a single-ventricle pathway, at least in the present state of knowledge (see Indications for Operation later in this section).\(^14\)

Deaths occurring late after operation are in various modes, and inferences are made with difficulty. Thus “sudden death” has been reported as the mode of death in 12% of patients included in one long-term follow-up study, but the majority had severe residual or recurrent stenosis or severe aortic regurgitation.\(^1,14\) Among neonates for whom staging of repair is necessary for a univentricular pathway, few late deaths now occur between the cavopulmonary shunt stage and completed Fontan.\(^14\)

**Incremental Risk Factors for Premature Death**

**Coexisting Severe Left-Sided Cardiac Anomalies**

Left-sided cardiac defects (components of the spectrum of the hypoplastic left heart physiology, such as small aortic valve diameter, aortic hypoplasia, severe endocardial fibroelastosis, LV hypoplasia, extreme LV hypertrophy with small cavity size, and congenital mitral valve disease\(^22\)) are associated with high mortality after operation.\(^3,7,14\) (Table 47-4). These coexisting major cardiac anomalies, poor preoperative functional class, and young age at admission tend to occur together, and all are risk factors.

The important study by Karl and colleagues from Melbourne, Australia, emphasized the major role of these coexisting important cardiac anomalies in the early postsurgical mortality in neonates.\(^23\) No deaths (0%; CL 0%-19%) occurred after open valvotomy in neonates with no coexisting anomaly or only a patent duc tus, whereas early mortality was 47% (CL 39%-62%) among those with important coexisting cardiac anomalies.

<sup>d</sup>Logarithmic transformation.

Poor Preoperative Functional Class

Advanced symptoms, or NYHA class IV and particularly class V, are associated with a considerably increased risk of death early after operation. Thus, for patients preoperatively in NYHA class I or II (most older infants and children), 15-year survival (all deaths, including those in hospital) after the primary valve operation is about 90%.<sup>44,87</sup> In preoperatively very ill neonates and young infants, 10-year survival is about 30%.<sup>83</sup> However, the risk of death in the constant hazard phase (after about 5 years postoperatively) is no greater in this group than in older patients.

These ideas came from an era when critically ill neonates and young infants were not resuscitated preoperatively by the infusion of prostaglandin E<sub>1</sub> (PGE<sub>1</sub>). This risk factor can be neutralized at a cost of only about 5% mortality among neonates by management that includes stabilization on PGE<sub>1</sub> and usually low-dose inotropic support.<sup>82</sup>

Type of Congenital Valvar Aortic Stenosis

In a few patients, a truly unicuspid or severely dysplastic bicuspid valve may be essentially uncorrectable.<sup>57</sup> In a few patients, the very small aortic anulus may prevent a satisfactory outcome. Again, these situations usually are found in very sick neonates and young infants. Currently such patients typically are managed by a staged protocol leading to a univentricular repair.<sup>134</sup>

Young Age

Very young age at operation is associated with a high risk of early death postoperatively.<sup>17,14,87</sup> However, in the past, most patients coming to operation as neonates have been in NYHA functional class IV or V. It is important to recall, however, that with contemporary medical management, survival after operation is possible in critically ill neonates and young infants.<sup>81,87,62,23,23,13,14,76,76</sup>

<sup>a</sup>Data from 78 patients, UAB experience 1967-1982. Key: NYHA, New York Heart Association.

Functional Status

Most surviving patients, including those who have had reoperations, are in NYHA class I or II (Table 47-5). Objective evidence of improvement in functional capacity is provided by Whitmer and colleagues, who demonstrated marked regression of exercise-induced ST depression 1 year after operation, as well as an increase in mean total work and peak exercise systolic blood pressure.<sup>57</sup>

Electrocardiographic Changes

ECG evidence of LV hypertrophy may persist after valvotomy or valve replacement either because of residual stenosis or regurgitation or a progressive secondary cardiomyopathy. Intraoperative damage to the LV or preexisting ischemic myocardial fibrosis exacerbated by delaying operation can contribute to or cause this condition.<sup>57,225</sup> Usually, however, LV hypertrophy is reversible.

Left Ventricular Morphology and Function

Preoperative inordinate LV hypertrophy and wall thickness often found in children with congenital valvar aortic stenosis often regresses after successful valvotomy or valve replacement, which reduces LV afterload and increases systolic function.<sup>61</sup>

Residual or Recurrent Left Ventricular–Aortic Pressure Gradients

Pressure gradient usually is substantially reduced after valvotomy and persists for 5 to 10 years.<sup>31,35,318</sup> Thereafter, the gradient tends to rise steadily, occurring earlier and more frequently when valvotomy was necessary during the neonatal period or in infancy.<sup>57</sup> In patients with a good initial result, the later rise in gradient is mainly the result of progressive cusp immobility and calcification.<sup>81</sup> Recurrence and progression of LV-aortic pressure gradient is usually an indication for reintervention with either percutaneous balloon valvotomy or operation.

Following aortic cusp extension procedures with autologous pericardium, long-term durability of repair has been incompletely studied. Alsoufi and colleagues have...
emphasized the importance of satisfactory relief of aortic stenosis at the time of operation. Among 22 children who underwent this procedure, those with postoperative peak echocardiographic gradients of less than 30 mmHg had stabilization of their peak gradient over the next 2 to 3 years. However, progressive worsening of aortic stenosis was noted in those with early gradients exceeding 30 mmHg (moderate or greater aortic stenosis).

Aortic Regurgitation

Important aortic valve regurgitation is uncommon after valvotomy when the operation has been performed as described (see Technique of Operation earlier in this section). Moderate to severe regurgitation without residual stenosis is present at late follow-up in about 10% of patients, but some regurgitation is combined with moderate or severe residual or recurrent stenosis in an additional 15% to 20%. Postoperative regurgitation occurs more frequently when valvotomy is radical, and particularly when an attempt is made to convert a bicuspid into a tricuspid valve.

Infective Endocarditis

The incidence of endocarditis is not lessened by valvotomy and may even be somewhat higher than in the natural history.

Diastolic Heart Failure

Rarely, patients with severe valvar aortic stenosis who undergo surgical or balloon valvotomy as neonates or in infancy develop severe diastolic heart failure years later. Robinson and colleagues at Boston Children’s Hospital reported four such patients who presented 14 to 19 years after balloon valvotomy with heart failure and severe diastolic dysfunction. All had evidence of a confluent layer of LV subendocardial hyperenhancement demonstrated by gadolinium-enhanced magnetic resonance imaging that was documented by histopathology in two patients to be endocardial fibroelastosis (EFE). One patient experienced clinical improvement following aortic valve replacement and extensive EFE resection. Robinson and colleagues hypothesize that EFE may result from early (possibly in utero) and irreversible myocardial damage induced by subendocardial ischemia secondary to persistent pressure overload with decreased ventricular flow, which may gradually progress irrespective of relief of LV outflow obstruction.

Reintervention

As with time-related freedom from death, time-related depictions of freedom from reintervention and aortic valve replacement are of limited value when they are derived from a heterogeneous population.

In general, however, about 85% to 95% of children and young adults (excluding neonates and infants) are free of reintervention (usually valve replacement) for at least 10 years after the initial operation (Figs. 47-12 through 47-14). Then, although constant in the intermediate term, the hazard function (rate of reintervention) begins to rise. By 20 years after initial operation, only 60% of patients will be free of reintervention, and by 40 years only 10% will be free. The older the patient, the more likely it is that the reintervention will be valve replacement.

Reintervention appears to be required at a shorter interval and in greater prevalence when the initial intervention has been performed in neonatal life or infancy, and is more likely to consist of valvotomy than valve replacement. Greater frequency of reintervention may be related to generally higher residual gradients in these cases. Reintervention appears to be required more frequently when initial valvotomy has been performed by some method other than an open...
operation using CPB. Reintervention rate increases 15 years after operation from 0.73% per year to 2.3% per year ($P < 0.0001$).

Procedures done at reoperation are generally more varied than at initial operation (Table 47-6). A satisfactory repeat valvotomy is sometimes possible, especially when the initial operation has been done in infancy. At times, an overlooked second level of obstruction is found that requires treatment such as patch graft supravalvar enlargement, a Konno procedure (see Technique of Operation in Section II), or an aortic root replacement (see “Aortic Valve Replacement in Children” under Technique of Operation earlier in this section). These reoperations carry a low risk, but generally carry greater risk than primary operation (see Table 47-6).

Freedom from further reoperation following aortic valve cusp extension procedures has been variable, with freedom from subsequent aortic valve repair or replacement of 60% to 80% at 5 years and about 50% at 15 years. Durability of repair appears greater if a tricuspid valve can be created.

INDICATIONS FOR OPERATION

Initial Valvotomy

Neonates and Young Infants

In neonates and young infants with severe congenital valvar aortic stenosis, medical treatment is begun on an emergency basis. When the diagnosis is suspected before transport of a neonate to a cardiac surgical center in the first week or two of life, or as soon as such a patient, usually moribund or in metabolic acidosis, is admitted, prostaglandin $E_2$ is begun (see Indications for Operation in Chapter 49). This substance usually opens the ductus arteriosus, particularly if the neonate is just a few days old, improves systemic oxygenation, and relieves metabolic acidosis because the right ventricle can support both systemic and pulmonary circulations. The child’s condition should be stable and good before operation is begun.

Before intervention, care must be taken to distinguish the neonates or very young infants with isolated severe congenital valvar aortic stenosis from those whose anomaly is part of the spectrum of hypoplastic left heart physiology. When the anomaly is hypoplastic left heart physiology class III (see Table 48-1 in Chapter 48), the Norwood operation rather than aortic valvotomy is indicated; simple aortic valvotomy is futile. The criteria for using the more extensive operation are (1) mitral valve area less than 4.75 cm$^2$ · m$^2$; (2) LV inflow dimension less than 25 mm; (3) small LV, evidenced by a ratio between the apex-to-base dimension of the LV and that of the right ventricle of less than 0.8; or (4) transverse cavitary and aortic “anular” dimension of 6 mm or less.

In the Congenital Heart Surgeons multi-institutional study of decision making based on 362 neonates, greater intermediate-term survival was obtained by a strategy of an initial Norwood procedure vs. two-ventricle strategy if the arch was small, LV dysfunction was present, or LV outflow tract was small, particularly when less than 4 mm. Colan and colleagues have also developed and subsequently revalidated a scoring algorithm for decision making in neonates with aortic stenosis and a mitral valve $z$ value of greater than $-2$. In those patients in whom aortic valvotomy alone is indicated, the decision to use percutaneous balloon aortic valvotomy (see Special Situations and Controversies later in this section) or surgical valvotomy remains controversial. Surgical valvotomy may be accomplished by closed transventricular valvotomy, open surgical valvotomy with CPB, or using hypothermic or normothermic circulatory arrest. The preference is for surgical valvotomy using CPB, as well as more sophisticated methods of myocardial management than have been generally used. However, a large trial may be the only way to determine comparative outcomes in this complex setting.

Older Infants and Children

Severe congenital valvar aortic stenosis is an indication for operation in older infants and children. Symptoms of angina or syncope always indicate severe stenosis and thus are indications for operation. Conversely, severe stenosis requiring operation frequently occurs without symptoms, but in such circumstances there will usually be physical signs, particularly in the pulse and behavior of the second heart sound. Also, the ECG will usually show an LV hypertrophy pattern; an ECG that shows severe hypertrophy (important ST-T depression) is an indication for operation even if the gradient is less than 50 mmHg.

Mild congenital aortic stenosis is not an indication for operation. Because of the natural history, these patients require long-term periodic noninvasive reevaluation and invasive study and operation if indicated.

Older infants and children with moderate stenosis are a controversial group. Many recommend operation, and others recommend periodic reevaluation of LV-aortic gradient, subendocardial oxygen requirement, or valve area. Those against possibly premature operation argue that (1) sudden death is rare in children whose systolic gradient is 50 to 75 mmHg, (2) operation and probable valve replacement will still be necessary, and (3) valve replacement cannot be delayed by early operation. Therefore, operation usually is not recommended in this group, but is advised if stenosis becomes severe on repeated noninvasive follow-up.

\textsuperscript{a}Data from 24 patients undergoing reoperation anywhere after initial operation at UAB, 1967-1982.

Key: AVR, Aortic valve replacement; LV-Ao, left ventricular to aortic.

Reoperation

When restenosis becomes severe or when symptoms develop with moderate restenosis, reoperation is indicated. Initially, dysplastic valve cusps should not be a contraindication to reoperation, because in a number of patients the cusps have been more normal in appearance at reoperation than in early life.\textsuperscript{22} Although repeat valvotomy or valve replacement is usually required, subvalvar stenosis may have also developed and must not be overlooked. Important subvalvar stenosis is often associated with a small “anulus,” as well as some supravalvar narrowing. In this case a Konno operation, aortic root replacement operation, or Ross-Konno operation may be advisable.

SPECIAL SITUATIONS AND CONTROVERSIES

Technique of Operation

Periodic enthusiasm for closed transventricular aortic valvotomy in critically ill neonates and young infants is motivated by high early mortality in this group.\textsuperscript{27} Closed transventricular dilations have been performed with Hegar dilators and balloon catheters designed for percutaneous use.\textsuperscript{25,27} Considering the early mortality, need for reintervention, and amount of valvar regurgitation produced, however, no convincing evidence indicates that this method is as good as or superior to the techniques described under Technique of Operation earlier in this section.\textsuperscript{23}

A few groups have preferred to perform valvotomy under inflow stasis at normothermia or mild hypothermia.\textsuperscript{23} Operation under these circumstances is a semiopen one, and forceful stretching or tearing of the valve may result if exposure is not ideal. In children, the method can be used safely, but 7 (26%; CL 17%-37%) of 27 patients followed up to 15 years by Stewart and colleagues had moderate or severe aortic valve regurgitation.\textsuperscript{28} Sink and colleagues reported two (25%; CL 9%-50%) hospital deaths among eight infants, six of whom were neonates.\textsuperscript{314}

Ilbawi and colleagues reported use of extended aortic valvuloplasty in which the commissurotomy incision is extended into the aortic wall around the cusp insertion, mobilizing the valve cusp attachment at the commissures and freeing the
aortic insertion of the rudimentary commissure. They showed reduced aortic valve gradients compared with standard aortic valvotomy at 1.7 years after operation. The method has possible merit, but has not had wide application. Kadri and colleagues, as well as Tolan and colleagues, have described similar operations in which the raphe or fused commissure of the larger cusp of a bicuspid aortic valve is incised, and a triangular piece of pericardium is folded and inserted between the free edges of the incised raphe. Auto- logical or bovine pericardium is attached to the free edges of the incised raphe and vertically to the aortic wall. This procedure produces a tricuspid valve and restores the deficient intercusp triangle, preventing cusp prolapse. Experience with this and other cusp reconstruction procedures (see “Cusp Reconstruction” under Technique of Operation earlier in this section) is limited, so caution should be used in applying these methods until more is known about their efficacy in palliating aortic valve stenosis.

### Percutaneous Balloon Aortic Valvotomy in Neonates, Infants, and Children

Percutaneous balloon aortic valvotomy for severe aortic stenosis in neonates was described by Ruppenthal and Neuhaus in 1985 and Lababidi and Weinhaus in 1986. A large experience with this technique has accumulated since then, well summarized in the neonatal group by Zeevi and colleagues from Boston Children’s Hospital. They found no difference when the results were compared with those of surgical valvotomy in a previous era. Similar results have been reported by others. New technology may improve results further.

In the Congenital Heart Surgeons multi-institutional study, 110 neonates for whom the strategy for management was biventricular repair were treated by either surgical ($n = 28$) or percutaneous balloon ($n = 82$) aortic valvotomy. Propensity score adjustment (see “Clinical Studies with Nonrandomly Assigned Treatment” in Section I of Chapter 6) was used to account for procedure selection bias and achieve comparability of patient characteristics. Time-related survival to age 5 years was similar after surgical and percutaneous balloon aortic valvotomy, as was risk of reintervention.

Moore and colleagues studied midterm results of balloon dilatation of congenital aortic stenosis performed at Boston Children’s Hospital in 148 children, all more than 1 month old. Mortality was 0.7% and was successful in 87% of patients, with average peak gradient reduction of 56±20%. At 8 years postoperatively, 95% were alive, but only 50% were free of another intervention (surgical or repeat balloon aortic valvotomy). Aortic valve regurgitation of grade 3 or higher occurred immediately after the procedure in 13% (CL 10%-16%) and was a major factor in determining another intervention.

Gatzoulis and colleagues compared results of balloon aortic valvotomy in 34 children (8 neonates) and surgical valvotomy in 17 children (7 neonates) treated between 1988 and 1993. Results were equivalent. Two deaths occurred in each group, attributable to small LVs. Peak gradient reduction was equivalent.

Shim and colleagues showed that repeat balloon aortic valvotomy is an effective palliative procedure for children with aortic valve stenosis. Repeat balloon aortic valvotomy provided immediate gradient reduction comparable with the results reported with initial balloon valvotomy, with no increased risk of developing aortic regurgitation.

Hawkins and colleagues followed 60 patients for 1 to 110 months after balloon aortic valvotomy. Operation was required in 23 patients (38%), and aortic valve operation was required in 5% to 7% of patients per year after balloon aortic valvotomy. Aortic valve regurgitation was the predominant indication. Aortic valve repair (valvotomy) was possible in 9 of 23 patients requiring operation after balloon aortic valvotomy. Aortic valve replacement was required in the remaining 14 patients.

Sandhu and colleagues showed that balloon aortic valvotomy can be effective in young adults with congenital aortic stenosis. Of 15 patients aged 16 to 24 years having balloon aortic valvotomy, three required aortic valve replacement for high residual gradient or severe aortic valve regurgitation. Immediate reduction of the pressure gradient by 55% persisted for an average of 1.5 years. Equivalent results were found in 70 children.

Beneficial results of balloon aortic valvotomy in adult patients, especially those with degenerative aortic stenosis, are not long lasting, and restenosis occurs in most patients within 6 months. Wang and colleagues reviewed results of balloon aortic valvotomy in adults, including results from two large registries. They concluded that long-term survival for adults after balloon aortic valvotomy is similar to the natural history of untreated severe aortic stenosis. Survival for patients having balloon valvotomy alone at 3 years was less than 25%, vs. almost 90% for those having balloon aortic valvotomy followed by aortic valve replacement. Balloon aortic valvotomy is reserved only for those patients who are not candidates for aortic valve replacement because of comorbidity illness or advanced age. Balloon aortic valvotomy has not been effective in reducing risk of noncardiac surgery or acting as a bridge to future aortic valve replacement (see Special Situations and Controversies in Chapter 12).

Even with these data, it remains difficult to evaluate balloon aortic valvotomy and determine its effectiveness compared with surgical valvotomy. Immediate, early, and probably midterm results appear to be equivalent to operation in the neonate and child and perhaps in the young adult with congenital aortic stenosis. Long-term results are not currently available. Balloon aortic valvotomy is not effective treatment for adult patients, especially when aortic stenosis is the degenerative type. Application of percutaneous balloon aortic valvotomy seems to be determined by local preference at present.

### Section II Congenital Discrete Subvalvar Aortic Stenosis

#### DEFINITION

Congenital discrete subvalvar aortic stenosis is an obstruction beneath the aortic valve caused by either a short, localized, fibrous or fibromuscular ridge or a longer diffuse fibrous tunnel. “Diffuse subvalvar aortic stenosis” is a phrase best not used to avoid confusion; it was originally used to
distinguish what is now termed *hypertrophic obstructive cardiomyopathy* (HOCM) from congenital aortic stenosis (see Chapter 19). K13 Subvalvar aortic stenosis may also be a part of other cardiac anomalies. In these situations, the obstruction may be fibromuscular and indistinguishable from the entity discussed here or may consist of a localized muscular bar or shelf (e.g., in coarctation or aortic arch interruption with VSD) or abnormalities of the mitral valve. In other words, subvalvar aortic stenosis, as well as valvar stenosis, may be part of the spectrum of hypoplastic left heart physiology.

**HISTORICAL NOTE**

The first description of discrete subvalvar stenosis is attributed to Chevers in 1842. C18 In 1956, Brock and Fleming from Guys Hospital in London published an early report of diagnosing the condition during life using transventricular puncture to measure LV pressure. B21 The catheter was then advanced across the aortic valve from below and the level of obstruction demonstrated. Brock reported results of transventricular dilatation in 1959. B23 Spencer and colleagues published the first substantial report of treatment using CPB in 1960. S18 The lesion was illustrated clearly in patients operated on at the Mayo Clinic between 1956 and 1960. S4, S5

The long fibrous tunnel form of the stenosis was described by Spencer and was later reemphasized by Reis and Morrow and colleagues. R7 Its effective treatment under difficult circumstances became possible with the introduction of aortoventriculoplasty by Rastan and Koncz, and independently by Konno and colleagues in 1975. K15, R2, R3 Complete relief of subvalvar stenosis without sacrifice of the aortic valve became possible with the introduction of the modified Konno operation in 1978 (see Technique of Operation later in this section). The aortoseptal approach was introduced by Vouhe and colleagues in 1984. V5 An alternative form of treatment, LV-aortic conduit, was developed about the same time. C21, N5

**MORPHOLOGY**

**Left Ventricular Outflow Tract**

**Localized Subvalvar Aortic Stenosis**

The localized form of discrete subvalvar aortic stenosis may be fibrous or fibromuscular. The fibrous form involves a spectrum of pathology varying from a discrete short fibrous ridge, a thicker but still discrete fibromuscular shelf, to a long fibrous tunnel. When a fibrous ridge is firmly adherent to the hypertrophied septum anteriorly and to the left, the condition is termed *discrete fibromuscular stenosis*. K12, N4

Whether isolated, localized, or only muscular, subvalvar stenosis occurring as an entity separate from HOCM is controversial.

An obstructing localized circumferential fibrous shelf or ridge may be situated at any level between the nadir of the aortic cusps and the free edge of the anterior mitral leaflet, as well as anywhere along the aortic-mitral anulus. An immediately subvalvar fibrous ridge may be adherent to the base of the aortic cusps (only the right or all three), but more often it is separated from the cusps by several millimeters. Such a high (distal) ridge tends to be narrow, and unless there is severe LV hypertrophy, the remainder of the outflow beneath it remains relatively normal. R12 A low (proximal) fibrous ridge may be attached almost at the hinge line of the anterior mitral leaflet, but most frequently it occupies an intermediate position well above this and several millimeters below the aortic valve (Fig. 47-15). Usually the ridge is 2 to 3 mm thick and is more prominent anteriorly and laterally than posteriorly on the aortic-mitral anulus. The ridge may be present as a complete fibrous diaphragm, however, and the stenotic orifice may be central and circular or eccentric and slitlike. The aortic-mitral anulus is longer than normal in hearts with discrete subvalvar aortic stenosis, and on average, the diameter of the aortic valve anulus is smaller than normal. R12 The muscular ventricular septum beneath the right aortic cusp shows a variable degree of hypertrophy and prominence, and in severe cases may contribute importantly to the stenosis.

**Tunnel Subvalvar Aortic Stenosis**

Much less common, tunnel stenosis presents as a circumferential irregular zone of fibrosis commencing at or close to the LV-aortic junction (“anulus”) and extending...
downward for 10 to 30 mm. Tunnel stenosis has varying degrees of severity, and its spectrum blends into localized subvalvar aortic stenosis. In its most severe form—the form that requires a special surgical procedure—the stenotic tunnel is long and the diameter of the aortic anulus small, even though aortic valve cusps are normally formed. In patients with less severe disease, the tunnel may be shorter and aortic anulus normal in size; morphology then resembles localized fibromuscular discrete subvalvar aortic stenosis. These gradations explain the differing prevalences in reported series. Fibrous stenosis is sufficiently long to justify the term tunnel in about one fifth of cases of congenital subvalvar aortic stenosis; the full-blown entity with anular hypoplasia is rare.

Aortic Valve
The aortic valve is usually tricuspid and either entirely normal or has some diffuse cusp thickening. Trivial or mild aortic regurgitation is present in about two thirds of patients. The aortic valve, however, may be bicuspid, and congenital commissural fusion may produce varying degrees of valvar stenosis. The valve may have been damaged by endocarditis, a complication of subvalvar stenosis, which can result in severe regurgitation. Rarely, the subaortic membrane may be infected. Bases of valve cusps are thick when a high-lying fibrous ridge is continuous with them. Infrequently, supravalvar as well as valvar stenosis coexists with the subvalvar narrowing. This combination is at the mild end of the spectrum of hypoplastic left heart physiology.

Left Ventricle
The LV is usually concentrically hypertrophied. Subendocardial ischemia, and probably fibrosis, occur in subvalvar aortic stenosis as well as in congenital valvar stenosis. Rarely, there may be excessive hypertrophy of the septum (vs. thickening of the posterior LV wall) and muscle fiber disorientation histologically. This histology complicates the distinction in a few patients between discrete subvalvar aortic stenosis and HOCM.

Roberts and his group have noted coronary artery luminal narrowing due to structural wall changes of intramural coronary arteries in both humans and dogs with fibrous subvalvar aortic stenosis. These changes have not been observed in valvar aortic stenosis.

Coexisting Cardiac Anomalies
Discrete subvalvar aortic stenosis occurs as an isolated anomaly in only about half to two thirds of patients coming to operation. Coexisting anomalies include a VSD that is frequently large, and the fibromuscular obstruction is then often located immediately below (upstream to) the VSD. When there is aortic arch interruption and patent ductus arteriosus or occasionally coarctation, localized muscular subvalvar stenosis may be associated with a subpulmonary VSD and occasionally tetralogy of Fallot, atrial septal defect, aortopulmonary window, sinus of Valsalva aneurysm, and aneurysm of the membranous ventricular septum may also coexist, occurring more frequently in pediatric surgical patients.

The complex relationship between VSD and discrete subvalvar aortic stenosis is further evidenced by stenosis developing after spontaneous closure or narrowing of the VSD. Typical discrete subvalvar aortic stenosis may also develop both before and after repair of a complete atrioventricular (AV) septal defect, repair of coarctation, LV-to-aorta internal rerouting in double outlet right ventricle or transposition with VSD, and other forms of congenital cardiac anomalies.

Other Types of Discrete Subvalvar Aortic Stenosis
Localized subvalvar aortic stenosis may be caused by morphomechanism other than those just described. In an autopsy series that included complex congenital heart disease, Freedom and colleagues found the typical fibrous or fibromuscular variety to be the least common in infancy. Mitral valve anomalies involving accessory tissue or leaflet malposition (including that found in AV septal defects) may be a cause of obstruction and may occur in the absence of functional abnormality of the mitral valve or other cardiac anomalies. Localized muscular obstructions related to abnormal infundibular development or malalignment are frequent and often associated with a VSD and aortic coarctation or interruption. A developmental complex described by Shone and associates consists of a parachute mitral valve and LV outflow tract obstruction that usually includes localized fibromuscular subaortic stenosis. Discrete muscular subvalvar aortic stenosis may develop after pulmonary trunk banding for VSD.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Symptoms
Symptoms of congenital subvalvar aortic stenosis are similar to those of the valvar variety. About 25% of patients requiring operation are asymptomatic despite presence of important obstruction.

Signs
A systolic ejection murmur is heard, but a click is rare. There is an unimpressive aortic diastolic murmur in 65% of patients. It is secondary either to (1) cusp thickening with or without adherence of the fibrous ridge to the cusps or (2) effects of eddy currents produced by the subvalvar stenosis upon aortic valve closure.

When severe stenosis is present, the pulse is slow rising, the second heart sound is single or paradoxically split, a third and occasionally fourth heart sound are audible, and a mid-diastolic murmur may be heard at the apex, usually in association with a fibrotic obstruction that limits anterior mitral leaflet movement. It is important to recognize, particularly in children, that one or more of these signs may be minimal or absent despite severe obstruction.

Occasionally, aortic regurgitation may be caused by severe congenital cusp deformities or infective endocarditis. When endocarditis occurs on the aortic valve, signs of regurgitation produced by cusp destruction may be less than expected because a tight fibrous stenosis beneath the valve may limit aortic runoff. Moreover, vegetations on the fibrous shelf itself may increase subaortic obstruction.
Two-dimensional echocardiogram in localized discrete subvalvar aortic stenosis. Fibromuscular ridge is observed narrowing left ventricular outflow tract below aortic valve.

**Figure 47-16**

Chest Radiography

The ascending aorta is not usually dilated in the chest radiograph, and valvar calcification is absent. The LV is usually enlarged.

Electrocardiography

The ECG usually shows severe LV hypertrophy.

Echocardiography

Two-dimensional echocardiography can be diagnostic, accurately demonstrating and outlining the obstructing shelf\(^{12,3,5}\) (Fig. 47-16). The technique is so sensitive that it can demonstrate a subvalvar discrete lesion before a gradient develops. Color flow Doppler imaging sufficiently defines the gradient across the obstruction to allow a definitive decision regarding operation. Siggrusson and colleagues suggested that the angle formed by the septum and aorta (aortoseptal angle) may have prognostic value in patients with discrete subaortic stenosis,\(^{12,3}\) because it is steeper in patients with subaortic stenosis than in normal persons. They suggested this anatomic feature may be causative in development of this condition. M-mode echocardiography is helpful in differentiating this lesion from HOCM.\(^{11,3}\)

Cardiac Catheterization and Cineangiography

Cardiac catheterization shows a systolic pressure gradient below the valve on withdrawal of the catheter across the LV outflow tract. When the fibrous ridge is immediately beneath the valve, the gradient may be apparent at valve level. Postectopic pressure pulse response is normal, and the aortic pulse contour does not show an accessory wave; these features distinguish the lesion from HOCM.

Angiography supports the definitive diagnosis.\(^{3,12,3,4}\) The tilted left anterior oblique (LAO) view provides good visualization of the fibrous ridge because it overcomes the foreshortening of the LV outflow tract region present in the conventional LAO projection (Figs. 47-17 through 47-19). Level and thickness of obstruction can be accurately defined in this manner, and additional valvar stenosis and regurgitation also can be evaluated.

Summary

In discrete subvalvar aortic stenosis, features characteristic of HOCM are usually absent. Rarely, however, particularly in severe forms of fibrous subvalvar aortic stenosis,\(^{11}\) including the tunnel variety,\(^{3}\) there may be abnormal systolic anterior motion (SAM) of the mitral leaflet and an abnormal posttropic response. These signs indicate either a particularly prominent anterior muscular shelf or, in patients who also show an abnormal septal to posterior wall thickness ratio on echocardiography (with disorientation of the muscular pattern of hypertrophy histologically), associated HOCM.

**NATURAL HISTORY**

Discrete subaortic stenosis is present in 8% to 30% of patients with congenital LV outflow tract obstruction.\(^{11,5,3,11,3,4}\) Rather, obstruction is often absent in early life and then becomes evident and progressively more severe in childhood or young adulthood.\(^{11,11,5,3,11,8}\)

The subvalvar gradient has first appeared several years after an early study in infancy before VSD and coarctation repair. Also, the lesion appears infrequently after age 30, suggesting that survival beyond this time is rare without surgery or that the lesion gradually takes on the appearance of HOCM.\(^{11}\)

Pyle and colleagues provided further support for these concepts in their study of fibrous subaortic stenosis in Newfoundland dogs.\(^{59}\) In these animals, subaortic stenosis was never present at birth but was important by 12 weeks of age. Evidence also shows that stenosis might be an inherited trait. A familial occurrence has been reported in humans.\(^{11,14,3}\)

Reports of serial cardiac catheterizations indicate that discrete subvalvar aortic stenosis progresses quite rapidly,\(^{10,4,1,5,3,4,24,4}\) probably more rapidly than valvar stenosis. Such features probably explain why, in published surgical series in which ages of patients are listed, the youngest patients operated on are age 3 to 6 years and surgery is uncommon beyond age 20.\(^{15,3,11,5,12,1,3,3,5,3,18}\)

Aortic regurgitation, often associated with discrete subvalvar aortic stenosis, is progressive and caused by cusp thickening from poststenotic turbulence.\(^{34}\) Cusp thickening most likely explains the frequency of endocarditis before and after surgical excision of the membrane.\(^{34,1,2,3,3,2,3,3,0}\)

**TECHNIQUE OF OPERATION**

Resection of Localized Subvalvar Aortic Stenosis

Preparation for operation for congenital subvalvar aortic stenosis in children is accomplished as described for valvotomy in Section I. Fig. 47-20 shows anatomic relationships of the subaortic fibromuscular ridge.

A transverse aortotomy is made (Fig. 47-21, A). The aortic cusps are retracted and the subvalvar fibrous ridge exposed. Beginning beneath the nadir of the right coronary cusp, a vertical incision is made through the ridge and into the underlying muscle, with depth of incision proportional to estimated septal thickness (Fig. 47-21, B). A second incision parallel to the first is made through the ridge below the commissure between right and left aortic valve cusps. Excision of the fibromuscular ridge begins by carrying a vertical incision circumferentially between the parallel incisions.
Figure 47-17  Left ventricular cineangiogram in crani-ally tilted left anterior oblique projection in patient with localized discrete fibrous subvalvar aortic stenosis, in diastole (A) and early systole (B). A thin ridge obstructing left ventricular outflow tract about 1 cm below aortic valve is well profiled and indicated by white arrows. In systole, aortic valve is domed (arrows), indicating a valvar abnormality in addition to subaortic ridge. Key: a, Ante-rior mitral leaflet; Ao, aorta; L, left; LV, left ventricle; N, noncoronary sinus; R, right coronary sinus.

Figure 47-18  Left ventricular cineangiogram in cranially tilted left anterior oblique projection in patient with fibromuscular subvalvar aortic stenosis. Cineangiogram frame in systole shows thick fibromuscular outflow obstruction commencing just beneath aortic valve. Aortic cusps fail to open completely but show no doming. Diverticulum just below obstructing shelf on septal aspect of outflow tract represents a surgically closed ventricular septal defect (arrow).

Figure 47-19  Left ventricular cineangiogram in lateral projection in patient with tunnel subvalvar aortic stenosis. Cineangiogram frame in late systole shows outflow tract narrowing 1 cm below aortic ring and extending down into base of left ventricle. Anterior mitral valve leaflet forms posterior margin of stenotic zone (arrows) and is prevented from moving back to its normal systolic position. Anterior (septal) margin of outflow tract shows irregular encroach-ment by obstructing fibromuscular tissue.
Chapter 47 Congenital Aortic Stenosis

(Fig. 47-21, C), removing fibrous tissue and myocardium deep into the ventricular septum until the mitral apparatus is encountered at the leftward extremity of the LV outflow tract. In this process, care is taken not to penetrate the ventricular septum and produce a VSD. As the dissection is carried down over the anterior mitral leaflet, only the fibrous ridge is removed, shaving it off the leaflet or mitral-aortic anulus with the knife or a Freer septum elevator (Fig. 47-21, D). Dissection is carried rightward as far as the mitral leaflet and mitral-aortic anulus extend.

Returning anteriorly, only the fibrous ridge is shaved off the muscular septum to the right of the nadir of the right coronary cusp using a knife or septum elevator (see Fig. 47-21, D). The ridge excision is carried rightward over the membranous septum. This technique preserves the integrity of the underlying bundle of His and cores out the entire subvalvar stenosis as a single mass. When the fibromuscular ridge is attached to the undersurface of the belly of one or more of the aortic cusps, it is carefully shaved away from the cusp tissue.

The procedure is not considered complete unless a generous amount of muscle has been removed leftward of the nadir of the right coronary cusp. If only the fibrous component has been enucleated, a deep trough of muscle is cut from the ventricular septum anteriorly. The trough is centered beneath the commissure between the right and left aortic valve cusps as in the operation for HOCM (see Technique of Operation in Chapter 19). This step is of value even when the fibrous ridge is immediately subvalvar, because the ventricular septum is always hypertrophied.

Yacoub and colleagues propose mobilization of the left and right fibrous trigones along with extensive resection of all components of the subvalvular fibrous ring. Their proposal is based on the concept that the aortic and mitral orifices interact, with the fibrous trigones acting as a hinge mechanism for movement of the subaortic curtain and anterior mitral leaflet during the cardiac cycle. The incision to resect the fibrous ring is extended laterally at the location of the left and right fibrous trigones to excise this fibrous tissue in continuity with the obstructing ring. Resection of the left fibrous trigone carries the risk of creating an opening to the outside of the heart or into the anterior mitral leaflet, and injury to the conduction system could occur during resection of the right fibrous trigone. The technique was used in 57 consecutive patients operated on over the course of 25 years without these complications occurring. Pressure gradient over the LV outflow tract after the repair ranged from 0 to 30 mmHg (mean 8 mmHg), and no change in gradient was observed on follow-up assessment.

After determining that the ventricular septum has not been perforated and aortic valve cusps have not been damaged, the aortotomy is closed and the remainder of the procedure accomplished as described under Technique of Operation in Section I for valvotomy.

Ross-Konno Procedure

Aortic valve replacement may be required in some older children or adults when important aortic valve regurgitation coexists with severe subaortic stenosis. Modification of the Ross and Konno procedures is used in these patients (Ross-Konno procedure). CPB is established using either two can- nulae for venous uptake (with venae cavae tourniquets) or a single two-stage cannula, with the atrial uptake placed deep in the atrium at the inferior vena cava (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2). Oxygenated blood is returned through a cannula in the ascending aorta. The aorta is occluded and cold cardioplegia adminis- tered through a cannula in the coronary sinus (see “Technique of Retrograde Infusion” in Chapter 3), directly into the coronary ostia, or both. The ascending aorta is divided and aortic valve excised. The coronary ostia are mobilized with a rim of sinus aorta, and the noncoronary sinus aorta is removed (see Chapter 12). The pulmonary trunk is removed from the right ventricular (RV) outflow tract in the usual manner for a Ross procedure (see “Autograft Pulmonary
Figure 47-21  Repair of discrete fibromuscular subvalvar aortic stenosis. A, Operation is performed on cardiopulmonary bypass with aorta occluded. Cold cardioplegic solution is infused to achieve total electromechanical arrest. A transverse aortotomy is made. B, Subaortic ridge is exposed by retracting right coronary cusp. Broken lines indicate proposed incision points. C, Scalpel is used to make two incisions through fibromuscular ridge, with one below the commissure between right and left aortic valve cusps and the other parallel to first incision and beneath the nadir of right coronary cusp. Septal myocardium is removed deeply between the two incisions. D, Fibrous ridge is dissected from the septum to the right and over anterior leaflet of mitral valve using a Freer septum elevator. Deep incision of ventricular septum carries hazard of heart block. Similarly, deep incision over anterior leaflet of mitral valve risks its perforation.

Valve” under Technique of Operation in Chapter 12). A slightly longer portion of the RV outflow tract below the pulmonary valve may be removed (Fig. 47-22, A). A short incision is made through the fibrous tissue of the aortic valve attachment at the nadir of the right coronary sinus into the ventricular septum, as in the Konno procedure (Fig. 47-22, B). This incision is not as deep into the septum as in the Konno procedure, however, and should not extend beyond the medial papillary muscle (Lancisi) of the tricuspid valve to avoid injury to the first septal branch of the left anterior descending coronary artery. The fibromuscular subaortic ridge is excised and septal myocardium shaved from the left side to reduce thickness of the hypertrophied ventricular septum in order to widen the LV outflow tract and completely relieve the obstruction (Fig. 47-22, C). The pulmonary autograft is then attached to the LV outflow tract (Fig. 47-22, D). The lengthened tongue of the attached RV outflow tract is inserted to the depth of the incision in the
Figure 47-22  Repair of complex subvalvar aortic stenosis requiring aortic valve replacement by pulmonary autograft (Ross-Konno procedure).  

A, Operation is performed on cardiopulmonary bypass with aorta occluded and cold cardioplegia infusion for myocardial management. Aorta is divided and aortic valve excised. Coronary arteries are mobilized with a button of sinus aorta. Rest of sinus aorta is removed. Pulmonary trunk is divided at its bifurcation and removed from right ventricular outflow tract. An extension of the anterior wall of right ventricular outflow tract may be included to fill defect in ventricular septum created by the Konno incision.  

B, An incision is made into ventricular septum (Konno) at the midpoint of right coronary sinus of Valsalva. This incision is not nearly as deep into ventricular septum as in the classic Konno operation, and ordinarily would not pass the depth of the medial papillary muscle (Lancisi) of the tricuspid valve to avoid injury to first septal branch of left anterior descending coronary artery.  

C, Subaortic obstructing ridge is cut away from ventricular septum on left side. Hypertrophied ventricular septum is shaved down on left side to achieve an unobstructed left ventricular outflow tract.  

D, Pulmonary autograft is attached to ventricular septum with interrupted polypropylene stitches. Anterior extension of right ventricular outflow tract may be beneficial when incision of ventricular septum is extensive and deep.
ventricular septum. If no extra length of RV outflow tract has been removed, the pulmonary autograft is simply inserted deep into the LV outflow tract. The operation is completed as described for the Ross procedure (see “Autograft Pulmonary Valve” under Technique of Operation in Chapter 12).

Repair of Tunnel Stenosis by Aortoventriculoplasty (Konno Operation)

When a tunnel type of subaortic stenosis coexists with hypoplasia and narrowing of the LV-aortic junction, aortoventriculoplasty is a reasonable procedure, using the modification described by Misbach and Ebert and colleagues and others. The preliminaries and preparations for CPB are identical to those described earlier for congenital valvar aortic stenosis (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2). CPB is established using two caval cannulae and caval taping, because the RV will be opened. The aorta is occluded, cold cardioplegic solution is infused, and perfusate temperature is stabilized at 20°C to 25°C. Through a small oblique right atriotomy incision, the pump-oxygenator sump sucker is placed across a naturally occurring or surgically created foramen ovale.

Before establishing CPB, position of the right coronary artery must be accurately noted, and a marking stitch placed leftward from this to indicate the RV incision site. A vertical aortotomy is made beginning about 10 mm downstream to the level of the right coronary artery (Fig. 47-23, A). The incision is carried well to the left of the right coronary artery and onto the RV over the junction of the contiguous portions of right and left coronary cusps. The right ventriculotomy may be made first to visualize the pulmonary valve cusps, because these lie near the point of entry of the incision into the RV. After the RV is opened, the scissors are positioned with one blade in the LV through the aortotomy and one in the RV through the ventriculotomy; a scissors cut is made to the left side of the nadir of the right coronary cusp (see Fig. 47-23, A). This incision is carried far enough into the two ventricles to gain access below (or upstream to) the tunnel stenosis. The newly created and enlarged anulus is sized, and an appropriately sized mechanical valve prosthesis is chosen. A double-velour collagen or gel-coated polyester graft is fashioned to form an oval-shaped patch. Beginning at the inferior angle of the incision in the ventricular septum, this patch is sewn into place from the RV side out to beyond the aortic anulus and posteriorly through it. A triangular patch of polyester is attached to the primary aortic patch with the anteriorly placed valve stitches (Fig. 47-23, B). Horizontal mattress sutures in the anterior aspect of the prosthesis are passed through the patch. The remainder of the polyester patch is sutured into place to enlarge and close the aortotomy (Fig. 47-23, C).

The triangular polyester patch is used to close the RV opening (see Fig. 47-23, C). The patch must be wide enough to enlarge the RV outflow tract as compensation for projection of the enlarged LV outflow tract into the RV outflow tract. Particular care is taken to anchor the patch at the junction of RV and aorta so that hemostasis is secure in that area.

The left atrial suction device is removed from across the foramen ovale. The foramen is closed, then the right atrium. The remainder of the operation is carried out in the usual manner (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2).

Aortoventriculoplasty by “Mini” Aortic Root Replacement

Enlarging the subvalvar and valvar area of the LV outflow tract can also be accomplished using biological material, either an ascending aorta valved allograft or a pulmonary artery valved autograft. The operation is begun in the same manner as the Konno operation, extending the incision into the ventricular septum as far toward the apex as required by the extent of subaortic stenosis; incision into the aorta is kept as short as possible. The aorta is then transected just downstream to the distal extent of the vertical incision, and the coronary ostia with generous buttons of surrounding sinus wall are removed from the aorta. The remnant of aortic root and valve cusps are then excised, leaving a fringe of aortic wall attached to the LV-aortic junction. The V-shaped defect in the ventricular septum is filled in with a polyester patch. This reconstructs and enlarges that portion of the LV outflow tract to which the aortic valved allograft (or pulmonary valved autograft) is attached proximally. The graft is sewn into place, and the coronary buttons are implanted. Finally, the opening in the anterior RV wall is closed with a patch, using a triangular piece of pericardium sutured into the incision and distally onto the anterior aspect of the graft.

The anterior mitral leaflet may be left in place on an aortic valved allograft and used to fill in the ventricular septum. However, this dictates the orientation of the valved cylinder, which may be disadvantageous because the curvature of the aorta is brought anteriorly and to the right. This problem can be overcome by using an aortic allograft with attached anterior mitral leaflet to widen the LV outflow tract posteriorly into the anterior leaflet of the mitral valve, as suggested by Milsom and Doty. This places the allograft in anatomic position for treating the complex but localized subvalvar aortic stenosis.

Modified Konno Operation

The modified Konno operation, originally described in the first edition of this book, is effective in patients with difficult and complex localized subaortic stenosis or tunnel stenosis when the aortic anulus and valve are normal. This procedure has also been found to be useful in other patients.

Preparations for operation and establishment of CPB are exactly as described for the Konno operation (see “Repair of Tunnel Stenosis by Aortoventriculoplasty [Konno Operation]” earlier in this section). The aorta is occluded, cold cardioplegic solution infused, and a suction device placed across the foramen ovale (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3). Because the Konno operation usually would not be done with a normal-sized anulus and valve, a transverse aortotomy is made just as for the operation for aortic valvotomy (see Section I of this chapter) or resection of discrete subaortic stenosis as described earlier in this section (Fig. 47-24, A). When it has been determined that the usual procedures will not enlarge the LV outflow tract sufficiently, the RV is opened through a transverse incision about 2 cm inferior (upstream) to the level of the pulmonary valve cusps. A right-angled clamp is passed
Aortoventriculoplasty (Konno operation) and aortic valve replacement. **A**, Vertical aortotomy is directed slightly rightward of the commissure between left and right coronary cusps of aortic valve. As incision is being made, orifice of right coronary artery is visualized, and incision passes clearly leftward of this. Right ventricle (RV) is opened with a oblique incision, pulmonary valve is located, and the two incisions are joined. Before or after excising aortic valve, an incision is made into base of the right coronary cusp just to the left of its nadir. This incision is extended into ventricular septum and toward apex of left ventricle. It is leftward of conduction system. **B**, Patch of collagen-coated polyester is cut into a diamond shape and attached to ventricular septum. A second triangular-shaped patch is fashioned for closing RV outflow tract. This patch and a prosthetic valve are attached to the primary patch at the level of the aortic anulus. A single suture line will suffice for this portion of the reconstruction. Prosthetic valve is attached directly to aortic anulus.
from the aortotomy through the aortic valve and into the left side of the LV outflow tract and positioned 1 cm or so upstream to the valve. The tip of the clamp can be palpated through the ventricular septum, and at that point an incision is made in the septum from the RV side (Fig. 47-24, B). It is extended inferiorly for about 1 cm, parallel to the LV outflow tract and thus at an angle to the RV outflow tract. The incision through the ventricular septum is now extended superiorly with great care to keep it clearly upstream to the aortic valve (Fig. 47-24, C). Hypertrophied myocardium of the ventricular septyum is removed to thin it out and relieve obstruction. As described for the Konno operation, an oval patch is trimmed from a double-velour collagen-coated polyester graft. This is sewn into place so as to enlarge the LV outflow tract (Fig. 47-24, D). The right ventriculotomy and aortotomy are closed with continuous sutures (Fig. 47-24, E).

Valve-Preserving Technique for Enlarging Left Ventricular Outflow Tract and Mitral Anulus

Jonas and colleagues have described an operation for enlarging the LV outflow tract and mitral anulus in patients with tunnel subaortic stenosis, often as a component of Shone syndrome and therefore associated with mitral stenosis and hypoplasia of the mitral anulus. The aortic valve, if normal, is preserved. The operation consists of an incision from the aorta through the commissure between the left and noncoronary cusps of the aortic valve. The incision is extended into the roof of the left atrium and across the anulus of the mitral valve. The mitral valve is removed and replaced with a mechanical prosthesis. A triangular patch is used to enlarge the mitral anulus and close the left atrium. The aorta is reclosed, preserving the aortic valve. Some regurgitation of the aortic valve may occur, but this is not necessarily negative, because it serves to hasten growth of the aortic anulus.

RESULTS

Early (Hospital) Death

Hospital mortality for repair of localized subvalvar aortic stenosis is low but has not quite approached zero. In a combined series of 314 patients compiled from the literature, with operation performed primarily in an earlier era, mortality was 4.8% (CL 3.5%-6.4%).

Extensive operations, such as aortoventriculoplasty by the Konno or Rastan technique, have a higher mortality. In older children and young adults, aortoventriculoplasty has been performed with hospital mortalities of 5% to 15%.

Although experience is limited, results for the Ross-Konno procedure have been good. Reddy and colleagues, Daenen and colleagues, and Brown and colleagues all report mortalities under 10% for series of 11 to 14 patients. The operation can be successfully accomplished even in neonates.

Time-Related Survival

About 85% to 95% of heterogeneous groups of children and young adults coming to operation for discrete subvalvar aortic stenosis are alive 15 years later.

Incremental Risk Factors for Premature Death

Absence of formal multivariable analysis of a sizable and representative group of patients undergoing appropriate surgical treatment handicaps the effort to identify incremental risk factors in patients with subvalvar aortic stenosis.

However, the nature of the morphology is clearly the dominant risk factor. The tunnel form of subvalvar aortic stenosis
Figure 47-24  Modified Konno operation, used only for complex or recurrent discrete subaortic stenosis or tunnel stenosis with normal-sized aortic valve and anulus. 

A, Ascending aorta is opened through small transverse incision to inspect valve and guide incision into ventricular septum. Transverse incision is made in infundibulum of right ventricle. 

B, An incision is then made through ventricular septum parallel to direction of left ventricular outflow tract, keeping incision well anterior to the level of the muscle of Lancisi (i.e., well to the left) to avoid heart block or central right bundle branch block. Usually a finger or instrument is passed through aortic valve to protect it while making this incision. 

C, Fibromuscular components of subvalvar stenosis are excised as much as possible. Incision in septum is carried to within 1 to 2 mm of aortic valve anulus. 

D, Left ventricular outflow tract is widened by inserting a patch. 

E, Ventriculotomy and aortotomy are closed with continuous sutures.
and small aortic anulus increase the risk of premature death. Increased risk in the early hazard phase after operation is related to more extensive operations required for optimal therapy. Increase in the later hazard phase is related to the tendency of patients with these complex morphologies to have persistent stenosis or develop restenosis that requires complex reoperations.

Morphologic risk factors can be eliminated by using an appropriate but extensive surgical procedure as the initial operation and by making it safe and durable by optimal myocardial management and improved techniques.

Complications
Complications of the resection procedure are rare with current techniques, but include complete heart block, iatrogenic VSD, hemorrhage, and injury to the mitral valve. Reddy and colleagues reported that 1 of 11 patients (9%; CL 1.5%-28%) required a permanent pacemaker after aortoventriculoplasty.

Functional Status
Functional status of surviving patients is generally good. Of 38 surviving and traced patients in the UAB experience, 31 (82%; CL 73%-88%) were in NYHA functional class I and six (16%; CL 6%-24%) in NYHA class II. Whitmer and colleagues have shown objective evidence of improved exercise tolerance.

Hemodynamic Status
Most patients, including those with the less severe forms of tunnel stenosis, have an excellent hemodynamic result late (10 years) postoperatively. The operation usually results in a dramatic immediate gradient reduction, which is sustained or improved over the subsequent 10 years. In a few patients, gradient is mildly increased 5 to 10 years postoperatively compared with measurements in the operating room, but these data are difficult to interpret because of the variability of postrepair operating room measurements.

Sreeram and colleagues suggested that intraoperative echocardiography provides better morphologic information about obstructive lesions of the LV outflow tract and enables immediate assessment of the adequacy of operative repair. Kuralay and colleagues suggested that use of intraoperative transesophageal echocardiography in adult patients allows optimal resection of the obstruction and reduces complications such as complete heart block and VSD. Results from simple resection are less good in patients with severe tunnel stenosis. Wright and colleagues found that in six patients, mean LV-aortic gradient was reduced from 102 to 72 mmHg. This was a smaller reduction in gradient (30 ± 17 mmHg) than was achieved in patients with discrete subvalvar aortic stenosis (52 ± 40 mmHg) (P for difference < .05). The advantages of the Konno or modified Konno procedure in this setting are clear.

Recurrence and Reoperation
Stewart and colleagues found that about half of their patients having operations for localized and diffuse forms of subvalvar aortic stenosis required reoperation, some as long as 17 years after the initial procedure. The hazard function for reoperation increased at 5 years. Serraf and colleagues analyzed long-term results including risk factors for recurrence and reoperation in 160 patients followed for a median of 13.3 years. Freedom from reoperation at 15 years was 85%. Recurrence and reoperation were most influenced by coarctation of the aorta and immediate postoperative LV outflow tract gradient.

Brauner and colleagues followed 75 patients an average of 6.7 years after operation for subvalvar aortic stenosis. They found 18 recurrences in 15 patients (20%). The linearized hazard of recurrence and reoperation was 3.8% per patient-year. When patients had a preoperative LV outflow tract gradient greater than 40 mmHg, risk of reoperation was sevenfold higher, suggesting that early intervention or more extensive operation may prevent recurrence, reoperation, and secondary progressive aortic valve disease. In discussing these findings, Freedom conjectured that the problem of recurrence may be more complex and somehow related to abnormal cellular response in the LV outflow tract. Recalling earlier work of Ferrans and colleagues in which at least five cell layers are present in resected subvalvar fibrous rings, Freedom called for better understanding of the fundamental mechanisms of mechanical stress and genetic regulation of the endothelial surface of the LV outflow tract in subvalvar aortic stenosis.

Recent discrete subvalvar stenosis is usually indistinguishable morphologically from the primary disease, although its recurrent rather than persistent nature has been documented. This entity of recurrent discrete subvalvar stenosis is to be clearly distinguished from persistent subvalvar stenosis after an inadequate initial operation, although their effect and treatment are the same.

Aortic Regurgitation
Some investigators have suggested that aortic regurgitation may progress after a satisfactory operation. Typically, however, aortic regurgitation remains trivial or mild unless endocarditis occurs. Serraf and colleagues found that relief of subvalvar aortic stenosis improved the degree of aortic regurgitation in 86% of patients (CL 80%-91%) with preoperative aortic regurgitation.

INDICATIONS FOR OPERATION
Because obstruction from localized congenital subvalvar aortic stenosis tends to progress rather rapidly, and because the propensity for sudden death when it becomes severe is presumably the same as in severe congenital valvar aortic stenosis, operation is advisable whenever the stenosis is moderate (LV-aortic gradient > 50 mmHg) or severe. When the stenosis is severe (gradient > 100 mmHg), operation without delay is indicated. Resection of the subvalvar obstruction is usually the initial procedure of choice.

When the diagnosis has been made but obstruction is mild (LV-aortic gradient less than 50 mmHg), reevaluation with echocardiography is indicated every 6 months because rapid progression can occur. However, some evidence indicates that intervention at an earlier age and at a lower gradient (30 mmHg) may improve late results, depending on the extent of relief of obstruction at the initial operation.
When discrete subvalvar stenosis is long (tunnel stenosis), and perhaps particularly when it is recurrent, simple resection is usually not effective. In these circumstances, an initial modified Konno operation is indicated.

When there are multiple levels of LV outflow tract obstruction or major associated cardiac anomalies, the general indications previously described pertain, but each patient must be considered with respect to individual morphology and circumstances. The Ross-Konno aortoventriculoplasty is the most generally applicable procedure, because the autograft may grow, and if it does it is the preferred technique in young patients. Either the Konno procedure or the “mini” aortic root replacement may also be used.

SPECIAL SITUATIONS AND CONTROVERSIES

Type of Operation

Simple resection of a discrete subaortic membrane (or shelf) has been recommended by some as equivalent to membrane resection plus transaortic myectomy in terms of likelihood of restenosis. However, Lupinetti and colleagues and Barkhordarian and colleagues found that adding septal myectomy to resection of discrete subvalvar aortic stenosis reduced the frequency of reoperation.

Aortoseptal Approach for Tunnel Stenosis

The modified Konno procedure provides only a limited exposure of the subvalvar area. Vouhe and colleagues have used an “aortoseptal approach” similar to the Konno operation, but without the need to replace the aortic valve. A longitudinal incision in the aorta is carried obliquely down toward the top of the adjacent portions of right and left aortic cusps. A roughly transverse incision is made in the RV infundibulum, beginning at a point just over this. The aortic and RV incisions come together just over the top of the left anterior fibrous trigone. The aortic “anulus” is now divided through the trigone, going exactly between adjacent extremities of left and right cusps; this can be done without damaging the cusps. This incision is carried well into the ventricular septum, as in the Konno procedure, opening the LV outflow tract widely. After resecting obstructing tissue, the septal incision is closed, the left anterior fibrous trigone reconstructed, and the RV and aortic incisions closed. The authors also describe widening the LV outflow tract with a polyester patch in closing the septal incision, as in the modified Konno procedure. The aortic valve is replaced if it is part of the obstructing process or if it is regurgitant.

Left Ventricular–Aortic Conduit

The LV-aortic conduit (apicoaortic conduit) operation has enjoyed some popularity in the past. Norwood and colleagues reported a hospital mortality of 22% (CL 8%-45%) with use of this technique in infants. Complications both early and late postoperatively are common, and 4 (24%; CL 12%-39%) of 17 hospital survivors reported by Brown and colleagues required reoperation, as did 7 (78%; CL 55%–92%) of 9 hospital survivors reported by Di Donato and colleagues. Currently, few indications exist for the procedure in cases of congenital aortic stenosis. Cooley and colleagues revived interest in apicoaortic conduits with a report of its use in seven patients with complex LV outflow tract obstruction. They used a transthoracic approach to avoid redo sternotomy and compromise to coronary arteries, the conduction system, and other valves. Two patients died of respiratory insufficiency (29%; CL 10%-55%). The others survived and were improved by operation.

Section III Congenital Supravalvar Aortic Stenosis

DEFINITION

Congenital supravalvar aortic stenosis is an obstruction caused by localized or diffuse narrowing of the aortic lumen commencing immediately above the aortic valve.

HISTORICAL NOTE

The first description of supravalvar aortic stenosis is attributed to Mencarelli in 1930. It was seldom recognized, however, until Denie and Verheugt emphasized in 1958 that supravalvar stenosis could be differentiated from other varieties of aortic stenosis by retrograde arterial catheterization. In 1959, Morrow and colleagues pointed out the usefulness of angiography in diagnosis.

In 1961, Williams, Barratt-Boyce, and Lowe described the association of supravalvar aortic stenosis with unusual “elfin” facies and mental retardation, a syndrome that was soon confirmed by others. This constellation of signs and symptoms has since been referred to as Williams syndrome or elfin facies syndrome. In 1964, Beuren and colleagues reported 10 cases of this syndrome, all associated with multiple peripheral pulmonary artery stenoses. Watson and Bourassa and Campeau had also noted this association a year earlier. The similarity between the facies of patients with supravalvar aortic stenosis and severe infantile hypercalcemia was noted in 1963 by Hoofit and colleagues and Black and Bonham Carter. Garcia and colleagues reported the first patient with Williams syndrome and a documented history of infantile hypercalcemia. The occurrence of a familial form of supravalvar stenosis without elfin facies was reported by Sissman and colleagues in 1959. Nakinski and colleagues reported supravalvar aortic stenosis in monozygotic twins without phenotypic features of Williams syndrome.

Successful operation for supravalvar stenosis using patch graft enlargement of the noncoronary sinus of Valsalva was reported by McGoon and colleagues in 1961, the first patient being operated on in 1956. Before this publication, successful procedures using a similar technique had been performed.

In 1960, Hara and colleagues successfully performed an excision and end-to-end aortic anastomosis in a patient with supravalvar aortic stenosis, as did Chard and Cartmell. Hancock satisfactorily relieved the stenosis by excising the intimal ridge without patch enlargement. Neither of these procedures is currently recommended.

Most surgeons have placed the patch into the noncoronary sinus of Valsalva, but in Williams and colleagues’ original report, it was placed into the right sinus to relieve any narrowing between the right cusp and aortic wall. Doty
and colleagues recommended using a double-flanged patch that extends into both noncoronary and right sinuses, incising the stenosing ring at points 180 degrees apart. Resecting the remaining stenotic ring above the left coronary sinus may be performed to enhance the repair. Their report introduced the concept of more anatomic repair of the aortic root and led to a number of modifications of the classic operations for supravalvar aortic stenosis. Subsequent modification of their extended aortoplasty technique employed incision in the left coronary sinus and repositioning of the commissure between left and right coronary cusp of the aortic valve to achieve a more anatomic repair. Steinberg and colleagues proposed a modification of extended aortoplasty in which an additional separate incision is made across the sinotubular junction into the left coronary sinus of Valsalva to the right of the left coronary ostium. This incision is closed around an oval-shaped prosthetic patch, and the primary Y-shaped incision is closed with a pantaloon-shaped patch.

Brom introduced an even more symmetric aortoplasty, enlarging all three sinuses of Valsalva by a three-patch technique. The first patient was operated on using this method in 1978, but the technique was not published until 1988. The aorta is transected distal to the obstruction and incisions made into each of the three sinuses. Pericardial patches are inserted into each of the aortic sinuses to relieve the obstruction while retaining normal geometric relationships of the aortic root.

Myers and Waldhausen and colleagues described a technique of repair that is symmetric and obviates need for prosthetic patch material. The aorta is divided distal to the obstruction, and incisions are made into each aortic sinus. Distally, three incisions are made in the ascending aorta corresponding to the position of the commissures of the aortic valve. The aorta is mobilized sufficiently to advance the ascending aorta into the incisions in the aortic root.

**MORPHOGENESIS AND MORPHOLOGY**

**Supravalvar Stenosis**

*Morphogenesis*

The vascular pathology of supravalvar aortic stenosis and Williams syndrome results from mutations involving the elastin gene on chromosome 7q11.23. These mutations include intragenic deletions, translocations, and complete deletion of the elastin gene, suggesting that a quantitative reduction in elastin during vascular development is pathogenically important. Point mutations of the elastin gene (ELN) are especially important in supravalvar aortic stenosis. Stamm and colleagues found Williams syndrome in 61% of patients treated operatively for supravalvar aortic stenosis, and more recently the clinical diagnosis was supported by the chromosome 7q11.23 abnormality.

*Morphology*

Stenosis may be localized or diffuse. Most often the narrowing is localized to the supravalvar area of the aorta just above or at the most superior level of the attachments of the valve commissures. Narrowing of the aorta at this point is usually apparent externally; in association with some dilatation of the sinuses of Valsalva and absence of poststenotic dilatation, this produces an hourglass appearance. In addition, variable intimal thickening in the form of an internal shelf increases the stenosis and may obstruct or even close the ostium of the left main coronary artery (see “Coronary Arteries” later in this section).

Less often, the narrowing is diffuse, extending throughout the length of the ascending aorta and even beyond into the arch and into the origins of brachiocephalic arteries.

**Other Aortic Lesions**

Supravalvar aortic stenosis should be considered a complex anomaly of the aortic root. Too often the surgeon focuses attention on only the defect at the sinus rim; narrowing and thickening of the sinus rim are fundamental to the morphology, but this defect involves more anomalies. Thickening of the aortic media and intimal hyperplasia reduces aortic circumference at the sinus rim. The morphologic process may not be circumferential but may involve only the sinus rim over one or two sinuses. The sinuses of Valsalva beneath the thick and short sinus rim may be abnormal or hypoplastic. Ostia of the coronary arteries may be obstructed not only by the overhanging thick sinus rim, but also by an aortic cusp that becomes bound down or fused to the aorta at the sinus rim.

The aortic valve cusps are reported to be thickened in about 30% of patients with supravalvar aortic stenosis. True valvar stenosis resulting from leaflet fusion is rare. The aortic valves are actually involved in every case, because the relationships of the commissures are distorted as they are drawn close together by the shortened and thickened sinus rim. This distortion produces a characteristic buckling of the free edge of the aortic cusp. The free edge of the aortic cusp has normal length in most young patients. It buckles as it accommodates to the shortened space at the sinus rim. The buckled aortic cusps become part of the obstruction within a space too small to accommodate them properly. Thickening of the edges of the aortic cusps, however, is eventually produced by turbulent blood flow from stenosis at the sinus rim. The thickened valve cusps then become an even more important part of the stenosing process.

The aortic anulus may occasionally be hypoplastic. Subvalvar stenosis of the LV outflow tract may also be part of this total deformity of the aortic root. McElhinney and colleagues focused attention on the fact that supravalvar aortic stenosis involves not only the supravalvar aorta but the entire aortic root in the 36 patients who were operated on consecutively over 6 years. Procedures were required on the aortic valve in 39%, which agrees closely with the series reported by Delius and colleagues. In that series, resection of the subvalvar LV outflow tract was performed in 11 patients, and two patients underwent procedures on the coronary arteries. Four patients had aortic root deformity so severe that the entire root was replaced with a pulmonary autograft (Ross procedure). The authors compared their series to six others and found similar high frequency of associated pathology and LV outflow tract procedures.

Bicuspid aortic valve is common (6 of 15 patients, 40% in the series of Delius and colleagues).

**Coronary Arteries**

The aortic valve cusp free edges near the aortic wall may become adherent to the intimal shelf, producing stenosis
at the entry into the sinus of Valsalva, thereby obstructing coronary flow. This is more common in the left sinus but can occur in the right. When extreme, the proliferative process of the intimal ridge may extend into and narrow or even obstruct the ostium of the left coronary sinus. Stamm and colleagues found partial adhesion of the leaflets to the stenosing ridge in 54% of patients with supravalvar aortic stenosis. In 30%, the valve leaflets were thickened and less mobile than normal. The sinuses of Valsalva were enlarged in 75% of cases. Coronary angiography demonstrated evidence of coronary ostial stenosis in 45%. The authors concluded that the entire valvular apparatus is always affected in patients with supravalvar aortic stenosis.

In the absence of obstruction to inflow into the sinus of Valsalva or of ostial stenosis, the coronary arteries are exposed to a high pressure and show dilatation, tortuosity, medial hypertrophy, and early onset of arteriosclerosis.

Other Cardiac Anomalies

The most common associated anomaly consists of multiple stenoses in the peripheral pulmonary arteries, which may be severe enough to produce right ventricular hypertension and hypertrophy. Pulmonary valve stenosis occurs infrequently. Diffuse hypoplasia of the pulmonary trunk may be associated with diffuse hypoplasia of the aorta with both arteries showing marked wall thickening and fibromuscular dysplasia histologically in association with disorganization and replacement of the elastic tissue of the media. These patients usually give a familial history, and sudden death in infancy is common.

Less common anomalies include stenosis of the origins of subclavian and carotid and rarely other major systemic arteries, coarctation of the aorta (with or without patent ductus arteriosus), and VSD. Mitral regurgitation occurs rarely, although the mitral valve may be thickened and redundant. The patient reported by Denie and Verheugt in 1958 had Marfan syndrome, which has been noted subsequently in about 5% of patients with supravalvar aortic stenosis.

CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Symptoms

Symptoms rarely develop in infancy, but appear frequently in childhood, and may appear as late as the second or third decade. They are similar to those of other types of congenital aortic stenosis, although angina may occur more often because of early-onset coronary arteriosclerosis.

Signs

Auscultatory findings are similar to those of congenital valvar aortic stenosis, and the correct diagnosis may not be possible from physical signs. An ejection click is absent, however, and the murmur and thrill tend to be situated higher than in valvar stenosis. An aortic diastolic murmur is uncommon. Blood pressure may be lower in the left arm than in the right, resulting from stenosis at the origin of the left subclavian artery or from a jet effect. Similarly, the left carotid pulse may be diminished.

A diagnostic clinical feature may be elfin facies, combined with reduced intelligence quotient and failure to thrive. These retarded children are characteristically small, friendly, and loquacious. Each component of the syndrome varies in severity, however, and the supravalvar stenosis may be mild or occasionally absent in patients with the typical facies. The disease in this form is always sporadic and the facies identical to severe infantile hypercalcemia. Hypercalcemia has been documented in less than 5% of these infants, although it is more common when the elfin facies is not present. Less than half of patients with congenital supravalvar aortic stenosis have elfin facies and mental retardation. In the remainder without elfin facies, the disease may be sporadic or familial.

Echocardiography

Diagnosis and definition of severity can be made with two-dimensional echocardiography and color flow Doppler examination (Fig. 47-26).

Cardiac Catheterization and Angiography

The site of pressure change can be localized on withdrawal of a catheter from LV to aorta. Morphology of the supravalvar stenosis can be outlined on angiography (Fig. 47-26, C, and Fig. 47-27), and coexisting anomalies can be identified (Fig. 47-28). For these last reasons, cardiac catheterization and angiocardiography are usually indicated.
60% of children with the anomaly. Some of the children with elfin facies and the severe form of infantile hypercalcemia die from complications of hypercalcemia. However, a longitudinal study by Hickey and colleagues indicates a more favorable prognosis for children with moderate (mean LV outflow tract systolic gradient 30 mmHg) supravalvar aortic stenosis. Many such children, particularly those with Williams syndrome, show gradual regression of gradient without intervention. Kitchiner and colleagues followed 81 patients with supravalvar aortic stenosis from 1 to 29 years (median 8.3 years); 40 patients (49%) had Williams syndrome, 19 (23%) had additional levels of LV outflow tract obstruction, and 47 (58%) had surgical intervention, 20% in the first year after diagnosis. The data indicated that 88% of the patients would be operated on within 30 years. Predicted survival at 30 years after presentation was 66%.

**NATURAL HISTORY**

The supravalvar form is the least common type of congenital aortic stenosis. Genders are equally affected.

In infants with elfin facies, mental retardation, and combined congenital supravalvar aortic stenosis and pulmonary stenoses of the diffuse variety, sudden death is common early in life. Sudden death can occur in all age groups, presumably from severe LV outflow tract obstruction and coronary artery disease.

Progression of supravalvar aortic stenosis may be more rapid and severe than in congenital valvar aortic stenosis. Because the lesion is uncommon in adults, most untreated patients probably die before reaching adult life. Death before adult life is particularly likely to occur in those with elfin facies, because they constitute only 11% of adults but...
Figure 47-27  Left ventriculogram and aortogram in diffuse supravalvar aortic stenosis. **A,** Ascending aorta becomes diffusely narrow at the level of the aortic valve commissures, just beyond area of right and left coronary arteries. Narrowing extends into transverse arch. **B,** In this patient, diffuse supravalvar stenosis extends through aortic arch. Origin of left carotid artery is stenotic, and left subclavian artery is occluded.

Figure 47-28  Cineangiograms of localized supravalvar aortic stenosis with coexisting diffuse right and left pulmonary artery narrowing. **A,** Left ventriculogram and aortogram in lateral projection in long-axial position. **B,** Right ventriculogram in posteroanterior projection.
valvotomy for congenital valvar aortic stenosis in Section I of this chapter. After occluding the aorta and infusing cold cardioplegic solution, the aortotomy is made.

The aorta is opened above the valve and the incision carried into the noncoronary sinus of Valsalva. The aortic valve and subvalvar areas are examined to exclude obstruction at those levels. The intimal shelf is resected (Fig. 47-29, B), in part to ensure adequate inflow into the sinuses of Valsalva. A diamond-shaped patch of pericardium or collagen-coated knitted polyester or polytetrafluoroethylene (PTFE) is then incorporated into the incision with a running polypropylene suture (Fig. 47-29, C). The patch must be of sufficient size

Interestingly, the peripheral pulmonary stenosis seems to decrease in severity as patients age.\textsuperscript{G8, W9}

**Figure 47-29** Repair of congenital supravalvar aortic stenosis. **A,** External hourglass deformity of aorta is usually less prominent than internal narrowing. **B,** When prominent, as usually occurs, this ridge is excised. **C,** Supravalvar narrowing is eliminated by incorporating an enlarging patch of pericardium (or polyester) into closure of incision.

**TECHNIQUE OF OPERATION**

**Repair of Localized Type**

**Classic Repair**

The external hourglass deformity of the aorta is usually less prominent than the internal narrowing caused by the thick ridge of the sinutubular junction (Fig. 47-29, A). The operation is begun exactly as described for the procedure of
to enlarge the aortic diameter to normal. The remainder of the procedure is completed as usual (see “Completing Cardiopulmonary Bypass” in Section III of Chapter 2).

Pressure is measured in the LV and ascending aorta to determine whether there is any residual gradient across the repair. Intraoperative echocardiography with color flow Doppler examination should be done to assess the degree of turbulence over the repair and determine whether aortic valve regurgitation is present.

**Extended Aortoplasty (Doty)**

The operation is performed on cardiopulmonary bypass (CPB) using a single two-stage venous uptake cannula, with oxygenated blood returned to a cannula in the ascending aorta (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2). The aorta is occluded and cold cardioplegia infused through a cannula in the coronary sinus (see “Technique of Retrograde Infusion” in Chapter 3). A vent catheter is placed in the right superior pulmonary vein.

An oblique incision is made in the aorta, extending it across the obstructing ridge at the sinutubular junction and into the middle of the noncoronary sinus. The primary incision is also extended to the left to cross the sinutubular junction into the right sinus of Valsalva just anterior to the commissure between the left and right coronary cusps of the aortic valve (Fig. 47-30, A). The incisions into the aortic root are nearly directly opposite each other at the sinutubular junction, allowing the aorta to be divided into almost equal portions. The anterior portion of the aortic root that contains the origin of the right coronary artery may move forward (anterior) to widen the space at the sinutubular junction. Buckling of the aortic valve leaflets is relieved as the halves of the aorta are separated anteriorly and posteriorly. The thick ridge of the supravalvar stenosis located above the left coronary sinus is excised (Fig. 47-30, B). A crimped tubular polyester graft whose diameter approximates that of the ascending aorta is used for reconstruction. About half of the circumference of the graft is used, and the length should be sufficient to place enough graft into the aortotomy to prevent the anterior portion of the aortic root from being pulled down into the plane of the aorta. A wedge is removed from the graft to accommodate the portion of the aorta containing the right coronary artery. The resulting two limbs of the graft are used to widen both the right and noncoronary sinuses of Valsalva (see Fig. 47-30, B) partially closing the aortotomy; the distal end of the graft fills the aortotomy in the ascending aorta.

Entrapment of the left coronary cusp of the aortic valve may be treated not only by resection of the supravalvar thickened rim but also by incision into the left sinus of Valsalva to the left of the left coronary ostium (Fig. 47-30, C). This incision mobilizes the commissure between the left and the right coronary cusps and allows the commissure to be moved anteriorly for greater symmetry of the position of the three commissures. The pantaloon-shaped patch is attached to the adventitia of the aorta behind the commissure between the left and right cusps at the anular level. The commissure is attached directly to the patch to achieve equal distance between the three commissures at the sinutubular junction relative to the aortic anulus is difficult to accomplish.

**Three-Patch Repair (Brom)**

The operation is performed on CPB using a single two-stage venous uptake cannula and an arterial cannula in the ascending aorta (see “Preparation for Cardiopulmonary Bypass” in Section III of Chapter 2). The aorta is occluded and cold cardioplegia infused (see “Cold Cardioplegia, Controlled Aortic Root Reperfusion, and [When Needed] Warm Cardioplegic Induction” in Chapter 3).

The aorta is divided above the sinutubular junction. Three longitudinal incisions are made through the area of stenosis into the aortic root (Fig. 47-31, A). The first is placed in the middle of the noncoronary sinus of Valsalva. The other two are determined by position of the coronary arteries. Incision into the left coronary sinus is usually to the right of the left coronary ostium, and incision into the right sinus is usually to the left of the right coronary ostium. The incisions end about halfway into the sinus aorta, but may go deeper if necessary to achieve good separation of the edges of the aorta at the stenosing ridge. Three triangular patches of autologous pericardium are inserted (Fig. 47-31, B). Width of the patch at the sinutubular junction should restore correct dimensions. The diameter at the sinutubular junction should be 10% to 15% less than the diameter at the ventriculoaortic junction (“anulus”). Larger patches achieve a greater diameter but carry the risk of reducing the coaptation area of the aortic valve by lateral displacement of commissural attachments of the valve, possibly resulting in aortic regurgitation.

The reconstructed aortic root is anastomosed to the ascending aorta.

**Sliding Aortoplasty (Myers-Waldhausen)**

The operation is performed on CPB. The aorta is divided above the supravalvar obstruction. Three longitudinal incisions are made through the area of stenosis into the three sinuses of Valsalva as described for the “Three-Patch Repair (Brom)” in the preceding text. Incisions are made into the ascending aorta distally and correspond exactly to the commissures of the aortic valve (Fig. 47-32, A). The ascending aorta is mobilized extensively to allow it to be displaced inferiorly so as to slide the flaps of the ascending aorta into the incisions in the aortic root in a “V-Y” pattern. A continuous stitch of monofilament suture is started at the nadir of each incision in the sinus aorta. The corresponding flap of ascending aorta is attached to the edges of the incision in the sinus aorta by sewing from the nadir to the top of the commissural attachment of the aortic valve (Fig. 47-32, B). The diameter of the aortic root at the sinutubular junction will be determined by the diameter of the ascending aorta and should approximate normal dimensions (see “Dimensions of Normal Cardiac and Great Artery Pathways” in Chapter 1). No prosthetic material is employed in this repair.

**Repair of Diffuse Type**

The operation proceeds as described for the localized type, except that the skin incision is carried about 2 cm more superiorly than usual. The femoral artery is exposed for arterial cannulation. Origins of the brachiocephalic, left common carotid, and left subclavian arteries and the transverse portion
Figure 47-30 Repair of supravalvar aortic stenosis by extended aortoplasty (Doty). A, Oblique incision is made in aorta extending across supravalvar ridge into middle of noncoronary sinus of Valsalva. A second incision is made as an inverted “Y” into right sinus, just anterior to commissure between left and right coronary cusps. This divides the stenosing ring at two points almost directly opposite on circumference of ring. B, Supravalvar ridge is removed from above left coronary sinus of Valsalva. A patch is fashioned from a tubular polyester graft approximately the diameter of aorta. A wedge is removed to create two limbs on the patch and accommodate position of right coronary ostium (pantaloon patch). Patch is attached to edges of aortotomy in right and noncoronary sinuses of Valsalva and to primary incision in aorta. Sufficient length of graft must be placed into aortotomy to allow portion of aorta containing right coronary ostium to separate anteriorly from primary aortic incision.

of the aortic arch are dissected below and above the left brachiocephalic vein.

CPB is established with arterial inflow to the patient through the femoral artery, and body temperature is taken to 18°C. The operating table is placed with the patient in moderate Trendelenburg position. The aorta is occluded while cold cardioplegia is infused. Aortic reconstruction is done with hypothermic circulatory arrest (see Section IV of Chapter 2).

A longitudinal incision is made in the ascending aorta and carried well down into one or two sinuses of Valsalva, as in repair of the localized form. Any intimal ridge above each sinus of Valsalva is excised as described for the localized type. The incision is carried up the ascending aorta, which is usually thick walled and has a small lumen, and around onto the aortic arch, then if necessary into the upper descending thoracic aorta (Fig. 47-33, A). Incisions are made across any stenosis present at the origin of the brachiocephalic and left common carotid arteries, and intimal proliferations dissected away. Thickened interna and media is dissected away from the aortic adventitia by endarterectomy (Fig. 47-33, B). A patch of double-velour collagen-coated polyester or PTFE is
Figure 47-31, cont’d  C, Greater symmetry of the repair may be accomplished by a third incision into left coronary sinus of Valsalva just posterior to commissure between right and left sinuses. This incision mobilizes the commissure so that it can move anteriorly to achieve better spacing between commissures of aortic valve and to achieve better configuration of left cusp. Pantaloon patch is attached to adventitia of aorta behind commissure at level of “anulus.” Commissure is attached directly to inside of patch.

Figure 47-31  Repair of supravalvar aortic stenosis by three-patch technique (Brom). A, Aorta is divided above supravalvar stenosing ridge. Three longitudinal incisions are made through the area of stenosis. First is made into middle of noncoronary sinus of Valsalva; second is into left coronary sinus to the right of left coronary ostium; third is into right sinus to the left of right coronary ostium. B, Three triangular patches of autologous pericardium are fashioned for insertion to each incision. Width of patches at the top should restore correct dimensions of the sinutubular junction, or 10% to 15% less than the diameter of the ventriculooaortic junction (“anulus”). These patches are attached to aorta by continuous stitches of fine polypropylene suture. Ends of aorta are reanastomosed.
Figure 47-32  Repair of supravalvar aortic stenosis by sliding aortoplasty (Myers-Waldhausen). A, Aorta is divided above supravalvar ridge. Three incisions are made in proximal aorta through the stenosing ring into sinuses of Valsalva (see Fig. 47-31). Three incisions are made into distal ascending aorta at points corresponding exactly to position of commissures of aortic valve. Ascending aorta is mobilized to allow it to be displaced inferiorly, sliding the flaps of ascending aorta into the incisions in aortic root in “V-Y” fashion. B, Continuous stitch of fine polypropylene suture is started at nadir of each incision in aortic root. Corresponding flap of ascending aorta is attached to edges of incision in aortic sinus by sewing from nadir to top of commissural attachment of aortic valve.

Figure 47-33  Repair of diffuse supravalvar aortic stenosis. A, Operation is performed with hypothermic circulatory arrest. Incision is made in ascending aorta extending deep into noncoronary sinus of Valsalva. It is extended distally into aortic arch or even into proximal descending thoracic aorta. B, Thickened intima and media is dissected away from aortic adventitia by endarterectomy. C, Patch of collagen-coated polyester or polytetrafluoroethylene is used to widen aorta as it is attached to edges of aortotomy.
fashioned to an appropriate size and shape (Fig. 47-33, C). In young patients, an allograft of ascending aorta and arch can be used, as in the Norwood operation. Beginning distally, the patch is sutured into place with continuous 4-0 or 5-0 polypropylene. An ear or projection is fashioned into the patch to go across the orifices of the left common carotid and brachiocephalic arteries. Once the arch reconstruction suture lines are into the ascending aorta proximal to origin of the brachiocephalic artery, CPB is reestablished.

A right-angled cannula is inserted through a purse-string suture into the superior vena cava. The vena cava is occluded between the cannula and the right atrium, the cannula is attached to the arterial tubing, and retrograde cerebral perfusion is begun at about 25 mmHg pressure. When air and blood have been flushed out, perfusion through the systemic arterial cannula is reestablished, air is extruded from beneath the patch graft, and the clamp is repositioned on the ascending aorta just proximal to the brachiocephalic artery. Reconstruction of the ascending aorta is continued into the aortic root, attaching the patch to the edges of the aortotomy. Rewarming is accomplished during reconstruction of the ascending aorta and aortic root.

RESULTS

Early (Hospital) Death

Primary repair of isolated localized congenital supravalvar aortic stenosis has a low hospital mortality. Early risks are greater in patients with diffuse congenital supravalvar aortic stenosis. Sharma and colleagues reported the total experience with operative treatment of supravalvar aortic stenosis at the Texas Heart Institute, an experience that spanned 29 years and involved 73 patients. Twenty-four patients (32%) had isolated localized supravalvar aortic stenosis and were treated by patch aortoplasty. The results were good, with only one death (4%; CL 0.5%-13%).

Time-Related Survival

Late survival is good. In analyses of 30 to 100 patients, 10-year survival after repair was 88% to 98%, with 20-year survival of 60% to 90%. Similar findings in support of the progressive nature of supravalvar stenosis, operation was advisable in patients with localized or diffuse congenital supravalvar aortic stenosis in 75 patients. A single patch in the noncoronary sinus was used in 34 patients, an extended aortoplasty to two sinuses of Valsalva in 35 patients, and three-sinus reconstruction in six patients. Multiple-sinus reconstructions (two or three) resulted in superior hemodynamics (lower gradients) and were associated with fewer reoperations (P = .007). The only independent risk factor for reoperation was type of operation (P < .001): risk was higher when a single sinus repair was used (approximately 50% by 15 years) compared with two-sinus repair (approximately 15% by 15 years). Similar findings in support of multiple-sinus aortoplasty were reported by Kaushal and colleagues.

No long-term data are available for the sliding aortoplasty, but the method may retain more of the elastic properties of the aortic root than other repair methods. However, this technique is not suitable for patients with diffuse disease.

INDICATIONS FOR OPERATION

Operation is advisable in patients with localized or diffuse congenital supravalvar aortic stenosis when peak pressure gradient across the stenosis is 50 mmHg or more. Because of the progressive nature of supravalvar stenosis, operation should be performed without delay at whatever age the criteria for surgery are met. It can be inferred from the experience reported by Sharma and colleagues that about one third of patients have a simple anomaly that can be treated with a simple operation. However, nearly half (45% in Sharma and colleagues’ experience) have a localized form of supravalvar aortic stenosis plus another obstructive lesion of the LV outflow tract that
requires patch aortoplasty plus aortic valvotomy, aortic valve replacement, or subvalvar resection. Therefore, about half of patients with supravalvar aortic stenosis classified as having only localized lesions actually have a complex LV outflow tract anomaly.

Patients with a diffuse form of the defect or with associated cardiac anomalies or infection do less well, with results commensurate with severity and complexity of the defects. Therefore, coexisting diffuse right and left pulmonary arterial stenoses should probably not be approached surgically, because the stenoses usually extend into branches. The possibility of their improvement by percutaneous balloon dilatation\textsuperscript{[12]} and the tendency for their physiologic effect to decrease as patients age indicate that, in general, their presence should not be a contraindication to surgical relief of supravalvar aortic stenosis.

**SPECIAL SITUATIONS AND CONTROVERSIES**

**Choice of Patch Material**

Inserting a patch of prosthetic material or pericardium to enlarge the aortic diameter, combined with resection of the intimal shelf, is a safe and effective procedure.\textsuperscript{[14],[16]} Theoretically, a false aneurysm may develop at the edge of a polyester onlay patch, similar to when a polyester patch is used in repair of coarctation (see “Late Aneurysm Formation” in Section I of Chapter 48). Polyester graft may also stimulate overgrowth of fibrous tissue (pannus). Pericardium is a more desirable material but might be constrictive, although it does not seem to constrict when applied in the aorta. Tanning with a short exposure to glutaraldehyde may reduce the tendency of pericardium to constrict and makes handling easier during the repair. Glutaraldehyde-fixed bovine pericardium may also have a place in this repair if autologous pericardium is not available. PTFE graft may also be useful.

Al-Halees and colleagues reported using autologous pulmonary artery for the patch in an extended aortoplasty.\textsuperscript{[21]} The pulmonary trunk above the valve and below the bifurcation was removed and fashioned to provide a pantaloon-shaped patch for reconstructing two aortic sinuses and extending the aorta after resecting the obstructing rim. They suggested that this patch material would grow with the patient.

Section I: Coarctation of the Aorta

DEFINITION

Coarctation of the aorta is a congenital narrowing of the upper descending thoracic aorta adjacent to the site of attachment of the ductus arteriosus. The aortic lumen may be atretic in the most severe form of this defect, but aortic walls above and below the atresia are in continuity, as distinguished from aortic arch interruption, in which a short distance separates the aortic ends (see Section II). Uncommonly, coarctation occurs more proximally, between the left common carotid and subclavian arteries. Occasional examples of coarctation of the lower thoracic and abdominal aorta are not considered in this chapter.

Coarctation with or without patent ductus arteriosus but without other major associated cardiac anomalies is termed primary, pure, or isolated coarctation.

HISTORICAL NOTE

Morgagni is credited in 1760 with the first description of an aortic coarctation found at autopsy, and Paris some 30 years later was the first to fully describe its pathologic features. In 1903, Bonnett suggested dividing the lesion into adult (postductal) and infantile (preductal) types, a classification that has tended to persist despite its inaccuracy. Regardless of age at presentation, essentially all coarctations are periductal. By 1928, Abbott was able to review 200 autopsy cases in individuals older than 2 years of age.11 The natural history of this age group was further elucidated in a collective review of 104 autopsy cases between 1928 and 1946 by Reifenstein, Levine, and Gross.14 That coarctation was frequently a cause of death in infancy was not appreciated in these early reports; in the 1950s this aspect was adequately documented.59,61

Animal experiments designed to develop surgical treatment were published in 1944 by Blalock and Park.525 Their procedure involved turndown of the divided left subclavian artery onto the aorta, a technique they recognized would not provide complete relief. Experiments involving excision and end-to-end anastomosis were commenced in 1938 by Gross and Hufnagel.63 In their classic article published in 1945, they described the technique of end-to-end anastomosis, including the method of suturing and the design of appropriate clamps.63 They also noted that hindquarter paralysis occurring in some of their experimental animals was unlikely to be a problem in humans because of collateral circulation. It seemed to be prevented “by packing the entire back of the animal in ice.” They predicted use of aortic allografts when end-to-end anastomosis was not practical.

The first coarctation repair in a patient was performed by Crafoord and Nylin in October 1944.24 Gross’s first patient was operated on in June 1945.61 The procedure was rapidly adopted worldwide. Thus, Clagett in 1948 was able to report the first 21 patients operated on at the Mayo Clinic.6 In
eight of these, end-to-end anastomosis was not considered wise, and Blalock’s left subclavian turnaround operation was performed instead. Extending the operation to infants began in 1950 when Burford attempted unsuccessfully to reconstruct an infant aorta using an arterial graft. A successful end-to-end anastomosis in an infant was reported by Lynxwiler and colleagues in 1951 and by Kirklin and colleagues at the Mayo Clinic in a 10-week-old infant in 1952. Mustard and colleagues reported a successful result in a 12-day-old infant in 1953. Repair of coarctation in neonates became more successful after documentation in 1975 to 1977 of the favorable effect of prostaglandin E₁ (PGE₁) in these sick small babies, achieved by maintaining patency of the ductus arteriosus until time of repair.

Subsequent modifications of surgical technique included use of prosthetic onlay grafts across the coarctation site or of a simple vertical incision and its transverse closure by Vorsschulte in 1957 and subclavian patch aortoplasty by Waldhausen and Nahrwold in 1966. Use of a prosthetic tube graft as an alternative to the allograft, which was preferred by Gross, was reported by Morris, Cooley, DeBakey, and Crawford in 1960.

**MORPHOLOGY AND MORPHOGENESIS**

Coarctation

Coarctations vary in severity. When stenosis is localized, the lumen must be reduced in cross-sectional area by more than about 50% before there is a hemodynamically important pressure gradient across it, but longer tubular coarctations may be hemodynamically important with lesser narrowing.

Thirty-three percent of autopsy specimens (patients aged 2 years to adulthood) examined prior to the era in which operation was available show moderate luminal narrowing, 42% severe (pinhole) stenosis, and 25% luminal atresia. Occasionally the adult aorta may be redundant and severely kinked opposite the ligamentum arteriosum, without any pressure gradient; this is called a pseudocoarctation lesion.

The localized morphology of classic coarctation is a shelf, projection, or infolding of the aortic media into the lumen. It is most prominent in that portion of the circumference opposite the ductus arteriosus (the posterior and leftward wall). This inward projection is present also on anterior and posterior walls but absent on the ductal side (inferior or rightward wall). The shelf is usually marked externally by a localized indentation or waisting of the left aortic wall as if a string had been placed around it, pulling the aorta toward the ductus (Figs. 48-1 and 48-2). External narrowing may be absent in the young infant. The aorta beyond the narrowing usually shows poststenotic dilatation, and paradoxically the wall beyond the stricture is usually thicker than that just proximal to it where the pressure is higher. The localized shelf or curtain of media and intima lies adjacent to the ductus arteriosus in utero and to the ligamentum arteriosum if the ductus closes. The shelf may be preductal or postductal but is usually periductal. Hutchins pointed out that the histologic features of this aortic media infolding are identical to those seen at a branch point of the normal aorta.

In addition to infolding of aortic media, there is usually a localized ridge of intimal hypertrophy (intimal veil) that extends the shelf circumferentially and further narrows the lumen. This, and perhaps other portions of the coarctation area, consists of ductal tissue. It forms a sling that completely surrounds the periductal aorta, which may progressively proliferate after birth and cause restenoses after repair of coarctation in neonates and young infants. It is well documented that use of PGE₁ can result in symptomatic relief of a critical coarctation in some young infants by relaxing the coarctation site without reopening the ductus.

Rodbard has presented experimental and theoretical evidence that lowering of lateral pressure on the aortic wall secondary to the increase in velocity that occurs across a site of narrowing (according to the Bernoulli principle) allows the intimal cells to multiply until probe patency is reached. Resistance to flow across this stenosis then lowers the velocity so that ingrowth usually stops.

Rudolph and colleagues postulated that prevalence and type of coarctation are related to fetal flow patterns through the ductus and aorta. These investigators have shown that flow through that portion of the arch between origins of the left common carotid and left subclavian arteries in the normal fetal lamb is approximately half that across the ductus, explaining the normally smaller diameter of the arch compared with the ascending and descending aorta in the normal human newborn. A localized shelf opposite the ductus may...
result from a reorientation of the angle at which the ductus meets the aorta, which results in abnormal fetal flow patterns in some types of cardiac anomalies. The tendency for a shelf to develop is present when ductal flow is increased more than usual relative to isthmus flow; for example, with a ventricular septal defect (VSD). However, intrauterine events that account for the relatively frequent association of coarctation with lesions that produce left-to-right shunts postpartum are not fully identified.

Coarctation, as well as isthmus hypoplasia, is more common than usual when ascending aorta flow is diminished during fetal life (and ductal flow is relatively increased) by lesions such as aortic stenosis or atresia (see Chapters 47 and 49), and mitral stenosis or regurgitation (see Chapter 50). Conversely, prevalence of coarctation is severely reduced and size of the isthmus increased when pulmonary flow and thus right-to-left ductal flow is decreased by lesions such as pulmonary stenosis or atresia, tetralogy of Fallot, and tricuspid atresia. Coarctation is uncommon when the aortic arch is right sided, presumably because of alteration of ductal and isthmus flow patterns in this situation.

Distal Aortic Arch Narrowing

Narrowing of the isthmus—the segment of aorta between a discrete coarctation and the left subclavian artery—commonly exists with coarctation. Narrowing of the distal aortic arch between the left subclavian and left common carotid arteries also coexists commonly, particularly in neonates and infants. This narrowing appears in some cases to be a transient finding related to prenatal flow pattern (excessive ductal flow extending proximally in the aorta and out the left subclavian artery), which reduces flow in the distal aortic arch between the left subclavian and left common carotid arteries (PDA). Large left vertebral artery arises separately from arch proximal to left subclavian artery (LSCA). This neonate also had perimembranous and muscular ventricular septal defects and mild mitral valve hypoplasia. Key: Asc Ao, Ascending aorta; Desc Ao, descending aorta; PT, pulmonary trunk; RCC, right common carotid; RSC, right subclavian artery.

Figure 48-3 Autopsy specimen from 5-day-old neonate with coarctation, demonstrating tubular hypoplasia of aortic arch between left common carotid artery (LCC) and patent ductus arteriosus (PDA). Large left vertebral artery arises separately from arch proximal to left subclavian artery (LSCA). This neonate also had perimembranous and muscular ventricular septal defects and mild mitral valve hypoplasia. Key: Asc Ao, Ascending aorta; Desc Ao, descending aorta; PT, pulmonary trunk; RCC, right common carotid; RSC, right subclavian artery.
Collateral Circulation

Collateral circulation between aorta proximal to the coarctation and that distal to it is one of the striking features of coarctation. When well developed, it is responsible for some of the classic signs of the malformation, such as parascapular pulsations and rib notching. It is usually present to some extent in newborns but increases in size and extensiveness as the patient ages (Fig. 48-4).

Inflow into the collateral circulation is widespread, but is primarily from branches of both subclavian arteries, particularly internal thoracic, vertebral, costocervical, and thyrocervical trunks. Outflow from the collateral system is primarily into the upper descending thoracic aorta. The largest vessels participating in this outflow are usually the first two pairs of intercostal arteries distal to the coarctation. These are the third and fourth intercostal arteries, and they are greatly enlarged by the large reversed flow (outflow from collateral circulation). This reversed flow into the aorta can be documented by magnetic resonance imaging (MRI) and has been demonstrated at operation by directional Doppler velocity detector probes. Flow returns to a normal direction immediately after coarctation repair. Only the intercostals carrying this large reversed flow are sufficiently enlarged to participate in this outflow.

Degenerative changes occur in the peripheral arterial vasculature proximal to the coarctation, and these changes persist after coarctation repair and can be identified in children. Surrogate markers of arteriosclerosis, such as impaired flow-mediated vasodilatation and increased intima media thickness, were apparent in a study group with a mean age of 12 years.

The abnormalities extend out to all major arteries supplied by the aorta proximal to the coarctation.

These abnormalities may be primary ones that have developed in utero. Coarctation has been documented by fetal echocardiography in utero as early as 21 weeks of gestation, but it likely exists much earlier. Hypoplasia of the isthmus and, in some patients at least, the distal aortic arch develops during intrauterine development. It is hypothesized that either the coarctation was present very early in development and the hypoplasia is secondary, or the hypoplasia is related to a primary aortic wall abnormality rather than to the coarctation. Or the hypoplasia and coarctation are a result of altered patterns of blood flow caused by intracardiac abnormalities that lead to decreased flow to the arch and increased flow to the ductus during fetal development.

Degenerative changes occur in the peripheral arterial vasculature proximal to the coarctation, and these changes persist after coarctation repair and can be identified in children. Surrogate markers of arteriosclerosis, such as impaired flow-mediated vasodilatation and increased intima media thickness, were apparent in a study group with a mean age of 12 years.

Figure 48-4 Major collateral channels in coarctation of the aorta. (From Edwards and colleagues.)
produce rib notching, which explains lack of notching of the first and second ribs, whose intercostals arise above the coarctation. The lower intercostal arteries provide less outflow from the collateral circulation, as do the inferior epigastric artery and other branches of the abdominal aorta.

Collateral circulation and its clinical manifestations are altered by anatomic variations associated with classic coarctation. Associated stenosis at the origin of the left subclavian artery excludes this artery as an important source of inflow into the collateral circulation; thus, rib notching occurs only on the right side. When the right subclavian artery arises as the fourth aortic branch (see Morphology in Section I of Chapter 51) and distal to the coarctation, it does not serve as a source of inflow, and rib notching occurs only on the left side.

Aneurysm Formation

Enlarged, tortuous third and fourth intercostal arteries may become aneurysmal, but this is rare before about age 10 years. Resulting thin-walled aneurysms are usually saccular and are most likely to occur at the aortic origin of intercostal arteries. This is a weak point of surgical importance; if an enlarged intercostal artery must be ligated, the ligation should be placed a few millimeters beyond its aortic origin.

The aorta itself may become aneurysmal adjacent to the site of maximal narrowing as a result of hemodynamic effects, aortic dissection, or mycotic aneurysm. This is uncommon in young children. Prevalence of aneurysm is about 10% by the end of the second decade of life, 20% by the end of the third decade, and probably even higher in older patients.

Coronary Arteries

Left ventricular hypertrophy occurring in untreated patients is accompanied by histologic changes in coronary arteries. In young patients, nonarteriosclerotic lesions are conspicuous in the intimal layer. These consist of degenerative and proliferative changes of the elastic fibers and excess collagens tissue. The media thickens to about twice normal with a rich elastic fiber network and often hyaline changes. Mean total area of the coronary arteries is increased, so they have greater than normal capacity, presumably in response to increased metabolic requirements of the left ventricle. As a result of prolonged hypertension, arteriosclerotic changes are apt to occur more often and at a younger age. In adolescents and young adults, reduced myocardial perfusion reserve is apparent.

Atria

In newborn infants it is common for the “valve” of the foramen ovale to be prolapsed, causing left-to-right shunting. This prolapse often resolves after coarctation repair. A true secundum atrial septal defect (ASD) may also occur with coarctation. Moderate to large ASDs appear to show the same tendency to close when coarctation is present and when it is not. In about 10% of patients with ASD, however, intractable heart failure will develop in infancy following coarctation repair, requiring ASD closure. The best predictor of development of heart failure when ASD coexists with coarctation is small mitral valve diameter, not the size of the ASD itself.

Left Ventricle

Left ventricular hypertrophy without volume increase is present in most patients with coarctation within a few days of birth. This progresses as the patient ages and may be aggravated by associated cardiac anomalies.

The left ventricular outflow tract may be abnormal in patients with arch obstruction, particularly when a VSD coexists. The left ventricular papillary muscles may be abnormally positioned, typically with a reduced interpapillary distance.

Aortic Valve

A bicuspid aortic valve is common, although its exact prevalence is uncertain. In two autopsy series, it was 46% and 27%, with an additional 6% and 7%, respectively, with congenital valvar stenosis. Tawes and colleagues report that among 250 living children with long-term follow-up, 32 (13%) had clinical evidence of aortic valve disease (mainly stenosis but also regurgitation). When aortic regurgitation appears in coarctation, it is usually based on a bicuspid aortic valve combined with persistent hypertension. Bicuspid aortic valve is known to be associated with dilatation of the ascending aorta. In one study, presence of coarctation in this setting was not associated with increased magnitude or rate of ascending aortic dilatation. Another study indicates that patients with coarctation and bicuspid aortic valve have greater aortic root dilatation than those with coarctation and tricuspid aortic valves. In the presurgical era, aortic dissection was noted to occur in 19% of coarctation patients without bicuspid aortic valve, but in 50% of those with bicuspid aortic valve.

Intracranial Aneurysm

Coarctation and berry-type intracranial aneurysm coexist in some patients. Some instances of sudden death in untreated as well as treated coarctation are from rupture of the intracranial aneurysm. That coarctation, bicuspid aortic valve, and intracranial aneurysm are associated leads to the inference that coarctation is only one manifestation of a diffuse arteriopathy.

Coarctation as Part of Hypoplastic Left Heart Physiology

Coarctation (with or without a patent ductus arteriosus, and with or without hypoplasia of the isthmus or distal aortic arch between left common carotid and left subclavian arteries) sometimes coexists with anomalies that also affect left ventricular function and structure directly (see Morphogenesis and Morphology in Chapter 49). This is particularly a problem in symptomatic neonates and infants. These anomalies include:

- Hypoplasia of ascending aorta
- Supravalvar, valvar, subvalvar, and anular aortic stenosis or hypoplasia
- Aortic atresia
- Left ventricular hypoplasia or hypertrophy
- Endocardial fibroelastosis
Two congenital anomalies affecting left ventricular outflow

Coexisting Cardiac Anomalies

When coarctation first presents in older children and young adults (as it did in the early years of cardiac surgery, but uncommonly now), coexisting cardiac anomalies are uncommon. When it presents in neonates, and to some extent in infants, coexisting cardiac anomalies are common (Table 48-2). These associations are explained by the fact that survival beyond infancy is much less likely when coexisting anomalies are present; thus, long-term survivors tend to have simple lesions. Because in the current era most coarctations are diagnosed in neonates or infants, it follows that prevalence of associated anomalies found in neonates with coarctation closely approximates true prevalence.

Patent ductus arteriosus is present in almost 100% of neonates and in most infants with a preductal type of coarctation.26 This is considered part of isolated coarctation rather than an additional anomaly. Tubular hypoplasia of the distal aortic arch is also considered to be part of the anomaly of coarctation rather than an associated anomaly. ASD is not considered as an additional anomaly unless large enough to need closure. This excludes the fairly numerous examples of infants presenting with a left-to-right shunt through a stretched patent foramen ovale that may subsequently close. Anomalous right subclavian artery occurs in about 1% of cases of coarctation and may be proximal or distal to the coarctation.26 This variation does not appear to affect the collateral circulation that develops in any clinically significant way.26

Approximately 82% of individuals born with coarctation have it as an isolated lesion (with or without continuing patency of the ductus arteriosus). About 11% have an important coexisting VSD, and approximately 7% have other important coexisting cardiac anomalies. These prevalences are different from those in patients who become symptomatic during neonatal life or infancy and require early intervention (see Table 48-2).

Prevalence of isolated coarctation in patients with an otherwise normal heart appears to be about 40 per 100,000 live births. Persons with pulmonary stenosis or atresia, tetralogy of Fallot, and tricuspid atresia with concordant ventriculoarterial connection have a prevalence of coarctation close to 0 per 100,000. Patients with aortic stenosis and mitral stenosis or regurgitation have a considerably higher prevalence than patients with otherwise normal hearts. Patients with VSD and other lesions such as transposition, double outlet right ventricle, truncus arteriosus, atrioventricular septal defect, and single ventricle who have associated VSD also appear to have a relatively high prevalence of coexisting coarctation. This may relate to altered blood flow patterns within the heart that result in less flow across the aortic isthmus during fetal development.
CLINICAL FEATURES AND DIAGNOSTIC CRITERIA

Mode of presentation and diagnostic criteria depend to a considerable degree on prevalence and severity of coexisting cardiac anomalies, and thus on the patient’s age at presentation.

Neonates and Infants

Severe heart failure in a neonate or infant requires that coarctation be considered, especially when a favorable response to medical treatment does not occur promptly. It may be unsuspected in complex lesions when the baby is in extremis, because even when the ductus is closed, a large left-to-right shunt proximal to the aorta can decrease manifestation of hypertension in the arms. Severe proximal obstructing lesions (aortic or mitral stenosis) can have a similar effect. Control of heart failure and tachycardia in these situations frequently unmask differential pressures in upper and lower extremities as cardiac output improves.

Signs and symptoms of coarctation presenting in the neonate are those of heart failure. After a variable period of well-being, tachypnea, feeding problems, and sweating develop. On examination, there is a gallop rhythm and a systolic murmur along the left sternal edge and usually posteriorly over the coarctation site. Femoral pulses are absent or reduced in volume and delayed compared with radial or brachial pulses, although in small, sick infants with tachycardia, pulse delay may be difficult to detect. Blood pressure is higher in the arms than in the legs (by >20 mmHg). Delay in onset of heart failure is probably related, at least in isolated coarctation, to the variable time it takes for the ductus to close. Ductal closure usually commences at the pulmonary end, and generally it is not until the aortic end closes that the periductal aortic shelf produces severe obstruction (see Morphology earlier in this section). Thus, femoral pulses can be normal at birth but absent at 1 week.

When the ductus arteriosus remains widely patent and a severe coarctation lies proximal to it (predisual coarctation), there may be a right-to-left shunt into the descending aorta and, classically, cyanosis of the toes and sometimes the left hand while the right hand and lips remain pink (differential cyanosis). Femoral pulses are normal, and there is no ductus murmur. In fact, differential cyanosis is uncommon, either because flow through the coarctation is large or because PO₂ of the pulmonary artery blood is high from an additional intracardiac shunt through a VSD, an interatrial communication, or both. Moreover, despite presence of a severe coarctation proximal to a patent ductus arteriosus, systemic vascular resistance in the lower compartment usually exceeds pulmonary vascular resistance, so the ductal shunt is left to right or bidirectional.

In infancy, hypertension may be present but is seldom severe, and a collateral circulation is not palpable, although it is usually present angiographically (Fig. 48-5). Marked cardiomegaly is almost invariable on chest radiograph. The electrocardiogram (ECG) usually shows right ventricular hypertrophy in the first few months of life, even with isolated coarctation. About two thirds of infants operated on in the first year of life have right ventricular hypertrophy or combined hypertrophy, and fewer than 25% have pure left ventricular hypertrophy.

Left-to-right shunt through a stretched patent foramen ovale is common in infants with severe coarctation in heart failure. When heart failure disappears, so does the atrial shunt. Congenital aortic stenosis may not be evident clinically (or by catheter withdrawal pressure differential) in infancy, and yet it may be severe enough to require surgical relief at age 2 to 5 years, particularly when it is subvalvar (see Section II in Chapter 47).

Childhood (Age 1 to 14 Years)

Almost all patients who first present at age 1 to 14 years are asymptomatic unless they have important associated anomalies. Tawes and colleagues noted that children with associated anomalies may present in heart failure up to age 3 years, and Patel and colleagues noted heart failure in 7 of 65 children (11%) age 1 to 14 years. Subarachnoid hemorrhage from rupture of a berry aneurysm occurs occasionally but is rare in children younger than 7 years, and spontaneous paresis or paraplegia caused by dilated intercostal arteries compressing the anterior spinal artery or by epidural hemorrhage is even less common. Hypertension occurs in almost 90% of patients.

The chest radiograph shows cardiomegaly in 33% and rib notching in about 15% (Fig. 48-6), but this feature does not occur before age 3 years. ECG shows predominantly left ventricular hypertrophy, with right ventricular hypertrophy present only when there is pulmonary hypertension with elevated pulmonary vascular resistance. ECG is normal in about one third of children.

Adolescence (Beyond 14 Years) and Adult Life

Many adolescent and young adult patients remain asymptomatic and are diagnosed at routine examination because femoral pulses are noted to be absent or reduced and delayed in the presence of a cardiac murmur, hypertension, or an abnormal chest radiograph. Hypertension is common and more severe than in younger patients, and heart failure may occur after about age 30 years. Heart failure is preceded by effort dyspnea, cardiomegaly, and important left ventricular hypertrophy on ECG. Headache, nose bleeds, fatigue, and calf claudication occasionally occur. Collaterals are usually palpable or audible posteriorly. Radiographic findings include a “figure-3” sign in the left upper mediastinal shadow (Fig. 48-7) and, almost always, rib notching. (Absence of rib notching in the right chest suggests an anomalous origin of the right subclavian artery and in the left chest a stenosis of the left subclavian artery origin.)

Associated Syndromes

There is an association between Turner syndrome and von Recklinghausen disease and coarctation. Rarely, patients with coarctation have Noonan syndrome or congenital rubella.

Special Diagnostic Methods

Two-dimensional echocardiography can visualize coarctation in neonates and small infants (Fig. 48-8) and is usually the definitive study. Associated intracardiac defects can also be defined in detail. Severity of coarctation can often be assessed...
Figure 48-5  Cineangiograms in left anterior oblique view with injection into left ventricle of a severe coarctation 5 mm in length in a 7-week-old infant without other associated anomalies. **A**, Aortic arch and branches are outlined proximal to coarctation, but distal aorta is not opacified. Collateral vessels are visible. **B**, Dense collateral network is visible in this later frame, with contrast in descending aorta below coarctation. **C**, Descending aorta is well outlined, most of its filling coming from collaterals, although a tiny lumen about 5 mm long could be identified connecting the two ends. Key: LCA, Left coronary artery.
by characterizing intracardiac and great artery blood flow patterns using color Doppler signaling. Fetopatologically, measurements of the z value of the aortic isthmus and the isthmus-to-ductus ratio are sensitive indicators of postnatal coarctation.\textsuperscript{M15} Outside infancy, echocardiography may still be helpful but is usually not definitive. In moderate or mild coarctation, presence of an open ductus may obscure a coarctation at echocardiographic examination. This is due partly to altered blood flow patterns associated with the patent ductus, but more importantly to the fact that the coarctation itself may evolve as the ductus closes.

MRI and computed tomography (CT) are currently the imaging modalities of choice for coarctation in patients beyond infancy.\textsuperscript{B15,C11,G10,R11,R18,S6,S33} Excellent detailed imaging of pertinent vascular structures can be obtained, often exceeding the detail seen with aortography (Fig. 48-9). Three-dimensional rendering can be particularly informative (Fig. 48-10). Post-surgical changes also can be defined in detail (Fig. 48-11). Hemodynamic data can be assessed by MRI and may be particularly useful in older patients with well-developed collaterals, or in patients with restenosis, in whom there may be little or no gradient across the

**Figure 48-6** Portion of chest radiograph showing severe rib notch-
ing in patient with coarctation of the aorta. Note that changes are not present in first two ribs and are typically less severe below the fifth rib.

**Figure 48-7** Radiographic studies in patient with coarctation, demonstrating classic figure-3 sign present in some patients with coarctation of the aorta. **A**, Chest radiograph. Upper convexity of sign is formed by the aortic isthmus and left subclavian artery, lower convexity by the upper descending aorta at site of poststenotic dilatation. **B**, Barium esophagogram. Note how the two shadows overlap. Isthmus and descending aorta produce upper and lower indentations on leftward margin of barium-filled esophagus.
Figure 48-8  Echocardiographic images of neonatal aortic coarctation. A, Parasternal view showing small-diameter ascending aorta with origins of brachiocephalic and left carotid arteries, severe hypoplasia of distal aortic arch between left carotid and subclavian arteries, discrete coarctation, and descending aorta. B, Color imaging showing discrete narrowing at coarctation site.

Continued
Figure 48-8, cont’d  C. Image details hypoplasia of distal arch and isthmus, and a large ductus arteriosus entering descending aorta. A discrete coarctation, which was also present in this case, is not seen well in this image. Key: AA, Ascending aorta; AI, aortic isthmus; BA, brachiocephalic artery; CO, coarctation; DA, distal aortic arch; DES, descending aorta; LCA, left carotid artery; LSCA, left subclavian artery; PDA, patent ductus arteriosus.
