Periods of Susceptibility to Teratogenesis

- **0–2 weeks**: Not sensitive usually. High rate of lethality may occur.
- **3–8 weeks**: Period of greatest sensitivity. Each organ system will also have a period of peak sensitivity.

**Risk of Birth Defects Being Induced**

![Graph showing risk of birth defects over weeks of gestation]
Embryonic Development in Days

Day 1  Fertilization
Day 2  Two-cell stage
Day 3  Morula
Day 4  Early blastocyst

Day 5  Bilaminar disc forms
Day 6  Trophoblast with lacunae
Day 7  Early blastocyst in uterus
Day 8  Bilaminar disc forms

Day 9  Trophoblast with lacunae
Day 10  Embryo in uterus
Day 11  Corpus luteum of pregnancy
Day 12  Compress layer

Day 13  Embryo migrates
Day 14  Placenta forms
Day 15  Trophoblast lacunae
Day 16  Bilaminar disc

Day 17  Embryo in uterus
Day 18  Bilaminar disc forms
Day 19  Two-celled stage
Day 20  Embryo in uterus

Day 21  Embryo in uterus
Day 22  Bilaminar disc forms
Day 23  Trophoblast with lacunae
Day 24  Early blastocyst

Day 25  Embryo in uterus
Day 26  Bilaminar disc forms
Day 27  Trophoblast with lacunae
Day 28  Early blastocyst

Day 29  Arm and leg buds
Day 30  Developing face
Day 31  Gut development
Day 32  Embryo in chorionic cavity

Day 33  Bilaminar disc forms
Day 34  Trophoblast with lacunae
Day 35  Early blastocyst
Day 36  Embryo in uterus

Day 37  Arm and leg buds
Day 38  Developing face
Day 39  Gut development
Day 40  Muscle development

Day 41  Bilaminar disc forms
Day 42  Trophoblast with lacunae
Day 43  Early blastocyst
Day 44  Embryo in uterus

Day 45  Bilaminar disc forms
Day 46  Trophoblast with lacunae
Day 47  Early blastocyst

Day 118-119 Atrial septum formed

Day 120-121 Digit formation
Dedication

For each and every child

Special thanks to Drs. David Weaver and Roger Stevenson for all of their help with the clinical material, including providing many of the clinical figures.
Every student will be affected by pregnancy, either their mother’s, because what happens in the womb does not necessarily stay in the womb, or by someone else’s. As health care professionals, you will often encounter women of childbearing age who may be pregnant, or you may have children of your own, or maybe it is a friend who is pregnant. In any case, pregnancy and childbirth are relevant to all of us, and unfortunately, these processes often culminate in negative outcomes. For example, 50% of all embryos are spontaneously aborted. Furthermore, prematurity and birth defects are the leading causes of infant mortality and major contributors to disabilities. Fortunately, new strategies can improve pregnancy outcomes, and health care professionals have a major role to play in implementing these initiatives. However, a basic knowledge of embryology is essential to the success of these strategies, and with this knowledge, every health care professional can play a role in providing healthier babies.

To accomplish its goal of providing a basic understanding of embryology and its clinical relevance, Langman’s Medical Embryology retains its unique approach of combining an economy of text with excellent diagrams and clinical images. It stresses the clinical importance of the subject by providing numerous clinical examples that result from abnormal embryological events. The following pedagogic features and updates in the 13th edition help facilitate student learning.

**Organization of Material:** Langman’s Medical Embryology is organized into two parts. The first provides an overview of early development from gametogenesis through the embryonic period. Also included in this section are chapters on placental and fetal development as well as prenatal diagnosis and birth defects. The second part of the text provides a description of the fundamental processes of embryogenesis for each organ system.

**Clinical Correlates:** In addition to describing normal events, each chapter contains clinical correlates that appear in highlighted boxes. This material is designed to demonstrate the clinical relevance of embryology and the importance of understanding key developmental events as a first step to improving birth outcomes and having healthier babies. Clinical pictures and case descriptions are used to provide this information, and this material has been increased and updated in this edition.

**Genetics:** Because of the increasingly important role of genetics and molecular biology in embryology and the study of birth defects, basic genetic and molecular principles are discussed. The first chapter provides an introduction to molecular processes, defines terms commonly used in genetics and molecular biology, and describes key pathways used in embryonic development. Then, throughout the text, major signaling pathways and genes that regulate embryological development are identified and discussed.

**Extensive Art Program:** Nearly 100 new illustrations have been added to enhance understanding of the text, including four-color line drawings, scanning electron micrographs, and clinical pictures. Additional color pictures of clinical cases have been added to enhance the clinical correlate sections.

**Summary:** At the end of each chapter is a summary that serves as a concise review of the key points described in detail throughout the chapter. Key terms are highlighted and defined in these summaries.

**Problems to Solve:** Problems related to the key elements of each chapter are provided to assist the students in assessing their understanding of the material. Detailed answers are provided in an appendix at the back of the book.

**Glossary:** A glossary of key terms is located in the back of the book and has been expanded extensively.

**thePoint Web site:** This site for students and instructors provides the full text of the book and its figures online—an interactive question bank of USMLE board-type questions. Teaching aids for instructors will also be provided in the form of an image bank and a series of lectures on the major topics in embryology presented in PowerPoint with accompanying notes.

I hope you find this edition of Langman’s Medical Embryology to be an excellent resource for learning embryology and its clinical significance. Together, the textbook and online site, thePoint, are designed to provide a user-friendly and innovative approach to understanding the subject.

Summary 56

CHAPTER 5 | Third Week of Development: Trilaminar Germ Disc 58
Gastrulation: Formation of Embryonic Mesoderm and Endoderm 58
Formation of the Notochord 58
Establishment of the Body Axes 59
Fate Map Established during Gastrulation 64
Growth of the Embryonic Disc 64
Further Development of the Trophoblast 67
Summary 68

CHAPTER 6 | Third to Eighth Weeks: The Embryonic Period 71
Derivatives of the Ectodermal Germ Layer 71
Derivatives of the Mesodermal Germ Layer 78
Derivatives of the Endodermal Germ Layer 86
Pattern of the Anteroposterior Axis:
Regulation by Homeobox Genes 88
External Appearance during the Second Month 88
Summary 92

CHAPTER 7 | The Gut Tube and the Body Cavities 95
A Tube on Top of a Tube 95
Formation of the Body Cavity 96
Serous Membranes 96
Diaphragm and Thoracic Cavity 100
Formation of the Diaphragm 101
Summary 103

CHAPTER 8 | Third Month to Birth: The Fetus and Placenta 105
Development of the Fetus 105
Fetal Membranes and Placenta 109
Chorion Frondosum and Decidua Basalis 112
Structure of the Placenta 112
Amnion and Umbilical Cord 117
Placental Changes at the End of Pregnancy 118
Amniotic Fluid 118
Fetal Membranes in Twins 120
Parturition (Birth) 120
Summary 125

CHAPTER 9 | Birth Defects and Prenatal Diagnosis 126
Birth Defects 126
Prenatal Diagnosis 136
Fetal Therapy 139
Summary 139

Limb Growth and Development 163
Limb Musculature 166
Summary 174

CHAPTER 13 | Cardiovascular System 175
Establishment and Pattern of the Primary Heart Field 175
Formation and Position of the Heart Tube 177
Formation of the Cardiac Loop 179
Molecular Regulation of Cardiac Development 182
**Placode:** A local thickening in the embryonic ectoderm layer that develops into a sensory organ or ganglion.

**ODE TO A PLACODE**

There once was a flat sheet of cells  
That were stumpy and ugly as hell;  
But one day they arose, stood tall on their toes,  
and declared they were the best cells of all.  

Presumptuously they cried that their lineage was high  
and right proudly they bragged of their codes;  
But soon it was clear, they weren’t like the ear  
and they were nixed in their dreams as placodes.  

Semantics, they screamed, please maintain our dreams,  
but their pleas were unheeded and late;  
And now to this day in repast they must lay  
as a misconstrued, flat neural plate!

INTRODUCTION

Embryology: Clinical Relevance and Historical Perspective

**CLINICAL RELEVANCE**

From a single cell to a baby in 9 months—a developmental process that represents an amazing integration of increasingly complex phenomena. The study of these phenomena is called *embryology*, and the field includes investigations of the molecular, cellular, and structural factors contributing to the formation of an organism. These studies are important because they provide knowledge essential for creating health care strategies for better reproductive outcomes. Thus, our increasingly better understanding of embryology has resulted in new techniques for prenatal diagnoses and treatments; therapeutic procedures to circumvent problems with infertility; and mechanisms to prevent birth defects, the leading cause of infant mortality. These improvements in prenatal and reproductive health care are significant not only for their contributions to improved birth outcomes but also for their long-term effects postnatally. In fact, both our cognitive capacity and our behavioral characteristics are affected by our prenatal experiences, and factors such as maternal smoking, nutrition, stress, diabetes, etc., play a role in our postnatal health. Furthermore, these experiences, in combination with molecular and cellular factors, determine our potential to develop certain adult diseases, such as cancer and cardiovascular disease. Thus, our prenatal development produces many ramifications affecting our health for both the short and long term, making the study of embryology and fetal development an important topic for all health care professionals. Also, with the exception of a few specialties, most physicians and health care workers will have an opportunity to interact with women of childbearing age, creating the potential for these providers to have a major impact on the outcome of these developmental processes and their sequelae.

**A BRIEF HISTORY OF EMBRYOLOGY**

The process of progressing from a single cell through the period of establishing organ primordia (the first 8 weeks of human development) is called the period of *embryogenesis* (sometimes called the period of *organogenesis*); the period from that point on until birth is called the *fetal period*, a time when differentiation continues while the fetus grows and gains weight. Scientific approaches to study embryology have progressed over hundreds of years. Not surprisingly, anatomical approaches dominated early investigations. Observations were made, and these became more sophisticated with advances in optical equipment and dissection techniques. Comparative and evolutionary studies were part of this equation as scientists made comparisons among species and so began to understand the progression of developmental phenomena. Also investigated were offspring with birth defects, and these were compared to organisms with normal developmental patterns. The study of the embryological origins and causes for these birth defects was called *teratology*.

In the 20th century, the field of experimental embryology blossomed. Numerous experiments were devised to trace cells during development to determine their cell lineages. These approaches included observations of transparent embryos from tunicates that contained pigmented cells which could be visualized through a microscope. Later, vital dyes were used to stain living cells to follow their fates. Still later in the 1960s, radioactive labels and autoradiographic techniques were employed. One of the first genetic markers also arose about this time with the creation of chick-quail chimeras. In this approach, quail cells, which have a unique pattern to their heterochromatin distribution around the nucleolus, were grafted into chick embryos at early stages of development. Later, host embryos were
examined histologically, and the fates of the quail cells were determined. Permutations of this approach included development of antibodies specific to quail cell antigens that greatly assisted in the identification of these cells. Monitoring cell fates with these and other techniques provides valuable information about the origins of different organs and tissues.

Grafting experiments also provided the first insights into signaling between tissues. Examples of such experiments included grafting the primitive node from its normal position on the body axis to another and showing that this structure could induce a second body axis. In another example, employing developing limb buds, it was shown that if a piece of tissue from the posterior axial border of one limb was grafted to the anterior border of a second limb, then digits on the host limb would be duplicated as the mirror image of each other. This posterior signaling region was called the **zone of polarizing activity (ZPA)**, and it is now known that the signaling molecule is **SONIC HEDGEHOG (SHH)**.

About this same time (1961), the science of teratology became prominent because of the drug **thalidomide** that was given as an antinauseant and sedative to pregnant women. Unfortunately, the drug caused birth defects, including unique abnormalities of the limbs in which one or more limbs was absent (amelia) or was lacking the long bones such that only a hand or foot was attached to the torso (phocomelia). The association between the drug and birth defects was recognized independently by two clinicians, W. Lenz and W. McBride, and showed that the conceptus was vulnerable to maternal factors that crossed the placenta. Soon, numerous animal models demonstrating an association between environmental factors, drugs, and genes provided further insights between developmental events and the origin of birth defects.

Today, molecular approaches have been added to the list of experimental paradigms used to study normal and abnormal development. Numerous means of identifying cells using reporter genes, fluorescent probes, and other marking techniques have improved our ability to map cell fates. Using other techniques to alter gene expression, such as knockout, knock-in, and antisense technologies, has created new ways to produce abnormal development and allowed the study of a single gene’s function in specific tissues. Thus, the advent of molecular biology has advanced the field of embryology to the next level, and as we decipher the roles of individual genes and their interplay with environmental factors, our understanding of normal and abnormal developmental processes progresses.
PART 1

General Embryology
Molecular biology has opened the doors to new ways to study embryology and to enhance our understanding of normal and abnormal development. Sequencing the human genome, together with creating techniques to investigate gene regulation at many levels of complexity, has taken embryology to the next level. Thus, from the anatomical to the biochemical to the molecular level, the story of embryology has progressed, and each chapter has enhanced our knowledge.

Embryonic development is directed by genomes that contain all of the information required to make an individual. The information is encoded in DNA in sequences called genes that code for proteins. In turn, proteins regulate expression of other genes and act as signal molecules to orchestrate development.

There are approximately 23,000 genes in the human genome, which represents only one-fifth of the number (100,000) predicted prior to completion of the Human Genome Project. Because of various levels of regulation, however, the number of proteins derived from these genes is closer to the original predicted number of genes. What has been disproved is the one gene–one protein hypothesis. Thus, through a variety of mechanisms, a single gene may give rise to many proteins.

Gene expression can be regulated at several levels: (1) Different genes may be transcribed, (2) DNA transcribed from a gene may be selectively processed to regulate which RNAs reach the cytoplasm to become messenger RNAs (mRNAs), (3) mRNAs may be selectively translated, and (4) proteins made from the mRNAs may be differentially modified.

**GENE TRANSCRIPTION**

Genes are contained in a complex of DNA and proteins (mostly histones) called chromatin, and its basic unit of structure is the nucleosome (Fig. 1.1). Each nucleosome is composed of an octamer of histone proteins and approximately 140 base pairs of DNA. Nucleosomes themselves are joined into clusters by binding of DNA existing between nucleosomes (linker DNA) with other histone proteins (H1 histones; Fig. 1.1). Nucleosomes keep the DNA tightly coiled, such that it cannot be transcribed. In this inactive state, chromatin appears as beads of nucleosomes on a string of DNA and is referred to as heterochromatin. For transcription to occur, this DNA must be uncoiled from the beads. In this uncoiled state, chromatin is referred to as euchromatin.

Genes reside within the DNA strand and contain regions called exons, which can be translated into proteins, and introns, which are interspersed between exons and which are not transcribed into proteins (Fig. 1.2). In addition to exons and introns, a typical gene includes the following: a promoter region that binds RNA polymerase for the initiation of transcription; a transcription initiation site; a translation initiation site to designate the first amino acid in the protein; a translation termination codon; and a 3’ untranslated region that includes a sequence...
FIGURE 1.2 Drawing of a “typical” gene showing the promoter region containing the TATA box; exons that contain DNA sequences that are translated into proteins; introns; the transcription initiation site; the translation initiation site that designates the code for the first amino acid in a protein; and the 3’ untranslated region that includes the poly A addition site that participates in stabilizing the mRNA, allows it to exit the nucleus, and permits its translation into a protein.

FIGURE 1.3 Drawing showing binding of RNA polymerase II to the TATA box site of the promoter region of a gene. This binding requires a complex of proteins plus an additional protein called a transcription factor. Transcription factors have their own specific DNA-binding domain and function to regulate gene expression.

(transcribed site) that assists with stabilizing the mRNA, allows it to exit the nucleus, and permits it to be translated into protein (Fig. 1.2). By convention, the 5’ and the 3’ regions of a gene are specified in relation to the RNA transcribed from the gene. Thus, DNA is transcribed from the 5’ to the 3’ end, and the promoter region is upstream from the transcription initiation site (Fig. 1.2). The promoter region, where the RNA polymerase binds, usually contains the sequence TATA, and this site is called the TATA box (Fig. 1.2). In order to bind to this site, however, the polymerase requires additional proteins called transcription factors (Fig. 1.3). Transcription factors also have a specific DNA-binding domain plus a transactivating domain that activates or inhibits transcription of the gene whose promoter or enhancer it has bound. In combination with other proteins, transcription factors activate gene expression by causing the DNA nucleosome complex to unwind, by releasing the polymerase so that it can transcribe the DNA template, and by preventing new nucleosomes from forming.

Enhancers are regulatory elements of DNA that activate utilization of promoters to control their efficiency and the rate of transcription from the promoter. Enhancers can reside anywhere along the DNA strand and do not have to reside close to a promoter. Like promoters, enhancers bind transcription factors (through the transcription factor’s transactivating domain) and are used to regulate the timing of a gene’s expression and its cell-specific location. For example, separate enhancers in a gene can be used to direct the same gene to be expressed in different tissues. The PAX6 transcription factor, which participates in pancreas, eye, and neural tube development, contains three separate enhancers, each of which regulates the gene’s expression in the appropriate tissue. Enhancers act by altering chromatin to expose the promoter or by facilitating binding of the RNA polymerase. Sometimes, enhancers can inhibit transcription and are called silencers. This phenomenon allows a transcription factor to activate one gene while silencing another by binding to different enhancers. Thus, transcription factors themselves have a DNA-binding domain specific to a region of DNA plus a transactivating domain that binds to a promoter or an enhancer and activates or inhibits the gene regulated by these elements.
DNA Methylation Represses Transcription

Methylation of cytosine bases in the promoter regions of genes represses transcription of those genes. Thus, some genes are silenced by this mechanism. For example, one of the X chromosomes in each cell of a female is inactivated (X chromosome inactivation) by this methylation mechanism. Similarly, genes in different types of cells are repressed by methylation, such that muscle cells make muscle proteins (their promoter DNA is mostly unmethylated), but not blood proteins (their DNA is highly methylated). In this manner, each cell can maintain its characteristic differentiated state. DNA methylation is also responsible for genomic imprinting in which only a gene inherited from the father or the mother is expressed, whereas the other gene is silenced. Approximately 40 to 60 human genes are imprinted, and their methylation patterns are established during spermatogenesis and oogenesis. Methylation silences DNA by inhibiting binding of transcription factors or by altering histone binding resulting in stabilization of nucleosomes and tightly coiled DNA that cannot be transcribed.

 OTHER REGULATORS OF GENE EXPRESSION

The initial transcript of a gene is called nuclear RNA (nRNA) or sometimes premessenger RNA. nRNA is longer than mRNA because it contains introns that are removed (spliced out) as the nRNA moves from the nucleus to the cytoplasm. In fact, this splicing process provides a means for cells to produce different proteins from a single gene. For example, by removing different introns, exons are “spliced” in different patterns, a process called alternative splicing (Fig. 1.4). The process is carried out by spliceosomes, which are complexes of small nuclear RNAs (snRNAs) and proteins that recognize specific splice sites at the 5’ or the 3’ ends of the nRNA. Proteins derived from the same gene are called splicing isoforms (also called splice variants or alternative splice forms), and these afford the opportunity for different cells to use the same gene to make proteins specific for that cell type. For example, isoforms of the WTI gene have different functions in gonadal versus kidney development.

Even after a protein is made (translated), there may be post-translational modifications that affect its function. For example, some proteins have to be cleaved to become active, or they might have to be phosphorylated. Others need to combine with other proteins or be released from sequestered sites or be targeted to specific cell regions. Thus, there are many regulatory levels for synthesizing and activating proteins, such that although only 23,000 genes exist, the potential number of proteins that can be synthesized is probably closer to five times the number of genes.

INDUCTION AND ORGAN FORMATION

Organs are formed by interactions between cells and tissues. Most often, one group of cells or tissues causes another set of cells or tissues to

![FIGURE 1.4](image.png)

**FIGURE 1.4** Drawing of a hypothetical gene illustrating the process of alternative splicing to form different proteins from the same gene. Spliceosomes recognize specific sites on the initial transcript of nRNA from a gene. Based on these sites, different introns are “spliced out” to create more than one protein from a single gene. Proteins derived from the same gene are called splicing isoforms.
change their fate, a process called induction. In each such interaction, one cell type or tissue is the inducer that produces a signal, and one is the responder to that signal. The capacity to respond to such a signal is called competence, and competence requires activation of the responding tissue by a competence factor. Many inductive interactions occur between epithelial and mesenchymal cells and are called epithelial–mesenchymal interactions (Fig. 1.5). Epithelial cells are joined together in tubes or sheets, whereas mesenchymal cells are fibroblastic in appearance and dispersed in extracellular matrices (Fig. 1.5).

Examples of epithelial–mesenchymal interactions include the following: gut endoderm and surrounding mesenchyme to produce gut-derived organs, including the liver and pancreas; limb mesenchyme with overlying ectoderm (epithelium) to produce limb outgrowth and differentiation; and endoderm of the ureteric bud and mesenchyme from the metanephric blastema to produce nephrons in the kidney. Inductive interactions can also occur between two epithelial tissues, such as induction of the lens by epithelium of the optic cup. Although an initial signal by the inducer to the responder initiates the inductive event, crosstalk between the two tissues or cell types is essential for differentiation to continue (Fig. 1.5, arrows).

**CELL SIGNALING**

Cell-to-cell signaling is essential for induction, for conferment of competency to respond, and for crosstalk between inducing and responding cells. These lines of communication are established by paracrine interactions, whereby proteins synthesized by one cell diffuse over short distances to interact with other cells, or by juxtacrine interactions, which do not involve diffusable proteins. The diffusible proteins responsible for paracrine signaling are called paracrine factors or growth and differentiation factors (GDFs).

**Signal Transduction Pathways**

**Paracrine Signaling**

Paracrine factors act by signal transduction pathways either by activating a pathway directly or by blocking the activity of an inhibitor of a pathway (inhibiting an inhibitor, as is the case with hedgehog signaling). Signal transduction pathways include a signaling molecule (the ligand) and a receptor (Fig. 1.6). The receptor spans the cell membrane and has an extracellular domain (the ligand-binding region), a transmembrane domain, and a cytoplasmic domain. When a ligand binds its receptor, it induces a conformational change in the receptor that activates its cytoplasmic domain. Usually, the result of this activation is to confer enzymatic activity to the receptor, and most often, this activity is a kinase that can phosphorylate other proteins using ATP as a substrate. In turn, phosphorylation activates these proteins to phosphorylate additional proteins, and thus a cascade of protein interactions is established that ultimately activates a transcription factor. This transcription factor then activates or inhibits gene expression. The pathways are numerous and complex and in some cases are characterized by one protein inhibiting another that in turn activates another protein (much like the situation with hedgehog signaling).

**Juxtacrine Signaling**

Juxtacrine signaling is mediated through signal transduction pathways as well but does not involve diffusable factors. Instead, there are three ways juxtacrine signaling occurs: (1) A protein on one cell surface interacts with a receptor on an adjacent cell in a process analogous to paracrine signaling (Fig. 1.6). The Notch pathway represents an example of this type of signaling (see “Key Signaling Pathways for Development,” p. 8). (2) Ligands in the extracellular matrix secreted by one cell interact with their receptors on neighboring cells. The extracellular matrix is the milieu in which cells reside. This milieu consists
of large molecules secreted by cells including collagen, proteoglycans (chondroitin sulfates, hyaluronic acid, etc.), and glycoproteins, such as fibronectin and laminin. These molecules provide a substrate for cells on which they can anchor or migrate. For example, laminin and type IV collagen are components of the basal lamina for epithelial cell attachment, and fibronectin molecules form scaffolds for cell migration. Receptors that link extracellular molecules such as fibronectin and laminin to cells are called integrins. These receptors “integrate” matrix molecules with a cell’s cytoskeletal machinery (e.g., actin microfilaments), thereby creating the ability to migrate along matrix scaffolding by using contractile proteins, such as actin. Also, integrins can induce gene expression and regulate differentiation as in the case of chondrocytes that must be linked to the matrix to form cartilage. (3) There is direct transmission of signals from one cell to another by gap junctions. These junctions occur as channels between cells through which small molecules and ions can pass. Such communication is important in tightly connected cells like epithelia of the gut and neural tube because they allow these cells to act in concert. The junctions themselves are made of connexin proteins that form a channel, and these channels are “connected” between adjacent cells.

It is important to note that there is a great amount of redundancy built into the process of signal transduction. For example, paracrine signaling molecules often have many family members such that other genes in the family may compensate for the loss of one of their counterparts. Thus, the loss of function of a signaling protein through a gene mutation does not necessarily result in abnormal development or death. In addition, there is crosstalk between pathways, such that they are intimately interconnected. These connections provide numerous additional sites to regulate signaling.

**Paracrine Signaling Factors**

There is a large number of paracrine signaling factors acting as ligands, which are also called GDFs. Most are grouped into four families, and members of these same families are used repeatedly to regulate development and differentiation of organ systems. Furthermore, the same GDFs regulate organ development throughout the animal kingdom from *Drosophila* to humans. The four groups of GDFs include the fibroblast growth factor (FGF), WNT, hedgehog, and transforming growth factor-β (TGF-β) families. Each family of GDFs interacts with its own family of receptors, and these receptors are as important as the signal molecules themselves in determining the outcome of a signal.
Fibroblast Growth Factors
Originally named because they stimulate the growth of fibroblasts in culture, there are now approximately two dozen FGF genes that have been identified, and they can produce hundreds of protein isoforms by altering their RNA splicing or their initiation codons. FGF proteins produced by these genes activate a collection of tyrosine receptor kinases called fibroblast growth factor receptors (FGFRs). In turn, these receptors activate various signaling pathways. FGFs are particularly important for angiogenesis, axon growth, and mesoderm differentiation. Although there is redundancy in the family, such that FGFs can sometimes substitute for one another, individual FGFs may be responsible for specific developmental events. For example, FGF8 is important for development of the limbs and parts of the brain.

Hedgehog Proteins
The *hedgehog* gene was named because it coded for a pattern of bristles on the leg of *Drosophila* that resembled the shape of a hedgehog. In mammals, there are three hedgehog genes, *desert*, *Indian*, and *sonic hedgehog*. Sonic hedgehog (SHH) is involved in a multitude of developmental events (see “Key Signaling Pathways for Development,” p. 8).

WNT Proteins
There are at least 15 different WNT genes that are related to the segment polarity gene, *wingless* in *Drosophila*. Their receptors are members of the frizzled family of proteins. WNT proteins are involved in regulating limb patterning, midbrain development, and some aspects of somite and urogenital differentiation among other actions.

The TGF-β Superfamily
The TGF-β superfamily has more than 30 members and includes the TGF-βs, the bone morphogenetic proteins (BMPs), the activin family, the müllerian inhibiting factor (MIF, anti-müllerian hormone), and others. The first member of the family, TGF-β1, was isolated from virally transformed cells. TGF-β members are important for extracellular matrix formation and epithelial branching that occurs in lung, kidney, and salivary gland development. The BMP family induces bone formation and is involved in regulating cell division, cell death (apoptosis), and cell migration among other functions.

Other Paracrine Signaling Molecules
Another group of paracrine signaling molecules important during development are neurotransmitters, including serotonin, γ-amino butyric acid (GABA), epinephrine, and norepinephrine that act as ligands and bind to receptors just as proteins do. These molecules are not just transmitters for neurons; they also provide important signals for embryological development. For example, serotonin (5-HT) acts as a ligand for a large number of receptors, most of which are G protein-coupled receptors. Acting through these receptors, 5-HT regulates a variety of cellular functions, including cell proliferation and migration, and is important for establishing laterality, gastrulation, heart development, and other processes during early stages of differentiation. Norepinephrine also acts through receptors and appears to play a role in apoptosis (programmed cell death) in the interdigital spaces and in other cell types.

### KEY SIGNALING PATHWAYS FOR DEVELOPMENT

**Sonic Hedgehog: Master Gene for Embryogenesis**

In the days before molecular biology, embryologists were convinced of the existence of a master signal that directed all of embryonic development. This signal would act as a morphogen, a secreted molecule that would establish concentration gradients and instruct cells in how to become different tissues and organs. Although we now know that there are a multitude of signaling molecules that coordinately regulate development, the protein SHH comes closest to being the master morphogen of them all. This protein is involved in development of the vasculature, left–right axis formation, midline, cerebellum, neural patterning, limbs, smooth muscle patterning, heart, gut, pharynx, lungs, pancreas, kidneys, bladder, hair follicles, teeth, thymocytes, inner ear, eyes, and taste buds: a veritable plethora of developmental events. Sonic signaling is via the pathway shown in Figure 1.7. The protein binds to its receptor *Patched* (Ptc), a protein that normally inhibits the receptor-like protein *Smoothened* (Smo). Upon binding of SHH to Ptc, Ptc activity is eliminated, the inhibition of Smo is removed, and Smo is activated to, ultimately, upregulate activity of the **GLI** family (1 to 3) of transcription factors that control expression of target genes. The speci-
The SHH protein has some unique characteristics, including the fact that after translation it is cleaved and cholesterol is added to the C-terminus of its N-terminal domain. It is the addition of cholesterol that links SHH to the plasma membrane. Then, a palmitic acid moiety is added to the N-terminus and SHH becomes fully functional. Its release from the plasma membrane is produced by the transmembrane protein Dispatched, and at this point, SHH can establish the concentration gradients characteristic of its action as a morphogen.

**The Planar Cell Polarity: Convergent Extension Pathway**

The planar cell polarity (PCP) pathway regulates the process of convergent extension whereby a tissue becomes longer and narrower
PCP refers to the reorganization of cells and cell sheets in the plane of a tissue, such as occurs during convergent extension. The principal PCP signaling pathway is the noncanonical WNT pathway, which includes the Wnt receptor Frizzled (Fz) and two other transmembrane proteins called Celsr and Vangl (Fig. 1.8B). These transmembrane proteins primarily target activation of DISHEVELLED (DVL), either directly or through downstream effectors, such as Prickle (Pk) and Diego (Dgo). In turn, Dvl regulates signaling via the Rho and Rac kinases to upregulate c-Jun N-terminal kinases (JNK) that control cytoskeletal changes and other downstream effectors including transcription factors. Mutations in many of these genes, including Fz, CELSR, VANGL, and DVL have been shown to cause neural tube defects in mice and mutations in VANGL genes have been linked to these types of defects in humans.

The Notch Pathway

Notch transmembrane receptors bind to transmembrane ligands of the DSL (Delta/Serrate/LAG-2) family, which requires cell-to-cell contact (juxtacrine signaling) for signaling to occur. In mammals, there are four Notch family members and five transmembrane ligands (Jagged 1 and 2 and Delta 1 to 3). Binding of one of these proteins to a Notch receptor causes a conformational change in the Notch protein such that part of it on the cytoplasmic side of the membrane is cleaved. The pathway is very straight forward in that there are no second messengers involved. Thus, the cleaved portion of the protein enters the nucleus directly and binds to a DNA-binding protein that normally represses transcription of Notch target genes. Binding of Notch removes the inhibitory activity of the repressor and permits activation of downstream genes (Fig. 1.9).

Notch signaling is involved in cell proliferation, apoptosis, and epithelial to mesenchymal transitions. It is especially important in neuronal differentiation, blood vessel formation and specification (angiogenesis), somite segmentation, pancreatic β-cell development, B- and T-cell differentiation in the immune system, development of inner ear hair cells, and septation of the outflow tract of the heart. Mutations in JAG1 or NOTCH2 cause Alagille syndrome characterized by cardiac outflow tract defects as well as skeletal, ocular, renal, and hepatic abnormalities. JAG1 mutations have also been linked to cases of tetralogy of Fallot (a cardiac outflow tract defect).

**SUMMARY**

During the past century, embryology has progressed from an observational science to one involving sophisticated technological and molecular advances. Together, observations and modern techniques provide a clearer understanding of the origins of normal and abnormal development and, in turn, suggest ways to prevent and treat birth defects. In this regard, knowledge of gene function has created entirely new approaches to the subject.

There are approximately 23,000 genes in the human genome, but these genes code for approximately 100,000 proteins. Genes are contained in a complex of DNA and proteins called chromatin, and its basic unit of structure is the nucleosome. Chromatin appears tightly coiled as beads of nucleosomes on a string and is called heterochromatin. For transcription to occur, DNA must be uncoiled from the beads as euchromatin. Genes reside within strands of DNA and contain regions that can be translated into proteins, called exons, and untranslatable regions, called introns. A typical gene also contains a promoter region that binds RNA polymerase for the initiation of transcription; a transcription initiation site, to designate the first amino acid in the protein; a translation termination codon; and a 3' untranslated region that includes a sequence (the poly A addition site) that assists with stabilization of the mRNA. The RNA polymerase binds to the promoter region that usually contains the sequence TATA, the TATA box. Binding requires additional proteins called transcription factors. Methylation of cytosine bases in the promoter region silences genes and prevents transcription. This process is responsible for X chromosome
FIGURE 1.8 A. Drawing illustrating the process of convergent extension whereby cells intercalate with their neighbors to increase the long axis of a tissue, such as occurs during lengthening of the neural tube during neurulation. Convergent extension is dependent on the PCP pathway (the reorganization of cells and cell sheets in the plane of a tissue) that is regulated by the noncanonical WNT signaling pathway (B). Wnt binds to its receptor Frizzled, which, together with two other transmembrane proteins Celsr and Vangl, activate DISHEVELLED. Dishevelled then acts through Rho and Rac kinases to upregulate c-jun N-terminal kinases (JNK) that control cytoskeletal changes and downstream effectors, including transcription factors.
inactivation whereby the expression of genes on one of the X chromosomes in females is silenced and also for genomic imprinting in which either a paternal or a maternal gene’s expression is repressed.

Different proteins can be produced from a single gene by the process of alternative splicing that removes different introns using spliceosomes. Proteins derived in this manner are called splicing isoforms or splice variants. Also, proteins may be altered by post-translational modifications, such as phosphorylation or cleavage.

Induction is the process whereby one group of cells or tissues (the inducer) causes another group (the responder) to change their fate. The capacity to respond is called competence and must be conferred by a competence factor. Many inductive phenomena involve epithelial-mesenchymal interactions.

Signal transduction pathways include a signaling molecule (the ligand) and a receptor. The receptor usually spans the cell membrane and is activated by binding with its specific ligand. Activation usually involves the capacity to phosphorylate other proteins, most often as a kinase. This activation establishes a cascade of enzyme activity among proteins that ultimately activates a transcription factor for initiation of gene expression.

Cell-to-cell signaling may be paracrine, involving diffusible factors, or juxtacrine, involving a variety of nondiffusible factors. Proteins responsible for paracrine signaling are called paracrine factors or GDFs. There are four major families of GDFs: FGFs, WNTs, hedgehogs, and TGF-βs. In addition to proteins, neurotransmitters, such as serotonin (5-HT) and norepinephrine, also act through paracrine signaling, serving
as ligands and binding to receptors to produce specific cellular responses. Juxtacrine factors may include products of the extracellular matrix, ligands bound to a cell’s surface, and direct cell-to-cell communications.

There are many cell signaling pathways important for development, but two key pathways involve the protein SHH and the noncanonical WNT pathway, better known as the PCP pathway that regulates convergent extension. SHH is almost a master gene, and when this gene’s protein product binds to its receptor patched, it removes patched’s inhibition of smoothened. Once activated, smoothened causes upregulation of the GLI family of transcription factors that control downstream signaling by SHH. SHH is a diffusible factor with a cholesterol molecule bound to it, and it serves as a morphogen by establishing concentration gradients that regulate cell responses. SHH signaling is involved in many developmental events, including establishing the midline and left–right asymmetry and in patterning many different organs.

The PCP regulates movements of cells and sheets of cells in the plane of a tissue, such that the cells intercalate with other cells in such a way that the tissue elongates, a process called convergent extension. These types of cell movements are responsible for lengthening the embryo and the neural tube during gastrulation and neurulation, respectively. Several genes are involved in regulating this process, including WNT and its receptor FRIZZLED, CELSR, and VANGL that code for transmembrane proteins, and DISHEVELLED that codes for a protein that acts through Rho and Rac kinases to affect the cytoskeleton and other genes regulating cell movements. Mutations in these genes cause neural tube defects in mice and those involving VANGL have been linked to these defects in humans.

### Problems to Solve

1. What is meant by “competence to respond” as part of the process of induction? What tissues are most often involved in induction? Give two examples.

2. Under normal conditions, FGFs and their receptors (FGFRs) are responsible for growth of the skull and development of the cranial sutures. How might these signaling pathways be disrupted? Do these pathways involve paracrine or juxtacrine signaling? Can you think of a way that loss of expression of one FGF might be circumvented?
Gametogenesis: Conversion of Germ Cells into Male and Female Gametes

**PRIMORDIAL GERM CELLS**

Development begins with fertilization, the process by which the male gamete, the sperm, and the female gamete, the oocyte, unite to give rise to a zygote. Gametes are derived from primordial germ cells (PGCs) that are formed in the epiblast during the second week, move through the primitive streak during gastrulation, and migrate to the wall of the yolk sac (Fig. 2.1). During the fourth week, these cells begin to migrate from the yolk sac toward the developing gonads, where they arrive by the end of the fifth week. Mitotic divisions increase their number during their migration and also when they arrive in the gonad. In preparation for fertilization, germ cells undergo gametogenesis, which includes meiosis, to reduce the number of chromosomes and cytodifferentiation to complete their maturation.

**FIGURE 2.1** An embryo at the end of the third week, showing the position of primordial germ cells (PGCs) in the wall of the yolk sac, close to the attachment of the future umbilical cord. From this location, these cells migrate to the developing gonad.

---

**Clinical Correlates**

**Primordial Germ Cells and Teratomas**

Teratomas are tumors of disputed origin that often contain a variety of tissues, such as bone, hair, muscle, gut epithelia, and others. It is thought that these tumors arise from pluripotent stem cells that can differentiate into any of the three germ layers or their derivatives. Some evidence suggests that PGCs that have strayed from their normal migratory paths could be responsible for some of these tumors (Fig. 2.2). Another source may be epiblast cells that give rise to all three germ layers during gastrulation (see p. 65 and Fig. 5.9, p. 66).

**FIGURE 2.2** Oropharyngeal teratoma. These tumors may arise from PGCs or from epiblast cells (see Chapter 5), both of which are pluripotent. Tissues within the tumors include derivatives of all three germ layers and may include gut, bone, skin, teeth, and so forth.
THE CHROMOSOME THEORY OF INHERITANCE

Traits of a new individual are determined by specific genes on chromosomes inherited from the father and the mother. Humans have approximately 23,000 genes on 46 chromosomes. Genes on the same chromosome tend to be inherited together and so are known as linked genes. In somatic cells, chromosomes appear as 23 homologous pairs to form the diploid number of 46. There are 22 pairs of matching chromosomes, the autosomes, and one pair of sex chromosomes. If the sex pair is XX, the individual is genetically female; if the pair is XY, the individual is genetically male. One chromosome of each pair is derived from the maternal gamete, the oocyte, and one from the paternal gamete, the sperm. Thus, each gamete contains a haploid number of 23 chromosomes, and the union of the gametes at fertilization restores the diploid number of 46.

Mitosis

Mitosis is the process whereby one cell divides, giving rise to two daughter cells that are genetically identical to the parent cell (Fig. 2.3). Each daughter cell receives the complete complement of 46 chromosomes. Before a cell enters mitosis, each chromosome replicates its DNA. During this replication phase, chromosomes are extremely long, they are spread diffusely through the nucleus, and they cannot be recognized with the light microscope. With the onset of mitosis, the chromosomes begin to coil, contract, and condense; these events mark the beginning of prophase. Each chromosome now consists of two parallel subunits, chromatids, that are joined at a narrow region common to both called the centromere. Throughout prophase, the chromosomes continue to condense, shorten, and thicken (Fig. 2.3A), but only at prometaphase do the chromatids become distinguishable (Fig. 2.3B). During metaphase, the chromosomes line up in the equatorial plane, and their doubled structure is clearly visible (Fig. 2.3C). Each is attached by microtubules extending from the centromere to the centriole, forming the mitotic spindle. Soon, the centromere of each chromosome divides, marking the beginning of anaphase, followed by migration of chromatids to opposite poles of the spindle. Finally, during telophase, chromosomes uncoil and lengthen, the nuclear envelope reforms, and the cytoplasm

![FIGURE 2.3 Various stages of mitosis. In prophase, chromosomes are visible as slender threads. Doubled chromatids become clearly visible as individual units during metaphase. At no time during division do members of a chromosome pair unite. Blue, paternal chromosomes; red, maternal chromosomes.](image-url)
divides (Fig. 2.3D–F). Each daughter cell receives half of all doubled chromosome material and thus maintains the same number of chromosomes as the mother cell.

**Meiosis**

Meiosis is the cell division that takes place in the germ cells to generate male and female gametes, sperm and egg cells, respectively. Meiosis requires two cell divisions, meiosis I and meiosis II, to reduce the number of chromosomes to the haploid number of 23 (Fig. 2.4). As in mitosis, male and female germ cells (spermatocytes and primary oocytes) at the beginning of meiosis I replicate their DNA so that each of the 46 chromosomes is duplicated into sister chromatids. In contrast to mitosis, however, homologous chromosomes then align themselves in pairs, a process called **synapsis**. The pairing is exact and point for point except for the XY combination. Homologous pairs then separate into two daughter cells, thereby reducing the chromosome number from diploid to haploid. Shortly thereafter, meiosis II separates sister chromatids. Each gamete then contains 23 chromosomes.

**Crossover**

Crossovers, critical events in meiosis I, are the **interchange of chromatid segments** between paired homologous chromosomes (Fig. 2.4C). Segments of chromatids break and are exchanged as homologous chromosomes separate. As separation occurs, points of interchange are temporarily united and form an X-like structure,

![Figure 2.4](image-url)

**FIGURE 2.4** First and second meiotic divisions. **A.** Homologous chromosomes approach each other. **B.** Homologous chromosomes pair, and each member of the pair consists of two chromatids. **C.** Intimately paired homologous chromosomes interchange chromatid fragments [crossover]. Note the chiasma. **D.** Double-structured chromosomes pull apart. **E.** Anaphase of the first meiotic division. **F,G.** During the second meiotic division, the double-structured chromosomes split at the centromere. At completion of division, chromosomes in each of the four daughter cells are different from each other.
a chiasma (Fig. 2.4C). The approximately 30 to 40 crossovers (one or two per chromosome) with each meiotic I division are most frequent between genes that are far apart on a chromosome. As a result of meiotic divisions:

- **Genetic variability** is enhanced through crossover, which redistributes genetic material
- random distribution of homologous chromosomes to the daughter cells
- Each germ cell contains a haploid number of chromosomes, so that at fertilization the diploid number of 46 is restored.

**Clinical Correlates**

**Birth Defects and Spontaneous Abortions: Chromosomal and Genetic Factors**

Chromosomal abnormalities, which may be numerical or structural, are important causes of birth defects and spontaneous abortions. It is estimated that 50% of conceptions end in spontaneous abortion and that 50% of these abortuses have major chromosomal abnormalities. Thus, approximately 25% of conceptuses have a major chromosomal defect. The most common chromosomal abnormalities in abortuses are 45, X [Turner syndrome], triploidy, and trisomy 16. Chromosomal abnormalities account for 10% of major birth defects, and gene mutations account for an additional 8%.

**Numerical Abnormalities**

The normal human somatic cell contains 46 chromosomes; the normal gamete contains 23. Normal somatic cells are diploid, or 2n;

normal gametes are haploid, or n. Euploid refers to any exact multiple of n [e.g., diploid or triploid]. Aneuploid refers to any chromosome number that is not euploid; it is usually applied when an extra chromosome is present [trisomy] or when one is missing [monosomy]. Abnormalities in chromosome number may originate during meiotic or mitotic divisions. In meiosis, two members of a pair of homologous chromosomes normally separate during the first meiotic division, so that each daughter cell receives one member of each pair [Fig. 2.6A]. Sometimes, however, separation does not occur [nondisjunction], and both members of a pair move into one cell [Fig. 2.6B, C]. As a result of nondisjunction of the chromosomes, one cell receives 24 chromosomes, and the other receives 22 instead of the normal 23. When, at fertilization, a gamete having 23 chromosomes fuses with a gamete having 24 or 22 chromosomes, the result is an individual with either 47 chromosomes [trisomy] or 45 chromosomes [monosomy]. Nondisjunction, which occurs during either the first or the second meiotic division of the germ cells, may involve the autosomes or sex chromosomes. In women, the incidence of chromosomal abnormalities, including nondisjunction, increases with age, especially at 35 years and older.

Occasionally, nondisjunction occurs during mitosis [mitotic nondisjunction] in an embryonic cell during the earliest cell divisions. Such conditions produce mosaicism, with some cells having an abnormal chromosome number and others being normal. Affected individuals may exhibit few or many of the characteristics of a particular syndrome, depending on the number of cells involved and their distribution.

Sometimes chromosomes break, and pieces of one chromosome attach to another. Such translocations may be balanced, in which case breakage and reunion occur between two chromosomes, but no critical genetic material is lost and individuals are normal; or they may be unbalanced, in which case part of one chromosome is lost, and an altered phenotype is produced. For example, unbalanced translocations between the long arms of chromosomes 14 and 21 during meiosis I or II produce gametes with an extra copy of chromosome 21, one of the causes of Down syndrome [Fig. 2.7]. Translocations are particularly common between chromosomes 13, 14, 15, 21, and 22 because they cluster during meiosis.
Chapter 2 • Gametogenesis: Conversion of Germ Cells into Male and Female Gametes

FIGURE 2.7 A. Translocation of the long arms of chromosomes 14 and 21 at the centromere. Loss of the short arms is not clinically significant, and these individuals are clinically normal, although they are at risk for producing offspring with unbalanced translocations. B. Karyotype of translocation of chromosome 21 onto 14, resulting in Down syndrome.

**TRISOMY 21 (DOWN SYNDROME)**

*Down syndrome* is caused by an extra copy of chromosome 21 (trisomy 21) [Fig. 2.8]. Features of children with Down syndrome include growth retardation; varying degrees of intellectual disability; craniofacial abnormalities, including upward slanting eyes, epicanthal folds (extra skin folds at the medial corners of the eyes), flat facies, and small ears; cardiac defects; and hypotonia [Fig. 2.9]. These individuals also have an increased chance of developing leukemia, infections, thyroid dysfunction, and premature aging. Furthermore, an increased frequency and earlier onset of Alzheimer disease is observed among persons with Down syndrome.

In 95% of cases, the syndrome is caused by trisomy 21 resulting from meiotic nondisjunction, and in 75% of these instances, nondisjunction occurs during oocyte formation. The incidence of Down syndrome is approximately 1 in 2,000 conceptuses for women under age 25. This risk increases with maternal age to 1 in 300 at age 35 and 1 in 100 at age 40.

In approximately 4% of cases of Down syndrome, there is an unbalanced translocation between chromosome 21 and chromosome 13, 14, 15, or 21 [Fig. 2.7). The final 1% is caused by mosaicism resulting from mitotic nondisjunction. These individuals have some cells with a [continued]
normal chromosome number and some that are aneuploid. They may exhibit few or many of the characteristics of Down syndrome.

**Trisomy 18**

Patients with trisomy 18 show the following features: intellectual disability, congenital heart defects, low-set ears, and flexion of fingers and hands [Fig. 2.10]. In addition, patients frequently show micrognathia, renal anomalies, syndactyly, and malformations of the skeletal system. The incidence of this condition is approximately 1 in 5,000 newborns. Eighty-five percent are lost between 10 weeks of

Another characteristic of these children is a broad hand with a single transverse [simian] crease.
gestation and term, whereas those born alive usually die by 2 months of age. Approximately 5% live beyond 1 year.

**Trisomy 13**

The main abnormalities of trisomy 13 are intellectual disability, holoprosencephaly, congenital heart defects, deafness, cleft lip and palate, and eye defects, such as microphthalmia, anophthalmia, and coloboma [Fig. 2.11]. The incidence of this abnormality is approximately 1 in 20,000 live births, and more than 90% of the infants die in the first month after birth. Approximately 5% live beyond 1 year.

**Klinefelter Syndrome**

The clinical features of Klinefelter syndrome, found only in males and usually detected by amniocentesis, are sterility, testicular atrophy, hyalinization of the seminiferous tubules, and usually gynecomastia. The cells have 47 chromosomes with a sex chromosomal complement of the XXY type, and a **sex chromatin (Barr) body** is found in 80% of cases. A Barr body is also present in normal females because one of the X chromosomes is normally inactivated. The incidence is approximately 1 in 500 males. Nondisjunction of the XX homologues is the most common causative event. Occasionally, patients with Klinefelter syndrome have 48 chromosomes: 44 autosomes and 4 sex chromosomes [48, XXXY]. Although intellectual disability is not generally part of the syndrome, the more X chromosomes there are, the more likely there will be some degree of cognitive impairment.

**Turner Syndrome**

Turner syndrome, with a 45, X karyotype, is the only monosomy compatible with life. Even then, 98% of all fetuses with the syndrome are spontaneously aborted. The few that survive are unmistakably female in appearance [Fig. 2.12] and are characterized by the absence of ovaries (gonadal dysgenesis) and short stature. Other common associated abnormalities are webbed neck, lymphedema of the extremities, skeletal deformities, and a broad chest with widely spaced nipples. Approximately 55% of affected females are
monosomic for the X and chromatin body negative because of nondisjunction. In 80% of these females, nondisjunction in the male gamete is the cause. In the remainder of females, structural abnormalities of the X chromosome or mitotic nondisjunction resulting in mosaicism are the causes.

**Triple X Syndrome**

Patients with *triple X syndrome* (47, XXX) often go undiagnosed because of their mild physical features. However, these girls frequently have problems with speech and self-esteem. They have two sex chromatin bodies in their cells.

**Structural Abnormalities**

Structural chromosome abnormalities, which involve one or more chromosomes, usually result from chromosome breakage. It has been suggested that breaks are caused by environmental factors, such as viruses, radiation,
and drugs, but the evidence is inconclusive. The result of breakage depends on what happens to the broken pieces. In some cases, the broken piece of a chromosome is lost, and the infant with partial deletion of a chromosome is abnormal. A well-known syndrome, caused by partial deletion of the short arm of chromosome 5, is the cri-du-chat syndrome. Affected infants have a cat-like cry, microcephaly (small head), intellectual disability, and congenital heart disease. Many other relatively rare syndromes are known to result from a partial chromosome deletion.

Microdeletions, spanning only a few contiguous genes, may result in microdeletion syndrome or contiguous gene syndrome. Sites where these deletions occur, called contiguous gene complexes, are usually identified by fluorescence in situ hybridization (FISH; see p. 24). An example of a microdeletion occurs on the long arm of chromosome 15 (15q11-15q13 [Note: Chromosomes have a long arm, designated “q,” and a short arm, designated “p,” based on the position of the centromere.]). When the microdeletion occurs on the maternal chromosome, it results in Angelman syndrome, and the children have intellectual disability, cannot speak, exhibit poor motor development, and are prone to unprovoked and prolonged periods of laughter [Fig. 2.13]. If the microdeletion occurs on the paternal chromosome, Prader-Willi syndrome results. Affected individuals are characterized by hypotonia, obesity, intellectual disability, hypogonadism, and undescended testes [Fig. 2.14]. Characteristics that are differentially expressed depending upon whether the genetic material is inherited from the mother or the father are examples of genomic imprinting. Other contiguous gene syndromes may be inherited from either parent, including Miller-Dieker syndrome (lissencephaly, developmental delay, seizures, and cardiac and facial abnormalities resulting from a deletion at 17p13) and most cases of 22q11 syndrome (palatal defects, conotruncal heart defects, speech delay, learning disorders, and schizophrenia-like disorder resulting from a deletion in 22q11).

Fragile sites are regions of chromosomes that demonstrate a propensity to separate or break under certain cell manipulations. For example, fragile sites can be revealed by culturing lymphocytes from a patient in folate-deficient medium. Although numerous fragile sites have been defined and consist of CGG repeats, only those in the FMRI gene on the long arm of the X chromosome (Xq27) have been correlated with an altered phenotype that is called the fragile X syndrome. Greater than 200 repeats occur in the promoter region of the gene in affected individuals compared to 6 to 54 repeats in normal subjects. Fragile X syndrome is characterized by intellectual disability, large ears, prominent jaw, and large testes. The syndrome occurs in 1 per 5,000 individuals, and because it is an X-linked condition, males are affected almost exclusively, which may account for the preponderance of males among the cognitively impaired. Fragile X syndrome is second only to Down syndrome as a cause of intellectual disability due to genetic abnormalities.

Gene Mutations
Many congenital malformations in humans are inherited, and some show a clear Mendelian pattern of inheritance. Many birth defects
are directly attributable to a change in the structure or function of a single gene, hence the name single gene mutation. This type of defect is estimated to account for approximately 8% of all human malformations.

With the exception of the X and Y chromosomes in the male, genes exist as pairs, or alleles, so that there are two doses for each genetic determinant: one from the mother and one from the father. If a mutant gene produces an abnormality in a single dose, despite the presence of a normal allele, it is a dominant mutation. If both alleles must be abnormal (double dose) or if the mutation is X-linked (occurs on the X chromosome) in the male, it is a recessive mutation. Variations in the effects of mutant genes may be a result of modifying factors.

The application of molecular biological techniques has increased our knowledge of genes responsible for normal development. In turn, genetic analysis of human syndromes has shown that mutations in many of these same genes are responsible for some congenital abnormalities and childhood diseases. Thus, the link between key genes in development and their role in clinical syndromes is becoming clearer.

In addition to causing congenital malformations, mutations can result in inborn errors of metabolism. These diseases, among which phenylketonuria, homocystinuria, and galactosemia are the best known, may be accompanied by or cause various degrees of intellectual disability if proper diets and medical care are not instituted.

**Diagnostic Techniques for Identifying Genetic Abnormalities**

Cytogenetic analysis is used to assess chromosome number and integrity. The technique requires dividing cells, which usually means establishing cell cultures that are arrested in metaphase by chemical treatment. Chromosomes are Giemsa-stained to reveal light and dark banding patterns (G-bands; Fig. 2.7) unique for each chromosome. Each band represents 5 to 10 × 10⁶ base pairs of DNA, which may include a few to several hundred genes. Recently, high-resolution metaphase banding techniques have been developed that demonstrate greater numbers of bands representing even smaller pieces of DNA, thereby facilitating diagnosis of small deletions.

Molecular techniques, such as fluorescent in situ hybridization (FISH), use specific DNA probes to identify ploidy for a few selected chromosomes and for detecting microdeletions. Fluorescent probes are hybridized to chromosomes or genetic loci using cells on a slide, and the results are visualized with a fluorescence microscope (Fig. 2.15).

Microarrays use spots of specific DNA sequences (probes) attached to a solid surface, usually glass or silicon (Affymetrix chips). These probes may be a short sequence from a gene or other DNA element that are used to hybridize a cDNA or cRNA sample (the target sample). Hybridization of probe–target sequences are detected and quantified using fluorescence or other reporter techniques. Results can detect single nucleotide polymorphisms, mutations, and changes in expression levels. Some companies now offer such techniques commercially for anyone who wants their genome tested or sequenced.

Exome sequencing represents a new approach to finding mutations and poly-
morphisms [single nucleotide changes in a DNA sequence] responsible for birth defects and diseases. With this technique, only the coding regions (exons) in the genome are sequenced. Together, these coding regions make up the exome and represent only 1% of the entire human genome, thereby making sequencing them more practical than trying to sequence all of the genome. Because most genetic variants lie within the coding regions for proteins, the technique is an efficient way to discover these differences. The technique is also superior to older approaches that relied on linkage studies followed by positional cloning (searching for candidate genes in specific regions of chromosomes) because these techniques required large numbers of affected individuals within a family and were not applicable to studying affected individuals from different families. In contrast, exome sequencing can find a causative mutation in a single affected individual if the exomes from both parents can also be sequenced. Even sequencing-affected individuals from different families regardless of kinship can be successful. It must be remembered, however, that exome sequencing can only identify variants in the coding regions of genes that alter proteins. Other genetic causes of birth defects that lie outside the coding region will have to be identified by whole genome sequencing, but for now, the expense and time required to conduct these studies is prohibitive.

■ MORPHOLOGICAL CHANGES DURING MATURATION OF THE GAMETES

Oogenesis

Oogenesis is the process whereby oogonia differentiate into mature oocytes.

Maturation of Oocytes Begins Before Birth

Once PGCs have arrived in the gonad of a genetic female, they differentiate into oogonia (Fig. 2.16A,B). These cells undergo a number of mitotic divisions, and by the end of the third month, they are arranged in clusters surrounded by a layer of flat epithelial cells (Figs. 2.17 and 2.18). Whereas all of the oogonia in one cluster are probably derived from a single cell, the flat epithelial cells, known as follicular cells, originate from surface epithelium covering the ovary. The majority of oogonia continue to divide by mitosis, but some of them arrest their cell division in prophase of meiosis I and form primary oocytes (Figs. 2.16C and 2.17A). During the next few months, oogonia increase rapidly in number, and by the fifth month of prenatal development, the total number of germ cells in the ovary reaches its maximum, estimated at 7 million. At this time, cell death begins, and many oogonia as well as primary oocytes degenerate and become atretic. By the seventh month, the majority of oogonia...
FIGURE 2.16 Differentiation of PGCs into oogonia begins shortly after their arrival in the ovary. By the third month of development, some oogonia give rise to primary oocytes that enter prophase of the first meiotic division. This prophase may last 40 or more years and finishes only when the cell begins its final maturation. During this period, it carries 46 double-structured chromosomes. All surviving primary oocytes have entered prophase of meiosis I, and most of them are individually surrounded by a layer of flat follicular epithelial cells (Fig. 2.17B). A primary oocyte, together with its surrounding flat epithelial cells, is known as a primordial follicle (Fig. 2.18A).

Maturation of Oocytes Continues at Puberty
Near the time of birth, all primary oocytes have started prophase of meiosis I, but instead of proceeding into metaphase, they enter the diplo-tene stage, a resting stage during prophase that is characterized by a lacy network of chromatin.
Chapter 2

Gametogenesis; Conversion of Germ Cells into Male and Female Gametes

Fiat epithelial (follicular) cell

Cuboidal beginning of follicular cell zona pellucida

Connective tissue of ovary

A. Primordial follicle consisting of a primary oocyte surrounded by a layer of flattened epithelial cells. B. Early primary or preantral stage follicle recruited from the pool of primordial follicles. As the follicle grows, follicular cells become cuboidal and begin to secrete the zona pellucida, which is visible in irregular patches on the surface of the oocyte. C. Mature primary (preantral) follicle with follicular cells forming a stratified layer of granulosa cells around the oocyte and the presence of a well-defined zona pellucida.

(Fig. 2.17C). Primary oocytes remain arrested in prophase and do not finish their first meiotic division before puberty is reached. This arrested state is produced by oocyte maturation inhibitor (OMI), a small peptide secreted by follicular cells. The total number of primary oocytes at birth is estimated to vary from 600,000 to 800,000. During childhood, most oocytes become atretic; only approximately 40,000 are present by the beginning of puberty, and fewer than 500 will be ovulated. Some oocytes that reach maturity late in life have been dormant in the diplotene stage of the first meiotic division for 40 years or more before ovulation. Whether the diplotene stage is the most suitable phase to protect the oocyte against environmental influences is unknown. The fact that the risk of having children with chromosomal abnormalities increases with maternal age indicates that primary oocytes are vulnerable to damage as they age.

At puberty, a pool of growing follicles is established and continuously maintained from the supply of primordial follicles. Each month, 15 to 20 follicles selected from this pool begin to mature. Some of these die, whereas others begin to accumulate fluid in a space called the antrum, thereby entering the antral or vesicular stage (Fig. 2.19A). Fluid continues to accumulate such that, immediately prior to ovulation, follicles are quite swollen and are called mature vesicular follicles or graafian follicles (Fig. 2.19B). The antral stage is the longest, whereas the mature vesicular stage encompasses approximately 37 hours prior to ovulation.

As primordial follicles begin to grow, surrounding follicular cells change from flat to cuboidal and proliferate to produce a stratified epithelium of granulosa cells, and the unit is called a primary follicle (Fig. 2.18B,C). Granulosa cells rest on a basement membrane separating them from surrounding ovarian connective tissue (stromal cells) that form the theca folliculi. Also, granulosa cells and the oocyte secrete a layer of glycoproteins on the surface of the oocyte, forming the zona pellucida (Fig. 2.18C). As follicles continue to grow, cells of the theca folliculi organize into an inner layer of secretory cells, the theca interna, and an outer fibrous capsule, the theca externa. Also, small, finger-like processes of the follicular cells extend across the zona pellucida and interdigitate with microvilli of the plasma membrane of the oocyte. These processes are important for transport of materials from follicular cells to the oocyte.

As development continues, fluid-filled spaces appear between granulosa cells. Coalescence of these spaces forms the antrum, and the follicle is termed a vesicular or an antral follicle. Initially, the antrum is crescent-shaped, but with time, it enlarges (Fig. 2.19). Granulosa cells surrounding
the oocyte remain intact and form the **cumulus oophorus**. At maturity, the mature vesicular (graafian) follicle may be 25 mm or more in diameter. It is surrounded by the theca interna, which is composed of cells having characteristics of steroid secretion, rich in blood vessels, and the theca externa, which gradually merges with the ovarian connective tissue (Fig. 2.19).

With each ovarian cycle, a number of follicles begin to develop, but usually, only one reaches full maturity. The others degenerate and become atretic. When the secondary follicle is mature, a surge in **luteinizing hormone (LH)** induces the preovulatory growth phase. Meiosis I is completed, resulting in formation of two daughter cells of unequal size, each with 23 double-stranded chromosomes (Fig. 2.20A,B). One cell, the **secondary oocyte**, receives most of the cytoplasm; the other, the **first polar body**, receives practically none. The first polar body lies

---

**FIGURE 2.19** A. Vesicular (antral) stage follicle. The oocyte, surrounded by the zona pellucida, is off center; the antrum has developed by fluid accumulation between intercellular spaces. Note the arrangement of cells of the theca interna and the theca externa. B. Mature vesicular (graafian) follicle. The antrum has enlarged considerably, is filled with follicular fluid, and is surrounded by a stratified layer of granulosa cells. The oocyte is embedded in a mound of granulosa cells, the cumulus oophorus.

**FIGURE 2.20** Maturation of the oocyte. A. Primary oocyte showing the spindle of the first meiotic division. B. Secondary oocyte and first polar body. The nuclear membrane is absent. C. Secondary oocyte showing the spindle of the second meiotic division. The first polar body is also dividing.
between the zona pellucida and the cell membrane of the secondary oocyte in the perivitelline space (Fig. 2.20B). The cell then enters meiosis II but arrests in metaphase approximately 3 hours before ovulation. Meiosis II is completed only if the oocyte is fertilized; otherwise, the cell degenerates approximately 24 hours after ovulation. The first polar body may undergo a second division (Fig. 2.20C).

**Spermatogenesis**

*Maturation of Sperm Begins at Puberty*

Spermatogenesis, which begins at puberty, includes all of the events by which spermatogonia are transformed into spermatozoa. At birth, germ cells in the male infant can be recognized in the sex cords of the testis as large, pale cells surrounded by supporting cells (Fig. 2.21A). Supporting cells, which are derived from the surface epithelium of the testis in the same manner as follicular cells, become sustentacular cells, or Sertoli cells (Fig. 2.21B).

 Shortly before puberty, the sex cords acquire a lumen and become the seminiferous tubules. At about the same time, PGCs give rise to spermatogonial stem cells. At regular intervals, cells emerge from this stem cell population to form type A spermatogonia, and their production marks the initiation of spermatogenesis. Type A cells undergo a limited number of mitotic divisions to form clones of cells. The last cell division produces type B spermatogonia, which then divide to form primary spermatocytes (Figs. 2.21B and 2.22). Primary spermatocytes then enter a prolonged prophase (22 days) followed by rapid completion of meiosis I and formation of secondary spermatocytes. During the second meiotic division, these cells immediately begin to form haploid spermatids (Figs. 2.21B to 2.23). Throughout this series of events, from the time type A cells leave the stem cell population to formation of spermatids, cytokinesis is incomplete, so that successive cell generations are joined by cytoplasmic bridges. Thus, the progeny of a single type A spermatogonium form a clone of germ cells that maintain contact throughout differentiation (Fig. 2.22). Furthermore, spermatogonia and spermatids

---

**FIGURE 2.21** A. Cross section through primitive sex cords of a newborn boy showing PGCs and their supporting Sertoli cells. B. Cross section through a seminiferous tubule at puberty. Note the different stages of spermatogenesis and that developing sperm cells are embedded in the cytoplasmic processes of a supporting Sertoli cell.
FIGURE 2.22 Type A spermatogonia, derived from the spermatogonial stem cell population, represent the first cells in the process of spermatogenesis. Clones of cells are established, and cytoplasmic bridges join cells in each succeeding division until individual sperm are separated from residual bodies. In fact, the number of individual interconnected cells is considerably greater than depicted in this figure.
remain embedded in deep recesses of Sertoli cells throughout their development (Fig. 2.21B). In this manner, Sertoli cells support and protect the germ cells, participate in their nutrition, and assist in the release of mature spermatozoa.

Spermatogenesis is regulated by LH production by the pituitary gland. LH binds to receptors on Leydig cells and stimulates testosterone production, which in turn binds to Sertoli cells to promote spermatogenesis. Follicle-stimulating hormone (FSH) is also essential because its binding to Sertoli cells stimulates testicular fluid production and synthesis of intracellular androgen receptor proteins.

**Spermiogenesis**

The series of changes resulting in the transformation of spermatids into spermatozoa is spermiogenesis. These changes include (1) formation of the acrosome, which covers half of the nuclear surface and contains enzymes to assist in penetration of the egg and its surrounding layers during fertilization (Fig. 2.24); (2) condensation of the nucleus; (3) formation of neck, middle piece, and tail; and (4) shedding of most of the cytoplasm as residual bodies that are phagocytized by Sertoli cells. In humans, the time required for a spermatogonium to develop into a mature spermatozoon is approximately 74 days, and approximately 300 million sperm cells are produced daily.

When fully formed, spermatozoa enter the lumen of seminiferous tubules. From there, they are pushed toward the epididymis by contractile elements in the wall of the seminiferous tubules. Although initially only slightly motile, spermatozoa obtain full motility in the epididymis.
Clinical Correlates

Abnormal Gametes

In humans and in most mammals, one ovarian follicle occasionally contains two or three clearly distinguishable primary oocytes (Fig. 2.25A). Although these oocytes may give rise to twins or triplets, they usually degenerate before reaching maturity. In rare cases, one primary oocyte contains two or even three nuclei (Fig. 2.25B). Such binucleated or trinucleated oocytes die before reaching maturity.

**SUMMARY**

Primordial germ cells (PGCs) are derived from the epiblast during gastrulation and migrate to the wall of the yolk sac in the fourth week and then to the indifferent gonad (Fig. 2.1), where they arrive at the end of the fifth week. In preparation for fertilization, both male and female germ cells undergo gametogenesis, which includes meiosis and cytodifferentiation. During meiosis I, homologous chromosomes pair and exchange genetic material; during meiosis II, cells fail to replicate DNA, and each cell is thus provided with a haploid number of chromosomes and half the amount of DNA of a normal somatic cell (Fig. 2.4). Hence, mature male and female gametes have 22 plus X or 22 plus Y chromosomes, respectively.

Birth defects may arise through abnormalities in chromosome number or structure and from single gene mutations. Approximately 10% of major birth defects are a result of chromosome abnormalities, and 8% are a result of gene mutations. Trisomies (an extra chromosome) and monosomies (loss of a chromosome) arise during mitosis or meiosis. During meiosis, homologous chromosomes normally pair and then separate. If separation fails (nondisjunction), however, one cell receives too many chromosomes, and one receives too few (Fig. 2.6). The incidence of abnormalities of chromosome number increases with age of the mother, particularly with mothers aged 35 years and older. Structural abnormalities of chromosomes include large deletions (cri-du-chat syndrome) and microdeletions. Microdeletions involve contiguous genes that may result in defects such as Angelman syndrome (maternal deletion, chromosome 15q11–15q13) or Prader-Willi syndrome (paternal deletion, 15q11–15q13). Because these syndromes depend on whether the affected genetic material is inherited from the mother or the father, they are also an example of imprinting. Gene mutations may be dominant (only one gene of an allelic pair has to be affected to produce an alteration) or recessive (both allelic gene pairs must be mutated). Mutations responsible for many birth defects affect genes involved in normal embryological development.

In contrast to atypical oocytes, abnormal spermatozoa are seen frequently, and up to 10% of all spermatozoa have observable defects. The head or the tail may be abnormal, spermatozoa may be giants or dwarfs, and sometimes, they are joined (Fig. 2.25C). Sperm with morphologic abnormalities lack normal motility and probably do not fertilize oocytes.
Diagnostic techniques for identifying genetic abnormalities include cytogenetics to test for chromosome numbers (ploidy) and for high-resolution metaphase banding techniques to test for small deletions. **Fluorescent in situ hybridization** (FISH) uses fluorescent DNA probes to identify specific chromosomes or regions of chromosomes to determine deletions, translocations and ploidy. **Microarrays** employ small sequences of DNA on chips as probes to detect mutations and changes in expression levels of specific genes. **Exome sequencing** sequences the protein coding region of DNA (1% of the total DNA; the **exome**) to identify mutations and polymorphisms responsible for birth defects and diseases. The technique is accurate, timely, and cost-effective compared to sequencing the entire genome.

In the female, maturation from primitive germ cell to mature gamete, which is called oogenesis, begins before birth; in the male, it is called spermatogenesis, and it begins at puberty. In the female, PGCs form oogonia. After repeated mitotic divisions, some of these arrest in prophase of meiosis I to form **primary oocytes**. By the seventh month, many oogonia have become atretic, and only primary oocytes remain surrounded by a layer of **follicular cells** derived from the surface epithelium of the ovary (Fig. 2.17). Together, they form the **primordial follicle**. At puberty, a pool of growing follicles is recruited and maintained from the finite supply of primordial follicles. Thus, every month, 15 to 20 follicles begin to grow, and as they mature, they pass through three stages: (1) **primary** or **preantral**, (2) **vesicular or antral**, and (3) **mature vesicular or graafian follicle**. The primary oocyte remains in prophase of the first meiotic division until the secondary follicle is mature. At this point, a surge in **luteinizing hormone** (LH) stimulates preovulatory growth: Meiosis I is completed, and secondary oocyte and polar body are formed. Then, the secondary oocyte is arrested in metaphase of meiosis II approximately 3 hours before ovulation and will not complete this cell division until fertilization.

In the male, primordial cells remain dormant until puberty, and only then do they differentiate into **primary spermatocytes**, which through two successive meiotic divisions produce four **spermatids** (Fig. 2.5). Spermatids go through a series of changes (**spermiogenesis**) (Fig. 2.24), including (1) formation of the acrosome; (2) condensation of the nucleus; (3) formation of neck, middle piece, and tail; and (4) shedding of most of the cytoplasm. The time required for a spermatogonium to become a mature spermatozoon is approximately 74 days.

### Problems to Solve

1. What is the most common cause of abnormal chromosome number? Give an example of a clinical syndrome involving abnormal numbers of chromosomes.
2. In addition to numerical abnormalities, what types of chromosomal alterations occur?
3. What is mosaicism, and how does it occur?
CHAPTER 3

First Week of Development: Ovulation to Implantation

**OVARIAN CYCLE**

At puberty, the female begins to undergo regular monthly cycles. These sexual cycles are controlled by the hypothalamus. Gonadotropin-releasing hormone (GnRH), produced by the hypothalamus, acts on cells of the anterior lobe (adenohypophysis) of the pituitary gland, which in turn secretes gonadotropins. These hormones, follicle-stimulating hormone (FSH) and luteinizing hormone (LH), stimulate and control cyclic changes in the ovary.

At the beginning of each ovarian cycle, 15 to 20 primary-stage (preantral) follicles are stimulated to grow under the influence of FSH. (The hormone is not necessary to promote development of primordial follicles to the primary follicle stage, but without it, these primary follicles die and become atretic.) Thus, FSH rescues 15 to 20 of these cells from a pool of continuously forming primary follicles (Figs. 3.1 and 3.2). Under normal conditions, only one of these follicles reaches full maturity, and only one oocyte is discharged; the others degenerate and become atretic. In the next cycle, another group of primary follicles is recruited, and again, only one follicle reaches maturity. Consequently, most follicles degenerate without ever reaching full maturity. When a follicle becomes atretic, the oocyte and surrounding follicular cells degenerate and are replaced by connective tissue, forming a corpus atreticum. FSH also stimulates maturation of follicular (granulosa) cells surrounding the oocyte. In turn, proliferation of these cells is mediated by growth differentiation factor 9, a member of the transforming growth factor-β (TGF-β) family. In cooperation, theca interna and granulosa cells produce estrogens: Theca interna cells produce androstenedione and testosterone, and granular cells convert these hormones to estrone and 17 β-estradiol. As a result of this estrogen production:

- The uterine endometrium enters the follicular or proliferative phase.
- Thinning of the cervical mucus occurs to allow passage of sperm.
- The anterior lobe of the pituitary gland is stimulated to secrete LH.

At midcycle, there is an LH surge that:

- Elevates concentrations of maturation-promoting factor, causing oocytes to complete meiosis I and initiate meiosis II
- Stimulates production of progesterone by follicular stromal cells (luteinization)
- Causes follicular rupture and ovulation

**Ovulation**

In the days immediately preceding ovulation, under the influence of FSH and LH, the vesicular follicle grows rapidly to a diameter of 25 mm to become a mature vesicular (graafian) follicle. Coincident with final development of the vesicular follicle, there is an abrupt increase in LH that causes the primary oocyte to complete meiosis I and the follicle to enter the preovulatory mature vesicular stage. Meiosis II is also initiated, but the oocyte is arrested in metaphase approximately 3 hours before ovulation. In the meantime, the surface of the ovary begins to bulge locally, and at the apex, an avascular spot, the stigma, appears. The high concentration of LH increases collagenase activity, resulting in digestion of collagen fibers surrounding the follicle. Prostaglandin levels also increase in response to the LH surge and cause local muscular contractions in the ovarian wall. Those contractions extrude the oocyte, which together with its surrounding granulosa cells from the region of the cumulus oophorus breaks free (ovulation).
FIGURE 3.1 Drawing showing the role of the hypothalamus and pituitary gland in regulating the ovarian cycle. Under the influence of GnRH from the hypothalamus, the pituitary releases the gonadotropins, FSH, and LH. Follicles are stimulated to grow by FSH and to mature by FSH and LH. Ovulation occurs when concentrations of LH surge to high levels. LH also promotes development of the corpus luteum. 1, primordial follicle; 2, growing follicle; 3, vesicular follicle; 4, mature vesicular (graafian) follicle.
and floats out of the ovary (Fig. 3.3). Some of the cumulus oophorus cells then rearrange themselves around the zona pellucida to form the corona radiata (Figs. 3.2B to 3.6).

**Corpus Luteum**

After ovulation, granulosa cells remaining in the wall of the ruptured follicle, together with cells from the theca interna, are vascularized by surrounding vessels. Under the influence of LH, these cells develop a yellowish pigment and change into lutein cells, which form the corpus luteum and secrete estrogens and progesterone (Fig. 3.3C). Progesterone, together with some estrogen, causes the uterine mucosa to enter the progestational or secretory stage in preparation for implantation of the embryo.

**Clinical Correlates**

**Ovulation**

During ovulation, some women feel a slight pain, called *mittelschmerz* (German for “middle pain”), because it normally occurs near the middle of the menstrual cycle. Ovulation is also generally accompanied by a rise in basal temperature, which can be monitored to aid couples in becoming pregnant or preventing pregnancy. Some women fail to ovulate because of a low concentration of gonadotropins. In these cases, administration of an agent to stimulate gonadotropin release, and hence ovulation, can be employed. Although such drugs are effective, they often produce multiple ovulations, so that the likelihood of multiple pregnancies is 10 times higher in these women than in the general population.

**Oocyte Transport**

Shortly before ovulation, fimbriae of the uterine tube sweep over the surface of the ovary, and the tube itself begins to contract rhythmically. It is thought that the oocyte, surrounded by some granulosa cells (Figs. 3.3B and 3.4), is carried into the tube by these sweeping movements of the fimbriae and by motion of cilia on the epithelial lining. Once in the tube, cumulus cells withdraw their cytoplasmic processes from the zona pellucida and lose contact with the oocyte.

Once the oocyte is in the uterine tube, it is propelled by peristaltic muscular contractions of the tube and by cilia in the tubal mucosa with the rate of transport regulated by the endocrine status during and after ovulation. In humans, the fertilized oocyte reaches the uterine lumen in approximately 3 to 4 days.

**Corpus Albicans**

If fertilization does not occur, the corpus luteum reaches maximum development approximately 9 days after ovulation. It can easily be recognized as a yellowish projection on the surface of the ovary. Subsequently, the corpus luteum shrinks...
because of degeneration of lutein cells (luteolysis) and forms a mass of fibrotic scar tissue, the corpus albicans. Simultaneously, progesterone production decreases, precipitating menstrual bleeding. If the oocyte is fertilized, degeneration of the corpus luteum is prevented by human chorionic gonadotropin, a hormone secreted by the syncytiotrophoblast of the developing embryo. The corpus luteum continues to grow and forms the corpus luteum of pregnancy (corpus luteum graviditatis). By the end of the third month, this structure may be one third to one half of the total size of the ovary. Yellowish luteal cells continue to secrete progesterone until the end of the fourth month; thereafter, they regress slowly as secretion of progesterone by the trophoblastic component of the placenta becomes adequate for maintenance of pregnancy. Removal of the corpus luteum of pregnancy before the fourth month usually leads to abortion.

Secondary oocyte in 2nd meiotic division

PHASE 3
Fusion of the sperm and oocyte cell membranes

Fusion oocyte and sperm cell membranes

FIGURE 3.5 A. Scanning electron micrograph of sperm binding to the zona pellucida. B. The three phases of oocyte penetration. In phase 1, spermatozoa pass through the corona radiata barrier; in phase 2, one or more spermatozoa penetrate the zona pellucida; and in phase 3, one spermatozoon penetrates the oocyte membrane while losing its own plasma membrane. Inset shows normal spermatocyte with acrosomal head cap.
Fertilization, the process by which male and female gametes fuse, occurs in the **ampullary region of the uterine tube**. This is the widest part of the tube and is close to the ovary (Fig. 3.4). Spermatozoa may remain viable in the female reproductive tract for several days.

Only 1% of sperm deposited in the vagina enter the cervix, where they may survive for many hours. Movement of sperm from the cervix to the uterine tube occurs by muscular contractions of the uterus and uterine tube and very little by their own propulsion. The trip from cervix to oviduct can occur as rapidly as 30 minutes or as slow as 6 days. After reaching the isthmus, sperm become less motile and cease their migration. At ovulation, sperm again become motile, perhaps because of chemoattractants produced by cumulus cells surrounding the egg, and swim to the ampulla, where fertilization usually occurs. Spermatozoa are not able to fertilize the oocyte immediately upon arrival in the female genital tract but must undergo (1) **capacitation** and (2) the **acrosome reaction** to acquire this capability.

**Capacitation** is a period of conditioning in the female reproductive tract that in the human lasts approximately 7 hours. Thus, speeding to the ampulla is not an advantage because capacitation has not yet occurred and such sperm are not capable of fertilizing the egg. Much of this conditioning during capacitation occurs in the uterine tube and involves epithelial interactions between the sperm and the mucosal surface of the tube. During this time, a glycoprotein coat and seminal plasma proteins are removed from the plasma membrane that overlies the acrosomal region of the spermatozoa. Only capacitated sperm can pass through the corona cells and undergo the acrosome reaction.

The **acrosome reaction**, which occurs after binding to the zona pellucida, is induced by zona proteins. This reaction culminates in the release of enzymes needed to penetrate the zona pellucida, including acrosin- and trypsin-like substances (Fig. 3.5).

The phases of fertilization include the following:

- Phase 1, penetration of the corona radiata
- Phase 2, penetration of the zona pellucida
- Phase 3, fusion of the oocyte and sperm cell membranes
**Phase 1: Penetration of the Corona Radiata**

Of the 200 to 300 million spermatozoa normally deposited in the female genital tract, only 300 to 500 reach the site of fertilization. Only one of these fertilizes the egg. It is thought that the others aid the fertilizing sperm in penetrating the barriers protecting the female gamete. Capacitated sperm pass freely through corona cells (Fig. 3.5).

**Phase 2: Penetration of the Zona Pellucida**

The zona is a glycoprotein shell surrounding the egg that facilitates and maintains sperm binding and induces the acrosome reaction. Both binding and the acrosome reaction are mediated by the ligand ZP3, a zona protein. Release of acrosomal enzymes (acrosin) allows sperm to penetrate the zona, thereby coming in contact with the plasma membrane of the oocyte (Fig. 3.5). Permeability of the zona pellucida changes when the head of the sperm comes in contact with the oocyte surface. This contact results in release of lysosomal enzymes from cortical granules lining the plasma membrane of the oocyte. In turn, these enzymes alter properties of the zona pellucida (zona reaction) to prevent sperm penetration and inactivate species-specific receptor sites for spermatozoa on the zona surface. Other spermatozoa have been found embedded in the zona pellucida, but only one seems to be able to penetrate the oocyte (Fig. 3.6).

**Phase 3: Fusion of the Oocyte and Sperm Cell Membranes**

The initial adhesion of sperm to the oocyte is mediated in part by the interaction of integrins on the oocyte and their ligands, disintegrins, on sperm. After adhesion, the plasma membranes of the sperm and egg fuse (Fig. 3.5). Because the plasma membrane covering the acrosomal head cap disappears during the acrosome reaction, actual fusion is accomplished between the oocyte membrane and the membrane that covers the posterior region of the sperm head (Fig. 3.5). In the human, both the head and the tail of the spermatozoon enter the cytoplasm of the oocyte, but the plasma membrane is left behind on the oocyte surface. As soon as the spermatozoon has entered the oocyte, the egg responds in three ways:

1. **Cortical and zona reactions.** As a result of the release of cortical oocyte granules, which contain lysosomal enzymes, (1) the oocyte membrane becomes impenetrable to other spermatozoa, and (2) the zona pellucida alters its structure and composition to prevent sperm binding and penetration. These reactions prevent polyspermy (penetration of more than one spermatozoon into the oocyte).

2. **Resumption of the second meiotic division.** The oocyte finishes its second meiotic division immediately after entry of the spermatozoon. One of the daughter cells, which receives hardly any cytoplasm, is known as the **second polar body**; the other daughter cell is the **definitive oocyte**. Its chromosomes (22 plus X) arrange themselves in a vesicular nucleus known as the **female pronucleus** (Figs. 3.6 and 3.7).

3. **Metabolic activation of the egg.** The activating factor is probably carried by the spermatozoon. Activation encompasses the initial cellular and molecular events associated with early embryogenesis.

![Figure 3.7](image-url)

**FIGURE 3.7** A. Phase contrast view of the pronuclear stage of a fertilized human oocyte with male and female pronuclei. B. Two-cell stage of human zygote.
The spermatozoon, meanwhile, moves forward until it lies close to the female pronucleus. Its nucleus becomes swollen and forms the **male pronucleus** (Fig. 3.6); the tail detaches and degenerates. Morphologically, the male and female pronuclei are indistinguishable, and eventually, they come into close contact and lose their nuclear envelopes (Fig. 3.7A). During growth of male and female pronuclei (both haploid), each pronucleus must replicate its DNA. If it does not, each cell of the two-cell zygote has only half of the normal amount of DNA. Immediately after DNA synthesis, chromosomes organize on the spindle in preparation for a normal mitotic division. The 23 maternal and 23 paternal (double) chromosomes split longitudinally at the centromere, and sister chromatids move to opposite poles, providing each cell of the zygote with the normal diploid number of chromosomes and DNA (Fig. 3.6D,E). As sister chromatids move to opposite poles, a deep furrow appears on the surface of the cell, gradually dividing the cytoplasm into two parts (Figs. 3.6F and 3.7B).

**Clinical Correlates**

**Contraceptive Methods**

**Barrier methods** of contraception include the male condom, made of latex and often containing chemical spermicides, which fits over the penis, and the female condom, made of polyurethane, which lines the vagina. Other barriers placed in the vagina include the diaphragm, the cervical cap, and the contraceptive sponge.

**Hormonal methods** are another commonly used form of contraception. These approaches provide the female hormones estrogen and/or progesterin. These hormones produce their effects by inhibiting ovulation (by preventing the release of FSH and LH from the pituitary gland), changing the lining of the uterus, and thickening cervical mucus, making it difficult for sperm to enter the uterus. Hormonal contraception can be provided through birth control pills, a skin patch, vaginal ring, injection, or implant. There are two types of contraceptive pills: The first is a combination of estrogen and the progesterone analogue progestin; the second is composed of progestin alone. Both pills are effective, but one may suit some women better than others for various health-related issues.

A **male “pill”** has been developed and tested in clinical trials. It contains a synthetic androgen that prevents both LH and FSH secretion and either stops sperm production (70% to 90% of men) or reduces it to a level of infertility.

The **intrauterine device (IUD)** is a small T-shaped unit and there are two types: hormonal and copper. The hormonal device releases progestin that causes thickening of cervical mucus to prevent sperm from entering the uterus. Also, it may make sperm less active and both eggs and sperm less viable. The copper type releases copper into the uterus that prevents fertilization or inhibits attachment of the fertilized egg to the uterine wall. It also helps prevent sperm from entering the uterine tubes.

**Emergency contraceptive pills (ECPs)** are used as birth control measures that may prevent pregnancy if taken 120 hours after sexual intercourse. These pills may be administered as high doses of progestin alone or in combination with estrogen [Plan B]. Other types of ECPs [mifepristone [RU-486] and ulipristal acetate [Ella]] act as antihormonal agents. Also, mifepristone is effective as an abortifacient if taken after the time of implantation.

**Sterilization** is another form of birth control. The method for men is a vasectomy, which prevents the release of sperm by blocking the ductus deferens, the tube that transports sperm from the testes to the penis. The sterilization method for women is tubal sterilization in which the uterine tubes are blocked or ligated. These procedures for both men and women can be reversed in some cases.

**Infertility**

Infertility is a problem for 15% to 30% of couples. Male infertility may be a result of insufficient numbers of sperm and/or poor motility. Normally, the ejaculate has a volume of 2 to 6 mL, with as many as 100 million sperm per milliliter. Men with 20 million sperm per milliliter or 50 million sperm per total ejaculate (continued)
are usually fertile. Infertility in a woman may be due to a number of causes, including occluded uterine tubes [most commonly caused by pelvic inflammatory disease], hostile cervical mucus, immunity to spermatozoa, absence of ovulation, and others.

**Clomiphene citrate (Clomid)** is a drug used to increase FSH concentrations to stimulate ovulation. The drug is given early in the menstrual cycle to cause ovulation in women who do not ovulate or who ovulate irregularly. Also, it is given to stimulate egg development for use in in vitro fertilization procedures.

One percent to 2% of all pregnancies in the United States occur using **assisted reproductive technology (ART)**. Offspring from these conceptions show increases in prematurity (<37 weeks’ gestation), low birth weight (<2,500 g), very low birth weight (<1,500 g), and some types of birth defects. Most of these adverse outcomes are caused by increased rates of multiple births (twins, triplets, etc.), which occur more commonly among ART pregnancies. Recent studies indicate, however, that even among singleton births after ART, there are increases in preterm birth and malformed infants. Some of the approaches used for ART include the following.

**In vitro fertilization (IVF)** of human ova and embryo transfer is the standard procedure used by laboratories throughout the world. Follicle growth in the ovary is stimulated by administration of gonadotropins. Oocytes are recovered by laparoscopy from ovarian follicles with an aspirator just before ovulation when the oocyte is in the late stages of the first meiotic division. The egg is placed in a simple culture medium, and sperm are added immediately. Alternatively, a single sperm can be injected into an egg’s cytoplasm to produce fertilization. This technique is called **intracytoplasmic sperm injection (ICSI)** and can be used to circumvent male infertility [see following discussion]. With either approach, fertilized eggs are monitored to the eight-cell stage and then placed in the uterus to develop to term.

The success rate of IVF depends upon maternal age. Approximately 30% of couples will conceive after one attempt if the woman is younger than 35 years of age. The rate drops to 25% for women aged 35 to 37, 17% for those aged 38 to 40, and to <5% for those over 40. In addition to these relatively low success rates, the technique is also associated with a higher rate of birth defects. To increase chances of a successful pregnancy, four or five ova are collected, fertilized, and placed in the uterus. This approach sometimes leads to multiple births.

The frequency of multiple births depends on maternal age [with a higher incidence in younger women] and the number of embryos transferred. For a 20- to 29-year-old woman and three embryos transferred, the risk is 46%. Multiple births are a disadvantage because they have high rates of morbidity and mortality.

Severe male infertility, in which the ejaculate contains very few live sperm (**oligozoospermia**) or even no live sperm (**azoospermia**), can be overcome using ICSI. With this technique, a single sperm, which may be obtained from any point in the male reproductive tract, is injected into the cytoplasm of the egg to cause fertilization. This approach offers couples an alternative to using donor sperm for IVF. The technique carries an increased risk for fetuses to have Y chromosome deletions and appears to be associated with a higher incidence of birth defects than standard IVF techniques.

The main results of fertilization are as follows:

- **Restoration of the diploid number of chromosomes**, half from the father and half from the mother. Hence, the zygote contains a new combination of chromosomes different from both parents.

- **Determination of the sex of the new individual**. An X-carrying sperm produces a female (XX) embryo, and a Y-carrying sperm produces a male (XY) embryo. Therefore, the chromosomal sex of the embryo is determined at fertilization.

- **Initiation of cleavage**. Without fertilization, the oocyte usually degenerates 24 hours after ovulation.

**CLEAVAGE**

Once the zygote has reached the two-cell stage, it undergoes a series of mitotic divisions, increasing the numbers of cells. These cells, which
become smaller with each cleavage division, are known as blastomeres (Fig. 3.8). Until the eight-cell stage, they form a loosely arranged clump (Fig. 3.9A). After the third cleavage, however, blastomeres maximize their contact with each other, forming a compact ball of cells held together by tight junctions (Fig. 3.9B). This process, compaction, segregates inner cells, which communicate extensively by gap junctions, from outer cells. Approximately 3 days after fertilization, cells of the compacted embryo divide again to form a 16-cell morula (mulberry). Inner cells of the morula constitute the inner cell mass, and surrounding cells compose the outer cell mass. The inner cell mass gives rise to tissues of the embryo proper, and the outer cell mass forms the trophoblast, which later contributes to the placenta.

FIGURE 3.9 Scanning electron micrographs of [A] uncompacted and [B] compacted eight-cell mouse embryos. In the uncompacted state, outlines of each blastomere are distinct, whereas after compaction, cell-cell contacts are maximized, and cellular outlines are indistinct.

BLASTOCYST FORMATION

About the time the morula enters the uterine cavity, fluid begins to penetrate through the zona pellucida into the intercellular spaces of the inner cell mass. Gradually, the intercellular spaces become confluent, and finally, a single cavity, the blastocoele, forms (Fig. 3.10A,B). At this time, the embryo is a blastocyst. Cells of the inner cell mass, now called the embryoblast, are at one pole, and those of the outer cell mass, or trophoblast, flatten and form the epithelial wall of the blastocyst (Fig. 3.10A,B). The zona pellucida has disappeared, allowing implantation to begin. In the human, trophoblastic cells over the embryoblast pole begin to penetrate between the epithelial cells of the uterine mucosa on about the sixth day (Fig. 3.10C). New studies suggest
that **L-selectin** on trophoblast cells and its **carbohydrate receptors** on the uterine epithelium mediate initial attachment of the blastocyst to the uterus. Selectins are carbohydrate-binding proteins involved in interactions between leukocytes and endothelial cells that allow leukocyte “capture” from flowing blood. A similar mechanism is now proposed for “capture” of the blastocyst from the uterine cavity by the uterine epithelium. Following capture by selectins, further attachment and invasion by the trophoblast involve integrins, expressed by the trophoblast and the extracellular matrix molecules laminin and fibronectin. Integrin receptors for laminin promote attachment, whereas those for fibronectin stimulate migration. These molecules also interact along signal transduction pathways to regulate trophoblast differentiation, so that implantation is the result of mutual trophoblastic and endometrial action. Hence, by the end of the first week of development, the human zygote has passed through the morula and blastocyst stages and has begun implantation in the uterine mucosa.
**Clinical Correlates**

### Embryonic Stem Cells

**Embryonic stem cells (ES cells)** are derived from the inner cell mass of the embryo. Because these cells are **pluripotent** and can form virtually any cell or tissue type, they have the potential for curing a variety of diseases, including diabetes, Alzheimer and Parkinson diseases, anemias, spinal cord injuries, and many others. Using animal model research with stem cells has been encouraging. For example, mouse ES cells in culture have been induced to form insulin-secreting cells, muscle and nerve stem cells, and glial cells. In whole animals, ES cells have been used to alleviate the symptoms of Parkinson disease and to improve motor ability in rats with spinal cord injuries.

ES cells may be obtained from embryos after **IVF**, a process called **reproductive cloning**. This approach has the disadvantage that the cells may cause immune rejection because they would not be genetically identical to their hosts. The cells could be modified to circumvent this problem, however. Another issue with this approach is based on ethical considerations, as the cells are derived from viable embryos. As the field of stem cell research progresses, scientific advances will provide more genetically compatible cells, and the approaches will be less controversial. Most recently, techniques have been devised to take nuclei from adult cells (e.g., skin) and introduce them into enucleated oocytes. This approach is called **therapeutic cloning** or **somatic nuclear transfer**. Oocytes are stimulated to differentiate into blastocysts, and ES cells are harvested. Because the cells are derived from the host, they are compatible genetically, and because fertilization is not involved, the technique is less controversial.

### Adult Stem Cells

Adult tissues contain stem cells that may also prove valuable in treating diseases. These cells are restricted in their ability to form different cell types and, therefore, are **multipotent**, not pluripotent, although scientists are finding methods to circumvent this disadvantage. Adult stem cells isolated from rat brains have been used to cure Parkinson disease in rats, suggesting that the approach has promise. Disadvantages of the approach include the slow rates of cell division characteristic of these cells and their scarcity, which makes them difficult to isolate in sufficient numbers for experiments.

### Abnormal Zygotes

The exact number of **abnormal zygotes** formed is unknown because they are usually lost within 2 to 3 weeks of fertilization, before the woman realizes she is pregnant, and therefore are not detected. Estimates are that as many as **50% of pregnancies end in spontaneous abortion** and that half of these losses are a result of chromosomal abnormalities. These abortions are a natural means of screening embryos for defects, reducing the incidence of congenital malformations. Without this phenomenon, approximately 12% instead of 2% to 3% of infants would have birth defects.

With the use of a combination of **IVF** and **polymerase chain reaction**, molecular screening of embryos for genetic defects is being conducted. Single blastomeres from early-stage embryos can be removed, and their DNA can be amplified for analysis. As the Human Genome Project provides more sequencing information, and as specific genes are linked to various syndromes, such procedures will become more commonplace.

---

**Uterus at Time of Implantation**

The wall of the uterus consists of three layers:

1. **Endometrium** or mucosa lining the inside wall
2. **Myometrium**, a thick layer of smooth muscle
3. **Perimetrium**, the peritoneal covering lining the outside wall (Fig. 3.11)

From puberty (11 to 13 years) until menopause (45 to 50 years), the endometrium undergoes changes in a cycle of approximately 28 days under hormonal control by the ovaries. During this menstrual cycle, the uterine endometrium passes through three stages:

1. **Follicular or proliferative phase**
2. **Secretory or progestational phase**
3. **Menstrual phase** (Figs. 3.12 and 3.13)
The proliferative phase begins at the end of the menstrual phase, is under the influence of estrogen, and parallels growth of the ovarian follicles. The secretory phase begins approximately 2 to 3 days after ovulation in response to progesterone produced by the corpus luteum. If fertilization does not occur, shedding of the endometrium (compact and spongy layers) marks the beginning of the menstrual phase. If fertilization does occur, the endometrium assists in implantation and contributes to formation of the placenta. Later in gestation, the placenta assumes the role of hormone production, and the corpus luteum degenerates.
At the time of implantation, the mucosa of the uterus is in the secretory phase (Fig. 3.12), during which time uterine glands and arteries become coiled and the tissue becomes succulent. As a result, three distinct layers can be recognized in the endometrium: a superficial compact layer, an intermediate spongy layer, and a thin basal layer (Fig. 3.12). Normally, the human blastocyst implants in the endometrium along the anterior or posterior wall of the body of the uterus, where it becomes embedded between the openings of the glands (Fig. 3.12).

If the oocyte is not fertilized, venules and sinusoidal spaces gradually become packed with blood cells, and an extensive diapedesis of blood into the tissue is seen. When the menstrual phase begins, blood escapes from superficial arteries, and small pieces of stroma and glands break away. During the following 3 or 4 days, the compact and spongy layers are expelled from the uterus, and the basal layer is the only part of the endometrium that is retained (Fig. 3.13). This layer, which is supplied by its own arteries, the basal arteries, functions as the regenerative layer in the rebuilding of glands and arteries in the proliferative phase (Fig. 3.13).

**SUMMARY**

With each ovarian cycle, a number of primary follicles begin to grow, but usually only one reaches full maturity, and only one oocyte is discharged at **ovulation**. At ovulation, the oocyte is in **metaphase** of the **second meiotic division** and is surrounded by the zona pellucida and some granulosa cells (Fig. 3.4). Sweeping action of tubal fimbriae carries the oocyte into the uterine tube.

Before spermatozoa can fertilize the oocyte, they must undergo:

1. **Capacitation**, during which time a glycoprotein coat and seminal plasma proteins are removed from the spermatozoan head.
2. The acrosome reaction, during which acrosin- and trypsin-like substances are released to penetrate the zona pellucida

During fertilization, the spermatozoon must penetrate:

1. The corona radiata
2. The zona pellucida
3. The oocyte cell membrane (Fig. 3.5)

As soon as the spermatocyte has entered the oocyte:

1. The oocyte finishes its second meiotic division and forms the female pronucleus.
2. The zona pellucida becomes impenetrable to other spermatozoa.
3. The head of the sperm separates from the tail, swells, and forms the male pronucleus (Figs. 3.6 and 3.7).

After both pronuclei have replicated their DNA, paternal and maternal chromosomes intermingle, split longitudinally, and go through a mitotic division, giving rise to the two-cell stage. The results of fertilization are the following:

1. Restoration of the diploid number of chromosomes
2. Determination of chromosomal sex
3. Initiation of cleavage

Infertility is a problem for 15% to 30% of couples and can be overcome using assisted reproductive technology (ART). In vitro fertilization (IVF) involves fertilizing eggs in a culture medium and placing them in the uterus at the eight-cell stage. In some cases, eggs are fertilized by intracytoplasmic sperm injection (ICSI), whereby a single sperm is injected into an egg’s cytoplasm. These in vitro techniques are associated with an increased risk for birth defects, prematurity, low birth weight, and multiple births. Approximately 1% to 2% of all live births in the United States occur through ART.

Cleavage is a series of mitotic divisions that results in an increase in cells, blastomeres, which become smaller with each division. After three divisions, blastomeres undergo compaction to become a tightly grouped ball of cells with inner and outer layers. Compacted blastomeres divide to form a 16-cell morula. As the morula enters the uterus on the third or fourth day after fertilization, a cavity begins to appear, and the blastocyst forms. The inner cell mass, which is formed at the time of compaction and will develop into the embryo proper, is at one pole of the blastocyst. The outer cell mass, which surrounds the inner cells and the blastocyst cavity, will form the trophoblast.

The uterus at the time of implantation is in the secretory phase, and the blastocyst implants in the endometrium along the anterior or posterior wall (Fig. 3.12). If fertilization does not occur, then the menstrual phase begins, and the spongy and compact endometrial layers are shed. The basal layer remains to regenerate the other layers during the next cycle (Fig. 3.13).

Problems to Solve

1. What is the role of the corpus luteum, and what is its origin?
2. What are the three phases of fertilization, and what reactions occur once fusion of the sperm and oocyte membranes takes place?
3. What are the primary causes of infertility in men and women?
4. A woman has had several bouts of pelvic inflammatory disease and now wants to have children; however, she has been having difficulty becoming pregnant. What is likely to be the problem, and what would you suggest?
his chapter gives a day-by-day account of the major events of the second week of development; however, embryos of the same fertilization age do not necessarily develop at the same rate. Indeed, considerable differences in rate of growth have been found even at these early stages of development.

**DAY 8**

At the eighth day of development, the blastocyst is partially embedded in the endometrial stroma. In the area over the embryoblast, the trophoblast has differentiated into two layers: (1) an inner layer of mononucleated cells, the *cytotrophoblast*, and (2) an outer multinucleated zone without distinct cell boundaries, the *syncytiotrophoblast* (Figs. 4.1 and 4.2). Mitotic figures are found in the cytotrophoblast but not in the syncytiotrophoblast. Thus, cells in the cytotrophoblast divide and migrate into the syncytiotrophoblast, where they fuse and lose their individual cell membranes.

Cells of the inner cell mass or embryoblast also differentiate into two layers: (1) a layer of small cuboidal cells adjacent to the blastocyst cavity, known as the *hypoblast layer*, and (2) a layer of high columnar cells adjacent to the amniotic cavity, the *epiblast layer* (Figs. 4.1 and 4.2).

Together, the layers form a flat disc. At the same time, a small cavity appears within the epiblast. This cavity enlarges to become the *amniotic cavity*. Epiblast cells adjacent to the cytotrophoblast are called *amnioblasts*, together with the rest of the epiblast, they line the amniotic cavity (Figs. 4.1 and 4.3). The endometrial stroma adjacent to the implantation site is edematous and highly vascular. The large, tortuous glands secrete abundant glycogen and mucus.

**FIGURE 4.1** A 7.5-day human blastocyst, partially embedded in the endometrial stroma. The trophoblast consists of an inner layer with mononuclear cells, the cytotrophoblast, and an outer layer without distinct cell boundaries, the syncytiotrophoblast. The embryoblast is formed by the epiblast and hypoblast layers. The amniotic cavity appears as a small cleft.
D A Y  9

The blastocyst is more deeply embedded in the endometrium, and the penetration defect in the surface epithelium is closed by a fibrin coagulum (Fig. 4.3). The trophoblast shows considerable progress in development, particularly at the embryonic pole, where vacuoles appear in the syncytium. When these vacuoles fuse, they form large lacunae, and this phase of trophoblast development is thus known as the lacunar stage (Fig. 4.3).
At the abembryonic pole, meanwhile, flattened cells probably originating from the hypoblast form a thin membrane, the exocoelomic (Heuser) membrane that lines the inner surface of the cytotrophoblast (Fig. 4.3). This membrane, together with the hypoblast, forms the lining of the exocoelomic cavity, or primitive yolk sac.

**DAYS 11 AND 12**

By the 11th to the 12th day of development, the blastocyst is completely embedded in the endometrial stroma, and the surface epithelium almost entirely covers the original defect in the uterine wall (Figs. 4.4 and 4.5). The blastocyst now produces a slight protrusion into the lumen of the uterus. The trophoblast is characterized by lacunar spaces in the syncytium that form an intercommunicating network. This network is particularly evident at the embryonic pole; at the abembryonic pole, the trophoblast still consists mainly of cytotrophoblastic cells (Figs. 4.4 and 4.5).

Concurrently, cells of the syncytiotrophoblast penetrate deeper into the stroma and erode the endothelial lining of the maternal capillaries. These capillaries, which are congested and dilated, are known as **sinusoids**. The syncytial lacunae become continuous with the sinusoids, and maternal blood enters the lacunar system (Fig. 4.4). As the trophoblast continues to erode more and more sinusoids, maternal blood begins to flow through the trophoblastic system, establishing the **uteroplacental circulation**.

In the meantime, a new population of cells appears between the inner surface of the cytotrophoblast and the outer surface of the exocoelomic cavity. These cells, derived from yolk sac cells, form a fine, loose connective tissue, the **extraembryonic mesoderm**, which eventually fills all of the space between the trophoblast externally and the amnion and exocoelomic membrane internally (Figs. 4.4 and 4.5). Soon, large cavities develop in the extraembryonic mesoderm, and when these become confluent, they form a new space known as the **extraembryonic cavity**, or **chorionic cavity** (Fig. 4.4). This space surrounds the primitive yolk sac and amniotic cavity, except where the...
Part I • General Embryology

germ disc is connected to the trophoblast by the connecting stalk (Fig. 4.6). The extraembryonic mesoderm lining the cytotrophoblast and amnion is called the extraembryonic somatic mesoderm; the lining covering the yolk sac is known as the extraembryonic splanchnic mesoderm (Fig. 4.4).

Growth of the bilaminar disc is relatively slow compared with that of the trophoblast; consequently, the disc remains very small (0.1 to 0.2 mm). Cells of the endometrium, meanwhile, become polyhedral and loaded with glycogen and lipids; intercellular spaces are filled with extravasate, and the tissue is edematous. These changes, known as the decidua reaction, at first are confined to the area immediately surrounding the implantation site but soon occur throughout the endometrium.

**DAY 13**

By the 13th day of development, the surface defect in the endometrium has usually healed. Occasionally, however, bleeding occurs at the implantation site as a result of increased blood flow into the lacunar spaces. Because this bleeding occurs near the 28th day of the menstrual cycle, it may be confused with normal menstrual bleeding and, therefore, may cause inaccuracy in determining the expected delivery date.

The trophoblast is characterized by villous structures. Cells of the cytotrophoblast proliferate locally and penetrate into the syncytiotrophoblast, forming cellular columns surrounded by syncytiotrophoblast. Cellular columns with the syncytial covering are known as primary villi (Figs. 4.6 and 4.7) (see Chapter 5, p. 67).

In the meantime, the hypoblast produces additional cells that migrate along the inside of the exocoelomic membrane (Fig. 4.4). These cells proliferate and gradually form a new cavity within the exocoelomic cavity. This new cavity is known as the secondary yolk sac or definitive yolk sac (Figs. 4.6 and 4.7). This yolk sac is much smaller than the original exocoelomic cavity, or primitive yolk sac. During its formation, large portions of the exocoelomic cavity are pinched off. These portions are represented by exocoelomic cysts, which are often found in the extraembryonic coelom or chorionic cavity (Figs. 4.6).

Meanwhile, the extraembryonic coelom expands and forms a large cavity, the chorionic cavity. The extraembryonic mesoderm lining the inside of the cytotrophoblast is then known as the chorionic plate. The only place where extraembryonic mesoderm traverses the chorionic cavity is in the connecting stalk (Fig. 4.6). With development of blood vessels, the stalk becomes the umbilical cord.
FIGURE 4.6 A 13-day human blastocyst. Trophoblastic lacunae are present at the embryonic as well as the abembryonic pole, and the uteroplacental circulation has begun. Note the primary villi and the extraembryonic coelom or chorionic cavity. The secondary yolk sac is entirely lined with endoderm.

FIGURE 4.7 Section through the implantation site of a 13-day embryo. Note the amniotic cavity, yolk sac, and chorionic cavity. Most of the lacunae are filled with blood.
Abnormal Implantation

The syncytiotrophoblast is responsible for hormone production [see Chapter 8, p. 117], including **human chorionic gonadotropin (hCG)**. By the end of the second week, quantities of this hormone are sufficient to be detected by radioimmunoassays, which serve as the basis for pregnancy testing.

Because 50% of the implanting embryo’s genome is derived from the father, it is a **foreign body** that potentially should be rejected by the maternal system, similar to rejection of a transplanted organ. A pregnant woman’s immune system needs to change in order for her to tolerate the pregnancy. How this occurs is not well understood, but it appears that a shift from cell-mediated immunity to humoral (antibody-mediated) immunity occurs and that this shift protects the embryo from rejection. However, the immune system alterations place pregnant women at increased risk for certain infections, such as influenza, which explains the increased risk of death from these infections in pregnant women. In addition, manifestations of autoimmune disease may change during pregnancy. For example, multiple sclerosis and rheumatoid arthritis, primarily cell-mediated conditions, show improvement during pregnancy, whereas women with systemic lupus erythematosus [a predominantly antibody-mediated immune disorder] are more severely affected when pregnant.

Abnormal implantation sites sometimes occur even within the uterus. Normally, the human blastocyst implants along the anterior or posterior wall of the body of the uterus. Occasionally, the blastocyst implants close to the internal os [opening] (Fig. 4.8) of the cervix, so that later in development, the placenta bridges the opening [placenta previa] and causes severe, even life-threatening bleeding in the second part of pregnancy and during delivery.

Occasionally, implantation takes place outside the uterus, resulting in an **extrauterine pregnancy**, or **ectopic pregnancy**. Ectopic pregnancies may occur at any place

![Figure 4.8](image-url)
FIGURE 4.9 Tubal pregnancy. Embryo is approximately 2 months old and is about to escape through a rupture in the tubal wall.

in the abdominal cavity, ovary, or uterine tube (Fig. 4.8). Ninety-five percent of ectopic pregnancies occur in the uterine tube, however, and most of these are in the ampulla (80%; Fig. 4.9). In the abdominal cavity, the blastocyst most frequently attaches itself to the peritoneal lining of the rectouterine cavity, or pouch of Douglas (Fig. 4.10). The blastocyst may also attach itself to the peritoneal covering of the intestinal tract or to

FIGURE 4.10 Midline section of bladder, uterus, and rectum shows an abdominal pregnancy in the rectouterine [Douglas] pouch.

(continued)
the omentum. Sometimes, the blastocyst develops in the ovary proper, causing a primary ovarian pregnancy. Ectopic pregnancies occur in 2% of all pregnancies and account for 9% of all pregnancy-related deaths for the mother. In most ectopic pregnancies, the embryo dies about the second month of gestation and may result in severe hemorrhaging in the mother.

Abnormal blastocysts are common. For example, in a series of 26 implanted blastocysts varying in age from 7.5 to 17 days recovered from patients of normal fertility, 9 (34.6%) were abnormal. Some consisted of syncytiotum only; others showed varying degrees of trophoblastic hypoplasia. In two, the embryo-blast was absent, and in some, the germ disc showed an abnormal orientation.

It is likely that most abnormal blastocysts would not have produced any sign of pregnancy because their trophoblast was so inferior that the corpus luteum could not have persisted. These embryos probably would have been aborted with the next menstrual flow and, therefore, pregnancy would not have been detected. In some cases, however, the trophoblast develops and forms placental membranes, although little or no embryonic tissue is present. Such a condition is known as a hydatidiform mole. Moles secrete high levels of hCG and may produce benign or malignant (invasive mole, choriocarcinoma) tumors.

Genetic analysis of hydatidiform moles indicates that although male and female pronuclei may be genetically equivalent, they may be different functionally. This evidence is derived from the fact that although cells of moles are diploid, their entire genome is paternal. Thus, most moles arise from fertilization of an oocyte lacking a nucleus followed by duplication of the male chromosomes to restore the diploid number. These results also suggest that paternal genes regulate most of the development of the trophoblast because in moles this tissue differentiates even in the absence of a female pronucleus.

Other examples of functional differences in maternal and paternal genes are provided by the observation that certain genetic diseases depend on whether the defective or missing gene is inherited from the father or the mother. For example, a microdeletion on chromosome 15 inherited from a father causes Prader-Willi syndrome (a condition characterized by hypotonia, intellectual disability, hypogonadism, and obesity), whereas inheriting the same deletion from the mother causes Angelman syndrome (a condition characterized by seizures, little to no speech, paroxysms of laughter, and severe intellectual disability). This phenomenon, in which there is differential modification and/or expression of homologous alleles or chromosome regions depending on the parent from whom the genetic material is derived, is known as genomic imprinting. Less than 1% of human genes are believed to be imprinted (see Chapter 2, p. 23).

Preimplantation and postimplantation reproductive failure occurs often. Even in some fertile women under optimal conditions for pregnancy, 15% of oocytes are not fertilized, and 10% to 15% start cleavage but fail to implant. Of the 70% to 75% that implant, only 58% survive until the second week, and 16% of those are abnormal. Hence, when the first expected menstruation is missed, only 42% of the eggs exposed to sperm are surviving. Of this percentage, a number will be aborted during subsequent weeks, and a number will be abnormal at the time of birth.

**SUMMARY**

At the beginning of the second week, the blastocyst is partially embedded in the endometrial stroma. The trophoblast differentiates into (1) an inner, actively proliferating layer, the cytotrophoblast; and (2) an outer layer, the syncytiotrophoblast, which erodes maternal tissues (Fig. 4.1). By day 9, lacunae develop in the syncytiotrophoblast. Subsequently, maternal sinusoids are eroded by the syncytiotrophoblast, maternal blood enters the lacunar network, and by the end of the second week, a primitive uteroplacental circulation begins (Fig. 4.6). The cytotrophoblast, meanwhile, forms cellular columns penetrating into and surrounded by the syncytium. These columns are primary villi.

By the end of the second week, the blastocyst is completely embedded, and the surface defect in the mucosa has healed (Fig. 4.6).

The inner cell mass or embryoblast, meanwhile, differentiates into (1) the epiblast and (2) the hypoblast, together forming a bilaminar disc (Fig. 4.6). Epiblast cells give rise to amniblasts that line the amniotic cavity superior to
the epiblast layer. Hypoblast cells are continuous with the **exocoelomic membrane**, and together they surround the **primitive yolk sac** (Fig. 4.4). By the end of the second week, extraembryonic mesoderm fills the space between the trophoblast and the amnion and exocoelomic membrane internally. When vacuoles develop in this tissue, the **extraembryonic coelom** or **chorionic cavity** forms (Fig. 4.6). **Extraembryonic mesoderm** lining the cytotrophoblast and amnion is **extraembryonic somatic mesoderm**; the lining surrounding the yolk sac is **extraembryonic splanchnic mesoderm** (Fig. 4.6).

The second week of development is known as the **week of 2’s**:

1. The trophoblast differentiates into 2 layers: the cytotrophoblast and syncytiotrophoblast
2. The embryoblast forms 2 layers: the epiblast and hypoblast
3. The extraembryonic mesoderm splits into 2 layers: the somatic and splanchnic layers
4. Two cavities form: the amniotic and yolk sac cavities

**Implantation** occurs at the end of the first week. Trophoblast cells invade the epithelium and underlying endometrial stroma with the help of proteolytic enzymes. Implantation may also occur outside the uterus, such as in the rectouterine pouch, on the mesentery, in the uterine tube, or in the ovary (**ectopic pregnancies**).

### Problems to Solve

1. The second week of development is known as the week of 2’s. Formation of what structures supports this statement?

2. During implantation, the trophoblast is invading maternal tissues, and because it contains approximately 50% paternal genes, it is a foreign body. Why is the conceptus not rejected by an immunologic response from the mother’s system?

3. A woman who believes she is pregnant complains of edema and vaginal bleeding. Examination reveals high plasma hCG concentrations and placental tissue but no evidence of an embryo. How would you explain this condition?

4. A young woman who has missed two menstrual periods complains of intense abdominal pain. What might an initial diagnosis be, and how would you confirm it?
The most characteristic event occurring during the third week of gestation is \textit{gastrulation}, the process that establishes all three \textit{germ layers} (ectoderm, mesoderm, and endoderm) in the embryo. Gastrulation begins with formation of the \textit{primitive streak} on the surface of the epiblast (Figs. 5.1 and 5.2A). Initially, the streak is vaguely defined (Fig. 5.1), but in a 15- to 16-day embryo, it is clearly visible as a narrow groove with slightly bulging regions on either side. The cephalic end of the streak, the \textit{primitive node}, consists of a slightly elevated area surrounding the small \textit{primitive pit} (Fig. 5.2). Cells of the epiblast migrate toward the primitive streak (Fig. 5.2). Upon arrival in the region of the streak, they become flask-shaped, detach from the epiblast, and slip beneath it (Fig. 5.2B,C). This inward movement is known as \textit{invagination}. Cell migration and specification are controlled by \textit{fibroblast growth factor 8} (FGF8), which is synthesized by streak cells themselves. This growth factor controls cell movement by down-regulating E-cadherin, a protein that normally binds epiblast cells together. FGF8 then controls cell specification into the mesoderm by regulating \textit{BRACHYURY (T)} expression. Once the cells have invaginated, some displace the hypoblast, creating the embryonic \textit{endoderm}, and others come to lie between the epiblast and newly created endoderm to form \textit{mesoderm}. Cells remaining in the epiblast then form \textit{ectoderm}. Thus, the epiblast, through the process of gastrulation, is the source of all of the germ layers (Fig. 5.2B), and cells in these layers will give rise to all of the tissues and organs in the embryo.

As more and more cells move between the epiblast and hypoblast layers, they begin to spread laterally and cranially (Fig. 5.2). Gradually, they migrate beyond the margin of the disc and establish contact with the extraembryonic mesoderm covering the yolk sac and amnion. In the cephalic direction, they pass on each side of the \textit{prechordal plate}. The prechordal plate itself forms between the tip of the notochord and the \textit{oropharyngeal membrane} and is derived from some of the first cells that migrate through the node in the midline and move in a cephalic direction. Later, the prechordal plate will be important for induction of the forebrain (Figs. 5.2 and 5.3). The oropharyngeal membrane at the cranial end of the disc consists of a small region of tightly adherent ectoderm and endoderm cells that represents the future opening of the oral cavity.

\section*{FORMATION OF THE NOTOCHORD}

Prenotochordal cells invaginating in the primitive node move forward cranially in the midline until they reach the \textit{prechordal plate} (Fig. 5.3). These prenotochordal cells become intercalated in the hypoblast so that for a short time, the midline of the embryo consists of two cell layers that form the \textit{notochordal plate} (Fig. 5.3B). As the hypoblast is replaced by endoderm cells moving in at the streak, cells of the notochordal plate proliferate and detach from the endoderm. They then form a solid cord of cells, the \textit{definitive notochord} (Fig. 5.3C), which underlies the neural tube and is a signalling center for inducing the axial skeleton. Because elongation of the notochord is a dynamic process, the cranial end forms first, and caudal regions are added as the primitive streak assumes a more caudal position. The notochord and prenotochordal cells extend cranially to the prechordal plate (an area just caudal to the oropharyngeal membrane) and caudally to the primitive pit. At the point where the pit forms an indentation in the epiblast, the \textit{neurenteric canal} temporarily connects the amniotic and yolk sac cavities (Fig. 5.3A).
FIGURE 5.1 A. Implantation site at the end of the second week. B. Representative view of the germ disc at the end of the second week of development. The amniotic cavity has been opened to permit a view of the dorsal side of the epiblast. The hypoblast and epiblast are in contact with each other, and the primitive streak forms a shallow groove in the caudal region of the embryo.

The cloacal membrane is formed at the caudal end of the embryonic disc (Fig. 5.2A). This membrane, which is similar in structure to the oropharyngeal membrane, consists of tightly adherent ectoderm and endoderm cells with no intervening mesoderm. When the cloacal membrane appears, the posterior wall of the yolk sac forms a small diverticulum that extends into the connecting stalk. This diverticulum, the allantoenteric diverticulum, or allantois, appears around the 16th day of development (Fig. 5.3A). Although in some lower vertebrates the allantois serves as a reservoir for excretion products of the renal system, in humans, it remains rudimentary but may be involved in abnormalities of bladder development (see Chapter 16, p. 257).

- **ESTABLISHMENT OF THE BODY AXES**

Establishment of the body axes, anterior-posterior (A–P; craniocaudal), dorso-ventral (D–V), and left-right (L–R), occurs early in embryogenesis and is probably initiated during the morula stage of development with the A–P and D–V axes specified prior to the L–R. By the blastocyst stage, the A–P axis is
Part I • General Embryology

B. Cross section through the cranial region of the streak at 15 days showing invagination of epiblast cells. The first cells to move inward displace the hypoblast to create the definitive endoderm. Once definitive endoderm is established, inwardly moving epiblast forms mesoderm. C. Dorsal view of an embryo showing the primitive node and streak and a cross section through the streak. The view is similar to the illustration in B; arrow, detaching epiblast cells in the primitive streak.
determined and cells that are destined to form the anterior visceral endoderm (AVE) at the cranial end of the endoderm layer of the bilaminar disc (Fig. 5.4) migrate toward what will become the head region. At this bilaminar disc stage, cells in the AVE express genes essential for head formation, including the transcription factors *OTX2*, *LIM1*, and *HESX1*, and the secreted factors *cerberus* and *lefty1* (members of the TGF-β family), which inhibit *nodal* (a member of the TGF-β family) activity, thereby establishing the cranial end of the embryo. The absence of *cerberus* and *lefty1* at the caudal end of the embryo allows nodal expression to continue, and this signal establishes and maintains the primitive streak (Fig. 5.4). Once the streak is formed, *NODAL* upregulates a number of genes responsible for formation of dorsal and ventral mesoderm and head and tail structures.

Another member of the TGF-β family, bone morphogenetic protein 4 (*BMP4*), is secreted throughout the embryonic disc (Fig. 5.4). In the presence of this protein and *FGF*, mesoderm will be ventralized to contribute to kidneys (intermediate mesoderm), blood, and body wall mesoderm (lateral plate mesoderm). In fact, all mesoderm would be ventralized if the activity of BMP4 were not blocked by other genes expressed in the node. For this reason,
the node is the organizer. It was given that designation by Hans Spemann, who first described this activity in the dorsal lip of the blastopore, a structure analogous to the node, in Xenopus embryos. Thus, CHORDIN (activated by the transcription factor GOOSECOID), noggin, and follistatin antagonize the activity of BMP4. As a result, cranial mesoderm is dorsalized into notochord, somites, and somitomeres (Fig. 5.4). Later, these three genes are expressed in the notochord and are important in neural induction in the cranial region.

As mentioned, Nodal is involved in initiating and maintaining the primitive streak. Similarly, HNF-3β maintains the node and later induces regional specificity in the forebrain and midbrain areas. Without HNF-3β, embryos fail to gastrulate properly and lack forebrain and midbrain structures. As mentioned previously, GOOSECOID activates inhibitors of BMP4 and contributes to regulation of head development. Over- or underexpression of this gene in laboratory animals results in severe malformations of the head region, including duplications, similar to some types of conjoined twins (Fig. 5.5).

Regulation of dorsal mesoderm formation in middle and caudal regions of the embryo is controlled by the BRACHYURY (T) gene expressed in the node, notochord precursor cells, and notochord. This gene is essential for cell migration through the primitive streak. BRACHYURY encodes a sequence-specific DNA-binding protein that functions as a transcription factor. The DNA-binding domain is called the T-box, and there are more than 20 genes in the T-box family. Thus, mesoderm formation in these regions depends on this gene product, and its absence results in shortening of the embryonic axis (caudal dysgenesis). The degree of shortening depends on the time at which the protein becomes deficient.

Laterality (L–R sidedness) also is established early in development. Normally, many organs exhibit asymmetries, including the heart, lungs, gut, spleen, stomach, liver, and others. Positioning these organs and establishing their asymmetries is orchestrated by a cascade of signal molecules and genes. When the primitive streak appears, FGF8 is secreted by cells in the node and primitive streak, and this growth factor induces
expression of NODAL (Fig. 5.6A). NODAL expression is then restricted to the left side of the embryo by the accumulation of serotonin (5-HT) on the left side. These high concentrations of 5-HT on the left activate expression of the transcription factor MAD3 that restricts NODAL expression to the left side of the primitive node (Fig. 5.6B). Midline genes like SONIC HEDGEHOG (SHH), LEFTY1, and ZIC3 (a gene on the X chromosome that codes for a zinc finger transcription factor) are involved in establishing the midline but also prevent NODAL expression from crossing over to the right side. Ultimately, Nodal protein in the left lateral plate mesoderm initiates a signaling cascade that includes LEFTY2 to upregulate PITX2 (Fig. 5.6B). PITX2 is a homeobox-containing transcription factor that is a “master gene” responsible for establishing left-sidedness, and its expression is repeated on the left side of the heart, stomach, and gut primordia as these organs are assuming their normal asymmetrical body positions. If the gene is expressed ectopically (e.g., on the right side), this abnormal expression results in laterality defects, including situs inversus and dextrocardia (placement of the heart to the right side; see “Clinical Correlates,” p. 65). Note that the neurotransmitter 5-HT also plays a critical role in this signaling cascade that establishes laterality. 5-HT is concentrated on the left side, which activates MAD3 and restricts Nodal signaling to the left side (Fig. 5.6B). Animal studies show that altering 5-HT signaling can result in situs inversus, dextrocardia, heart malformations, and a variety of laterality related birth defects called heterotaxy, whereas epidemiology studies indicate that similar malformations occur in humans when 5-HT signaling is disrupted by pharmaceutical agents. (see “Clinical Correlates,” p. 66).

Genes regulating right-sided development are not as well defined, although expression of
Part I  •  General Embryology

the transcription factor SNAIL is restricted to the right lateral plate mesoderm and probably regulates effector genes responsible for establishing the right side. Why the cascade is initiated on the left remains a mystery, but the mechanism may involve cilia on cells in the node that beat to create a gradient of Nodal toward the left or by a signaling gradient established by gap junctions and small ion transport.

**FATE MAP ESTABLISHED DURING GASTRULATION**

Regions of the epiblast that migrate and ingress through the primitive streak have been mapped, and their ultimate fates have been determined (Fig. 5.7). For example, cells that ingress through the cranial region of the node become prechordal plate and notochord; those migrating at the lateral edges of the node and from the cranial end of the streak become paraxial mesoderm; cells migrating through the midstreak region become intermediate mesoderm; those migrating through the more caudal part of the streak form lateral plate mesoderm; and cells migrating through the caudalmost part of the streak contribute to extraembryonic mesoderm (the other source of this tissue is the primitive yolk sac [hypoblast]).

**GROWTH OF THE EMBRYONIC DISC**

The embryonic disc, initially flat and almost round, gradually becomes elongated, with a broad cephalic and a narrow caudal end (Fig. 5.2A). Expansion of the embryonic disc occurs mainly in the cephalic region; the region of the primitive streak remains more or less the same size. Growth and elongation of the cephalic part of the disc are caused by a continuous migration of cells from the primitive streak region in a cephalic direction. Inagination of surface cells in the primitive streak and their subsequent migration forward and laterally continues until the end of the fourth week. At that stage, the primitive streak shows regressive changes, rapidly shrinks, and soon disappears.

That the primitive streak at the caudal end of the disc continues to supply new cells until the end of the fourth week has an important bearing on development of the embryo. In the cephalic part, germ layers begin their specific differentiation by the middle of the third week, whereas in the caudal part, differentiation begins by the end of the fourth week. Thus, gastrulation, or formation of the germ layers, continues in caudal segments while cranial structures are differentiating, causing the embryo to develop cephalocaudally.

---

**FIGURE 5.7** Dorsal view of the germ disc showing the primitive streak and a fate map for epiblast cells. Specific regions of the epiblast migrate through different parts of the node and streak to form mesoderm. Thus, cells migrating at the cranialmost part of the node will form the notochord (n); those migrating more posteriorly through the node and cranialmost aspect of the streak will form paraxial mesoderm (pm; somitomeres and somites); those migrating through the next portion of the streak will form intermediate mesoderm (im; urogenital system); those migrating through the more caudal part of the streak will form lateral plate mesoderm (lpm; body wall); and those migrating through the most caudal part will contribute to extraembryonic mesoderm (eem; chorion).
Clinical Correlates

Teratogenesis Associated with Gastrulation
The beginning of the third week of development, when gastrulation is initiated, is a highly sensitive stage for teratogenic insult. At this time, fate maps can be made for various organ systems, such as the eyes and brain anlage, and these cell populations may be damaged by teratogens. For example, animal studies indicate that high doses of alcohol at this stage kill cells in the anterior midline of the germ disc, producing a deficiency of the midline in craniofacial structures and resulting in holoprosencephaly [see Chapter 17, p. 300]. In such a child, the forebrain is small, the two lateral ventricles often merge into a single ventricle, and the eyes are close together (hypotelorism). Because this stage is reached 2 weeks after fertilization, it is approximately 4 weeks from the last menses. Therefore, the woman may not recognize that she is pregnant, having assumed that menstruation is late and will begin shortly. Consequently, she may not take precautions she would normally consider if she knew she was pregnant.

Gastrulation itself may be disrupted by genetic abnormalities and toxic insults. In caudal dysgenesis [sirenomelia], insufficient mesoderm is formed in the caudalmost region of the embryo. Because this mesoderm contributes to formation of the lower limbs, urogenital system [intermediate mesoderm], and lumbosacral vertebrae, abnormalities in these structures ensue.

Affected individuals exhibit a variable range of defects, including hypoplasia and fusion of the lower limbs, vertebral abnormalities, renal agenesis, imperforate anus, and anomalies of the genital organs [Fig. 5.8A,B]. In humans, the condition is associated with maternal diabetes and other causes. In mice, abnormalities of BRACHURY [T], WNT, and ENGRAILED genes produce a similar phenotype.

Tumors Associated with Gastrulation
Sometimes, remnants of the primitive streak persist in the sacrococcygeal region. These clusters of pluripotent cells proliferate and form tumors, known as sacrococcygeal teratomas, which commonly contain tissues derived from all three germ layers [Fig. 5.9]. This is the most common tumor in newborns, occurring with a frequency of 1 in 37,000. Teratomas may also arise from primordial germ cells that fail to migrate to the gonadal ridge [see Chapter 1, p. 14].

Birth Defects Associated with Laterality
Situs solitus refers to the normal positioning of the internal organs. Situs inversus refers to a condition where the positioning of all organs is reversed in a mirror image arrangement.

FIGURE 5.8 A, B. Two examples of sirenomelia (caudal dysgenesis). Loss of mesoderm in the lumbosacral region has resulted in fusion of the limb buds and other defects.
Discordant organ positioning with respect to symmetry, where one or more organs are abnormally reversed in position or if isomerisms (i.e., both atria in the heart look the same) or inversions (i.e., the two ventricles in the heart are reversed) are present is called **situs ambiguous** or heterotaxy. These individuals are considered to have **laterality defects** that have occurred because of a failure to properly establish the L-R axis. Patients with these conditions do not have complete **situs inversus** but appear to be predominantly bilaterally left-sided or right-sided. The spleen reflects the differences; those with left-sided bilaterality have polysplenia, and those with right-sided bilaterality have asplenia or hypoplastic spleen.

Individuals with **situs inversus** do not have a high risk for having other congenital abnormalities (although they have a slightly greater risk of having a heart defect), but their progeny have an increased risk for having laterality defects and an even higher risk for having a severe cardiac malformation. Also, approximately 20% of patients with complete **situs inversus** have bronchiectasis and chronic sinusitis because of abnormal cilia (**Kartagener syndrome**). Interestingly, cilia are normally present on the ventral surface of the primitive node and may be involved in L-R patterning.

In contrast, patients with **situs ambiguous** (heterotaxy) have a high risk of having other birth defects, including a variety of midline malformations, such as neural tube defects, cleft palate, anal atresia, etc. Furthermore, 90% of these individuals will have complex congenital heart defects. The heart exhibits more laterality than most organs and perhaps that explains its increased susceptibility when the L-R signaling pathway is disrupted. Mutations in the zinc finger transcription factor **ZIC3**, a gene located on the X chromosome, cause **X-linked heterotaxy**. These individuals have a variety of birth defects, including neural tube defects, limb abnormalities, and omphalocele, and most also have severe heart malformations. The association between laterality and midline defects (neural tube defects, cleft palate, etc.) suggests that signaling pathways establishing the A-P and L-R axes must interact to specify the correct positioning of the body’s organs and other structures.

The **neurotransmitter serotonin (5-HT)** is an important signal molecule for establishing laterality, and animal studies show that disrupting 5-HT signaling results in cases of situs inversus, heterotaxy, dextrocardia, and a wide variety of heart defects [see Chapter 13]. Epidemiology studies show that children born to mothers who take antidepressants from the class of drugs called **selective serotonin reuptake inhibitors** (SSRIs; Prozac, Paxil, Zoloft, Lexapro, Celexa, etc.) have an increased risk of having many different types of heart malformations and multiple other birth defects, thus providing additional evidence for 5-HT’s importance in establishing laterality.
FURTHER DEVELOPMENT OF THE TROPHOBLAST

By the beginning of the third week, the trophoblast is characterized by primary villi that consist of a cytotrophoblastic core covered by a syncytial layer (Figs. 5.10 and 5.11). During further development, mesodermal cells penetrate the core of primary villi and grow toward the decidua. The newly formed structure is known as a secondary villus (Fig. 5.11).

By the end of the third week, mesodermal cells in the core of the villus begin to differentiate into blood cells and small blood vessels, forming the villous capillary system (Fig. 5.11). The villus is now known as a tertiary villus or a definitive syncytiotrophoblast.

**FIGURE 5.10** A 13-day-old implantation site showing primary villi of the trophoblastic shell just beginning to be invaded by mesoderm from the chorionic plate.

**FIGURE 5.11** Development of a villus. **A.** Transverse section of a primary villus showing a core of cytotrophoblastic cells covered by a layer of syncytium. **B.** Transverse section of a secondary villus with a core of mesoderm covered by a single layer of cytotrophoblastic cells, which in turn is covered by syncytium. **C.** Mesoderm of the villus showing a number of capillaries and venules.
placental villus. Capillaries in tertiary villi make contact with capillaries developing in the mesoderm of the chorionic plate and in the connecting stalk (Figs. 5.12 and 5.13). These vessels, in turn, establish contact with the intraembryonic circulatory system, connecting the placenta and the embryo. Hence, when the heart begins to beat in the fourth week of development, the villous system is ready to supply the embryo proper with essential nutrients and oxygen.

Meanwhile, cytotrophoblastic cells in the villi penetrate progressively into the overlying syncytium until they reach the maternal endometrium. Here they establish contact with similar extensions of neighboring villous stems, forming a thin outer cytotrophoblast shell (Figs. 5.12 and 5.13). This shell gradually surrounds the trophoblast entirely and attaches the chorionic sac firmly to the maternal endometrial tissue (Fig. 5.12). Villi that extend from the chorionic plate to the decidua basalis (decidual plate: the part of the endometrium where the placenta will form; see Chapter 8) are called stem or anchoring villi. Those that branch from the sides of stem villi are free (terminal) villi, through which exchange of nutrients and other factors will occur.

The chorionic cavity, meanwhile, becomes larger, and by the 19th or the 20th day, the embryo is attached to its trophoblastic shell by a narrow connecting stalk (Fig. 5.12). The connecting stalk later develops into the umbilical cord, which forms the connection between the placenta and embryo.

SUMMARY
The most characteristic event occurring during the third week is gastrulation, which begins with the appearance of the primitive streak, which has at its cephalic end the primitive node. In the region of the node and streak, epiblast cells move inward (invaginate) to form new
cell layers, endoderm and mesoderm. Cells that do not migrate through the streak but remain in the epiblast form ectoderm. Hence, epiblast gives rise to all three germ layers in the embryo, ectoderm, mesoderm, and endoderm, and these layers form all of the tissues and organs (Figs. 5.2 and 5.3).

Prenotochordal cells invaginating in the primitive pit move forward until they reach the prechordal plate. They intercalate in the endoderm as the notochordal plate (Fig. 5.3). With further development, the plate detaches from the endoderm, and a solid cord, the notochord, is formed. It forms a midline axis, which will serve as the basis of the axial skeleton (Fig. 5.3). Cephalic and caudal ends of the embryo are established before the primitive streak is formed. Thus, cells in the hypoblast (endoderm) at the cephalic margin of the disc form the AVE, which expresses head-forming genes, including OTX2, LIM1, and HESX1 and the secreted factor cerberus. NODAL, a member of the TGF-β family of genes, is then activated and initiates and maintains the integrity of the node and streak. In the presence of FGF, BMP4 ventralizes mesoderm during gastrulation so that it forms intermediate and lateral plate mesoderm. Chordin, noggin, and follistatin antagonize BMP4 activity and dorsalize mesoderm to form the notochord and somitomeres in the head region. Formation of these structures in more caudal regions is regulated by the BRACHYURY (T) gene (Fig. 5.4A). Laterality (left–right asymmetry) is regulated by a cascade of signaling molecules and genes. FGF8, secreted by cells in the node and streak, induces NODAL and LEFTY2 expression on the left side, and these genes upregulate PITX2, a transcription factor and master gene for left-sidedness (Fig. 5.6). The neurotransmitter serotonin (5-HT) also plays a role in establishing laterality by restricting NODAL expression to the left side. Normal L–R positioning of the organs is called situs solitus, whereas their complete reversal is called situs inversus. When one or more organs are abnormally positioned the condition is called situs ambiguous or heterotaxy. Individuals with situs inversus have a low risk of having other birth defects, but their children have a higher risk, especially for heart defects. In contrast, patients with heterotaxy are at a high risk of having many types of congenital malformations, and almost all will have some type of cardiac abnormality. Disruption of 5-HT levels, or misexpression of genes in the laterality signaling pathway, such as PITX2 results in laterality defects, such as dex-
trocardia, situs inversus, and cardiac abnormalities. Mutations in the zinc finger transcription factor ZIC3 cause X-linked heterotaxy, with severe cardiac malformations and other defects.

Epiblast cells moving through the node and streak are predetermined by their position to become specific types of mesoderm and endoderm. Thus, it is possible to construct a fate map of the epiblast showing this pattern (Fig. 5.7).

By the end of the third week, three basic germ layers, consisting of ectoderm, mesoderm, and endoderm, are established in the head region, and the process continues to produce these germ layers for more caudal areas of the embryo until the end of the fourth week. Tissue and organ differentiation has begun, and it occurs in a cephalo-caudal direction as gastrulation continues.

In the meantime, the trophoblast progresses rapidly. Primary villi obtain a mesenchymal core in which small capillaries arise (Fig. 5.12). When these villous capillaries make contact with capillaries in the chorionic plate and connecting stalk, the villous system is ready to supply the embryo with its nutrients and oxygen (Fig. 5.13).

### Problems to Solve

1. A 22-year-old woman consumes large quantities of alcohol at a party and loses consciousness; 3 weeks later, she misses her second consecutive period. A pregnancy test is positive. Should she be concerned about the effects of her binge-drinking episode on her baby?

2. An ultrasound scan detects a large mass near the sacrum of a 28-week female fetus. What might the origin of such a mass be, and what type of tissue might it contain?

3. On ultrasound examination, it was determined that a fetus had well-developed facial and thoracic regions, but caudal structures were abnormal. Kidneys were absent, lumbar and sacral vertebrae were missing, and the hind limbs were fused. What process may have been disturbed to cause such defects?

4. A child has polysplenia and abnormal positioning of the heart. How might these two abnormalities be linked developmentally, and when would they have originated? Should you be concerned that other defects might be present? What genes might have caused this event, and when during embryogenesis would it have been initiated?

5. A young woman arrives at your obstetrics clinic and says that she is depressed and things are not going well, including her attempts to start a family. She indicates that her friend is taking one of the new SSRI antidepressants and she wonders if she should be taking one as well. How do you respond?
The embryonic period, or period of organogenesis, occurs from the third to the eighth weeks of development and is the time when each of the three germ layers, ectoderm, mesoderm, and endoderm, gives rise to a number of specific tissues and organs. By the end of the embryonic period, the main organ systems have been established, rendering the major features of the external body form recognizable by the end of the second month.

**DERIVATIVES OF THE ECTODERMAL GERM LAYER**

At the beginning of the third week of development, the ectodermal germ layer has the shape of a disc that is broader in the cephalic than in the caudal region (Fig. 6.1). Appearance of the notochord and prechordal mesoderm induces the overlying ectoderm to thicken and form the neural plate (Fig. 6.2A,B). Cells of the plate make up the neuroectoderm, and their induction represents the initial event in the process of neurulation.

**Molecular Regulation of Neural Induction**

Upregulation of fibroblast growth factor (FGF) signaling together with inhibition of the activity of bone morphogenetic protein 4 (BMP4), a transforming growth factor-β (TGF-β) family member responsible for ventralizing ectoderm and mesoderm, causes induction of the neural plate. FGF signaling probably promotes a neural pathway by an unknown mechanism while it represses BMP transcription and upregulates expression of CHORDIN and NOGGIN, which inhibit BMP activity. In the presence of BMP4, which permeates the mesoderm and ectoderm of the gastrulating embryo, ectoderm is induced to form epidermis, and mesoderm forms intermediate and lateral plate mesoderm. If ectoderm is protected from exposure to BMPs, its “default state” is to become neural tissue. Secretion of three other molecules, noggin, chordin, and follistatin, inactivates BMP. These three proteins are present in the organizer (primitive node), notochord, and prechordal mesoderm. They neuralize ectoderm by inhibiting BMP and cause mesoderm to become notochord and paraxial mesoderm (dorsalizes mesoderm); however, these neural inducers induce only forebrain and midbrain types of tissues. Induction of caudal neural plate structures (hindbrain and spinal cord) depends on two secreted proteins, WNT3a and FGF. In addition, retinoic acid (RA) appears to play a role in organizing the cranial-to-caudal axis because it can cause re specification of cranial segments into more caudal ones by regulating expression of homeobox genes (see p. 88).

**Neurulation**

Neurulation is the process whereby the neural plate forms the neural tube. One of the key events in this process is lengthening of the neural plate and body axis by the phenomenon of convergent extension, whereby there is a lateral to medial movement of cells in the plane of the ectoderm and mesoderm. The process is regulated by signaling through the planar cell polarity pathway (see Chapter 1, p. 9) and is essential for neural tube development. As the neural plate length ens, its lateral edges elevate to form neural folds, and the depressed midregion forms the neural groove (Fig. 6.2). Gradually, the neural folds approach each other in the midline, where they fuse (Fig. 6.3A,B). Fusion begins in the cervical region (fifth somite) and proceeds cranially and caudally (Fig. 6.3C,D). As a result, the neural tube is formed. Until fusion is complete, the cephalic and caudal ends of the neural tube communicate with the amniotic cavity by way of the anterior (cranial) and posterior (caudal) neuropores.
FIGURE 6.1 A. Dorsal view of a 16-day presomite embryo. The primitive streak and primitive node are visible. B. Dorsal view of an 18-day presomite embryo. The embryo is pear-shaped, with its cephalic region somewhat broader than its caudal end. C. Dorsal view of an 18-day human embryo. Note the primitive node and, extending forward from it, the notochord. The yolk sac has a somewhat mottled appearance. The length of the embryo is 1.25 mm, and the greatest width is 0.68 mm.

respectively (Figs. 6.3C, D and 6.4A). Closure of the cranial neuropore occurs at approximately day 25 (18- to 20-somite stage), whereas the posterior neuropore closes at day 28 (25-somite stage) (Fig. 6.4B). Neurulation is then complete, and the central nervous system is represented by a closed tubular structure with a narrow caudal portion, the spinal cord, and a much broader cephalic portion characterized by a number of dilations, the brain vesicles (see Chapter 18).
Neural Crest Cells

As the neural folds elevate and fuse, cells at the lateral border or crest of the neuroectoderm begin to dissociate from their neighbors. This cell population, the neural crest (Figs. 6.5 and 6.6), will undergo an epithelial-to-mesenchymal transition as it leaves the neuroectoderm by active migration and displacement to enter the underlying mesoderm. (Mesoderm refers to cells derived from the epiblast and extraembryonic tissues. Mesenchyme refers to loosely organized embryonic connective tissue regardless of origin.) Crest cells from the trunk region leave the neuroectoderm after closure of the neural tube and migrate along one of two pathways: (1) a dorsal pathway through the dermis, where they will enter the ectoderm through holes in the basal lamina to form melanocytes in the skin and hair follicles, and (2) a ventral pathway through the anterior half of each somite to become sensory ganglia, sympathetic and enteric neurons, Schwann cells, and cells of the adrenal medulla (Fig. 6.5). Neural crest cells also form and migrate from cranial neural folds, leaving the neural tube before closure in this region (Fig. 6.6). These cells contribute to the craniofacial skeleton as well as neurons for cranial ganglia, glial cells, melanocytes, and other cell types (Table 6.1, p. 77). Neural crest cells are so fundamentally important and contribute to so many organs and tissues that they are sometimes referred to as the fourth germ layer. Evolutionarily, these cells appeared at the dawn of vertebrate development and expanded this group extensively by perfecting a predatory lifestyle.

Molecular Regulation of Neural Crest Induction

Induction of neural crest cells requires an interaction at the junctional border of the neural plate and surface ectoderm (epidermis) (Fig. 6.5A). Intermediate concentrations of BMPs are established at this boundary compared to neural plate cells that are exposed to very low levels of BMPs and surface ectoderm cells that are exposed to very high levels. The proteins noggin and chordin regulate these concentrations by acting as BMP inhibitors. The intermediate concentrations of BMPs, together with FGF and WNT proteins, induce PAX3 and other transcription factors that “specify” the neural plate border (Fig. 6.5A). In turn, these transcription factors induce a second wave of transcription factors, including SNAIL and FOXD3, which specify cells as neural crest, and SLUG, which promotes crest cell migration from the neuroectoderm. Thus, the fate of the entire ectodermal germ layer depends on BMP concentrations: High levels induce epidermis formation; intermediate
Neural crest cells

**FIGURE 6.5** Formation and migration of neural crest cells in the spinal cord. A, B. Crest cells form at the tips of neural folds and do not migrate away from this region until neural tube closure is complete. C. After migration, crest cells contribute to a heterogeneous array of structures, including dorsal root ganglia, sympathetic chain ganglia, adrenal medulla, and other tissues (Table 6.1, p. 77). D. In a scanning electron micrograph, crest cells at the top of the closed neural tube can be seen migrating away from this area.

**FIGURE 6.6** Drawing shows the migratory paths of neural crest cells in the head region. These cells leave the crests of the neural folds prior to neural tube closure and migrate to form structures in the face and neck (blue area). 1 to 6, pharyngeal arches; V, VII, IX, and X, epipharyngeal placodes.

levels, at the border of the neural plate and surface ectoderm, induce the neural crest; and very low concentrations cause formation of neural ectoderm. BMPs, other members of the TGF-β family, and FGFs regulate neural crest cell migration, proliferation, and differentiation, and abnormal concentrations of these proteins have been associated with neural crest defects in the craniofacial region of laboratory animals (see Chapter 17).

By the time the neural tube is closed, two bilateral *otic placodes* and the *lens placodes*, become visible in the cephalic region of the embryo (Fig. 6.4B). During further development, the otic placodes
Connective tissue and bones of the face and skull
Cranial nerve ganglia (see Table 18.3, p. 336)
C cells of the thyroid gland
Conotruncal septum in the heart
Odontoblasts
Dermis in face and neck
Spinal [dorsal root] ganglia
Sympathetic chain and preaortic ganglia
Parasympathetic ganglia of the gastrointestinal tract
Adrenal medulla
Schwann cells
Glial cells
Meninges [forebrain]
Melanocytes
Smooth muscle cells to blood vessels of the face and forebrain

invaginate and form the otic vesicles, which will develop into structures needed for hearing and maintenance of equilibrium (see Chapter 19). At approximately the same time, the lens placodes appear. These placodes also invaginate and, during the fifth week, form the lenses of the eyes (see Chapter 20).

In general terms, the ectodermal germ layer gives rise to organs and structures that maintain contact with the outside world:

- The central nervous system
- The peripheral nervous system
- The sensory epithelium of the ear, nose, and eye
- The epidermis, including the hair and nails

In addition, it gives rise to the following:

- The subcutaneous glands
- The mammary glands
- The pituitary gland
- Enamel of the teeth

### Clinical Correlates

**Neural Tube Defects**

Neural tube defects (NTDs) result when neural tube closure fails to occur. If the neural tube fails to close in the cranial region, then most of the brain fails to form, and the defect is called anencephaly [Fig. 6.7A]. If closure fails anywhere from the cervical region caudally, then the defect is called spina bifida [Fig. 6.7B,C]. The most common site for spina bifida to occur is in the lumbosacral region [Fig. 6.7C], suggesting that the closure process in this area may be more susceptible to genetic and/or environmental factors. Anencephaly is a lethal defect, and most of these cases are diagnosed prenatally and the pregnancies terminated. Children with spina bifida lose a degree of neurological function based on the spinal cord level of the lesion and its severity.

Occurrence of these types of defects is common and varies by different regions. For example, prior to fortification of enriched flour with folic acid in the United States, the overall rate was 1 in 1,000 births, but in North and South Carolina, the rate was 1 in 500 births. In parts of China, rates were as high as 1 in 200 births. Various genetic and environmental factors apparently account for the variability. Genetic causes of NTDs remain elusive, although recently, mutations in the Vangl genes have been identified and associated with familial cases of these defects. The Vangl genes are part of the planar cell polarity pathway (see Chapter 1, p. 9) that regulates convergent extension, the process that lengthens the neural tube and is necessary for normal closure to occur.

Regardless of the region or country where NTDs occur, rates have been reduced significantly following folic acid administration. For example, rates throughout the United States are now approximately 1 in 1,500 births. It is estimated that 50% to 70% of NTDs can be prevented if women take **400 µg** of folic acid daily [the dose present in most multivitamins] beginning 3 months prior to conception and continuing throughout pregnancy. Because 50% of pregnancies are unplanned, it is recommended that all women of childbearing age take a multivitamin containing **400 µg** of folic acid daily. If a woman has had a child with an NTD or if there is a history of such defects in her family, it is recommended that she take **400 µg** of folic acid daily and then **4,000 µg** per day starting 1 month before she tries to become pregnant and continuing through the first 3 months of pregnancy.

[continued]
DERIVATIVES OF THE MESODERMAL GERM LAYER

Initially, cells of the mesodermal germ layer form a thin sheet of loosely woven tissue on each side of the midline (Fig. 6.8). By approximately the 17th day, however, cells close to the midline proliferate and form a thickened plate of tissue known as paraxial mesoderm (Fig. 6.8).

More laterally, the mesoderm layer remains thin and is known as the lateral plate. With the appearance and coalescence of intercellular cavities in the lateral plate, this tissue is divided into two layers (Fig. 6.8B,C):

- A layer continuous with mesoderm covering the amnion, known as the somatic or parietal mesoderm layer

---

FIGURE 6.7 Examples of NTDs, which occur when closure of the neural tube fails. A. Anencephaly. B,C. Infants with spina bifida. Most cases occur in the lumbosacral region. Fifty percent to 70% of all NTDs can be prevented by the vitamin folic acid.

Third to Eighth Weeks: The Embryonic Period

Notochord Amniotic cavity

A layer continuous with mesoderm covering the yolk sac, known as the splanchnic or visceral mesoderm layer (Figs. 6.8C,D and 6.9)

Together, these layers line a newly formed cavity, the intraembryonic cavity, which is continuous with the extraembryonic cavity on each side of the embryo. Intermediate mesoderm connects paraxial and lateral plate mesoderm (Figs. 6.8B,D and 6.9).

Paraxial Mesoderm

By the beginning of the third week, paraxial mesoderm begins to be organized into segments. These

The thin mesodermal sheet gives rise to paraxial mesoderm (future somites), intermediate mesoderm (future excretory units), and the lateral plate, which is split into parietal and visceral mesoderm layers lining the intraembryonic cavity.

FIGURE 6.9 Cross section through the somites and neural tube showing the organization of the paraxial mesoderm into somites and intermediate and lateral plate mesoderm.
segments, known as somitomeres, first appear in the cephalic region of the embryo, and their formation proceeds cephalocaudally. Each somitomere consists of mesodermal cells arranged in concentric whorls around the center of the unit. In the head region, somitomeres form in association with segmentation of the neural plate into neuromeres and contribute to mesenchyme in the head (see Chapter 17). From the occipital region caudally, somitomeres further organize into somites. The first pair of somites arises in the occipital region of the embryo at approximately the 20th day of development (Fig. 6.2C,D). From here, new somites appear in craniocaudal sequence (Fig. 6.10) at a rate of approximately three pairs per day until, at the end of the fifth week, 42 to 44 pairs are present (Figs. 6.4B and 6.10). There are 4 occipital, 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 8 to 10 coccygeal pairs. The first occipital and the last five to seven coccygeal somites later disappear, while the remaining somites form the axial skeleton (see Chapter 10). Because somites appear with a specified periodicity, the age of an embryo can be accurately determined during this early time period by counting somites (Table 6.2).

**Molecular Regulation of Somite Formation**

Formation of segmented somites from unsegmented presomatic (paraxial) mesoderm (Fig. 6.10) depends on a segmentation clock established by cyclic expression of a number of genes. The cyclic genes include members of the NOTCH and WNT signaling pathways that are expressed in an oscillating pattern in presomatic mesoderm. Thus, Notch protein accumulates in

**FIGURE 6.10** Dorsal view of somites forming along the neural tube (the ectoderm has been partially removed). Somites form from unsegmented presomatic paraxial mesoderm caudally and become segmented in more cranially positioned regions.
presomitic mesoderm destined to form the next somite and then decreases as that somite is established. The increase in Notch protein activates other segment-patterning genes that establish the somite. Boundaries for each somite are regulated by RA and a combination of FGF8 and WNT3a. RA is expressed at high concentrations cranially and decreases in concentration caudally, whereas the combination of FGF8 and WNT3a proteins is expressed at higher concentrations caudally and lower ones cranially. These overlapping expression gradients control the segmentation clock and activity of the NOTCH pathway.

**Somite Differentiation**

When somites first form from presomitic mesoderm, they exist as a ball of mesoderm (fibroblast-like) cells. These cells then undergo a process of **epithelization** and arrange themselves in a donut shape around a small lumen (Fig. 6.11).

![Figure 6.11](image-url)

**FIGURE 6.11** Stages in the development of a somite. **A.** Mesoderm cells that have undergone epithelization are arranged around a small cavity. **B.** Cells from the ventral and medial walls of the somite lose their epithelial arrangement and migrate around the neural tube and notochord. Collectively, these cells constitute the sclerotome that will form the vertebrae and ribs. Meanwhile, cells at the dorsomedial and ventrolateral regions differentiate into muscle precursor cells, whereas cells that remain between these locations form the dermatome. **C.** Both groups of muscle precursor cells become mesenchymal and migrate beneath the dermatome to form the dermomyotome, whereas some cells from the ventrolateral group also migrate into the parietal layer of lateral plate mesoderm. **D.** Eventually, dermatome cells also become mesenchymal and migrate beneath the ectoderm to form the dermis of the back.
By the beginning of the fourth week, cells in the ventral and medial walls of the somite lose their epithelial characteristics, become mesenchymal (fibroblast-like) again, and shift their position to surround the neural tube and notochord. Collectively, these cells form the **sclerotome** that will differentiate into the vertebrae and ribs (see Chapter 10). Cells at the dorsomedial and ventrolateral edges of the upper region of the somite form precursors for muscle cells, whereas cells between these two groups form the dermatome (Fig. 6.11B). Cells from both muscle precursor groups become mesenchymal again and migrate beneath the dermatome to create the dermomyotome (Fig. 6.11C,D). In addition, cells from the ventrolateral edge migrate into the parietal layer of lateral plate mesoderm to form most of the musculature for the body wall (external and internal oblique and transversus abdominis muscles) and most of the limb muscles (Fig. 6.11B; see Chapter 11). Cells in the dermomyotome ultimately form dermis for the skin of the back and muscles for the back, body wall (intercostal muscles), and some limb muscles (see Chapter 11).

Each myotome and dermatome retains its innervation from its segment of origin, no matter where the cells migrate. Hence, each somite forms its own **sclerotome** (the tendon cartilage and bone component), its own **myotome** (providing the segmental muscle component), and its own **dermatome**, which forms the dermis of the back. Each myotome and dermatome also has its own segmental nerve component.

### Molecular Regulation of Somite Differentiation

Signals for somite differentiation arise from surrounding structures, including the notochord, neural tube, epidermis, and lateral plate mesoderm (Fig. 6.12). The secreted protein products of the **NOGGIN** genes and **sonic hedgehog** (SHH), produced by the notochord and floor plate of the neural tube, induce the ventromedial portion of the somite to become sclerotome. Once induced, sclerotome cells express the transcription factor **PAX1**, which initiates the cascade of cartilage- and bone-forming genes for vertebral formation. Expression of **PAX3**, regulated by **WNT** proteins from the dorsal neural tube, marks the dermomyotome region of the somite. **WNT** proteins from the dorsal neural tube also target the dorsomedial portion of the somite, causing it to initiate expression of the muscle-specific gene **MYF5** and to form primaxial muscle precursors. Interplay between the inhibiting protein **BMP4** (and probably **FGFs**) from the lateral plate mesoderm and activating **WNT** products from the epidermis direct the dorsolateral portion of the somite to express another muscle-specific gene, **MYOD**, and to form primaxial and abaxial muscle precursors. The midportion of the dorsal epithelium of the somite is directed by **neurotrophin 3** (NT-3), secreted by the dorsal region of the neural tube, to form dermis.

### Intermediate Mesoderm

Intermediate mesoderm, which temporarily connects paraxial mesoderm with the lateral plate (Figs. 6.8D and 6.9), differentiates into urogenital structures. In cervical and upper thoracic regions, it forms segmental cell clusters
Chapter 6 • Third to Eighth Weeks: The Embryonic Period

(future nephrotomes), whereas more caudally, it forms an unsegmented mass of tissue, the **nephrogenic cord**. Excretory units of the urinary system and the gonads develop from this partly segmented, partly unsegmented intermediate mesoderm (see Chapter 16).

**Lateral Plate Mesoderm**

Lateral plate mesoderm splits into **parietal** (somatic) and **visceral** (splanchnic) layers, which line the intraembryonic cavity and surround the organs, respectively (Figs. 6.8C,D, 6.9, and 6.13A). Mesoderm from the parietal layer, together with overlying ectoderm, forms the lateral body wall folds (Fig. 6.13A). These folds, together with the head (cephalic) and tail (caudal) folds, close the ventral body wall. The parietal layer of lateral plate mesoderm then forms the dermis of the skin in the body wall and limbs, the bones and connective tissue of the limbs, and the sternum. In addition, sclerotome and muscle precursor cells that migrate into the parietal layer of lateral plate mesoderm form the costal cartilages, limb muscles, and most of the body wall muscles (see Chapter 11). The visceral layer of lateral plate mesoderm, together with embryonic endoderm, forms the wall of the gut tube (Fig. 6.13B). Mesoderm cells of the visceral layer surrounding the intraembryonic cavity form thin membranes, the **mesothelial membranes**, or **serous membranes**, which will line the peritoneal, pleural, and pericardial cavities and secrete serous fluid (Fig. 6.13B). Mesoderm cells of the visceral layer form a thin serous membrane around each organ (see Chapter 7).

**Blood and Blood Vessels**

Blood cells and blood vessels also arise from mesoderm. Blood vessels form in two ways: **vasculogenesis**, whereby vessels arise from blood islands (Fig. 6.14), and **angiogenesis**, which entails sprouting from existing vessels. The first blood islands appear in mesoderm surrounding the wall of the yolk sac at 3 weeks of development and slightly later in lateral plate mesoderm and other regions (Fig. 6.15). These islands arise from mesoderm cells that are induced to form **hemangioblasts**, a common precursor for vessel and blood cell formation.

Although the first blood cells arise in blood islands in the wall of the yolk sac, this population is transitory. The definitive **hematopoietic stem cells** are derived from mesoderm surrounding the aorta in a site near the developing mesonephric kidney called the **aorta-gonad-mesonephros region** (AGM). These cells colonize the liver, which becomes the major hematopoietic organ of the embryo and fetus from approximately the second to seventh months of development. Stem cells from the liver colonize the bone marrow, the definitive blood-forming tissue, in the seventh month of gestation; thereafter, the liver loses its blood-forming function.

**Molecular Regulation of Blood Vessel Formation**

FGF2 induces blood island development from competent mesoderm cells that form hemangioblasts. Hemangioblasts are directed to form blood cells and vessels by **vascular endothelial growth factor** (VEGF), which is secreted...
Blood vessels form in two ways: vasculogenesis (top), in which vessels arise from blood islands, and angiogenesis (bottom), in which new vessels sprout from existing ones. During vasculogenesis, fibroblast growth factor 2 (FGF2) binds to its receptor on subpopulations of mesoderm cells and induces them to form hemangioblasts. Then, under the influence of vascular endothelial growth factor (VEGF) acting through two different receptors, these cells become endothelial and coalesce to form vessels. Angiogenesis is also regulated by VEGF, which stimulates proliferation of endothelial cells at points where new vessels will sprout from existing ones. Final modeling and stabilization of the vasculature are accomplished by PDGF and TGF-β.

Figure 6.14 Extraembryonic blood vessel formation in the villi, chorion, connecting stalk, and wall of the yolk sac in a presomite embryo of approximately 19 days.
by surrounding mesoderm cells. The signal to express VEGF may involve HOXB5, which up-regulates the VEGF receptor FLK1 (Fig. 6.14). Hemangioblasts in the center of blood islands form hemangioblastic stem cells, the precursors of all blood cells, whereas peripheral hemangioblasts differentiate into angioblasts, the precursors to blood vessels. These angioblasts proliferate and are eventually induced to form endothelial cells by VEGF secreted by surrounding mesoderm cells (Fig. 6.14). This same factor then regulates coalescence of these endothelial cells into the first primitive blood vessels.

Once the process of vasculogenesis establishes a primary vascular bed, which includes the dorsal aorta and cardinal veins, additional vasculature is added by angiogenesis, the sprouting of new vessels (Fig. 6.14). This process is also mediated by VEGF, which stimulates proliferation of endothelial cells at points where new vessels are to be formed. Maturation and modeling of the vasculature are regulated by other growth factors, including platelet-derived growth factor (PDGF) and TGF-β, until the adult pattern is established. Specification of arteries, veins, and the lymphatic system occurs soon after angioblast induction. SHH, secreted by the notochord, induces surrounding mesenchyme to express VEGF. In turn, VEGF expression induces the NOTCH pathway (a transmembrane receptor pathway), which specifies arterial development through expression of EPHRINB2 (ephrins are ligands that bind to Eph receptors in a pathway involving tyrosine kinase signaling). In addition to specifying arteries, expression of EPHRINB2 suppresses venous cell fate. NOTCH signaling also up-regulates expression of EPHB4, a vein-specific gene, but how this gene and others specify venous development is not clear. On the other hand, PROX1, a homeodomain-containing transcription factor, appears to be the master gene for lymphatic vessel differentiation. Vessel outgrowth is patterned, not random, and appears to involve guidance factors similar to those employed by the nervous system.

**Clinical Correlates**

**Capillary Hemangiomas**

Capillary hemangiomas are abnormally dense collections of capillary blood vessels that form the most common tumors of infancy, occurring in approximately 10% of all births. They may occur anywhere but are often associated with craniofacial structures (Fig. 6.16A). Facial lesions may be focal or diffuse, with diffuse lesions causing more secondary complications, including ulcerations, scarring, and airway obstruction (mandibular hemangiomas; Fig. 6.16B). INSULIN-LIKE GROWTH FACTOR 2 is highly expressed in the lesions and may be one factor promoting abnormal vessel growth. Whether or not VEGF plays a role has not been determined.

**FIGURE 6.16** A. Focal capillary hemangioma. B. Diffuse capillary hemangioma involving the oral cavity.
The gastrointestinal tract is the main organ system derived from the endodermal germ layer. This germ layer covers the ventral surface of the embryo and forms the roof of the yolk sac (Fig. 6.17A). With development and growth of the brain vesicles, however, the embryonic disc begins to bulge into the amniotic cavity. Lengthening of the neural tube now causes the embryo to curve into the fetal position as the head and tail regions (folds) move ventrally (Fig. 6.17). Simultaneously, two lateral body wall folds form and also move ventrally to close the ventral body wall (Fig. 6.18). As the head and tail and two lateral folds move ventrally, they pull the amnion down with them, such that the embryo lies within the amniotic cavity (Figs. 6.17 and 6.18). The ventral body wall closes completely except for the umbilical region where the connecting stalk and yolk sac duct remain attached (Figs. 6.17 and 6.19). Failure of the lateral body folds to close the body wall results in ventral body wall defects (see Chapter 7).

As a result of cephalocaudal growth and closure of the lateral body wall folds, a continuously larger portion of the endodermal germ layer is incorporated into the body of the embryo to form the gut tube. The tube is divided into three regions: the foregut, midgut, and hindgut (Fig. 6.17C). The midgut communicates with the yolk sac by way of a broad stalk, the vitelline (yolk sac) duct (Fig. 6.17D). This duct is wide initially, but with further growth of the embryo, it becomes narrow and much longer (Figs. 6.17D and 6.18B).

At its cephalic end, the foregut is temporarily bounded by an ectodermal–endodermal
membrane called the oropharyngeal membrane (Fig. 6.17A,C). This membrane separates the stomodeum, the primitive oral cavity derived from ectoderm, from the pharynx, a part of the foregut derived from endoderm. In the fourth week, the oropharyngeal membrane ruptures, establishing an open connection between the oral cavity and the primitive gut (Fig. 6.17D). The hindgut also terminates temporarily at an ectodermal–endodermal membrane, the cloacal membrane (Fig. 6.17C). This membrane separates the upper part of the anal canal, derived from endoderm, from the lower part, called the proctodeum, which is formed by an invaginating pit lined by ectoderm. The membrane breaks down in the seventh week to create the opening for the anus.

Another important result of cephalocaudal growth and lateral folding is partial incorporation of the allantois into the body of the embryo, where it forms the cloaca (Fig. 6.19A).
The distal portion of the allantois remains in the connecting stalk. By the fifth week, the yolk sac duct, allantois, and umbilical vessels are restricted to the umbilical region (Fig. 6.19).

The role of the yolk sac is not clear. It may function as a nutritive organ during the earliest stages of development prior to the establishment of blood vessels. It also contributes some of the first blood cells, although this role is very transitory. One of its main functions is to house germ cells that reside in its posterior wall and later migrate to the gonads to form eggs and sperm (see Chapter 16).

Hence, the endodermal germ layer initially forms the epithelial lining of the primitive gut and the intraembryonic portions of the allantois and vitelline duct (Fig. 6.19A). During further development, endoderm gives rise to the following:

- The epithelial lining of the respiratory tract
- The parenchyma of the thyroid, parathyroids, liver, and pancreas (see Chapters 15 and 17)
- The reticular stroma of the tonsils and the thymus
- The epithelial lining of the urinary bladder and the urethra (see Chapter 16)
- The epithelial lining of the tympanic cavity and auditory tube (see Chapter 19)

**PATTERNING OF THE ANTEROPosterior AXIS: REGULATION BY HOMEBOX GENES**

Homebox genes are known for their homeodomain, a DNA-binding motif, the homeobox. They code for transcription factors that activate cascades of genes regulating phenomena such as segmentation and axis formation. Many homebox genes are collected into homeotic clusters, although other genes also contain the homeodomain. An important cluster of genes specifying the cranio-caudal axis is the homeotic gene complex Hom-C in *Drosophila*. These genes, which contain the Antennapedia and Bithorax classes of homeotic genes, are organized on a single chromosome as a functional unit. Thus, genes specifying more cranial structures lie at the 3’ end of the DNA and are expressed first, with genes controlling posterior development expressed sequentially and lying increasingly toward the 5’ end (Fig. 6.20). These genes are conserved in humans, existing as four copies—HOXA, HOXB, HOXC, and HOXD—which are arranged and expressed like those in *Drosophila*. Thus, each cluster lies on a separate chromosome, and the genes in each group are numbered 1 to 13 (Fig. 6.20). Genes with the same number, but belonging to different clusters, form a paralogous group, such as HOXA4, HOXB4, HOXC4, and HOXD4. The pattern of expression of these genes, along with evidence from knockout experiments in which mice are created that lack one or more of these genes, supports the hypothesis that they play a role in cranial-to-caudal patterning of the derivatives of all three germ layers. For example, an overlapping expression pattern of the HOX code exists in the somites and vertebrae, with genes located more toward the 3’ end in each cluster being expressed in and regulating development of more cranial segments (Fig. 6.20).

**EXTERNAL APPEARANCE DURING THE SECOND MONTH**

At the end of the fourth week, when the embryo has approximately 28 somites, the main external features are the somites and pharyngeal arches (Fig. 6.21). The age of the embryo is therefore usually expressed in somites (Table 6.2, p. 80). Because counting somites becomes difficult during the second month of development, the age of the embryo is then indicated as the crown-rump length (CRL) and expressed in millimeters (Table 6.3, p. 90). CRL is the measurement from the vertex of the skull to the midpoint between the apices of the buttocks.

During the second month, the external appearance of the embryo is changed by an increase in head size and formation of the limbs, face, ears, nose, and eyes. By the beginning of the fifth week, forelimbs and hind limbs appear as paddle-shaped buds (Fig. 6.22). The former are located dorsal to the pericardial swelling at the level of the fourth cervical to the first thoracic somites, which explains their innervation by the brachial plexus. Hind limb buds appear slightly later just caudal to attachment of
FIGURE 6.20 Drawing showing the arrangement of homeobox genes of the Antennapedia (ANT-C) and Bithorax (BX-C) classes of Drosophila and conserved homologous genes of the same classes in humans. During evolution, these genes have been duplicated, such that humans have four copies arranged on four different chromosomes. Homology between Drosophila genes and those in each cluster of human genes is indicated by color. Genes with the same number, but positioned on different chromosomes, form a paralogous group. Expression of the genes is in a cranial-to-caudal direction from the 3' (expressed early) to the 5' (expressed later) end as indicated in the fly and mouse embryo diagrams. Retinoic acid (RA) modulates expression of these genes, with those at the 3' end being more responsive to the compound.

FIGURE 6.21 A. Lateral view of a 28-somite human embryo. The main external features are the pharyngeal arches and somites. Note the pericardial liver bulge. B. The same embryo taken from a different angle to demonstrate the size of the yolk sac.
the umbilical stalk at the level of the lumbar and upper sacral somites. With further growth, the terminal portions of the buds flatten, and a circular constriction separates them from the proximal, more cylindrical segment (Fig. 6.23). Soon, four radial grooves separating five slightly thicker areas appear on the distal portion of the buds, foreshadowing formation of the digits (Fig. 6.23).

These grooves, known as rays, appear in the hand region first and shortly afterward in the foot, as the upper limb is slightly more advanced in development than the lower limb. While fingers and toes are being formed (Fig. 6.24), a sec-

These grooves, known as rays, appear in the hand region first and shortly afterward in the foot, as the upper limb is slightly more advanced in development than the lower limb. While fingers and toes are being formed (Fig. 6.24), a second constriction divides the proximal portion of the buds into two segments, and the three parts characteristic of the adult extremities can be recognized (Fig. 6.25).
Clinical Correlates

Birth Defects

Most major organs and organ systems are formed during the third to eighth weeks. This period, which is critical for normal development, is therefore called the period of organogenesis or embryogenesis. Stem cell populations are establishing each of the organ primordia, and these interactions are sensitive to insult from genetic and environmental influences. Thus, from the third to eighth weeks is the time when most gross structural birth defects are induced. Unfortunately, the mother may not realize she is pregnant during this critical time, especially during the third and fourth weeks, which are particularly vulnerable. Consequently, she may not avoid harmful influences, such as cigarette smoking and alcohol. Understanding the main events of organogenesis is important for identifying the time that a particular defect was induced and, in turn, determining possible causes for the malformation (see Chapter 9).

**FIGURE 6.24** Human embryo [CRL 21 mm, seventh week] [×4]. The chorionic sac is open to show the embryo in its amniotic sac. The yolk sac, umbilical cord, and vessels in the chorionic plate of the placenta are clearly visible. Note the size of the head in comparison with the rest of the body.
The **embryonic period**, which extends from the **third to the eighth weeks** of development, is the period during which each of the three germ layers, **ectoderm**, **mesoderm**, and **endoderm**, gives rise to its own tissues and organ systems. As a result of organ formation, major features of body form are established (Table 6.4, p. 93).

The **ectodermal germ layer** gives rise to the organs and structures that maintain contact with the outside world:

- Central nervous system
- Peripheral nervous system
- Sensory epithelium of ear, nose, and eye
- Skin, including hair and nails
- Pituitary, mammary, and sweat glands and enamel of the teeth

Induction of the **neural plate** is regulated by inactivation of the growth factor BMP4. In the cranial region, inactivation is caused by noggin, chordin, and follistatin secreted by the node, notochord, and prechordal mesoderm. Inactivation of BMP4 in the hindbrain and spinal cord regions is effected by WNT3a and FGF. In the absence of inactivation, BMP4 causes ectoderm to become epidermis and mesoderm to ventralize to form intermediate and lateral plate mesoderm.

Important components of the mesodermal germ layer are **paraxial**, **intermediate**, and **lateral plate** mesoderm. Paraxial mesoderm forms **somitomeres**, which give rise to mesenchyme of the head and organize into **somites** in occipital and caudal segments. Somites give rise to the **myotome** (muscle tissue), **sclerotome** (cartilage and bone), and **dermatome** (dermis of the skin), which are **all supporting tissues of the body**. Signals for somite differentiation are derived from surrounding structures, including the notochord, neural tube, and epidermis. The notochord and floor plate of the neural tube secrete **SHH**, which induces the sclerotome.

Two muscle-forming regions differentiate. One is induced in the dorsomedial region of the somite by **WNT proteins** secreted by the dorsal...
portion of the neural tube. The other is induced in the ventrolateral region of the somite by a combination of BMP4 and FGF, secreted by lateral plate mesoderm, and by WNT proteins, secreted by the overlying ectoderm.

The dorsal midportion of the somite becomes dermis under the influence of NT-3, secreted by the dorsal neural tube (Fig. 6.12). Mesoderm also gives rise to the vascular system (i.e., the heart, arteries, veins, lymph vessels, and all blood and lymph cells). Furthermore, it gives rise to the urogenital system: kidneys, gonads, and their ducts (but not the bladder). Finally, the spleen and cortex of the suprarenal glands are mesodermal derivatives.

The endodermal germ layer provides the epithelial lining of the gastrointestinal tract, respiratory tract, and urinary bladder. It also forms the parenchyma of the thyroid, parathyroids, liver, and pancreas. Finally, the epithelial lining of the tympanic cavity and auditory tube originates in the endodermal germ layer.

Craniocaudal patterning of the embryonic axis is controlled by homeobox genes. These genes, conserved from Drosophila, are arranged in four clusters—HOXA, HOXB, HOXC, and HOXD—on four different chromosomes. Genes toward the 3’ end of the chromosome control development of more cranial structures; those more toward the 5’ end regulate differentiation

of more posterior structures. Together, they regulate patterning of the hindbrain and axis of the embryo (Fig. 6.20).

As a result of formation of organ systems and rapid growth of the central nervous system, the initial flat embryonic disc begins to lengthen and to form head and tail regions (folds) that cause the embryo to curve into the fetal position. The embryo also forms two **lateral body wall folds** that grow ventrally and close the ventral body wall. As a result of this growth and folding, the amnion is pulled ventrally and the embryo lies within the amniotic cavity (Fig. 6.17). Connection with the yolk sac and placenta is maintained through the **vitelline duct** and **umbilical cord**, respectively.

---

**Problems to Solve**

1. Describe the process of neurulation and include definitions for the terms **neural folds**, **neural tube**, and **neural tube closure**. Where is neural tube closure initiated and how does it proceed? What week in gestation is the process completed? What happens if neural tube closure fails cranially? Caudally? What is an NTD and how can most be prevented?

2. What is the embryological origin of neural crest cells? Are they ectodermal, mesodermal, or endodermal in origin? To what structures do they contribute? What protein is primarily responsible for their induction?

3. From what germ layer are somites formed? How are they organized, and what tissues do they form?

4. What are the two ways that blood vessels arise? What growth factor plays a key role in early blood cell and vessel formation? What type of tumor is caused by abnormal proliferations of capillary blood vessels?

5. What are the major subdivisions of the gut tube, and what germ layer gives rise to these parts? What structure forms a connection from the midgut to the yolk sac? What membranes close the gut tube cranially and caudally?

6. Why are the third to eighth weeks of embryogenesis so important for normal development and the most sensitive for induction of structural defects?
During the third and fourth weeks, the top layer (ectoderm) of the trilaminar embryonic disc forms the neural plate that rolls up into a tube to form the brain and spinal cord by the process called neurulation (see Chapter 6, p. 71).

Almost simultaneously, the ventral layer (endoderm) rolls down to form the gut tube, such that the embryo consists of a tube on top of a tube: the neural tube dorsally and the gut tube ventrally (Fig. 7.1). The middle layer (mesoderm) holds the two tubes together and the lateral plate component of this mesoderm layer also splits.

**FIGURE 7.1** Transverse sections through embryos at various stages of closure of the gut tube and ventral body wall. **A.** At approximately 19 days, intercellular clefts are visible in the lateral plate mesoderm. **B.** At 20 days, the lateral plate is divided into somatic and visceral mesoderm layers that line the primitive body cavity [intraembryonic cavity]. **C.** By 21 days, the primitive body cavity [intraembryonic cavity] is still in open communication with the extraembryonic cavity. **D.** By 24 days, the lateral body wall folds, consisting of the parietal layer of lateral plate mesoderm and overlying ectoderm are approaching each other in the midline. **E.** At the end of the fourth week, visceral mesoderm layers are continuous with parietal layers as a double-layered membrane, the dorsal mesentery. Dorsal mesentery extends from the caudal limit of the foregut to the end of the hindgut.
Part I • General Embryology

into visceral (splanchnic) and parietal (somatic) layers. The visceral layer rolls ventrally and is intimately connected to the gut tube; the parietal layer, together with the overlying ectoderm, forms the lateral body wall folds (one on each side of the embryo), which move ventrally and meet in the midline to close the ventral body wall (Fig. 7.1). The space between visceral and parietal layers of lateral plate mesoderm is the primitive body cavity, which at this early stage is a continuous cavity, because it has not yet been subdivided into the pericardial, pleural, and abdominopelvic regions.

**FORMATION OF THE BODY CAVITY**

At the end of the third week, intraembryonic mesoderm differentiates into paraxial mesoderm, which forms somitomeres and somites that play a major role in forming the skull and vertebrae; intermediate mesoderm, which contributes to the urogenital system; and lateral plate mesoderm, which is involved in forming the body cavity (Fig. 7.1). Soon after it forms as a solid mesodermal layer, clefts appear in the lateral plate mesoderm that coalesce to split the solid layer into two (Fig. 7.1B): (1) the parietal (somatic) layer adjacent to the surface ectoderm and continuous with the extraembryonic parietal mesoderm layer over the amnion. Together, the parietal (somatic) layer of lateral plate mesoderm and overlying ectoderm are called the somatopleure; (2) the visceral (splanchnic) layer adjacent to endoderm forming the gut tube and continuous with the visceral layer of extraembryonic mesoderm covering the yolk sac (Figs. 7.1B). Together, the visceral (splanchnic) layer of lateral plate mesoderm and underlying endoderm are called the splanchnopleure. The space created between the two layers of lateral plate mesoderm constitutes the primitive body cavity. During the fourth week, the sides of the embryo begin to grow ventrally forming two lateral body wall folds (Fig. 7.1B and C). These folds consist of the parietal layer of lateral plate mesoderm, overlying ectoderm, and cells from adjacent somites that migrate into the mesoderm layer across the lateral somitic frontier (see Chapter 11, p. 156). As these folds progress, the endoderm layer also folds ventrally and closes to form the gut tube (Fig. 7.1D and E). By the end of the fourth week, the lateral body wall folds meet in the midline and fuse to close the ventral body wall (Fig. 7.1C–E). This closure is aided by growth of the head and tail regions (folds) that cause the embryo to curve into the fetal position (Fig. 7.2). Closure of the ventral body wall is complete except in the region of the connecting stalk (future umbilical cord). Similarly, closure of the gut tube is complete except for a connection from the midgut region to the yolk sac called the vitelline duct (Fig. 7.2D). This duct is incorporated into the umbilical cord, becomes very narrow (Fig. 8.16, p. 118), and degenerates with the yolk sac between the second and third months of gestation. (Note that throughout the process of body cavity and gut tube development, the parietal and visceral layers of lateral plate mesoderm are continuous with each other at the junction of the gut tube with the posterior body wall [Fig. 7.1D,E].)

**SEROUS MEMBRANES**

Some cells of the parietal layer of lateral plate mesoderm lining the body wall of the primitive embryonic cavity become mesothelial and form the parietal layer of the serous membranes lining the outside of the peritoneal, pleural, and pericardial cavities. In a similar manner, some cells of the visceral layer of lateral plate mesoderm form the visceral layer of the serous membranes covering the abdominal organs, lungs, and heart (Fig. 7.1E). Visceral and parietal layers are continuous with each other as the dorsal mesentery (Fig. 7.1E), which suspends the gut tube from the posterior body wall into the peritoneal cavity. Dorsal mesentery extends continuously from the caudal limit of the foregut to the end of the hindgut. Ventral mesentery exists only from the caudal foregut to the upper portion of the duodenum and results from thinning of mesoderm of the septum transversum, a block of mesoderm that forms connective tissue in the liver and the central tendon of the diaphragm (see Figs. 7.2D and 7.5). These mesenteries are double layers of peritoneum that provide a pathway for blood vessels, nerves, and lymphatics to the organs.

Clinical Correlates

Ventral Body Wall Defects

Ventral body wall defects occur in the thorax, abdomen, and pelvis and involve the heart (ectopia cordis), abdominal viscera (gastroschisis), and/or urogenital organs (bladder or cloacal extrophy), depending upon the location and size of the abnormality. The malformations are due to a failure of the ventral body wall to close and probably involve the lateral body wall folds to a greater extent than the head and tail folds. Thus, one or both of the lateral body wall folds fail to progress ventrally or there are abnormalities in the fusion process once they meet in the midline. An omphalocele also represents a ventral body wall defect; however, its primary cause is not due to inhibition of body wall closure. Instead, this abnormality occurs when a portion of the gut tube fails to return to the abdominal cavity following its normal herniation into the umbilical cord (see p. 243).

Ectopia cordis occurs when lateral body wall folds fail to close the midline in the thoracic region causing the heart to lie outside the body cavity [Fig. 7.3A]. Sometimes, the closure defect begins at the caudal end of the sternum and extends into the upper abdomen resulting in a spectrum of abnormalities called Cantrell pentalogy. This spectrum includes ectopia cordis, defects in the anterior region of the diaphragm, absence of the pericardium, defects in the sternum, and abdominal wall closure. This spectrum includes ectopia cordis, defects in the anterior region of the diaphragm, absence of the pericardium, defects in the sternum, and abdominal wall closure (continued)
Part I • General Embryology

FIGURE 7.3 Examples of ventral body wall defects due to failure of the ventral body wall to close.

A. Ectopia cordis. The heart lies outside the thorax, and there is a cleft in the thoracic wall.

B. Gastroschisis. Intestines have herniated through the abdominal wall to the right of the umbilicus, the most common location for this defect.

C. Bladder extrophy. Closure in the pelvic region has failed. In males, the defect usually includes a split in the dorsum of the penis, a defect called epispadias.

D. Cloacal extrophy. A larger closure defect in which most of the pelvic region has failed to close, leaving the bladder, part of the rectum, and the anal canal exposed.
defects including omphalocele and gastroschisis. (Note: Omphaloceles that may occur in Cantrell pentalogies are secondary to the body wall closure defect, not primary. The closure defect reduces the size of the abdominal cavity and prevents the return of the intestinal loops from the umbilical cord; see p. 243).

**Gastroschisis** occurs when body wall closure fails in the abdominal region [Fig. 7.3S]. As a result, intestinal loops herniate into the amniotic cavity through the defect, which usually lies to the right of the umbilicus. The incidence of gastroschisis is increasing [3.5/10,000], and it is most common in infants from thin women younger than 20 years of age. The defect can be detected by fetal ultrasound and by elevated α-fetoprotein (AFP) concentrations in maternal serum and the amniotic fluid. The malformation is not associated with chromosome abnormalities, but other defects occur in 15% of cases. Affected loops of bowel may be damaged by exposure to amniotic fluid, which has a corrosive effect, or by twisting around each other (volvulus) and compromising their blood supply.

**Bladder or cloacal exstrophy** results from abnormal body wall closure in the pelvic region. Bladder exstrophy represents a less severe closure defect in this region and only the bladder is exposed [Fig. 7.3C; in males, the penis may be involved and epispadias (a split in the dorsum of the penis; see Chapter 16, p. 260) is common]. Cloacal exstrophy results from a more severe failure of body wall closure in the pelvis such that the bladder and rectum, which are derived from the cloaca [see Chapter 16, p. 260], are exposed [Fig. 7.3D].

**Omphalocele** represents another ventral body wall defect [Fig. 7.4], but it does not arise from a failure in body wall closure. Instead, it originates when portions of the gut tube (the midgut) that normally herniates into the umbilical cord during the 6th to the 10th weeks (physiological umbilical herniation) fails to return to the abdominal cavity [see Chapter 15, p. 243]. Subsequently, loops of bowel, and other viscera, including the liver, may herniate into the defect. Because the umbilical cord is covered by a reflection of the amnion, the defect is covered by this epithelial layer. [In contrast, loops of bowel in gastroschisis are not covered by amnion because they herniate through the abdominal wall directly into the amniotic cavity.] Omphalocele, which occurs in 2.5/10,000 births, is associated with high mortality rates and severe malformations, including cardiac abnormalities and neural tube defects. Furthermore, chromosome abnormalities are present in 15% of cases. Like gastroschisis, omphaloceles are associated with elevated AFP concentrations.

---

**FIGURE 7.4** Examples of omphaloceles, a defect that occurs when loops of bowel, which normally herniate into the umbilical cord during the 6th to the 10th weeks of gestation (physiological umbilical herniation), fail to return to the body cavity. **A.** Drawing showing loops of herniated bowel within the umbilical cord that have failed to return to the abdominal cavity. The bowel is covered by amnion because this membrane normally reflects onto the umbilical cord. **B.** Infant with an omphalocele. The defect is associated with other major malformations and chromosome abnormalities.
DIAPHRAGM AND THORACIC CAVITY

The septum transversum is a thick plate of mesodermal tissue occupying the space between the thoracic cavity and the stalk of the yolk sac (Fig. 7.5A,B). The septum is derived from visceral (splanchnic) mesoderm surrounding the heart and assumes its position between the primitive thoracic and abdominal cavities when the cranial end of the embryo grows and curves.

**FIGURE 7.5** A. Drawing showing the ventral view of an embryo at 24 days of gestation. The gut tube is closing, the anterior and posterior intestinal portals are visible, and the heart lies in the primitive pleuropericardial cavity, which is partially separated from the abdominal cavity by the septum transversum. B. Portion of an embryo at approximately 5 weeks with parts of the body wall and septum transversum removed to show the pericardioperitoneal canals. Note the size and thickness of the septum transversum and liver cords penetrating the septum. C. Growth of the lung buds into the pericardioperitoneal canals. Note the pleuropericardial folds.
into the fetal position (Fig. 7.2B–D). This septum does not separate the thoracic and abdominal cavities completely but leaves large openings, the pericardioperitoneal canals, on each side of the foregut (Fig. 7.5B).

When lung buds begin to grow, they expand caudolaterally within the pericardioperitoneal canals (Fig. 7.5C). As a result of the rapid growth of the lungs, the pericardioperitoneal canals become too small, and the lungs begin to expand into the mesenchyme of the body wall dorsally, laterally, and ventrally (Fig. 7.5C). Ventral and lateral expansion is posterior to the pleuropericardial folds. At first, these folds appear as small ridges projecting into the primitive undivided thoracic cavity (Fig. 7.5C). With expansion of the lungs, mesoderm of the body wall forms two components (Fig. 7.6): (1) the definitive wall of the thorax and (2) the pleuropericardial membranes, which are extensions of the pleuropericardial folds that contain the common cardinal veins and phrenic nerves. Subsequently, descent of the heart and positional changes of the sinus venosus shift the common cardinal veins toward the midline, and the pleuropericardial membranes are drawn out in mesentery-like fashion (Fig. 7.6A). Finally, they fuse with each other and with the root of the lungs, and the thoracic cavity is divided into the definitive pericardial cavity and two pleural cavities (Fig. 7.6B). In the adult, the pleuropericardial membranes form the fibrous pericardium.

**Formation of the Diaphragm**

Although the pleural cavities are separate from the pericardial cavity, they remain in open communication with the abdominal (peritoneal) cavity by way of the pericardioperitoneal canals (Fig. 7.7A). During further development, the opening between the prospective pleural and peritoneal cavities is closed by crescent-shaped folds, the pleuroperitoneal folds, which project into the caudal end of the pericardioperitoneal canals (Fig. 7.7A). Gradually, the folds extend medially and ventrally, so that by the seventh week, they fuse with the mesentery of the esophagus and with the septum transversum (Fig. 7.7B). Hence, the connection between the pleural and peritoneal portions of the body cavity is closed by the pleuroperitoneal membranes. Further expansion of the pleural cavities relative to mesenchyme of the body wall adds a peripheral rim to the pleuroperitoneal membranes (Fig. 7.7C). Once this rim is established, myoblasts originating from somites at cervical segments three to five (C3–5) penetrate the membranes to form the muscular part of the diaphragm.
Part I • General Embryology

FIGURE 7.7 Development of the diaphragm. A. Pleuroperitoneal folds appear at the beginning of the fifth week. B. Pleuroperitoneal folds fuse with the septum transversum and mesentery of the esophagus in the seventh week, separating the thoracic cavity from the abdominal cavity. C. Clinical Correlates

Diaphragmatic Hernias

A congenital diaphragmatic hernia, one of the more common malformations in the newborn [1/2,000], is most frequently caused by failure of one or both of the pleuroperitoneal membranes to close the pericardioperitoneal canals (Fig. 7.8). In that case, the peritoneal and pleural cavities are continuous with one another along the posterior body wall. This hernia allows abdominal viscera to enter the pleural cavity. In 85% to 90% of cases, the hernia is on the left side, and intestinal loops, stomach, spleen, and part of the liver may enter the thoracic cavity (Fig. 7.8). The

FIGURE 7.8 Congenital diaphragmatic hernia. A. Abdominal surface of the diaphragm showing a large defect of the pleuroperitoneal membrane. B. Hernia of the intestinal loops and part of the stomach into the left pleural cavity. The heart and mediastinum are frequently pushed to the right, and the left lung is compressed. C. Radiograph of a newborn with a large defect in the left side of the diaphragm. Abdominal viscera have entered the thorax through the defect.
abdominal viscera in the chest push the heart anteriorly and compress the lungs, which are commonly hypoplastic. A large defect is associated with a high rate of mortality (75%) from pulmonary hypoplasia and dysfunction. Occasionally, a small part of the muscular fibers of the diaphragm fails to develop, and a hernia may remain undiscovered until the child is several years old. Such a defect, frequently seen in the anterior portion of the diaphragm, is a parasternal hernia. A small peritoneal sac containing intestinal loops may enter the chest between the sternal and costal portions of the diaphragm [Fig. 7.8A].

Another type of diaphragmatic hernia, esophageal hernia, is thought to be due to congenital shortness of the esophagus. Upper portions of the stomach are retained in the thorax, and the stomach is constricted at the level of the diaphragm.

Thus, the diaphragm is derived from the following structures:

- The septum transversum, which forms the central tendon of the diaphragm
- The two pleuroperitoneal membranes
- Muscular components from somites at cervical segments three to five
- The mesentery of the esophagus, in which the crura of the diaphragm develop (Fig. 7.7C)

During the fourth week, the septum transversum lies opposite cervical somites, and nerve components of the third, fourth, and fifth cervical segments of the spinal cord grow into the septum. At first, the nerves, known as phrenic nerves, pass into the septum through the pleuropericardial folds (Fig. 7.5B). This explains why further expansion of the lungs and descent of the septum shift the phrenic nerves that innervate the diaphragm into the fibrous pericardium (Fig. 7.6).

Although the septum transversum lies opposite cervical segments during the fourth week, by the sixth week, the developing diaphragm is at the level of thoracic somites. The repositioning of the diaphragm is caused by rapid growth of the dorsal part of the embryo (vertebral column), compared with that of the ventral part. By the beginning of the third month, some of the dorsal bands of the diaphragm originate at the level of the first lumbar vertebra.

The phrenic nerves supply the diaphragm with its motor and sensory innervation. Because the most peripheral part of the diaphragm is derived from mesenchyme of the thoracic wall, it is generally accepted that some of the lower intercostal (thoracic) nerves contribute sensory fibers to the peripheral part of the diaphragm.

**SUMMARY**

At the end of the third week, the neural tube is elevating and closing dorsally while the gut tube is rolling and closing ventrally to create a “tube on top of a tube.” Mesoderm holds the tubes together and the lateral plate mesoderm splits to form a visceral (splanchnic) layer associated with the gut and a parietal (somatic) layer that, together with overlying ectoderm, forms the lateral body wall folds. The space between the visceral and parietal layers of lateral plate mesoderm is the primitive body cavity (Fig. 7.1). When the lateral body wall folds move ventrally and fuse in the midline, the body cavity is closed, except in the region of the connecting stalk (Figs. 7.1 and 7.2). Here the gut tube maintains an attachment to the yolk sac as the yolk sac (vitelline) duct. The lateral body wall folds also pull the amnion with them so that the amnion surrounds the embryo and extends over the connecting stalk, which becomes the umbilical cord (Fig. 7.1D and 7.2D). Failure of the ventral body wall to close results in ventral body wall defects, such as ectopia cordis, gastroschisis, and extrophy of the bladder and cloaca (Fig. 7.3).

Parietal mesoderm will form the parietal layer of serous membranes lining the outside (walls) of the peritoneal, pleural, and pericardial cavities. The visceral layer will form the visceral layer of the serous membranes covering the lungs, heart, and abdominal organs. These layers are continuous at the root of each organ as the organs lie in their respective cavities. (This relationship is similar to the picture created when you stick a finger [organ] into the side of a balloon: The layer of the balloon surrounding the finger [organ] being the visceral layer, and the rest of the balloon being
the somatic or parietal layer. The space between is the “primitive body cavity.” The two layers of the balloon are continuous at the base [root] of the finger.) In the gut, the layers form the peritoneum and in places suspend the gut from the body wall as double layers of peritoneum called mesenteries (Fig. 7.1E). Mesenteries provide a pathway for vessels, nerves, and lymphatics to the organs. Initially, the gut tube from the caudal end of the foregut to the end of the hindgut is suspended from the dorsal body wall by dorsal mesentery (Fig. 7.1E). Ventral mesentery, derived from the septum transversum, exists only in the region of the terminal part of the esophagus, the stomach, and the upper portion of the duodenum (see Chapter 15).

The diaphragm divides the body cavity into the thoracic and peritoneal cavities. It develops from four components: (1) septum transversum (central tendon), (2) pleuropertitoneal membranes, (3) dorsal mesentery of the esophagus, and (4) muscular components from somites at cervical levels three to five (C3–5) of the body wall (Fig. 7.7). Because the septum transversum is located initially opposite cervical segments three to five and because muscle cells for the diaphragm originate from somites at these segments, the phrenic nerve also arises from these segments of the spinal cord (C3, C4, and C5 keep the diaphragm alive!). Congenital diaphragmatic hernias involving a defect of the pleuropertitoneal membrane on the left side occur frequently.

The thoracic cavity is divided into the pericardial cavity and two pleural cavities for the lungs by the pleuropertitoneal membranes (Fig. 7.6).

Problems to Solve

1. A newborn infant cannot breathe and soon dies. An autopsy reveals a large diaphragmatic defect on the left side, with the stomach and the intestines occupying the left side of the thorax. Both lungs are severely hypoplastic. What is the embryological basis for this defect?

2. A child is born with a large defect lateral to the umbilicus. Most of the large and the small bowel protrude through the defect and are not covered by amnion. What is the embryological basis for this abnormality, and should you be concerned that other malformations may be present?

3. Explain why the phrenic nerve, which supplies motor and sensory fibers to the diaphragm, originates from cervical segments when most of the diaphragm is in the thorax. From which cervical segments does the nerve originate?
DEVELOPMENT OF THE FETUS

The period from the beginning of the ninth week to birth is known as the fetal period. It is characterized by maturation of tissues and organs and rapid growth of the body. The length of the fetus is usually indicated as the crown-rump length (CRL) (sitting height) or as the crown-heel length (CHL), the measurement from the vertex of the skull to the heel (standing height). These measurements, expressed in centimeters, are correlated with the age of the fetus in weeks or months (Table 8.1). Growth in length is particularly striking during the third, fourth, and fifth months, whereas an increase in weight is most striking during the last 2 months of gestation. In general, the length of pregnancy is considered to be 280 days, or 40 weeks after the onset of the last normal menstrual period (LNMP) or, more accurately, 266 days or 38 weeks after fertilization. For the purposes of the following discussion, age is calculated from the time of fertilization and is expressed in weeks or calendar months.

Monthly Changes

One of the most striking changes taking place during fetal life is the relative slowdown in growth of the head compared with the rest of the body. At the beginning of the third month, the head constitutes approximately half of the CRL (Figs. 8.1 and 8.2). By the beginning of the fifth month, the size of the head is about one third of the CHL, and at birth, it is approximately one quarter of the CHL (Fig. 8.2). Hence, over time, growth of the body accelerates but that of the head slows down.

During the third month, the face becomes more human looking (Figs. 8.3 and 8.4). The eyes, initially directed laterally, move to the ventral aspect of the face, and the ears come to lie close to their definitive position at the side of the head (Fig. 8.3). The limbs reach their relative length in comparison with the rest of the body, although the lower limbs are still a little shorter and less well developed than the upper extremities. Primary ossification centers are present in the long bones and skull by the 12th week. Also by the 12th week, external genitalia develop to such a degree that the sex of the fetus can be determined by external examination (ultrasound). During the sixth week, intestinal loops cause a large swelling (herniation) in the umbilical cord, but by the 12th week, the loops have withdrawn into the abdominal cavity. At the end of the third month, reflex activity can be evoked in aborted fetuses, indicating muscular activity.

During the fourth and fifth months, the fetus lengthens rapidly (Fig. 8.5 and Table 8.1), and at the end of the first half of intrauterine life, its CRL is approximately 15 cm, about half the total length of the newborn. The weight of the fetus increases little during this period and by the end of the fifth month is still <500 g. The fetus is covered with fine hair, called lanugo hair; eyebrows and head hair are also visible. During the fifth month, movements of the fetus can be felt by the mother.
During the second half of intrauterine life, weight increases considerably, particularly during the last 2.5 months, when 50% of the full-term weight (approximately 3,200 g) is added. During the sixth month, the skin of the fetus is reddish and has a wrinkled appearance because of the lack of underlying connective tissue. A fetus born early in the sixth month has great difficulty surviving. Although several organ systems are able to function, the respiratory system and the central nervous system have not differentiated sufficiently, and coordination between the two systems is not yet well established. By 6.5 to 7 months, the fetus has a CRL of about 25 cm

FIGURE 8.1 A 9-week fetus. Note the large head size compared with that of the rest of the body. The yolk sac and long vitelline duct are visible in the chorionic cavity. Note the umbilical cord and herniation of intestinal loops. One side of the chorion has many villi (chorion frondosum), whereas the other side is almost smooth (chorion laeve).

Chapter 8 • Third Month to Birth: The Fetus and Placenta

**FIGURE 8.3** An 11-week fetus. The umbilical cord still shows a swelling at its base, caused by herniated intestinal loops. The skull of this fetus lacks the normal smooth contours. Fingers and toes are well developed.

**FIGURE 8.4** A 12-week fetus in utero. Note the extremely thin skin and underlying blood vessels. The face has all of the human characteristics, but the ears are still primitive. Movements begin at this time but are usually not felt by the mother.

**FIGURE 8.5** An 18-week fetus connected to the placenta by its umbilical cord. The skin of the fetus is thin because of lack of subcutaneous fat. Note the placenta with its cotyledons and the amnion.
and weighs approximately 1,100 g. If born at this time, the infant has a 90% chance of surviving. Some developmental events occurring during the first 7 months are indicated in Table 8.2.

During the last 2 months, the fetus obtains well-rounded contours as the result of deposition of subcutaneous fat (Fig. 8.6). By the end of intrauterine life, the skin is covered by a whitish, fatty substance (vernix caseosa) composed of secretory products from sebaceous glands.

At the end of the ninth month, the skull has the largest circumference of all parts of the body, an important fact with regard to its passage through the birth canal. At the time of birth, the weight of a normal fetus is 3,000 to 3,400 g, its CRL is about 36 cm, and its CHL is about 50 cm. Sexual characteristics are pronounced, and the testes should be in the scrotum.

**Time of Birth**

The date of birth is most accurately indicated as 266 days, or 38 weeks, after fertilization. The oocyte is usually fertilized within 12 hours of ovulation; however, sperm deposited in the reproductive tract up to 6 days prior to ovulation can survive to fertilize oocytes. Thus, most pregnancies occur when sexual intercourse occurs within a 6-day period that ends on the day of ovulation. A pregnant woman usually will see her obstetrician when she has missed two successive menstrual bleeds. By that time, her recollection about coitus is usually vague, and it is readily understandable that the day of fertilization is difficult to determine.

The obstetrician calculates the date of birth as 280 days or 40 weeks from the first day of the LNMP. In women with regular 28-day menstrual periods, the method is fairly accurate, but when cycles are irregular, substantial miscalculations may be made. An additional complication occurs when the woman has some bleeding about 14 days after fertilization as a result of erosive activity by the implanting blastocyst (see Chapter 4, “Day 13,” p. 52). Hence, the day of delivery is not always easy to determine. Most fetuses are born within 10 to 14 days of the calculated delivery date. If they are born much earlier, they are categorized as premature; if born later, they are considered postmature.

Occasionally, the age of an embryo or small fetus must be determined. By combining data on the onset of the last menstrual period with fetal length, weight, and other morphological characteristics typical for a given month of development, a reasonable estimate of the age of the fetus can be formulated. A valuable tool for assisting in this determination is ultrasound, which can provide an accurate (1 to 2 days) measurement of CRL during the 7th to 14th weeks. Measurements commonly used in the 16th to 30th weeks are biparietal diameter (BPD), head and abdominal circumference, and femur length. An accurate determination of fetal size and age is important for managing pregnancy, especially if the mother has a small pelvis or if the baby has a birth defect.
Clinical Correlates

Low Birth Weight
There is considerable variation in fetal length and weight, and sometimes these values do not correspond with the calculated age of the fetus in months or weeks. Most factors influencing length and weight are genetically determined, but environmental factors also play an important role.

The average size of a newborn is 2,500 to 4,000 g (6 to 9 lb) with a length of 51 cm (20 in). The term low birth weight (LBW) refers to a weight <2,500 g, regardless of gestational age. Many infants weigh <2,500 g because they are preterm (born before 37 weeks of gestation). In contrast, the terms intrauterine growth restriction (IUGR) and small for gestational age (SGA) take into account gestational age.

IUGR is a term applied to infants who do not attain their optimal intrauterine growth. These infants are pathologically small and at risk for poor outcomes. Infants who are SGA have a birth weight that is below the 10th percentile for their gestational age. These babies may be pathologically small (they may have IUGR) or they may be constitutionally small (healthy but smaller in size). The challenge is to differentiate the two conditions so that healthy but small babies are not subjected to high-risk protocols used for babies with IUGR.

Approximately 1 in 10 babies have IUGR and therefore have an increased risk of neurological problems, congenital malformations, meconium aspiration, hypoglycemia, hypocalcemia, and respiratory distress syndrome (RDS). There are also long-term effects on these infants: In other words, what happens in the womb does not stay in the womb and adverse fetal exposures may predispose individuals to health problems as they get older. For example, babies with IUGR have been shown to have a greater chance as adults to develop a metabolic disorder later in life, such as obesity, hypertension, hypercholesterolemia, cardiovascular disease, and type 2 diabetes (called the Barker hypothesis).

The incidence of IUGR is higher in blacks than in whites. Causative factors include chromosomal abnormalities; teratogens; congenital infections [rubella, cytomegalovirus, toxoplasmosis, and syphilis]; poor maternal health [hypertension and renal and cardiac disease]; the mother’s nutritional status and socioeconomic level; her use of cigarettes, alcohol, and other drugs; placental insufficiency; and multiple births [e.g., twins, triplets].

The major growth-promoting factor during development before and after birth is insulin-like growth factor-I (IGF-I), which has mitogenic and anabolic effects. Fetal tissues express IGF-I, and serum levels are correlated with fetal growth. Mutations in the IGF-I gene result in IUGR, and this growth retardation is continued after birth. In contrast to the prenatal period, postnatal growth depends on growth hormone (GH). This hormone binds to its receptor (GHR), activating a signal transduction pathway and resulting in synthesis and secretion of IGF-I. Mutations in the GHR result in Laron dwarfism, which is characterized by marked short stature, and sometimes blue sclera. These individuals show little or no IUGR because IGF-I production does not depend on GH during fetal development.

---

FETAL MEMBRANES AND PLACENTA

The placenta is the organ that facilitates nutrient and gas exchange between the maternal and fetal compartments. As the fetus begins the ninth week of development, its demands for nutritional and other factors increase, causing major changes in the placenta. Foremost among these is an increase in surface area between maternal and fetal components to facilitate exchange. The disposition of fetal membranes is also altered as production of amniotic fluid increases.

Changes in the Trophoblast
The fetal component of the placenta is derived from the trophoblast and extraembryonic mesoderm (the chorionic plate); the maternal component is derived from the uterine endometrium. By the beginning of the second month, the trophoblast is characterized by a great number of secondary and tertiary villi, which give it a radial appearance (Fig. 8.7). Stem (anchoring) villi extend from the mesoderm of the chorionic plate to the cytotrophoblast shell. The surface of the villi
is formed by the syncytium, resting on a layer of cytotrophoblastic cells that in turn cover a core of vascular mesoderm (Fig. 8.8A,C). The capillary system developing in the core of the villous stems soon comes in contact with capillaries of the chorionic plate and connecting stalk, thus giving rise to the extraembryonic vascular system.

Maternal blood is delivered to the placenta by spiral arteries in the uterus. Erosion of these maternal vessels to release blood into intervillous spaces (Figs. 8.7 and 8.8) is accomplished by endovascular invasion by cytotrophoblast cells. These cells, released from the ends of anchoring villi (Figs. 8.7 and 8.8), invade the terminal ends of spiral arteries, where they replace maternal endothelial cells in the vessels’ walls, creating hybrid vessels containing both fetal and maternal cells. To accomplish this process, cytotrophoblast cells undergo an epithelial-to-endothelial transition. Invasion of the spiral arteries by cytotrophoblast cells transforms these vessels from small-diameter, high-resistance vessels to larger diameter, low-resistance vessels that can provide increased quantities of maternal blood to intervillous spaces (Figs. 8.7 and 8.8).

During the following months, numerous small extensions grow out from existing stem villi and extend as free villi into the surrounding lacunar or intervillous spaces. Initially, these newly formed free villi are primitive (Fig. 8.8C), but by the beginning of the fourth month, cytotrophoblastic cells and some connective tissue cells disappear. The syncytium and endothelial wall of the blood vessels are then the only layers that separate the maternal and fetal circulations (Fig. 8.8B,D). Frequently, the syncytium becomes very thin, and large pieces containing several nuclei may break off and drop into the intervillous blood lakes. These pieces, known as syncytial knots, enter the maternal circulation and usually degenerate without causing any symptoms. Disappearance of cytotrophoblastic cells progresses from the smaller to larger villi, and although some always persist in large villi, they do not participate in the exchange between the two circulations.
Preeclampsia is a condition characterized by maternal hypertension and proteinuria due to reduced organ perfusion and occurs in approximately 5% of pregnancies. The condition may progress to eclampsia, which is characterized by seizures. Preeclampsia begins suddenly anytime from approximately 20 weeks’ gestation to term and may result in fetal growth retardation, fetal death, or death of the mother. In fact, preeclampsia is a leading cause of maternal mortality in the United States and is completely reversible by delivery of the baby. However, delivery too early puts the infant at risk for complications related to preterm birth. Despite many years of research, the cause of preeclampsia is unknown. The condition appears to be a trophoblastic disorder related to failed or incomplete differentiation of cytotrophoblast cells, many of which do not undergo their normal epithelial-to-endothelial transformation. As a result, invasion of maternal blood vessels by these cells is rudimentary. How these cellular abnormalities lead to hypertension and other problems is not clear. Risk factors for preeclampsia include preeclampsia in a previous pregnancy, nulliparity (first pregnancy), obesity, family history of preeclampsia, multiple gestation (twins or more), and medical conditions, such as hypertension and diabetes. Preeclampsia also commonly occurs in women with hydatidiform moles (see Chapter 4, p. 56) in which case it occurs early in pregnancy.

**FIGURE 8.8** Structure of villi at various stages of development. **A.** During the fourth week. The extra-embryonic mesoderm penetrates the stem villi in the direction of the decidua plate. **B.** During the fourth month. In many small villi, the wall of the capillaries is in direct contact with the syncytium. **C,D.** Enlargement of the villus as shown in Figures 8.8A,B.
In the early weeks of development, villi cover the entire surface of the chorion (Fig. 8.7). As pregnancy advances, villi on the embryonic pole continue to grow and expand, giving rise to the chorion frondosum (bushy chorion). Villi on the abembryonic pole degenerate, and by the third month, this side of the chorion, now known as the chorion laeve, is smooth (Figs. 8.9 and 8.10A).

The difference between the embryonic and abembryonic poles of the chorion is also reflected in the structure of the decidua, the functional layer of the endometrium, which is shed during parturition. The decidua over the chorion frondosum, the decidua basalis, consists of a compact layer of large cells, decidual cells, with abundant amounts of lipids and glycogen. This layer, the decidual plate, is tightly connected to the chorion. The decidual layer over the abembryonic pole is the decidua capsularis (Fig. 8.10A). With growth of the chorionic vesicle, this layer becomes stretched and degenerates.

Subsequently, the chorion laeve comes into contact with the uterine wall (decidua parietalis) on the opposite side of the uterus, and the two fuse (Figs. 8.10 to 8.12), obliterating the uterine lumen. Hence, the only portion of the chorion participating in the exchange process is the chorion frondosum, which, together with the decidua basalis, makes up the placenta. Similarly, fusion of the amnion and chorion to form the amniochorionic membrane obliterates the chorionic cavity (Fig. 8.10A,B). It is this membrane that ruptures during labor (breaking of the water).

### STRUCTURE OF THE PLACENTA

By the beginning of the fourth month, the placenta has two components: (1) a fetal portion, formed by the chorion frondosum, and (2) a maternal portion, formed by the decidua basalis (Fig. 8.10B). On the fetal side, the placenta is bordered by the chorionic plate (Fig. 8.13); on its maternal side, it is bordered by the decidua basalis, of which the decidual plate is most intimately incorporated into the placenta. In the junctional zone, trophoblast and decidual cells intermingle. This zone, characterized by decidual and syncytial giant cells, is rich in amorphous extracellular material. By this time, most cytotrophoblast cells have degenerated. Between the chorionic and decidual plates are the intervillous spaces, which are filled with maternal blood. They are derived from lacunae in the syncytiotrophoblast and are lined with syncytium of fetal origin. The villous trees grow into the intervillous blood lakes (Figs. 8.8 and 8.13).

During the fourth and fifth months, the decidua forms a number of decidual septa, which project into intervillous spaces but do not reach the chorionic plate (Fig. 8.13). These septa have a core of maternal tissue, but their surface is covered by a layer of syncytial cells, so that at all times, a syncytial layer separates maternal blood in intervillous lakes from fetal tissue of the villi. As a result of this septum formation, the placenta is divided into a number of compartments, or cotyledons (Fig. 8.14). Because the decidual septa do not reach the chorionic plate, contact between intervillous spaces in the various cotyledons is maintained.

As a result of the continuous growth of the fetus and expansion of the uterus, the placenta
also enlarges. Its increase in surface area roughly parallels that of the expanding uterus, and throughout pregnancy, it covers approximately 15% to 30% of the internal surface of the uterus. The increase in thickness of the placenta results from arborization of existing villi and is not caused by further penetration into maternal tissues.

Full-Term Placenta
At full term, the placenta is discoid with a diameter of 15 to 25 cm, is approximately 3 cm thick, and weighs about 500 to 600 g. At birth, it is torn from the uterine wall and, approximately 30 minutes after birth of the child, is expelled from the uterine cavity as the afterbirth. When the placenta is viewed from the maternal side, 15 to 20 slightly bulging areas, the cotyledons, covered by a thin layer of decidua basalis, are clearly recognizable (Fig. 8.14B). Grooves between the cotyledons are formed by decidual septa.

The fetal surface of the placenta is covered entirely by the chorionic plate. A number of large arteries and veins, the chorionic vessels, converge toward the umbilical cord (Fig. 8.14A). The chorion, in turn, is covered by the amnion. Attachment of the umbilical cord is usually eccentric and occasionally even marginal. Rarely, however, does it insert into the chorionic membranes outside the placenta (velamentous insertion).

Circulation of the Placenta
Cotyledons receive their blood through 80 to 100 spiral arteries that pierce the decidual plate and enter the intervillous spaces at more or less regular intervals (Fig. 8.13). Pressure in these arteries forces the blood deep into the intervillous spaces and bathes the numerous small villi of the villous tree in oxygenated blood. As the
FIGURE 8.12 A 23-week fetus in the uterus. Portions of the wall of the uterus and the amnion have been removed to show the fetus. In the background are placental vessels converging toward the umbilical cord. The umbilical cord is tightly wound around the abdomen, possibly causing abnormal fetal position in the uterus (breech position).

FIGURE 8.13 The placenta in the second half of pregnancy. The cotyledons are partially separated by the decidual [maternal] septa. Most of the intervillous blood returns to the maternal circulation by way of the endometrial veins. A small portion enters neighboring cotyledons. The intervillous spaces are lined by syncytium.
pressure decreases, blood flows back from the chorionic plate toward the decidua, where it enters the endometrial veins (Fig. 8.13). Hence, blood from the intervillous lakes drains back into the maternal circulation through the endometrial veins.

Collectively, the intervillous spaces of a mature placenta contain approximately 150 mL of blood, which is replenished about three or four times per minute. This blood moves along the chorionic villi, which have a surface area of 4 to 14 m². Placental exchange does not take place in all villi, however, only in those that have fetal vessels in intimate contact with the covering syncytial membrane. In these villi, the syncytium often has a brush border consisting of numerous microvilli, which greatly increases the surface area and consequently the exchange rate between maternal and fetal circulations (Fig. 8.8D). The placental membrane, which separates maternal and fetal blood, is initially composed of four layers: (1) the endothelial lining of fetal vessels, (2) the connective tissue in the villus core, (3) the cytotrophoblastic layer, and (4) the syncytium (Fig. 8.8C). From the fourth month on, the placental membrane thins because the endothelial lining of the vessels comes in intimate contact with the syncytial membrane, greatly increasing the rate of exchange (Fig. 8.8D). Sometimes called the placental barrier, the placental membrane is not a true barrier, as many substances pass through it freely. Because the maternal blood in the intervillous spaces is separated from the fetal blood by a chorionic derivative, the human placenta is considered to be of the hemochorial type. Normally, there is no mixing of maternal and fetal blood. However, small numbers of fetal blood cells occasionally escape across microscopic defects in the placental membrane.

**Clinical Correlates**

**Erythroblastosis Fetalis and Fetal Hydrops**

Because some fetal blood cells escape across the placental barrier, there is a potential for these cells to elicit an antibody response by the mother’s immune system. The basis for this response is the fact that more than 400 red blood cell antigens have been identified, and although most do not cause problems during pregnancy, some can stimulate a maternal antibody response against fetal blood cells. This process is an example of **isoimmunization**, and if the maternal response is sufficient, the antibodies will attack and hemolyze fetal red blood cells, resulting in **hemolytic disease of the fetus and newborn**. Previously, the disease was called **erythroblastosis fetalis** because in some cases severe hemolysis stimulated an increase in production of fetal blood cells called **erythroblasts**. However, this severity of anemia occurs only in a few cases such that hemolytic disease of the fetus and newborn (continued)
newborn is a more appropriate terminology. In rare cases, the anemia becomes so severe that fetal hydrops (edema and effusions into the body cavities) occurs, leading to fetal death (Fig. 8.15). Most severe cases are caused by antigens from the CDE (Rhesus) blood group system. The D or Rh antigen is the most dangerous because immunization can result from a single exposure and occurs earlier and with greater severity with each succeeding pregnancy. The maternal antibody response occurs in cases when the fetus is D (Rh)-positive and the mother is D (Rh)-negative and is elicited when fetal red blood cells enter the maternal system because of small areas of bleeding at the surface of placental villi or at birth. This condition can be prevented by screening women at their first prenatal visit for Rh blood type and for the presence of anti-D antibodies to determine if she has been sensitized previously. In Rh-negative women without anti-D antibodies, recommendations include treatment with Rh immunoglobulin at 28 weeks’ gestation; following times when fetal-maternal mixing of blood may have occurred (e.g., after amniocentesis or pregnancy loss); and after delivery if the newborn is found to be Rh-positive. Since the introduction of Rh immunoglobulin in 1968, hemolytic disease in the fetus and newborn in the United States has almost been eliminated.

Antigens from the ABO blood group can also elicit an antibody response, but the effects are much milder than those produced by the CDE group. About 20% of all infants have an ABO maternal incompatibility, but only 5% will be clinically affected. These can be effectively treated postnatally.

---

### Function of the Placenta

Main functions of the placenta are (1) exchange of metabolic and gaseous products between maternal and fetal bloodstreams and (2) production of hormones.

**Exchange of Gases**

Exchange of gases—such as oxygen, carbon dioxide, and carbon monoxide—is accomplished by simple diffusion. At term, the fetus extracts 20 to 30 mL of oxygen per minute from the maternal circulation, and even a short-term interruption of the oxygen supply is fatal to the fetus. Placental blood flow is critical to oxygen supply, as the amount of oxygen reaching the fetus primarily depends on delivery, not diffusion.

**Exchange of Nutrients and Electrolytes**

Exchange of nutrients and electrolytes, such as amino acids, free fatty acids, carbohydrates, and vitamins, is rapid and increases as pregnancy advances.

**Transmission of Maternal Antibodies**

Immunological competence begins to develop late in the first trimester, by which time the fetus makes all of the components of complement. Immunoglobulins consist almost entirely of maternal immunoglobulin G (IgG), which begins to be transported from mother to fetus at approximately 14 weeks. In this manner, the fetus gains passive immunity against various infectious diseases. Newborns begin to produce their own IgG, but adult levels are not attained until the age of 3 years.

**Hormone Production**

By the end of the fourth month, the placenta produces progesterone in sufficient amounts to maintain pregnancy if the corpus luteum...
Clinical Correlates

The Placental Barrier

Maternal steroidal hormones readily cross the placenta. Other hormones, such as thyroxine, do so only at a slow rate. Some synthetic progestins rapidly cross the placenta and may masculinize female fetuses. Even more dangerous was the use of the synthetic estrogen diethylstilbestrol (DES), which easily crossed the placenta. This compound produced clear-cell carcinoma of the vagina and abnormalities of the cervix and uterus in females and in the testes of males in individuals who were exposed to the compound during their intrauterine life (see Chapter 9).

Although the placental barrier is frequently considered to act as a protective mechanism against damaging factors, many viruses—such as rubella, cytomegalovirus, coxsackie, variola, varicella, measles, and poliomyelitis virus—traverse the placenta without difficulty. Once in the fetus, some viruses cause infections, which may result in cell death and birth defects (see Chapter 9).

Unfortunately, most drugs and drug metabolites traverse the placenta without difficulty, and many cause serious damage to the embryo [see Chapter 9]. In addition, maternal use of heroin and cocaine can cause habituation in the fetus.

is removed or fails to function properly. In all probability, all hormones are synthesized in the syncytial trophoblast. In addition to progesterone, the placenta produces increasing amounts of estrogenic hormones, predominantly estriol, until just before the end of pregnancy, when a maximum level is reached. These high levels of estrogens stimulate uterine growth and development of the mammary glands.

During the first 2 months of pregnancy, the syncytiotrophoblast also produces human chorionic gonadotropin (hCG), which maintains the corpus luteum. This hormone is excreted by the mother in the urine, and in the early stages of gestation, its presence is used as an indicator of pregnancy. Another hormone produced by the placenta is somatomammotropin (formerly placental lactogen). It is a growth hormone–like substance that gives the fetus priority on maternal blood glucose and makes the mother somewhat diabetogenic. It also promotes breast development for milk production.

AMNION AND UMBILICAL CORD

The oval line of reflection between the amnion and embryonic ectoderm (amnio–ectodermal junction) is the primitive umbilical ring. At the fifth week of development, the following structures pass through the ring (Fig. 8.16A,C):

1. the connecting stalk, containing the allantois and the umbilical vessels, consisting of two arteries and one vein;
2. the yolk stalk (vitelline duct), accompanied by the vitelline vessels; and
3. the canal connecting the intraembryonic and extraembryonic cavities (Fig. 8.16C).

The yolk sac proper occupies a space in the chorionic cavity, that is, the space between the amnion and chorionic plate (Fig. 8.16B).

During further development, the amniotic cavity enlarges rapidly at the expense of the chorionic cavity, and the amnion begins to envelop the connecting and yolk sac stalks, crowding them together and giving rise to the primitive umbilical cord (Fig. 8.16B). Distally, the cord contains the yolk sac stalk and umbilical vessels. More proximally, it contains some intestinal loops and the remnant of the allantois (Fig. 8.16B,D). The yolk sac, found in the chorionic cavity, is connected to the umbilical cord by its stalk. At the end of the third month, the amnion has expanded so that it comes in contact with the chorion, obliterating the chorionic cavity (Fig. 8.16B). The yolk sac then usually shrinks and is gradually obliterated.

The abdominal cavity is temporarily too small for the rapidly developing intestinal loops, and some of them are pushed into the extraembryonic space in the umbilical cord. These extruding intestinal loops form a physiological umbilical hernia (see Chapter 15). At approximately the end of the third month, the loops are withdrawn into the body of the embryo, and the cavity in the cord is obliterated. When the allantois and the vitelline duct and its vessels are
also obliterated, all that remains in the cord are the umbilical vessels surrounded by Wharton jelly. This tissue, which is rich in proteoglycans, functions as a protective layer for the blood vessels. The walls of the arteries are muscular and contain many elastic fibers, which contribute to a rapid constriction and contraction of the umbilical vessels after the cord is tied off.

**PLACENTAL CHANGES AT THE END OF PREGNANCY**

At the end of pregnancy, a number of changes that occur in the placenta may indicate reduced exchange between the two circulations. These changes include (1) an increase in fibrous tissue in the core of the villus, (2) thickening of basement membranes in fetal capillaries, (3) obliteratorive changes in small capillaries of the villi, and (4) deposition of fibrinoid on the surface of the villi in the junctional zone and in the chorionic plate. Excessive fibrinoid formation frequently causes infarction of an intervillous lake or sometimes of an entire cotyledon. The cotyledon then assumes a whitish appearance.

**AMNIOTIC FLUID**

The amniotic cavity is filled with a clear, watery fluid that is produced in part by amniotic cells but is derived primarily from maternal blood. The amount of fluid increases from approximately 30 mL at 10 weeks of gestation to 450 mL at 20 weeks to 800 to 1,000 mL at 37 weeks. During the early months of pregnancy, the embryo is suspended by its umbilical cord in this fluid, which serves as a protective cushion. The fluid (1) absorbs jolts, (2) prevents adherence of the embryo to the amnion, and (3) allows for fetal movements. The volume of amniotic fluid is replaced every 3 hours. From the beginning of the fifth month, the fetus swallows its own amniotic fluid, and it is estimated that it drinks about 400 mL a day, about half of the total amount. Fetal urine is added daily to the amniotic fluid in the fifth month, but this urine is mostly water because the placenta is functioning as an exchange for metabolic wastes. During childbirth, the amniochorionic membrane forms a hydrostatic wedge that helps to dilate the cervical canal.
Chapter 8 • Third Month to Birth: The Fetus and Placenta

Clinical Correlates

Umbilical Cord Abnormalities

At birth, the umbilical cord is approximately 1 to 2 cm in diameter and 50 to 60 cm long. It is tortuous, causing false knots. Length of a cord reflects the amount of intrauterine movement of the fetus, and shortened cords have been observed in fetal movement disorders and with intrauterine constraint. An extremely long cord may encircle the neck of the fetus, usually without increased risk, whereas a short one may cause difficulties during delivery by pulling the placenta from its attachment in the uterus.

Normally, there are two arteries and one vein in the umbilical cord. In 1 in 200 newborns, however, only a single umbilical artery is present, and these babies have approximately 20% chance of having cardiac and other vascular defects. The missing artery either fails to form (agenesis) or degenerates early in development.

Amniotic Bands

Occasionally, tears in the amnion result in amniotic bands that may encircle part of the fetus, particularly the limbs and digits. Amputations, ring constrictions, and other abnormalities, including craniofacial deformations, may result [Fig. 8.17]. Origin of the bands is unknown.

![FIGURE 8.17 Limb abnormalities caused by amniotic bands. A. Limb constriction ring. B. Digit amputation (big toe) and ring constriction (second toe).](image)

Amniotic Fluid

Hydramnios or polyhydramnios is the term used to describe an excess of amniotic fluid (1,500 to 2,000 mL), whereas oligohydramnios refers to a decreased amount (<400 mL). Both conditions are associated with an increase in the incidence of birth defects. Primary causes of hydramnios include idiopathic causes (35%), maternal diabetes (25%), and congenital malformations, including central nervous system disorders (e.g., anencephaly) and gastrointestinal defects (atresias, e.g., esophageal) that prevent the infant from swallowing the fluid. Oligohydramnios is a rare occurrence that may result from renal agenesis. The lack of fluid in the amniotic cavity may constrict the fetus or there may be too little fluid for the fetus to “breathe” into its lungs resulting in lung hypoplasia.

Premature rupture of the membranes (PROM) refers to rupture of the membranes before uterine contractions begin and occurs in 10% of pregnancies. Preterm PROM occurs before 37 completed weeks of pregnancy, occurs in 3% of pregnancies, and is a common cause of preterm labor. Causes of preterm PROM are unknown, but risk factors include a previous pregnancy affected by prematurity or PROM, black race, smoking, infections, and severe polyhydramnios.
Fetal Membranes in Twins

The frequency of multiple gestation (e.g., twins, triplets) has increased substantially in recent years and now accounts for over 3% of all live births in the United States. The rate of twin births has increased to a high of 32.6 per 1,000 births in 2008. The reasons for this increase are twofold: the increasing age of mothers at the time of their infants' birth and the increasing use of fertility treatments, including assisted reproductive technologies (ART).

Dizygotic Twins

Approximately 90% of twins are dizygotic, or fraternal, and their incidence increases with maternal age (doubling at age 35) and with fertility procedures, including ART. They result from simultaneous shedding of two oocytes and fertilization by different spermatozoa. Because the two zygotes have totally different genetic constitutions, the twins have no more resemblance than any other brothers or sisters. They may or may not be of different sex. The zygotes implant individually in the uterus, and usually each develops its own placenta, amnion, and chorionic sac (Fig. 8.18A). Sometimes, however, the two placentas are so close together that they fuse. Similarly, the walls of the chorionic sacs may also come into close approach and fuse (Fig. 8.18B). Occasionally, each dizygotic twin possesses red blood cells of two different types (erythrocyte mosaicism), indicating that fusion of the two placentas was so intimate that red cells were exchanged.

Monozygotic Twins

The second type of twins, which develops from a single fertilized ovum, is monozygotic, or identical, twins. The rate for monozygotic twins is 3 to 4 per 1,000. They result from splitting of the zygote at various stages of development. The earliest separation is believed to occur at the twocell stage, in which case two separate zygotes develop. The blastocysts implant separately, and each embryo has its own placenta and chorionic sac (Fig. 8.19A). Although the arrangement of the membranes of these twins resembles that of dizygotic twins, the two can be recognized as partners of a monozygotic pair by their strong resemblance in blood groups, fingerprints, sex, and external appearance, such as eye and hair color.

Splitting of the zygote usually occurs at the early blastocyst stage. The inner cell mass splits into two separate groups of cells within the same blastocyst cavity (Fig. 8.19B). The two embryos have a common placenta and a common chorionic cavity but separate amniotic cavities (Fig. 8.19B). In rare cases, the separation occurs at the bilaminar germ disc stage, just before the appearance of the primitive streak (Fig. 8.19C). This method of splitting results in formation of two partners with a single placenta and a common chorionic and amniotic sac. Although the twins have a common placenta, blood supply is usually well balanced.

Although triplets are rare (about 1 per 7,600 pregnancies), birth of quadruplets, quintuplets, and so forth is rarer. In recent years, multiple births have occurred more frequently in mothers given gonadotropins (fertility drugs) for ovulatory failure.

Parturition (Birth)

For the first 34 to 38 weeks of gestation, the uterine myometrium does not respond to signals for parturition (birth). During the last 2 to 4 weeks of pregnancy, however, this tissue undergoes a transitional phase in preparation for the onset of labor. Ultimately, this phase ends with a thickening of the myometrium in the upper region of the uterus and a softening and thinning of the lower region and cervix.

Labor itself is divided into three stages: (1) effacement (thinning and shortening) and dilatation of the cervix (this stage ends when the cervix is fully dilated), (2) delivery of the fetus, and (3) delivery of the placenta and fetal membranes. Stage 1 is produced by uterine contractions that force the amniotic sac against the cervical canal like a wedge, or if the membranes have ruptured, then pressure will be exerted by the presenting part of the fetus, usually the head. Stage 2 is also assisted by uterine contractions, but the most important force is provided by increased intra-abdominal pressure from contraction of abdominal muscles. Stage 3 requires uterine contractions and is aided by increasing intra-abdominal pressure.

As the uterus contracts, the upper part retracts, creating a smaller and smaller lumen, while the lower part expands, thereby producing the force. Contractions usually begin about 10 minutes apart; then, during the second stage of labor, they may occur < 1 minute apart and last from 30 to 90 seconds. Their occurrence in pulses is essential to fetal survival, as they are of sufficient force to compromise uteroplacental blood flow to the fetus.

Clinical Correlates

Abnormalities Associated with Twins
Twin pregnancies have a high incidence of perinatal mortality and morbidity and an increased risk for preterm delivery. Approximately 60% of twins are born preterm and also have a high incidence of being LBW. Both of these factors put twin pregnancies at great risk and twin pregnancies have an infant mortality rate three times higher than that for singletons.

The incidence of twinning may be much higher than the number observed at birth because twins are conceived more often than they are born. Many twins die before birth,
and some studies indicate that only 29% of women pregnant with twins actually give birth to two infants. The term **vanishing twin** refers to the death of one fetus. This disappearance, which occurs in the first trimester or the early second trimester, may result from resorption or formation of a fetus papyraceus (Fig. 8.20).

Another problem leading to increased mortality among twins is twin-twin transfusion syndrome, which occurs in 15% of monochorionic monzygotic pregnancies. In this condition, placental vascular anastomoses, which occur in a balanced arrangement in most monochorionic placentas, are formed, so that one twin receives most of the blood flow, and flow to the other is compromised. As a result, one twin is larger than the other (Fig. 8.21). The outcome is poor, with the death of both twins occurring in 50% to 70% of cases.

At later stages of development, partial splitting of the primitive node and streak may result in formation of conjoined twins. These twins are classified according to the nature and degree of their union (Figs. 8.22 and 8.23). Occasionally, monozygotic twins are connected only by a common skin bridge or by a common liver bridge. The type of twins formed depends on when and to what extent abnormalities of the node and streak occurred. Misexpression of genes, such as GOOSECOID, may also result in conjoined twins. Many conjoined twins have survived, including the most famous pair, Chang and Eng, who were joined at the abdomen and who traveled to England and the United States on exhibitions in the mid-1800s. Finally settling in North Carolina, they farmed and fathered 21 children with their two wives.

In brother-sister pairs of dizygotic twins, testosterone from the male twin can affect development of the female. Thus, females in such pairs tend to have square jaws, larger teeth, perform better on spacial-ability tests and have better ball skills than most girls. They are 15% less likely to get married and they have fertility problems, producing 25% fewer children.
Clinical Correlates

Preterm Birth

Factors initiating labor are not known and may involve "retreat from maintenance of pregnancy," in which pregnancy-supporting factors [e.g., hormones] are withdrawn, or active induction caused by stimulatory factors targeting the uterus. Probably, components of both phenomena are involved. Unfortunately, a lack of knowledge about these factors has restricted progress in preventing preterm birth. Preterm birth [delivery before 37 completed weeks] of premature infants occurs in approximately 12% of births in the United States and is a leading cause of infant mortality and also contributes significantly to morbidity. It is caused by preterm PROM, premature onset of labor, or pregnancy complications requiring premature delivery. Risk factors include previous preterm birth; black race; multiple gestations; infections, such as periodontal disease and bacterial vaginosis; and low maternal body mass index.
SUMMARY

The fetal period extends from the ninth week of gestation until birth and is characterized by rapid growth of the body and maturation of organ systems. Growth in length is particularly striking during the third, fourth, and fifth months (approximately 5 cm per month), whereas increase in weight is most striking during the last 2 months of gestation (approximately 700 g per month) (Table 8.1, p. 105). Most babies weigh between 2,700 and 4,000 g (6 to 9 lb) at birth. Those babies weighing <2,500 g (5 lb 8 oz) are considered low birth weight; those below 1,500 g (3 lb 5 oz) are considered very low birth weight. IUGR is a term applied to babies who do not achieve their genetically determined potential size and are pathologically small. This group is distinct from babies that are healthy but are below the 10th percentile in weight for their gestational age and are classified as SGA.

A striking change is the relative slowdown in the growth of the head. In the third month, it is about half the size of the CRL. By the fifth month, the size of the head is about one third of the CHL, and at birth, it is one quarter of the CHL (Fig. 8.2). During the fifth month, fetal movements are clearly recognized by the mother, and the fetus is covered with fine, small hair. A fetus born during the sixth or the beginning of the seventh month has difficulty surviving, mainly because the respiratory and central nervous systems have not differentiated sufficiently.

In general, the length of pregnancy for a full-term fetus is considered to be 280 days, or 40 weeks after onset of the last menstruation, or, more accurately, 266 days or 38 weeks after fertilization.

The placenta consists of two components: (1) a fetal portion, derived from the chorion frondosum or villous chorion, and (2) a maternal portion, derived from the decidua basalis. The space between the chorionic and decidual plates is filled with intervillous lakes of maternal blood. Villous trees (fetal tissue) grow into the maternal blood lakes and are bathed in them. The fetal circulation is at all times separated from the maternal circulation by (1) a syncytial membrane (a chorion derivative) and (2) endothelial cells from fetal capillaries. Hence, the human placenta is of the hemochorial type.

Intervillous lakes of the fully grown placenta contain approximately 150 mL of maternal blood, which is renewed three or four times per minute. The villous area varies from 4 to 14 m², facilitating exchange between mother and child.

Main functions of the placenta are (1) exchange of gases; (2) exchange of nutrients and electrolytes; (3) transmission of maternal antibodies, providing the fetus with passive immunity; (4) production of hormones, such as progesterone, estradiol, and estrogen (in addition, it produces hCG and somatomammotropin); and (5) detoxification of some drugs.

The amnion is a large sac containing amniotic fluid in which the fetus is suspended by its umbilical cord. The fluid (1) absorbs jolts, (2) allows for fetal movements, and (3) prevents adherence of the embryo to surrounding tissues. The fetus swallows amniotic fluid, which is absorbed through its gut and cleared by the placenta. The fetus adds urine to the amniotic fluid, but this is mostly water. An excessive amount of amniotic fluid (hydramnios) is associated with anencephaly and esophageal atresia, whereas an insufficient amount (oligohydramnios) is related to renal agenesis.

The umbilical cord, surrounded by the amnion, contains (1) two umbilical arteries, (2) one umbilical vein, and (3) Wharton jelly, which serves as a protective cushion for the vessels.

Fetal membranes in twins vary according to their origin and time of formation. Two thirds of twins are dizygotic, or fraternal; they have two amnions, two chorions, and two placentas, which sometimes are fused. Monozygotic twins usually have two amnions, one chorion, and one placenta. In cases of conjoined twins, in which the fetuses are not entirely split from each other, there is one amnion, one chorion, and one placenta.

Signals initiating parturition (birth) are not clear, but preparation for labor usually begins between 34 and 38 weeks. Labor itself consists of three stages: (1) effacement and dilatation of the cervix, (2) delivery of the fetus, and (3) delivery of the placenta and fetal membranes.

### Problems to Solve

1. An ultrasound at 7 months’ gestation shows too much space (fluid accumulation) in the amniotic cavity. What is this condition called, and what are its causes?
2. Later in her pregnancy, a woman realizes that she was probably exposed to toluene in the workplace during the third week of gestation but tells a fellow worker that she is not concerned about her baby because the placenta protects her infant from toxic factors by acting as a barrier. Is she correct?
Birth Defects and Prenatal Diagnosis

birth defect, congenital malformation, and congenital anomaly are synonymous terms used to describe structural, behavioral, functional, and metabolic disorders present at birth. Terms used to describe the study of these disorders are teratology (Gr. teratos; monster) and dysmorphology. Dysmorphologists are usually within a department of clinical genetics. Major structural anomalies occur in approximately 3% of liveborn infants and birth defects are a leading cause of infant mortality, accounting for approximately 25% of infant deaths. They are the fifth leading cause of years of potential life lost prior to age 65 and a major contributor to disabilities. They are also nondiscriminatory; the frequencies of birth defects are the same for Asians, African Americans, Latin Americans, Whites, and Native Americans.

The causes of birth defects fall into three categories: those that are caused by environmental factors (15%), those caused by genetic factors (30%), and those caused by an interaction of the environment with a person’s genetic susceptibility. Most birth defects fall into this last category (55%), and for most of these congenital malformations, details of their origin are unknown (Fig. 9.1).

Minor anomalies occur in approximately 15% of newborns. These structural abnormalities, such as microtia (small ears), pigmented spots, and short palpebral fissures, are not themselves detrimental to health but, in some cases, are associated with major defects. For example, infants with one minor anomaly have a 3% chance of having a major malformation; those with two minor anomalies have a 10% chance; and those with three or more minor anomalies have a 20% chance. Therefore, minor anomalies serve as clues for diagnosing more serious underlying defects. In particular, ear anomalies are easily recognizable indicators of other defects and are

**FIGURE 9.1** Pie chart showing the contributions of various factors to the causes of birth defects. Approximately 15% will have purely environmental causes, such as drugs, environmental pollutants, infectious diseases, and maternal diseases, such as diabetes, phenylketonuria, obesity, etc.; 30% will be purely genetic, including chromosomal abnormalities and single gene mutations; and 55% will be multifactorial and will involve gene teratogen interactions. This latter group also includes birth defects of unknown origin.
Risk of Birth Defects Being Induced

FIGURE 9.2 Graph showing the times in gestation versus the risks of birth defects being induced. The most sensitive time is the embryonic period during the third to eighth weeks. The fetal period begins at the end of the eighth week and extends to term. During this time, the risk for gross structural defects being induced decreases, but organ systems may still be affected. For example, the brain continues to differentiate during the fetal period, such that toxic exposures may cause learning disabilities or intellectual disability. The fact that most birth defects occur prior to the eighth week makes it imperative to initiate birth defects prevention strategies prior to conception. Unfortunately, most women do not appear for their first prenatal visit until the eighth week, which is after the critical time for prevention of most birth defects.

observed in virtually all children with syndromic malformations.

Types of Abnormalities

Malformations occur during formation of structures, for example, during organogenesis. They may result in complete or partial absence of a structure or in alterations of its normal configuration. Malformations are caused by environmental and/or genetic factors acting independently or in concert. Most malformations have their origin during the third to eighth weeks of gestation (Fig. 9.2). However, some complex combinations of defects, such as those observed in cases of heterotaxy, may have their origins when the embryonic axes are being specified as early as the second week.

Disruptions result in morphological alterations of already formed structures and are caused by destructive processes. Vascular accidents leading to transverse limb defects and defects produced by amniotic bands are examples of destructive factors that produce disruptions (Fig. 9.3).

Deformations result from mechanical forces that mold a part of the fetus over a prolonged period. Clubfeet, for example, are caused by compression in the amniotic cavity (Fig. 9.4). Deformations often involve the musculoskeletal system and may be reversible postnatally.

A syndrome is a group of anomalies occurring together that have a specific common cause. This term indicates that a diagnosis has been made and that the risk of recurrence is known. In contrast, association is the nonrandom appearance of two or more anomalies that occur together more frequently than by chance alone, but the cause has not been determined. An example is the VACTERL association (vertebral, anal, cardiac, tracheoesophageal, renal, and limb anomalies). Although they do not constitute a diagnosis, associations are important because

recognition of one or more of the components promotes the search for others in the group.

Environmental Factors

Until the early 1940s, it was assumed that congenital defects were caused primarily by hereditary factors. With the discovery by N. Gregg that rubella (German measles) affecting a mother during early pregnancy caused abnormalities in the embryo, it suddenly became evident that congenital malformations in humans could also be caused by environmental factors. In 1961, observations by W. Lenz linked limb defects to the sedative thalidomide and made it clear that drugs could also cross the placenta and produce birth defects (Fig. 9.5). Since that time, many agents have been identified as teratogens (factors that cause birth defects) (Table 9.1, p. 130).

Principles of Teratology

Factors determining the capacity of an agent to produce birth defects have been defined and set forth as the principles of teratology. They include the following:

1. Susceptibility to teratogenesis depends on the genotype of the conceptus and the manner in which this genetic composition interacts with the environment. The maternal genome is also important with respect to drug metabolism, resistance to infection, and other biochemical and molecular processes that affect the conceptus.

2. Susceptibility to teratogens varies with the developmental stage at the time of exposure. The most sensitive period for inducing birth defects is the third to eighth weeks of gestation, the period of embryogenesis. Each organ system may have one or more stages of susceptibility. For example, cleft palate can be induced at the blastocyst stage (day 6), during gastrulation (day 14), at the early limb bud stage (fifth week), or when the palatal shelves are forming (seventh week). Furthermore, whereas most abnormalities are produced during embryogenesis, defects may also be induced before or after this period; no stage of development is completely safe (Fig. 9.2).
3. Manifestations of abnormal development depend on **dose and duration of exposure** to a teratogen.

4. Teratogens act in specific ways (mechanisms) on developing cells and tissues to initiate abnormal embryogenesis (pathogenesis). Mechanisms may involve inhibition of a specific biochemical or molecular process; pathogenesis may involve cell death, decreased cell proliferation, or other cellular phenomena.

5. Manifestations of abnormal development are death, malformation, growth retardation, and functional disorders.

**Infectious Agents**

Infectious agents that cause birth defects (Table 9.1) include a number of viruses. Birth defects due to **rubella** (German measles) during pregnancy (congenital rubella syndrome) used to be a major problem, but development and widespread use of a vaccine have nearly eliminated congenital malformations from this cause.

**Cytomegalovirus** is a serious threat. Often, the mother has no symptoms, but the effects on the fetus can be devastating. The infection can cause serious illness at birth and is sometimes fatal. On the other hand, some infants are asymptomatic at birth but develop abnormalities later, including hearing loss, visual impairment, and intellectual disability.

**Herpes simplex virus** and **varicella virus** can cause birth defects. Herpes-induced abnormalities are rare, and usually, infection is transmitted to the child during delivery, causing severe illness and sometimes death. Intrauterine infection with varicella causes scarring of the skin, limb hypoplasia, and defects of the eyes and central nervous system. The occurrence of birth defects after prenatal infection with varicella is infrequent and depends on the timing of the infection. Among infants born to women infected before 13 weeks’ gestation, 0.4% are malformed, whereas the risk increases to 2% among infants whose mothers are infected during 13 to 20 weeks of gestation.

**Other Viral Infections and Hyperthermia**

Malformations apparently do not occur following maternal infection with measles, mumps, hepatitis, poliomyelitis, echovirus, coxsackie virus, and influenza, but some of these infections may cause spontaneous abortion or fetal death or may be transmitted to the fetus. For example, coxsackie B virus may cause an increase in spontaneous abortion, whereas measles and mumps may cause an increase in early and late fetal death and neonatal measles and mumps. Hepatitis B has a high rate of transmission to the fetus, causing fetal and neonatal hepatitis, whereas hepatitis A, C, and E are rarely transmitted transplacentally. Echoviruses seem to

SSRIs, selective serotonin reuptake inhibitors; ACE, angiotensin-converting enzyme; FAS, fetal alcohol syndrome; DES, diethylstilbestrol.
have no adverse effects on the fetus. Also, there is no evidence that immunizations against any of these diseases harm the fetus.

A complicating factor introduced by these and other infectious agents is that most are pyrogenic (cause fevers), and elevated body temperature (hyperthermia) caused by fevers or possibly by external sources, such as hot tubs and saunas, is teratogenic. Characteristically, neurulation is affected by elevated temperatures, and neural tube defects, such as anencephaly and spina bifida, are produced.

Toxoplasmosis can cause birth defects. Poorly cooked meat; feces of domestic animals, especially cats; and soil contaminated with feces can carry the protozoan parasite Toxoplasmosis gondii. A characteristic feature of fetal toxoplasmosis infection is cerebral calcifications. Other features that may be present at birth include microcephaly (small head), macrocephaly (large head), or hydrocephalus (an increase in cerebrospinal fluid in the brain). In a manner similar to cytomegalovirus, infants who appear normal at birth may later develop visual impairment, hearing loss, seizures, and intellectual disability.

### Radiation

Ionizing radiation kills rapidly proliferating cells, so it is a potent teratogen, producing virtually any type of birth defect depending upon the dose and stage of development of the conceptus at the time of exposure. Radiation from nuclear explosions is also teratogenic. Among women survivors pregnant at the time of the atomic bomb explosions over Hiroshima and Nagasaki, 28% spontaneously aborted, 25% gave birth to children who died in their first year of life, and 25% gave birth to children who had severe birth defects involving the central nervous system. Similarly, the explosion of the nuclear reactor at Chernobyl, which released up to 400 times the amount of radiation as the nuclear bombs, has also resulted in an increase in birth defects throughout the region. Radiation is also a mutagenic agent and can lead to genetic alterations of germ cells and subsequent malformations.

### Pharmaceutical Drugs and Chemical Agents

The role of chemical agents and pharmaceutical drugs (medications) in the production of abnormalities in humans is difficult to assess for two reasons: (1) Most studies are retrospective, relying on the mother’s memory for a history of exposure, and (2) pregnant women take a large number of medications. A National Institutes of Health study discovered that pregnant women, on average, took four medications during pregnancy. Only 20% of pregnant women used no drugs during their pregnancy. Even with this widespread use of medications during pregnancy, insufficient information is available to judge the safety of approximately 90% of these drugs if taken during pregnancy.

On the other hand, relatively few of the many drugs used during pregnancy have been positively identified as being teratogenic. One example is thalidomide, an antinauseant and sleeping pill. In 1961, it was noted in West Germany that the frequency of amelia and meromelia (total or partial absence of the extremities), a rare abnormality that was usually inherited, had suddenly increased (Fig. 9.3). This observation led to examination of the prenatal histories of affected children and to the discovery that many mothers had taken thalidomide early in pregnancy. The causal relation between thalidomide and meromelia was discovered only because the drug produced such an unusual abnormality. If the defect had been a more common type, such as cleft lip or heart malformation, the association with the drug might easily have been overlooked.

The discovery that a drug like thalidomide could cross the placenta and cause birth defects was revolutionary and led directly to the science of teratology and founding of the Teratology Society. Today, thalidomide is still in use as an immunomodulatory agent in the treatment of people with AIDS and other immunopathological diseases such as leprosy, lupus erythematosus, and graft versus host disease. Limb defects still occur in babies exposed to the drug, but it is now clear that other malformations are produced as well. These abnormalities include heart malformations, orofacial clefts, intellectual disability, autism, and defects of the urogenital and gastrointestinal systems.

Isotretinoin (Accutane), an analogue of vitamin A, has been shown to cause a characteristic pattern of malformations known as the isotretinoin embryopathy. The drug is prescribed for the treatment of cystic acne and other chronic dermatoses, but it is highly teratogenic and can produce virtually any type of
malformation. Even topical retinoids, such as etretinate, may have the potential to cause abnormalities. Vitamin A itself may be teratogenic at high doses, based on animal studies and the fact that isotretinoin is a closely related compound. Precisely how much is potentially harmful (>10,000 or >25,000 IU) is controversial, but the amount of vitamin A typically contained in multivitamins (2,000 to 8,000 IU) is below these doses, unless an individual takes more than one multivitamin a day.

Other drugs with teratogenic potential include the anticonvulsants diphenylhydantoin (phenytoin), valproic acid, and trimethadione, which are used by women who have seizure disorders. Specifically, trimethadione and diphenylhydantoin produce a broad spectrum of abnormalities that constitute distinct patterns of dysmorphogenesis known as the trimethadione and fetal hydantoin syndromes. Facial clefts are particularly common in these syndromes. The anticonvulsant valproic acid increases the risk for several defects, including atrial septal defects, cleft palate, hypospadias, polydactyly, and craniosynostosis, but the highest risk is for the neural tube defect, spina bifida. The anticonvulsant carbamazepine also has been associated with an increased risk for neural tube defects and possibly other types of malformations. Even newer anticonvulsant drugs like Topamax (topiramate) increase the risk for cleft lip and/or cleft palate. A confounding issue with these patients is the fact that they require these medications to prevent seizures. Because of their teratogenic potential, however, the type of drug employed and the dose should be considered to provide the best outcome for the mother and her child.

Antipsychotic and antianxiety agents (major and minor tranquilizers, respectively) are suspected producers of congenital malformations. The antipsychotics phenothiazine and lithium have been implicated as teratogens. Although evidence for the teratogenicity of phenothiazines is conflicting, an association between lithium and congenital heart defects, especially Ebstein anomaly, is better documented, although the risk is small.

Antidepressant drugs that work as selective serotonin reuptake inhibitors (SSRIs) including fluoxetine (Prozac), paroxetine (Paxil), sertraline (Zoloft), citalopram (Celexa), and escitalopram (Lexapro) have been linked by epidemiological studies to multiple birth defects, presumably because of serotonin’s role in establishing the left–right axis (laterality; see Chapter 5, p. 62). The heart is particularly sensitive because of its complex laterality, and many types of heart defects have been observed in infants born to mothers taking the drugs. Even malformations in the midline, such as neural tube defects, cleft palate, and anal atresia have been associated with exposure to these drugs, which animal studies have demonstrated may be due to disruption of coordinated signaling essential to establishing the cranial-caudal and left-right axes of the embryo (see Chapter 5, p. 59; Chapter 13, p. 175).

Opioid medications such as codeine, hydrocodone, and oxycodone are used to treat severe pain, and both their use and abuse have been increasing in recent years. Epidemiology studies demonstrate an association with the use of these drugs and neural tube defects, heart defects, and gastroschisis (an abdominal wall defect).

Mycophenolate mofetil (MMF) is an immunosuppressant drug used to prevent rejection in organ transplant patients. Use of the drug in pregnancy has resulted in spontaneous abortions and birth defects, including cleft lip and palate, microtia (small ears), microcephaly, and heart defects.

The anticoagulant warfarin is teratogenic. Infants born to mothers with first trimester exposures typically have skeletal abnormalities, including nasal hypoplasia, abnormal epiphyses in their long bones, and limb hypoplasia. In contrast, the anticoagulant heparin does not appear to be teratogenic.

Antihypertensive agents that inhibit angiotensin-converting enzyme (ACE inhibitors) produce growth retardation, renal dysfunction, fetal death, and oligohydramnios if exposures occur during the second or third trimester. Effects of exposure to these compounds in the first trimester are less clear.

Caution has also been expressed regarding a number of other compounds that may damage the embryo or fetus. The most prominent among these are propylthiouracil and potassium iodide (goiter and intellectual disability), streptomycin (hearing loss), sulfonamides (kernicterus), the antidepressant imipramine (limb deformities), tetracyclines (bone and tooth anomalies), amphetamines (oral clefts and cardiovascular abnormalities), and quinine (hearing loss).
Illicit Drugs, Alcohol, and Cigarettes

One of the problems in today’s society is the effect of maternal use of social drugs, such as lysergic acid diethylamide (LSD), phencyclidine (PCP) or “angel dust”, marijuana, cocaine, alcohol, and tobacco on embryonic and fetal development. In the case of LSD, limb abnormalities and malformations of the central nervous system have been reported. A comprehensive review of more than 100 publications, however, led to the conclusion that pure LSD used in moderate doses is not teratogenic and does not cause genetic damage. A similar lack of conclusive evidence for teratogenicity has been described for marijuana and PCP.

Cocaine use has been linked to premature labor, intrauterine growth retardation, and spontaneous abortion. Also, malformations of the heart, genitourinary system, and brain have been observed in babies whose mothers used cocaine, and there may be long-term effects on behavior. One difficulty in assessing the drug’s effects is the fact that women who use cocaine often use other drugs as well, especially alcohol.

There is a well-documented association between maternal alcohol ingestion and congenital abnormalities. Because alcohol may induce a broad spectrum of defects, ranging from intellectual disability to structural abnormalities of the brain (microcephaly, holoprosencephaly), face, and heart, the term fetal alcohol spectrum disorder (FASD) is used to refer to any alcohol-related defects. Fetal alcohol syndrome (FAS) represents the severe end of the spectrum and includes structural defects, growth deficiency, and intellectual disability (Fig. 9.6). Alcohol-related neurodevelopmental disorder (ARND) refers to cases with evidence of involvement of the central nervous system that do not meet the diagnostic criteria for FAS.

The incidence of FAS and ARND together has been estimated to be 1 in 100 live births. Furthermore, alcohol is the leading cause of intellectual disability. It is not clear how much alcohol is necessary to cause a developmental problem. The dose and timing during gestation are both critical, but there is probably no “safe” level. Even binge drinking (>5 drinks per sitting) at a critical stage of development appears to increase the risk for birth defects, including orofacial clefts.

Cigarette smoking has been linked to an increased risk for orofacial clefts (cleft lip and cleft palate). It also contributes to intrauterine growth retardation and premature delivery.

Hormones

Androgenic Agents

In the past, synthetic progestins were frequently used during pregnancy to prevent abortion. The progestins ethisterone and norethisterone have considerable androgenic activity, and many cases of masculinization of the genitalia in female embryos have been reported. The abnormalities consist of an enlarged clitoris associated with varying degrees of fusion of the labioscrota1 folds.

Endocrine Disrupters

Endocrine disrupters are exogenous agents that interfere with the normal regulatory actions of hormones controlling developmental processes. Most commonly, these agents interfere with the action of estrogen through its receptor to cause developmental abnormalities of the central nervous system and reproductive tract. For some time, it has been known that the synthetic estrogen diethylstilbestrol
(DES), which was used to prevent abortion, raised the incidence of carcinomas of the vagina and cervix in women exposed to the drug in utero. Furthermore, a high percentage of these women had reproductive dysfunction caused in part by congenital malformations of the uterus, uterine tubes, and upper vagina. Male embryos exposed in utero can also be affected, as evidenced by an increase in malformations of the testes and abnormal sperm analysis among these individuals. In contrast to women, however, men do not demonstrate an increased risk of developing carcinomas of the genital system.

Today, environmental estrogens are a concern, and numerous studies to determine their effects on the unborn are under way. Decreasing sperm counts and increasing incidences of testicular cancer, hypospadias, and other abnormalities of the reproductive tract in humans, together with documented central nervous system abnormalities (masculinization of female brains and feminization of male brains) in other species with high environmental exposures, have raised awareness of the possible harmful effects of these agents. Many are formed from chemicals used for industrial purposes and from pesticides.

**ORAL CONTRACEPTIVES**

Birth control pills, containing estrogens and progestogens, appear to have a low teratogenic potential. Because other hormones such as DES produce abnormalities, however, use of oral contraceptives should be discontinued if pregnancy is suspected.

**CORTISONE**

Experimental work has repeatedly shown that cortisone injected into mice and rabbits at certain stages of pregnancy causes a high percentage of cleft palates in the offspring. Some recent epidemiologic studies also suggest that women who take corticosteroids during pregnancy are at a modestly increased risk for having a child with an orofacial cleft.

**In Vitro Fertilization**

Evidence from several studies indicates that in vitro fertilization techniques are associated with an increase in birth defects and that these rates are higher with intracytoplasmic sperm injection (ICSI) procedures. Furthermore, any treatment for infertility, whether chemical induction of ovulation or in vitro fertilization, is associated with an increased risk for stillbirths, low birth weight, and prematurity.

**Maternal Disease**

**DIABETES**

Disturbances in carbohydrate metabolism during pregnancy in diabetic mothers cause a high incidence of stillbirths, neonatal deaths, abnormally large infants, and congenital malformations. The risk of congenital anomalies in children born to mothers with pregestational diabetes (diabetes diagnosed before pregnancy; both type 1 [insulin dependent] and type 2 [non–insulin dependent]) is three to four times that for offspring of nondiabetic mothers and has been reported to be as high as 80% in the offspring of diabetics with long-standing disease. The increased risk is for a wide variety of malformations, including neural tube defects and congenital heart defects. There is also a higher risk for caudal dysgenesis (sirenomelia; see Fig. 5.8, p. 65).

Factors responsible for these abnormalities have not been delineated, although evidence suggests that altered glucose levels play a role and that insulin is not teratogenic. In this respect, a significant correlation exists between the severity and duration of the mother’s disease and the incidence of malformations. Also, strict control of maternal glucose levels beginning before conception and continuing throughout gestation reduces the occurrence of malformations to incidences approaching those in the general population.

The risk for birth defects associated with gestational diabetes (diabetes that is first diagnosed during pregnancy) is less clear, with some, but not all, studies showing a slightly increased risk. Given that the onset of gestational diabetes is believed to be after the critical period for inducing structural birth defects (3 to 8 weeks gestation), some investigators have suggested that any observed increased risk may be due to the fact that some women diagnosed with gestational diabetes probably had diabetes before pregnancy, but it was not diagnosed.

**Phenylketonuria**

Mothers with phenylketonuria (PKU), in which the enzyme phenylalanine hydroxylase
is deficient or reduced, resulting in increased serum concentrations of phenylalanine, are at risk for having infants with intellectual disability, microcephaly, and cardiac defects. Women with PKU who maintain their low-phenylalanine diet prior to conception and throughout pregnancy reduce the risk to their infants to that observed in the general population.

**Nutritional Deficiencies**

Although many nutritional deficiencies, particularly vitamin deficiencies, have been proven to be teratogenic in laboratory animals, the evidence for specific cause and effects in humans is more difficult to document. One example is **endemic cretinism**, caused by **iodine deficiency** and characterized by stunted mental and physical growth. Recent evidence also indicates that methyl-deficient diets alter expression of imprinted genes and may result in birth defects and diseases, such as cancer postnatally. Finally, recent studies show that poor maternal nutrition prior to and during pregnancy contributes to low birth weight and birth defects and that severe starvation during pregnancy is associated with a two- to threefold increase in schizophrenia in the offspring.

**Obesity**

Obesity has reached epidemic proportions in the United States and has nearly doubled in the past 15 years. In **2007 to 2008**, over one-third of women of reproductive age were obese (body mass index >30).

Prepregnancy obesity is associated with a twofold increased risk for having a child with a neural tube defect. Causation has not been determined but may relate to maternal metabolic disturbances affecting glucose, insulin, or other factors. Prepregnancy obesity also increases the risk for having a baby with a heart defect, omphalocele, and multiple congenital anomalies.

**Hypoxia**

Hypoxia induces congenital malformations in a great variety of experimental animals. Whether the same is valid for humans remains to be seen. Although children born at relatively high altitudes are usually lighter in weight and smaller than those born near or at sea level, no increase in the incidence of congenital malformations has been noted. In addition, women with cyanotic cardiovascular disease often give birth to small infants but usually without gross congenital malformations.

**Heavy Metals**

Several years ago, researchers in Japan noted that a number of mothers with diets consisting mainly of fish had given birth to children with multiple neurological symptoms resembling cerebral palsy. Further examination revealed that the fish contained an abnormally high level of organic mercury, which was spewed into Minamata Bay and other coastal waters of Japan by large industries. Many of the mothers did not show any symptoms themselves, indicating that the fetus was more sensitive to mercury than the mother. In the United States, similar observations were made when seed corn sprayed with a mercury-containing fungicide was fed to hogs and the meat was subsequently eaten by pregnant women. Likewise, in Iraq, several thousand babies were affected after mothers ate grain treated with mercury-containing fungicides.

**Lead** has been associated with increased abortions, growth retardation, and neurological disorders.

**Male-Mediated Teratogenesis**

A number of studies have indicated that exposures to chemicals and other agents, such as ethylnitrosourea and radiation, can cause mutations in male germ cells. Epidemiological investigations have linked paternal occupational and environmental exposures to mercury, lead, solvents, alcohol, cigarette smoking, and other compounds to spontaneous abortion, low birth weight, and birth defects. **Advanced paternal age** is a factor for an increased risk for some types of structural birth defects, Down syndrome, and new autosomal dominant mutations. With respect to mutations, men transmit a higher number of mutations to their children than women and the age of the father is the dominant factor in determining how many de novo mutations appear in the child. Thus, the age at which males reproduce can dramatically affect the rate of genomic change in a population, such that the older males are when they produce children the more mutations occur in their offspring. Even transmission of paternally mediated toxicity is possible through seminal fluid and from household contamination from chemicals brought home on work clothes by the father.
Clinical Correlates

Prevention of Birth Defects

Many birth defects can be prevented. For example, supplementation of salt with iodine eliminates intellectual disability and bone deformities resulting from cretinism. Placing women with diabetes or PKU under strict metabolic control prior to conception reduces the incidence of birth defects in their offspring. Folate supplementation lowers the incidence of neural tube defects, such as spina bifida and anencephaly, and also reduces the risk for hyperthermia-induced abnormalities. Avoidance of alcohol during all stages of pregnancy reduces the incidence of birth defects. An essential component of all prevention strategies is to initiate interventions prior to conception.

It is important for physicians prescribing medications to women of childbearing age to consider the possibility of pregnancy and the potential teratogenicity of the compounds. Hundreds of children have been born with severe birth defects produced by retinoids (isotretinoin embryopathy), compounds used for the treatment of cystic acne (isotretinoin [Accutane]). Because patients with acne are usually young and may be sexually active, these agents must be used cautiously.

Prenatal Diagnosis

The perinatologist has several approaches for assessing growth and development of the fetus in utero, including ultrasound, maternal serum screening, amniocentesis, and chorionic villus sampling (CVS). In combination, these techniques are designed to detect malformations, genetic abnormalities, overall fetal growth, and complications of pregnancy, such as placental or uterine abnormalities. The use and development of in utero therapies have heralded a new concept in which the fetus is now a patient.

Ultrasonography

Ultrasonography is a relatively noninvasive technique that uses high-frequency sound waves reflected from tissues to create images. The approach may be transabdominal or transvaginal, with the latter producing images with higher resolution (Fig. 9.7). In fact, the technique, which was first developed in the 1950s, has advanced

![FIGURE 9.7 Examples of the effectiveness of ultrasound in imaging the embryo and fetus. A. A 6-week embryo. B. Lateral view of the fetal face. C. Hand. D. Feet.](image-url)
to a degree whereby detection of blood flow in major vessels, movement of heart valves, and flow of fluid in the trachea and bronchi are possible. The technique is safe and commonly used, with approximately 80% of pregnant women in the United States receiving at least one scan.

Important parameters revealed by ultrasound include characteristics of fetal age and growth; presence or absence of congenital anomalies; status of the uterine environment, including the amount of amniotic fluid (Fig. 9.8A); placental position and umbilical blood flow; and whether multiple gestations are present (Fig. 9.8B). All of these factors are then used to determine proper approaches for management of the pregnancy.

Determination of fetal age and growth is crucial in planning pregnancy management, especially for low-birth-weight infants. In fact, studies show that ultrasound-screened and -managed pregnancies with low-birth-weight babies reduced the mortality rate by 60% compared with an unscreened group. Fetal age and growth are assessed by crown-rump length during the 5th to the 10th weeks of gestation. After that, a combination of measurements—including the biparietal diameter (BPD) of the skull, femur length, and abdominal circumference—are used (Fig. 9.9). Multiple measurements of these parameters over time improve the ability to determine the extent of fetal growth.

Congenital malformations that can be determined by ultrasound include the neural tube defects anencephaly and spina bifida (see Chapter 18); abdominal wall defects, such as omphalocele and gastroschisis (see Chapter 15); and heart (see Chapter 13) and facial defects, including cleft lip and palate (see Chapter 17).

Ultrasound can also be used to screen for Down syndrome and some other chromosome-related abnormalities through a test called nuchal translucency. This test involves measurement of the translucent space at the posterior of the baby’s neck, where fluid accumulates when Down syndrome and some other abnormalities, especially heart defects are present. The test is performed at 11 to 14 weeks of pregnancy. Information from this test, combined with maternal serum screening test results and the mother’s age, can be combined to provide a risk estimate for Down syndrome. Then, based on this risk assessment, a woman can decide whether she wants invasive testing, such as amniocentesis, which would provide a definitive diagnosis.

**Maternal Serum Screening**

A search for biochemical markers of fetal status led to development of maternal serum screening tests. One of the first of these tests assessed serum \( \alpha \)-fetoprotein (AFP) concentrations. AFP is produced normally by the fetal liver, peaks at approximately 14 weeks, and “leaks” into the maternal circulation via the placenta. Thus, AFP concentrations increase in maternal serum during the second trimester and then begin a steady decline after 30 weeks of gestation. In cases of neural tube defects and several other abnormalities, including omphalocele, gastroschisis, bladder extrophy, amniotic band syndrome, sacrococcygeal teratoma, and intestinal atresia, AFP levels increase in amniotic fluid and maternal serum. In other instances, AFP concentrations decrease, as, for example, in Down syndrome, trisomy 18, sex chromosome
Abnormalities, and triploidy. AFP screening, combined with testing other second trimester markers (e.g., human chorionic gonadotropin [hCG], unconjugated estriol, and inhibin A) can increase the detection rate for birth defects using these serum screening studies.

Amniocentesis

During amniocentesis, a needle is inserted trans-abdominally into the amniotic cavity (identified by ultrasound; Fig. 9.8A), and approximately 20 to 30 mL of fluid is withdrawn. Because of the amount of fluid required, the procedure is not usually performed before 14 weeks’ gestation, when sufficient quantities are available without endangering the fetus. Recent studies suggest that the risk of fetal loss related to the procedure is as low as 1 in 300 to 500 but may be even less for individuals and centers highly skilled in the technique.

The fluid itself is analyzed for biochemical factors, such as AFP and acetylcholinesterase. In addition, fetal cells, sloughed into the amniotic fluid, can be recovered and used for metaphase karyotyping and other genetic analyses (see Chapter 2). Unfortunately, the harvested cells are not rapidly dividing, and therefore, cell cultures containing mitogens must be established to provide sufficient metaphase cells for analysis. Thus, results are available 1 to 2 weeks after the procedure. Once chromosomes are obtained, major chromosomal alterations, such as translocations, breaks, trisomies, and monosomies, can be identified. With special stains (Giemsa) and high-resolution techniques, chromosome-banding patterns can be determined. Furthermore, with recent advances in molecular biology, more sophisticated molecular analyses using polymerase chain reaction (PCR) and genotyping assays have increased the level of detection for genetic abnormalities.

Chorionic Villus Sampling

CVS involves inserting a needle transabdominally or transvaginally into the placental mass and aspirating approximately 5 to 30 mg of
villus tissue. Cells may be analyzed immediately, but accuracy of results is problematic because of the high frequency of chromosomal errors in the normal placenta. Therefore, cells from the mesenchymal core are isolated by trypsinization of the external trophoblast and cultured. Because of the large number of cells obtained, only 2 to 3 days in culture are necessary to permit genetic analysis. Thus, the time for genetic characterization of the fetus is reduced compared with amniocentesis. The risk of procedure-related pregnancy loss from CVS when performed by experienced individuals appears to approach that of amniocentesis. However, there have been indications that the procedure carries an increased risk for limb reduction defects, especially of the digits.

In the past, with the exception of ultrasonography, these prenatal diagnostic tests were not used on a routine basis. However, beginning in 2007, the American College of Obstetricians and Gynecologists has recommended that invasive testing (amniocentesis or CVS) for aneuploidy (abnormal chromosome number) should be available to all women, regardless of maternal age. Factors that place women at higher risk include the following:

- Advanced maternal age (35 years and older)
- Previous family history of a genetic problem, such as the parents having had a child with Down syndrome or a neural tube defect
- The presence of maternal disease, such as diabetes
- An abnormal ultrasound or serum screening test

**FETAL THERAPY**

**Fetal Transfusion**

In cases of fetal anemia produced by maternal antibodies or other causes, blood transfusions for the fetus can be performed. Ultrasound is used to guide insertion of a needle into the umbilical cord vein, and blood is transfused directly into the fetus.

**Fetal Medical Treatment**

Treatment for infections, fetal cardiac arrhythmias, compromised thyroid function, and other medical problems is usually provided to the mother and reaches the fetal compartment after crossing the placenta. In some cases, however, agents may be administered to the fetus directly by intramuscular injection into the gluteal region or via the umbilical vein.

**Fetal Surgery**

Because of advances in ultrasound and surgical procedures, operating on fetuses has become possible. Because of risks to the mother, infant, and subsequent pregnancies, however, procedures are only performed in centers with well-trained teams and only when there are no reasonable alternatives. Several types of surgeries may be performed, including placing shunts to remove fluid from organs and cavities. For example, in obstructive urinary disease of the urethra, a shunt may be inserted into the fetal bladder. One problem is diagnosing the condition early enough to prevent renal damage. Ex utero surgery, in which the uterus is opened and the fetus is operated on directly, has been used for repairing congenital diaphragmatic hernias, removing cystic (adenomatoid) lesions in the lung, and repairing spina bifida defects. Also, in recent years, fetal intervention has become available for certain congenital heart defects. At this time, however, most fetal surgical interventions are considered experimental and are undergoing randomized clinical trials to determine their effectiveness.

**Stem Cell Transplantation and Gene Therapy**

Because the fetus does not develop any immunocompetence before 18 weeks’ gestation, it may be possible to transplant tissues or cells before this time without rejection. Research in this field is focusing on hematopoietic stem cells for treatment of immunodeficiency and hematologic disorders. Gene therapy for inherited metabolic diseases, such as Tay-Sachs and cystic fibrosis, is also being investigated.

**SUMMARY**

Various agents (Table 9.1, p. 130) and genetic factors are known to cause congenital malformations and approximately 3% of all live-born infants will have a birth defect. Agents that cause birth defects include viruses, such as rubella and cytomegalovirus; radiation; drugs, such as thalidomide, aminopterin, anticonvulsants, antipsychotics, and antianxiety compounds; social drugs, such as cigarettes, and alcohol; hormones, such as DES; and maternal
diabetes. Effects of teratogens depend on the maternal and fetal genotype, the stage of development when exposure occurs, and the dose and duration of exposure of the agent. Most major malformations are produced during the period of embryogenesis (teratogenic period; third to eighth weeks; Fig. 9.2), but in stages before and after this time, the fetus is also susceptible, so that no period of gestation is completely free of risk. Prevention of many birth defects is possible, but it depends on beginning preventative measures before conception and increasing physicians’ and women’s awareness of the risks.

Many techniques are available to assess the growth and developmental status of the fetus. Ultrasound can accurately determine fetal age, growth parameters, and can detect many malformations. Maternal serum screening for α-fetoprotein (AFP) and other markers can indicate the presence of a neural tube defect or other abnormalities. Combinations of maternal serum screening and ultrasound to detect nuchal translucency can be used for detecting Down syndrome and some other chromosome-related abnormalities. Amniocentesis is a procedure in which a needle is placed into the amniotic cavity and a fluid sample is withdrawn. This fluid can be analyzed biochemically and also provides cells for culture and genetic analysis. Chorionic villus sampling (CVS) involves aspirating a tissue sample directly from the placenta to obtain cells for genetic analysis. Previously, invasive procedures, such as amniocentesis and CVS, were offered only to women at higher risk, such as women of advanced maternal age (35 years and older), a history of neural tube defects in the family, previous gestation with a chromosome abnormality, chromosome abnormalities in either parent, and a mother who is a carrier for an X-linked disorder. In recent years, risks associated with these procedures have decreased, and consequently, these procedures have been made more widely available.

Modern medicine has also made the fetus a patient who can receive treatment, such as transfusions, medications for disease, fetal surgery, and gene therapy.

### Problems to Solve

1. Amniocentesis reveals an elevated AFP level. What should be included in a differential diagnosis, and how would a definitive one be made?
2. A 40-year-old woman is approximately 8 weeks pregnant. What tests are available to determine whether her unborn child has Down syndrome? What are the risks and advantages of each technique?
3. Why is it important to determine the status of an infant prenatally? What maternal or family factors might raise your concern about the well-being of an unborn infant?
4. What factors influence the action of a teratogen?
5. A young woman in only the third week of her pregnancy develops a fever of 104°F but refuses to take any medication because she is afraid that drugs will harm her baby. Is she correct?
6. A young woman who is planning a family seeks advice about folic acid and other vitamins. Should she take such a supplement, and if so, when and how much?
7. A young insulin-dependent diabetic woman who is planning a family is concerned about the possible harmful effects of her disease on her unborn child. Are her concerns valid, and what would you recommend?
The axial skeleton includes the skull, vertebral column, ribs, and sternum. In general, the skeletal system develops from paraxial and lateral plate (parietal layer) mesoderm and from neural crest. Paraxial mesoderm forms a segmented series of tissue blocks on each side of the neural tube, known as somitomeres in the head region and somites from the occipital region caudally. Somites differentiate into a ventromedial part, the sclerotome, and a dorsolateral part, the dermomyotome. At the end of the fourth week, sclerotome cells become polymorphous and form loosely organized tissue, called mesenchyme, or embryonic connective tissue (Fig. 10.1). It is characteristic for mesenchymal cells to migrate and to differentiate in many ways. They may become fibroblasts, chondroblasts, or osteoblasts (bone-forming cells).

The bone-forming capacity of mesenchyme is not restricted to cells of the sclerotome but occurs also in the parietal layer of the lateral plate mesoderm of the body wall. This layer of mesoderm forms bones of the pelvic and shoulder girdles, limbs, and sternum (see page 154). Neural crest cells in the head region also differentiate into mesenchyme and participate in formation of bones of the face and skull. The remainder of the skull is derived from occipital somites and somitomeres. In some bones, such as the flat bones of the skull, mesenchyme in the dermis differentiates directly into bone, a process known as intramembranous ossification (Fig. 10.2). In most bones, however, including the base of the skull and the limbs, mesenchymal cells first give rise to hyaline cartilage models, which in turn become ossified by endochondral ossification (Fig. 10.3). The following paragraphs discuss development of the most important bony structures and some of their abnormalities.

**SKULL**

The skull can be divided into two parts: the neurocranium, which forms a protective case around the brain, and the viscerocranium, which forms the skeleton of the face.
FIGURE 10.2 Skull bones of a 3-month-old fetus show the spread of bone spicules from primary ossification centers in the flat bones of the skull.

FIGURE 10.3 Endochondral bone formation. **A.** Mesenchyme cells begin to condense and differentiate into chondrocytes. **B.** Chondrocytes form a cartilaginous model of the prospective bone. **C,D.** Blood vessels invade the center of the cartilaginous model, bringing osteoblasts [black cells] and restricting proliferating chondrocytic cells to the ends [epiphyses] of the bones. Chondrocytes toward the shaft side [diaphysis] undergo hypertrophy and apoptosis as they mineralize the surrounding matrix. Osteoblasts bind to the mineralized matrix and deposit bone matrices. Later, as blood vessels invade the epiphyses, secondary ossification centers form. Growth of the bones is maintained by proliferation of chondrocytes in the growth plates.
Neurocranium

The neurocranium is most conveniently divided into two portions: (1) the membranous part, consisting of flat bones, which surround the brain as a vault, and (2) the cartilaginous part, or chondrocranium, which forms bones of the base of the skull.

Membranous Neurocranium

The membranous portion of the skull is derived from neural crest cells and paraxial mesoderm as indicated in Figure 10.4. Mesenchyme from these two sources invests the brain and undergoes intramembranous ossification. The result is formation of a number of flat, membranous bones that are characterized by the presence of needle-like bone spicules. These spicules progressively radiate from primary ossification centers toward the periphery (Fig. 10.2). With further growth during fetal and postnatal life, membranous bones enlarge by apposition of new layers on the outer surface and by simultaneous osteoclastic resorption from the inside.

Newborn Skull

At birth, the flat bones of the skull are separated from each other by narrow seams of connective tissue, the sutures. At points where more than two bones meet, sutures are wide and are called fontanelles (Fig. 10.5). The most prominent of these is the anterior fontanelle, which is found where the two parietal and two frontal bones meet. Sutures and fontanelles allow the bones of the skull to overlap (molding) during birth. Soon after birth, membranous bones move back to their original positions, and the skull appears large and round. In fact, the size of the vault is large compared with the small facial region (Fig. 10.5B).

Several sutures and fontanelles remain membranous for a considerable time after birth, which allows bones of the vault to continue to grow after birth to accommodate postnatal growth of the brain. Although a 5- to 7-year-old child has nearly all of his or her cranial capacity, some sutures remain open until adulthood. In the first few years after birth, palpation of the anterior fontanelle may give valuable information as to

---

**FIGURE 10.5** Skull of a newborn, seen from above [A] and the right side [B]. Note the anterior and posterior fontanelles and sutures. The posterior fontanelle closes about 3 months after birth; the anterior fontanelle closes around the middle of the second year. Many of the sutures disappear during adult life.
whether ossification of the skull is proceeding normally and whether intracranial pressure is normal. In most cases, the anterior fontanelle closes by 18 months of age, and the posterior fontanelle closes by 1 to 2 months of age.

**FIGURE 10.6** Dorsal view of the chondrocranium, or base of the skull, in the adult showing bones formed by endochondral ossification. Bones that form rostral to the rostral half of the sella turcica arise from neural crest and constitute the prechordal [chordal chondrocranium] (red). Those forming posterior to this landmark arise from paraxial mesoderm [chordal chondrocranium] (blue). Those forming posterior to this landmark arise from paraxial mesoderm [chordal chondrocranium] (red).

**Cartilaginous Neurocranium or Chondrocranium**

The cartilaginous neurocranium or chondrocranium of the skull initially consists of a number of separate cartilages. Those that lie in front of the rostral limit of the notochord, which ends at the level of the pituitary gland in the center of the sella turcica, are derived from neural crest cells. They form the prechordal chondrocranium. Those that lie posterior to this limit arise from occipital sclerotomes formed by paraxial mesoderm and form the chordal chondrocranium. The base of the skull is formed when these cartilages fuse and ossify by endochondral ossification (Figs. 10.3 and 10.6).

**Viscerocranium**

The viscerocranium, which consists of the bones of the face, is formed mainly from the first two pharyngeal arches (see Chapter 17). The first arch gives rise to a dorsal portion, the maxillary process, which extends forward beneath the region of the eye and gives rise to the maxilla, the zygomatic bone, and part of the temporal bone (Fig. 10.7). The ventral portion, the mandibular process, contains the Meckel cartilage. Mesenchyme around the Meckel cartilage condenses and ossifies by intramembranous ossification to give rise to the mandible. The Meckel cartilage

disappears except in the sphenomandibular ligament. The dorsal tip of the mandibular process, along with that of the second pharyngeal arch, later gives rise to the incus, the malleus, and the stapes (Fig. 10.7). Ossification of the three ossicles begins in the fourth month, making these the first bones to become fully ossified. Mesenchyme for formation of the bones of the face is derived from neural crest cells, including the nasal and lacrimal bones (Fig. 10.4).

At first, the face is small in comparison with the neurocranium. This appearance is caused by (1) virtual absence of the paranasal air sinuses and (2) the small size of the bones, particularly the jaws. With the appearance of teeth and development of the air sinuses, the face loses its babyish characteristics.

**Clinical Correlates**

### Craniofacial Defects and Skeletal Dysplasias

#### Neural Crest Cells

Neural crest cells originating in the neuroectoderm form the facial skeleton and part of the skull. These cells also constitute a vulnerable population as they leave the neuroectoderm; they are often a target for teratogens. Therefore, it is not surprising that craniofacial abnormalities are common birth defects (see Chapter 17).

#### Cranioschisis

In some cases, the cranial vault fails to form [cranioschisis], and brain tissue exposed to amniotic fluid degenerates, resulting in anencephaly. Cranioschisis is caused by failure of the cranial neuropore to close [Fig. 10.8A]. Children with such severe skull and brain defects cannot survive. Children with relatively small defects in the skull through which meninges and/or brain tissue herniate [cranial meningocele and meningoecephalocele, respectively] [Fig. 10.8B] may be treated successfully. In such cases, the extent of neurological deficits depends on the amount of damage to brain tissue.

#### Craniosynostosis

Another important category of cranial abnormalities is caused by premature closure of one or more sutures. These abnormalities are collectively known as craniosynostosis, which occurs in one in 2,500 births and is a feature of more than 100 genetic syndromes. Regulation of suture growth and closure is not well understood but may involve interactions between neural crest-mesoderm cell

---

**FIGURE 10.8**

[continued]
boundaries. For example, crest cells form the frontal bones, whereas paraxial mesoderm forms the parietal bones and the loose mesenchyme in the coronal sutures. Also, crest cells migrate between the parietal bones and form the first part of the sagittal suture. Molecular signaling at these boundaries regulates cell proliferation and differentiation. For example, EFNB1 encodes ephrin-B1, a ligand for EphB receptors that causes cells to repel each other, a kind of anti-adhesive activity and important for preventing premature suture closure. Loss of function mutations in EFNB1 causes craniofrontonasal syndrome, characterized by coronal suture synostosis and hypertelorism. Proliferation of neural crest cells in the frontal bones is regulated in part by the transcription factors MSX2 and TWIST1 that act cooperatively in parallel pathways. Mutations in MSX2 cause Boston-type craniosynostosis that can affect a number of sutures, whereas mutations in TWIST1 cause Saethre-Chotzen syndrome, characterized by coronal suture synostosis and polydactyly.

**Fibroblast growth factors (FGFs) and fibroblast growth factor receptors (FGFRs)** play important roles in most of skeletal development. There are many members of the FGF family and their receptors. Together, they regulate cellular events, including proliferation, differentiation, and migration. Signaling is mediated by the receptors, which are transmembrane tyrosine kinase receptors, each of which has three extracellular immunoglobulin domains, a transmembrane segment, and a cytoplasmic tyrosine kinase domain. FGFR1 and FGFR2 are coexpressed in prebone and precartilage regions, including craniofacial structures; FGFR3 is expressed in the cartilage growth plates of long bones and in the occipital region. In general, FGFR2 increases proliferation, and FGFR1 promotes osteogenic differentiation, whereas the role of FGFR3 is unclear. Mutations in these receptors, which often involve only a single amino acid substitution, have been linked to specific types of craniosynostosis [FGFR1, FGFR2, and FGFR3] and several forms of skeletal dysplasia [FGFR3] (Table 10.1).

The shape of the skull depends on which of the sutures closes prematurely. Early closure of the sagittal suture (57% of cases) results in frontal and occipital expansion, and the skull becomes long and narrow (sagittal constriction) [Fig. 10.9]. Premature closure of the coronal sutures (20% to 25% of cases) results in a short skull called **brachycephaly** [Fig. 10.10A]. If the coronal sutures close prematurely on one side only, then the result is an asymmetric flattening of the skull called **plagiocephaly** [Fig. 10.10B,C].

By far the most common causes of craniosynostosis are genetic (Table 10.1). Other causes include, vitamin D deficiency, exposure to teratogens, including, diphenylhydantoin, retinoids, valproic acid, methotrexate, and cyclophosphamide; and intrauterine factors that constrain the fetus, such as oligohydramnios and multiple birth pregnancies.

### Skeletal Dysplasias

**Achondroplasia (ACH)**, the most common form of skeletal dysplasia (1/20,000 live births), primarily affects the long bones [Fig. 10.11A]. Other skeletal defects include a large skull (megalencephaly) with a small midface [Fig. 10.11B], short fingers, and accentuated spinal curvature. ACH is inherited as an autosomal dominant, and 90% of cases appear sporadically due to new mutations.

**Thanatophoric dysplasia**, another autosomal dominant form of skeletal dysplasia, appears to be a milder type of ACH. Common to all of these forms of skeletal dysplasias are mutations in FGFR3 causing abnormal endochondral bone formation, so that growth of the long bones and the base of the skull are adversely affected.

**Generalized Skeletal Dysplasia**

**Cleidocranial dysostosis** is an example of a generalized dysplasia of osseous and dental tissues that is characterized by late closure of the fontanelles and decreased mineralization of the cranial sutures resulting in bossing (enlargement) of the frontal, parietal, and occipital bones [Fig. 10.13]. Other parts of the skeleton are affected as well and often times the clavicles are underdeveloped or missing.

Chapter 10 • The Axial Skeleton

FIGURE 10.11 A. Nine-year-old child with achondroplasia (ACH) showing a large head, short extremities, short fingers, and protruding abdomen. B. Lateral view of the patient’s head showing a prominent forehead and midfacial hypoplasia.

FIGURE 10.12 Patient with cloverleaf skull characteristic of thanatophoric dwarfism type II. The shape of the skull results from abnormal growth of the cranial base, caused by a mutation in FGFR3, followed by craniosynostosis. The sagittal, coronal, and lambdoid sutures are commonly involved.

FIGURE 10.13 Child with cleidocranial dysostosis with generalized skeletal dysplasias. One characteristic of the condition is delayed closure of the fontanelles and decreased mineralization of the cranial sutures, such that the head appears larger due to bossing of the frontal, parietal, and occipital bones. Other parts of the skeleton are affected as well and often the clavicles are underdeveloped or missing, as in this case.
Acromegaly

Acromegaly is caused by congenital hyperpituitarism and excessive production of growth hormone. It is characterized by disproportional enlargement of the face, hands, and feet. Sometimes, it causes more symmetrical excessive growth and gigantism.

Microcephaly

Microcephaly is usually an abnormality in which the brain fails to grow and, as a result, the skull fails to expand (Fig. 10.14). Many children with microcephaly are severely intellectually disabled.

**FIGURE 10.14** Child with microcephaly showing a small head due to the fact that the brain failed to grow to its normal size. One cause for this abnormality is exposure to alcohol in utero. In most cases, microcephaly is associated with significant intellectual disabilities.

**VERTEBRAE AND THE VERTEBRAL COLUMN**

Vertebrae form from the sclerotome portions of the somites, which are derived from paraxial mesoderm (Fig. 10.15A). A typical vertebra consists of a **vertebral arch** and **foramen** (through which the spinal cord passes), a **body**, **transverse processes**, and usually a **spinous process** (Fig. 10.15B). During the fourth week, sclerotome cells migrate around the spinal cord and notochord to merge with cells from the opposing somite on the other side. A cross section showing the developing regions of a somite. Sclerotome cells are dispersing to migrate around the neural tube and notochord to contribute to vertebral formation. B. Example of a typical vertebra showing its various components.
The process of formation and rearrangement of segmental sclerotomes into definitive vertebrae is complicated, and it is fairly common to have two successive vertebrae fuse asymmetrically or have half a vertebra missing, a cause of scoliosis (lateral curving of the spine). Also, the number of vertebrae is frequently more or less than the norm. In Klippel–Feil sequence, the cervical vertebrae...
are fused causing reduced mobility and a short neck.

One of the most serious vertebral defects is the result of imperfect fusion or nonunion of the vertebral arches. Such an abnormality, known as cleft vertebra (spina bifida), may involve only the bony vertebral arches, leaving the spinal cord intact. In these cases, the bony defect is covered by skin, and no neurological deficits occur [spina bifida occulta]. A more severe abnormality is spina bifida cystica, in which the neural tube fails to close, vertebral arches fail to form, and neural tissue is exposed. Any neurological deficits depend on the level and extent of the lesion (Fig. 10.17). This defect, which occurs in 1 per 2,500 births, may be prevented, in many cases, by providing mothers with folic acid prior to conception [see Chapter 6, p. 77]. Spina bifida can be detected prenatally by ultrasound, and if neural tissue is exposed, amniocentesis can detect elevated levels of α-fetoprotein in the amniotic fluid. [For the various types of spina bifida, see Fig. 6.7, p. 78.]

**FIGURE 10.17** A. Ultrasound scan of a 26-week fetus with spina bifida in the lumbosacral region (asterisk). B. Ultrasound scan showing the skull of a 26-week fetus with spina bifida. Because of the shape of the skull, the image is called the “lemon sign,” which occurs in some of these cases and is due to the brain being pulled caudally, changing the shape of the head [see Arnold-Chiari malformation, p. 316].

---

**RIBS AND STERNUM**

The bony portion of each rib is derived from sclerotome cells that remain in the paraxial mesoderm and that grow out from the costal processes of thoracic vertebrae. Costal cartilages are formed by sclerotome cells that migrate across the lateral somitic frontier into the adjacent lateral plate mesoderm (see Chapter 11 for a description of the lateral somitic frontier). The sternum develops independently in the parietal layer of lateral plate mesoderm in the ventral body wall. Two sternal bands are formed in the parietal (somatic) layer of lateral plate mesoderm on either side of the midline, and these later fuse to form cartilaginous models of the manubrium, sternebrae, and xiphoid process.

**Clinical Correlates**

**Rib Defects**

Occasionally, extra ribs are formed, usually in the lumbar or cervical regions. **Cervical ribs** occur in approximately 1% of the population and are usually attached to the seventh cervical vertebra. Because of its location, this type of rib may impinge on the brachial plexus or the subclavian artery, resulting in varying degrees of anesthesia in the limb.

**Defects of the Sternum**

**Cleft sternum** is a very rare defect and may be complete or located at either end of the sternum. Thoracic organs are covered only by skin and soft tissue. The defect arises when the sternal bands fail to grow together in the midline. **Hypoplastic ossification centers** and **premature fusion of sternal segments** also occur particularly in infants with congenital
heart defects [20% to 50%]. Multiple manubrial ossification centers occur in 6% to 20% of all children but are especially common in those with Down syndrome. 
Pectus excavatum is the term for a depressed sternum that is sunken posteriorly. Pectus carinatum refers to a flattening of the chest bilaterally with an anteriorly projecting sternum. The projection of the sternum resembles the keel of a boat. Both defects may result from abnormalities of ventral body wall closure or formation of the costal cartilages and sternum.

Summary
The skeletal system develops from mesenchyme, which is derived from the mesodermal germ layer and from the neural crest. Some bones, such as the flat bones of the skull, undergo intramembranous ossification; that is, mesenchyme cells are directly transformed into osteoblasts (Fig. 10.2). In most bones, such as the long bones of the limbs, mesenchyme condenses and forms hyaline cartilage models of bones (Fig. 10.3). Ossification centers appear in these cartilage models, and the bone gradually ossifies by endochondral ossification.

The skull consists of the neurocranium and the viscerocranium (face). The neurocranium includes a membranous portion, which forms the cranial vault, and a cartilaginous portion, the chondrocranium, which forms the base of the skull. Neural crest cells form the face, part of the cranial vault, and the prechordal part of the chondrocranium (the part that lies rostral to the pituitary gland). Paraxial mesoderm forms the remainder of the skull.

The vertebral column and ribs develop from the sclerotome compartments of the somites, and the sternum is derived from mesoderm in the ventral body wall. A definitive vertebra is formed by condensation of the caudal half of one sclerotome and fusion with the cranial half of the subjacent sclerotome (Fig. 10.16).

The many abnormalities of the skeletal system include vertebral (spina bifida), cranial (cranioschisis and craniosynostosis), and facial (cleft palate) defects. Major malformations of the limbs are rare, but defects of the radius and digits are often associated with other abnormalities (syndromes).

Problems to Solve

1. Why are cranial sutures important? Are they involved in any abnormalities?
2. Explain the origin of scoliosis as a vertebral anomaly. What genes might be involved in this abnormality?
With the exception of some smooth muscle tissue (see p. 160), the muscular system develops from the mesodermal germ layer and consists of skeletal, smooth, and cardiac muscle. Skeletal muscle is derived from paraxial mesoderm, which forms somites from the occipital to the sacral regions and somitomes in the head. Smooth muscle differentiates from visceral splanchnic mesoderm surrounding the gut and its derivatives and from ectoderm (pupillary, mammary gland, and sweat gland muscles). Cardiac muscle is derived from visceral splanchnic mesoderm surrounding the heart tube.

■ STRIATED SKELETAL MUSCULATURE

Head musculature (see Chapter 17) is derived from seven somitomeres, which are partially segmented whorls of mesenchymal cells derived from paraxial mesoderm (see Chapter 6, p. 78). Musculature of the axial skeleton, body wall, and limbs is derived from somites, which initially form as somitomeres and extend from the occipital region to the tail bud. Immediately after segmentation, these somitomeres undergo a process of epithelization and form a "ball" of epithelial cells with a small cavity in the center (Fig. 11.1A). The ventral region of each somite then becomes mesenchymal again and forms the sclerotome (Fig. 11.1B–D), the bone-forming cells for the vertebrae and ribs. Cells in the upper region of the somite form the dermatome and two muscle-forming areas at the ventrolateral (VLL) and dorsomedial (DML) lips (or edges), respectively (Fig. 11.1B). Cells from these two areas migrate and proliferate to form progenitor muscle cells ventral to the dermatome, thereby forming the dermomyotome (Figs. 11.1B,C and 11.2). Some cells from the VLL region also migrate into the adjacent parietal layer of the lateral plate mesoderm (Fig. 11.1B). Here they form infrayoid, abdominal wall (rectus abdominis, internal and external oblique, and transversus abdominis), and limb muscles. The remaining cells in the myotome form muscles of the back, shoulder girdle, and intercostal muscles (Table 11.1, p. 158).

Initially, there is a well-defined border between each somite and the parietal layer of lateral plate mesoderm called the lateral somitic frontier (Fig. 11.1B). This frontier separates two mesodermal domains in the embryo:

1. The primaxial domain that comprises the region around the neural tube and contains only somite-derived (paraxial mesoderm) cells
2. The abaxial domain that consists of the parietal layer of lateral plate mesoderm together with somite cells that have migrated across the lateral somitic frontier

Muscle cells that cross this frontier (those from the VLL edge of the myotome) and enter the lateral plate mesoderm comprise the abaxial muscle cell precursors and receive many of their signals for differentiation from lateral plate mesoderm (Fig. 11.3); those that remain in the paraxial mesoderm and do not cross the frontier (the remaining VLL cells and all of the DML cells) comprise the primaxial muscle cell precursors and receive many of their developmental signals from the neural tube and notochord (Fig. 11.3). Regardless of their domain, each myotome receives its innervation from spinal nerves derived from the same segment as the muscle cells.

The lateral somitic frontier also defines the border between dermis derived from dermatomes in the back and dermis derived from lateral plate mesoderm in the body wall. It also
defines a border for rib development, such that the bony components of each rib are derived from primaxial sclerotome cells and the cartilaginous parts of those ribs that attach to the sternum are derived from sclerotome cells that migrate across the lateral somitic frontier (abaxial cells).

**FIGURE 11.1** Cross-sectional drawings showing the stages of development in a somite. A. Mesoderm cells become epithelial and are arranged around a small lumen. B. Cells in the ventral and medial walls of the somite lose their epithelial characteristics and migrate around the neural tube and notochord, and some move into the parietal layer of lateral plate mesoderm. Collectively, these cells constitute the sclerotome. Cells at the DML and VLL regions of the somite form muscle cell precursors. Cells from both regions migrate ventral to the dermatome to form the dermomyotome. VLL cells also migrate into the parietal layer of lateral plate mesoderm across the lateral somitic frontier (green line). In combination, somitic cells and lateral plate mesoderm cells constitute the abaxial mesodermal domain, whereas the primaxial mesodermal domain only contains somitic cells (paraxial mesoderm). C. Together, dermatome cells and the muscle cells that associate with them form the dermomyotome. D. The dermomyotome begins to differentiate: Myotome cells contribute to primaxial muscles, and dermomyotome cells form the dermis of the back.

---

**INNERVATION OF AXIAL SKELETAL MUSCLES**

The new description of muscle development characterized by primaxial and abaxial domains differs from the old concept of epimeres (back muscles) and hypomeres (limb and body wall muscles), which was based on a functional

\(^{c}\)The precise origin of muscles in the pelvic region and lower limb has not been determined, but most if not all are abaxial in origin.

FIGURE 11.3 Expression patterns of genes that regulate somite differentiation. Sonic hedgehog (SHH) and noggin, secreted by the notochord and floor plate of the neural tube, cause the ventral part of the somite to form sclerotome and to express PAX7, which in turn controls chondrogenesis and vertebral formation. WNT and low concentrations of SHH proteins from the dorsal neural tube activate PAX3, which demarcates the dermatome. WNT proteins also direct the DML portion of the somite to form muscle precursor cells and to express the muscle-specific gene MYF5. The dermatome portion of the somite is directed to become dermis by neurotrophin 3 (NT-3) secreted by the dorsal neural tube. The combined influence of activating WNT proteins and inhibitory BMP4 protein activates MyoD expression in the VLL region to create a second group of muscle cell precursors.
Flexor muscle of limb

FIGURE 11.4 Cross section through half the embryo showing innervation to developing musculature. Epaxial [true back muscles] are innervated by dorsal [posterior] primary rami. Hypaxial muscles [limb and body wall] are innervated by ventral [anterior] primary rami.

definition of innervation: Epimeric muscles were innervated by dorsal primary rami, hypomeric muscles by ventral primary rami. The new description is based on the actual embryological origin of muscle cells from two different populations of muscle cell precursors, the abaxial and primaxial cells, and not their innervation. The description does not preclude the fact that epaxial (above the axis) muscles (back muscles) are innervated by dorsal primary rami, whereas hypaxial (below the axis) muscles (body wall and limb muscles) are innervated by ventral primary rami (Fig. 11.4).

■ MOLECULAR REGULATION OF MUSCLE DEVELOPMENT

Genes regulating muscle development have recently been identified. Bone morphogenetic protein 4 (BMP4) and probably fibroblast growth factors from lateral plate mesoderm, together with WNT proteins from adjacent ectoderm, signal VLL cells of the dermomyotome to express the muscle-specific gene MyoD (Fig. 11.3). BMP4 secreted by ectoderm cells induces production of WNT proteins by the dorsal neural tube at the same time that low concentrations of sonic hedgehog (SHH) proteins, secreted by the notochord and floor plate of the neural tube, reach the DML cells of the dermomyotome. Together these proteins induce expression of MYF5 and MyoD in these cells (note that SHH does not play a role in specifying VLL cells). Both MyoD and MYF5 are members of a family of transcription factors called myogenic regulatory factors (MRFs), and this group of genes activates pathways for muscle development.

■ PATTERNING OF MUSCLES

Patterns of muscle formation are controlled by connective tissue into which myoblasts migrate. In the head region, these connective tissues are derived from neural crest cells; in cervical and occipital regions, they differentiate from somitic mesoderm; and in the body wall and limbs, they originate from the parietal layer of lateral plate mesoderm.

■ HEAD MUSCULATURE

All voluntary muscles of the head region are derived from paraxial mesoderm (somitomeres and somites), including musculature of the tongue, eye (except that of the iris, which is derived from optic cup ectoderm), and that associated with the pharyngeal (visceral) arches (Table 11.2, p. 160, and Fig. 11.2). Patterns of muscle formation in the head are directed by connective tissue elements derived from neural crest cells.

■ LIMB MUSCULATURE

The first indication of limb musculature is observed in the seventh week of development as a condensation of mesenchyme near the

![Back (epaxial) muscles](image1)

Flexor muscle of limb

![Diagram](image2)
base of the limb buds (Fig. 11.2). The mesenchyme is derived from dorsolateral cells of the somites that migrate into the limb bud to form the muscles. As in other regions, connective tissue dictates the pattern of muscle formation, and this tissue is derived from the parietal layer of lateral plate mesoderm, which also gives rise to the bones of the limb (see Chapter 12).

### CARDIAC MUSCLE
Cardiac muscle develops from splanchnic mesoderm surrounding the endothelial heart tube. Myoblasts adhere to one another by special attachments that later develop into intercalated discs. Myofilaments develop as in skeletal muscle, but myoblasts do not fuse. During later development, a few special bundles of muscle cells with irregularly distributed myofilaments become visible. These bundles, Purkinje fibers, form the conducting system of the heart.

### SMOOTH MUSCLE
Smooth muscle for the dorsal aorta and large arteries is derived from lateral plate mesoderm and neural crest cells. In the coronary arteries, smooth muscle originates from proepicardial cells (see Chapter 13) and neural crest cells (proximal segments). Smooth muscle in the wall of the gut and gut derivatives is derived from the splanchnic layer of lateral plate mesoderm that surrounds these structures. Only the sphincter and dilator muscles of the pupil and muscle tissue in the mammary and sweat glands are derived from ectoderm.

Serum response factor (SRF) is a transcription factor responsible for smooth muscle cell differentiation. This factor is upregulated by growth factors through kinase phosphorylation pathways. Myocardin and myocardin-related transcription factors (MRTFs) then act as co-activators to enhance the activity of SRF, thereby initiating the genetic cascade responsible for smooth muscle development.

### Clinical Correlates
Partial or complete absence of a muscle is common and usually not debilitating. Examples include partial or complete absence of the palmaris longus, serratus anterior, or quadratus femoris muscles. A more serious defect is called **Poland sequence** that occurs in 1 per 20,000 individuals and is characterized by absence of the pectoralis minor and partial loss of the pectoralis major (usually the sternal head) muscles (Fig. 11.5). The nipple and areola are absent or displaced, and there are often digital defects (syndactyly [fused digits] and brachydactyly [short digits]) on the affected side. The disfiguring nature of the defects can be problematic, especially in females because of breast development.

Partial or complete absence of abdominal musculature is called **prune belly syndrome** (Fig. 11.6). Usually, the abdominal wall is so thin that organs are visible and easily palpated. This defect is sometimes associated with malformations of the urinary tract and

bladder, including urethral obstruction. These defects cause an accumulation of fluid that distends the abdomen, resulting in atrophy of the abdominal muscles.

**Muscular dystrophy** is the term for a group of inherited muscle diseases that cause progressive muscular wasting and weakness.

Dystrophin is a cytoplasmic protein that forms a dystrophin-associated protein complex linking the cytoskeleton to the extracellular matrix.

**SUMMARY**

Most muscles arise from the mesoderm. Skeletal muscles are derived from paraxial mesoderm, including (1) somites, which give rise to muscles of the axial skeleton, body wall, and limbs, and (2) somitomeres, which give rise to muscles of the head. Progenitor cells for muscle tissues are derived from the ventrolateral (VLL) and dorsomedial (DML) edges (lips) of the prospective dermomyotome. Cells from both regions contribute to formation of the myotome. Some cells from the VLL also migrate across the lateral somitic frontier into the parietal layer of the lateral plate mesoderm. This frontier or border separates two mesodermal domains in the embryo: (1) the **primaxial domain** that surrounds the neural tube and contains only somite-derived cells (paraxial mesoderm) and (2) the **abaxial domain** that consists of the parietal layer of lateral plate mesoderm in combination with somite-derived cells that migrate across the frontier into this region (Fig. 11.1). Abaxial muscle precursor cells differentiate into **infrahyoid, abdominal wall (rectus abdominus, external and internal obliques, transversus abdominus), and limb muscles.** Primaxial muscle precursor cells form **muscles of the back**, **some muscles of the shoulder girdle**, and **intercostal muscles** (Table 11.1, p. 158). Muscles of the back (epaxial muscles) are innervated by **dorsal primary rami**; muscles of the limbs and body wall (hypaxial muscles) are innervated by **ventral primary rami**. Molecular signals for muscle cell induction arise from tissues adjacent to prospective muscle cells. Thus, signals from lateral plate mesoderm (BMPs) and overlying ectoderm (WNTs) induce VLL cells, whereas signals from the neural tube and notochord (SHH and WNTs) induce DML cells. **Connective tissue** derived from somites, parietal mesoderm, and neural crest (head region)
provides a template for establishment of muscle patterns. Most smooth muscles and cardiac muscle fibers are derived from splanchnic mesoderm. Smooth muscles of the pupil, mammary gland, and sweat glands differentiate from ectoderm.

**Problems to Solve**

1. Muscle cells are derived from what two regions of the somite? Which region contributes to the abaxial mesodermal domain? What muscles form from the abaxial and primaxial domains?

2. In examining a newborn female infant, you note that her right nipple is displaced toward the axilla and that the right anterior axillary fold is nearly absent. What is your diagnosis?

3. Patterning of muscles is dependent on what type of tissue?

4. How do you explain the fact that the phrenic nerve, which originates from cervical segments 3, 4, and 5, innervates the diaphragm in the thoracic region?
The limbs, including the shoulder and pelvic girdles, comprise the appendicular skeleton. At the end of the fourth week of development, limb buds become visible as outpocketings from the ventrolateral body wall (Fig. 12.1A). The forelimb appears first followed by the hind limb 1 to 2 days later. Initially, the limb buds consist of a mesenchymal core derived from the parietal (somatic) layer of lateral plate mesoderm that will form the bones and connective tissues of the limb, covered by a layer of cuboidal ectoderm. Ectoderm at the distal border of the limb thickens and forms the apical ectodermal ridge (AER) (Fig. 12.2; see also Fig. 12.9A). This ridge exerts an inductive influence on adjacent mesenchyme, causing it to remain as a population of undifferentiated, rapidly proliferating cells, the undifferentiated zone. As the limb grows, cells farther from the influence of the AER begin to differentiate into cartilage and muscle. In this manner, development of each limb proceeds proximodistally into its three components: stylopod (humerus and femur), zeugopod (radius/ulna and tibia/fibula), and autopod (carpels, metacarpals, digits/tarsals, digits/metatarsals).

In 6-week-old embryos, the terminal portion of the limb buds becomes flattened to form the hand- and footplates and is separated from the proximal segment by a circular constriction (Fig. 12.1B). Later, a second constriction divides the proximal portion into two segments, and the main parts of the extremities can be recognized (Fig. 12.1C). Fingers and toes are formed when cell death in the AER separates this ridge into five parts (Fig. 12.3A). Further formation of the digits depends on their continued outgrowth under the influence of the five segments of ridge ectoderm, condensation of the mesenchyme to form cartilaginous digital rays, and the death of intervening tissue between the rays (Fig. 12.3B,C).

Development of the upper and lower limbs is similar except that morphogenesis of the lower limb is approximately 1 to 2 days behind that of the upper limb. Also, during the seventh week of gestation, the limbs rotate in opposite directions. The upper limb rotates 90° laterally, so that the...
extensor muscles lie on the lateral and posterior surface, and the thumbs lie laterally, whereas the lower limb rotates approximately 90° medially, placing the extensor muscles on the anterior surface and the big toe medially.

While the external shape is being established, mesenchyme in the buds begins to condense, and these cells differentiate into chondrocytes (Fig. 12.4). By the sixth week of development, the first **hyaline cartilage models**, foreshadowing the bones of the extremities, are formed by these chondrocytes (Figs. 12.4 and 12.5). Joints are formed in the cartilaginous condensations when chondrogenesis is arrested, and a joint **interzone** is induced. Cells in this region increase in number and density, and then a joint cavity is formed by cell death. Surrounding cells differentiate into a joint capsule. Factors regulating the positioning of the digits include the **Apical ectodermal ridge (AER)**, which thickens at the distal border of the limb to form the AER.

**FIGURE 12.2** A. Longitudinal section through the limb bud of a chick embryo, showing a core of mesenchyme covered by a layer of ectoderm that thickens at the distal border of the limb to form the AER. In humans, this occurs during the fifth week of development. B. External view of a chick limb at high magnification showing the ectoderm and the specialized region at the tip of the limb called the AER.

**FIGURE 12.3** Schematic of human hands. A. At 48 days. Cell death in the AER creates a separate ridge for each digit. B. At 51 days. Cell death in the interdigital spaces produces separation of the digits. C. At 56 days. Digit separation is complete.
of joints are not clear, but the secreted molecule WNT14 appears to be the inductive signal.

Ossification of the bones of the extremities, **endochondral ossification**, begins by the end of the embryonic period. Primary **ossification centers** are present in all long bones of the limbs by the 12th week of development. From the primary center in the shaft or **diaphysis** of the bone, endochondral ossification gradually progresses toward the ends of the cartilaginous model (Fig. 12.5).

At birth, the diaphysis of the bone is usually completely ossified, but the two ends, the **epiphyses**, are still cartilaginous. Shortly thereafter, however, ossification centers arise in the epiphyses. Temporarily, a cartilage plate remains between the diaphyseal and epiphyseal ossification centers. This plate, the **epiphyseal plate**, plays an important role in growth in the length of the bones. Endochondral ossification proceeds on both sides of the plate (Fig. 12.5). When the bone has acquired its full length, the epiphyseal plates disappear, and the epiphyses unite with the shaft of the bone.

In long bones, an epiphyseal plate is found on each extremity; in smaller bones, such as the phalanges, it is found only at one extremity; and in irregular bones, such as the vertebrae, one or more primary centers of ossification and usually several secondary centers are present.

**Synovial joints** between bones begin to form at the same time that mesenchymal condensations initiate the process of forming cartilage. Thus, in the region between two chondrifying bone primordia, called the **interzone** (e.g., between the tibia and femur at the knee joint), the condensed mesenchyme differentiates into dense fibrous tissue. This fibrous tissue then forms **articular cartilage**, covering the ends of the two adjacent bones; the **synovial membranes**; and the **menisci and ligaments within the joint capsule** (e.g., the anterior and posterior cruciate ligaments in the knee). The **joint capsule** itself is derived from mesenchyme cells surrounding the interzone region. **Fibrous joints** (e.g., the sutures in the skull) also form from interzone regions, but in this case, the interzone remains as a dense fibrous structure.
Limb musculature is derived from dorsolateral cells of the somites that migrate into the limb to form muscles, and initially, these muscle components are segmented according to the somites from which they are derived (Fig. 12.6).

However, with elongation of the limb buds, the muscle tissue first splits into flexor and extensor components (Fig. 12.7) and then additional splittings and fusions occur, such that a single muscle may be formed from more than one original segment. The resulting complex pattern
of muscles is determined by connective tissue derived from lateral plate mesoderm.

Upper limb buds lie opposite the lower five cervical and upper two thoracic segments (Fig. 12.6), and the lower limb buds lie opposite the lower four lumbar and upper two sacral segments. As soon as the buds form, ventral primary rami from the appropriate spinal nerves penetrate into the mesenchyme. At first, each ventral ramus enters with dorsal and ventral branches derived from its specific spinal segment, but soon branches in their respective divisions begin to unite to form large dorsal and ventral nerves (Fig. 12.7). Thus, the radial nerve, which supplies the extensor musculature, is formed by a combination of the dorsal segmental branches, whereas the ulnar and median nerves, which supply the flexor musculature, are formed by a combination of the ventral branches. Immediately after the nerves have entered the limb buds, they establish an intimate contact with the differentiating mesodermal condensations, and the early contact between the nerve and muscle cells is a prerequisite for their complete functional differentiation.

Spinal nerves not only play an important role in differentiation and motor innervation of the limb musculature but also provide sensory innervation for the dermatomes. Although the original dermatomal pattern changes with growth and rotation of the extremities, an orderly sequence can still be recognized in the adult (Fig. 12.8).
Molecular Regulation of Limb Development

Positioning of the limbs along the craniocaudal axis in the flank regions of the embryo is regulated by the HOX genes expressed along this axis. These homeobox genes are expressed in overlapping patterns from head to tail (see Chapter 6, p. 88), with some having more cranial limits than others. For example, the cranial limit of expression of HOXB8 is at the cranial border of the forelimb, and misexpression of this gene alters the position of these limbs. Specification of the forelimb is regulated by the transcription factor TBX5; specification of the hind limb is regulated by TBX4.

Once positioning along the craniocaudal axis is determined, growth must be regulated along the proximodistal, anteroposterior, and dorsoventral axes (Fig. 12.9). Limb outgrowth is initiated by fibroblast growth factor 10 (FGF10) secreted by lateral plate mesoderm cells (Fig. 12.9A). Once outgrowth is initiated, bone morphogenetic proteins (BMPs), expressed in ventral ectoderm, induce formation of the AER by signaling through the homeobox gene MSX2. Expression of RADICAL FRINGE, a homologue of Drosophila fringe, in the dorsal half of the limb ectoderm, restricts the location of the AER to the distal tip of the limbs. This gene induces expression of SER2, a homologue of Drosophila serrate, at the border between cells that are expressing RADICAL FRINGE and those that are not. It is at this border that the AER is established. Formation of the border itself is assisted by expression of ENGRAILED-1 in ventral ectoderm cells, because this gene represses expression of RADICAL FRINGE (Fig. 12.9A). After the ridge is established, it expresses FGF4.

FIGURE 12.9 Molecular regulation of patterning and growth in the limb. A. Limb outgrowth is initiated by FGF10 secreted by lateral plate mesoderm in the limb-forming regions. Once outgrowth is initiated, the AER is induced by BMPs and restricted in its location by the gene Radical fringe expressed in dorsal ectoderm. In turn, this expression induces that of SER2 in cells destined to form the AER. After the ridge is established, it expresses FGF4 and FGF8 to maintain the progress zone, the rapidly proliferating mesenchyme cells adjacent to the ridge. B. Anteroposterior patterning of the limb is controlled by cells in the ZPA at the posterior border. These cells produce retinoic acid (vitamin A), which initiates expression of SHH, regulating patterning. C. The dorsoventral limb axis is directed by WNT7a, which is expressed in the dorsal ectoderm. This gene induces expression of the transcription factor LMX1 in the dorsal mesenchyme, specifying these cells as dorsal.
Differentiation zone

FIGURE 12.10 Drawing showing limb patterning along the proximodistal axis. A. During early stages of limb outgrowth, cells beneath the AER are maintained in a highly proliferative undifferentiated state (the undifferentiated zone) by exposure to FGFs secreted by the AER. Meanwhile, cells that are farther away from the AER are exposed to retinoic acid secreted by flank mesenchyme cells. These two cell populations meet at the differentiation front. B. As continued growth occurs, proximal cells under the influence of retinoic acid and a genetic cascade differentiate into the stylopod. As this process occurs, the differentiation front moves distally and under the influence of SHH and other genes, the zeugopod differentiates. C. Finally, secretion of FGFs by the AER is terminated and the autopod differentiates. While the AER is active, the marker gene for the undifferentiated zone is the transcription factor AP2 (B), which may play a role in maintaining FGF secretion by the AER. Marker genes for the three differentiated limb regions (C) include MEIS1 (stylopod), HOXA11 (zeugopod), and HOXA13 (autopod).

and FGF8, which maintain the undifferentiated zone, the rapidly proliferating population of mesenchyme cells adjacent to the ridge (Fig. 12.9A). Distal growth of the limb is then effected by these rapidly proliferating cells under the influence of the FGFs. As growth occurs, mesenchymal cells at the proximal end of the undifferentiated zone are no longer influenced by signals from FGFs and, instead, begin to differentiate under the control of other signaling molecules (Fig. 12.10). For example, retinoic acid, made in flank mesenchyme cells, acts as a morphogen to initiate a genetic cascade to specify and cause differentiation of the stylopod. A marker gene for this region is the transcription factor MEIS1 that may participate in this process. Differentiation of the zeugopod and autopod regions involves other genes, including SONIC HEDGEHOG (SHH). Marker genes for these regions are HOXA11 for the zeugopod and HOXA13 for the autopod (Fig. 12.10C). It is not clear whether or not these markers play a role in the differentiation process, but HOX genes in general play a critical role in patterning the bones of the limbs.

Patterning of the anteroposterior axis of the limb is regulated by the zone of polarizing activity (ZPA), a cluster of mesenchymal cells at the posterior border of the limb near the AER (Fig. 12.9B). These cells produce the secreted factor SHH, a morphogen that contributes to specification of the anteroposterior axis. For example, digits appear in the proper order, with the thumb on the radial (anterior) side. As the limb grows, the ZPA moves distalward to remain in proximity to the posterior border of the AER. Misexpression of SHH in the anterior margin of a limb containing a normally expressing ZPA in the posterior border results in a mirror image duplication of limb structures (Fig. 12.11).

FIGURE 12.11 Experimental procedure for grafting a new ZPA from one limb bud into another using chick embryos. The result is the production of a limb with mirror image duplication of the digits much like that shown in the adjacent figure, indicating the role of the ZPA in regulating anteroposterior patterning of the limb. SHH protein is the molecule secreted by the ZPA responsible for this regulation.
The dorsoventral axis is also regulated by BMPs in the ventral ectoderm, which induce expression of the transcription factor EN1. In turn, EN1 represses WNT7a expression, restricting it to the dorsal limb ectoderm. WNT7a is a secreted factor that induces expression of LMX1, a transcription factor containing a homeodomain, in the dorsal mesenchyme (Fig. 12.9C). LMX1 specifies cells to be dorsal, establishing the dorsoventral components. In addition, WNT7a maintains SHH expression in the ZPA and therefore indirectly affects anteroposterior patterning as well. These two genes are also intimately linked in signaling pathways in Drosophila, and this interaction is conserved in vertebrates. In fact, all of the patterning genes in the limb have feedback loops. Thus, FGFs in the AER activate SHH in the ZPA, whereas WNT7a maintains the SHH signal, which in turn can up-regulate FGF expression in the AER.

Although patterning genes for the limb axes have been determined, it is the HOX genes that regulate the types and shapes of the bones of the limb. This HOX gene expression is dependent upon the combinatorial expression of FGF, SHH, and WNT7a genes that cause HOX expression in three phases in the limb that correspond to the proximal (stylopod: humerus and femur), middle (zeugopod: radius/ulna; tibia/fibula), and distal (autopod: hand and foot) regions. Genes of the HOXA and D clusters are the primary determinants in the limb accounting for patterning the bones. Thus, misexpression of either of these two genes may result in limb truncations and anterior–posterior duplications. Just as in the craniocaudal axis of the embryo, HOX genes are nested in overlapping patterns of expression that somehow regulate patterning. Factors designating forelimb versus hind limb are the transcription factors TBX5 (forelimbs) and TBX4 together with PITX1 (hind limbs).

### Clinical Correlates

**Bone Age**
Radiologists use the appearance of various ossification centers to determine whether a child has reached his or her proper maturation age. Useful information about bone age is obtained from ossification studies in the hands and wrists of children. Prenatal analysis of fetal bones by ultrasonography provides information about fetal growth and gestational age.

**Limb Defects**
Limb malformations occur in approximately 6 per 10,000 live births, with 3.4 per 10,000 affecting the upper limb and 1.1 per 10,000 affecting the lower. These defects are often associated with other birth defects involving the craniofacial, cardiac, and genitourinary systems. Abnormalities of the limbs vary greatly, and they may be represented by partial (meromelia) or complete absence (amelia) of one or more of the extremities (Fig. 12.12A). Sometimes, the long bones are absent, and rudimentary hands and feet are attached to the trunk by small, irregularly shaped bones (phocomelia, a form of meromelia) (Fig. 12.12B). Sometimes, all segments of the extremities are present but abnormally short (micromelia).

Although these abnormalities are rare and mainly hereditary, cases of teratogen-induced limb defects have been documented. For example, many children with limb malformations were born between 1957 and 1962. Many mothers of these infants had taken thalidomide, a drug widely used as a sleeping pill and anti-nauseant. It was subsequently established that thalidomide causes a characteristic syndrome of malformations consisting of absence or gross deformities of the long bones, intestinal atresia, and cardiac anomalies. Studies indicate that the fourth and the fifth weeks of gestation are the most sensitive period for induction of the limb defects. Because the drug is now being used to treat AIDS and cancer patients, distribution of thalidomide is carefully regulated to avoid its use by pregnant women.

A different category of limb defects involves the digits. Sometimes, the digits are shortened (brachydactyly; Fig. 12.13A). If two or more fingers or toes are fused, it is called syndactyly (Fig. 12.13B). Normally, mesenchyme between prospective digits in hands- and footplates is removed by cell death (apoptosis). In 1 per 2,000 births, this process fails, and the result is fusion between two or more digits. The presence of extra fingers or toes is called polydactyly (Fig. 12.13C). The extra digits frequently lack proper muscle connections. Abnormalities involving polydactyly are usually bilateral, whereas...
FIGURE 12.12 A. Child with unilateral amelia and multiple defects of the left upper limb. B. Patient with a form of meromelia called *phocomelia*. The hands are attached to the trunk by irregularly shaped bones.

FIGURE 12.13 Digital defects. A. Brachydactyly, short digits. B. Syndactyly, fused digits. C. Polydactyly, extra digits. D. Cleft foot. Any of these defects may involve either the hands or feet or both.

[continued]
absence of a digit [ectrodactyly], such as a thumb, usually occurs unilaterally.

Cleft hand and foot consists of an abnormal cleft between the second and fourth metacarpal bones and soft tissues. The third metacarpal and phalangeal bones are almost always absent, and the thumb and index finger and the fourth and fifth fingers may be fused (Fig. 12.13D). The two parts of the hand are somewhat opposed to each other.

A number of gene mutations have been identified that affect the limbs and sometimes other structures (see Table 10.1, p. 149). The role of the HOX genes in limb development is illustrated by two abnormal phenotypes produced by mutations in this family of genes: Mutations in HOXA13 result in hand-foot-genital syndrome, characterized by fusion of the carpal bones and small short digits. Affected females often have a partially (bicornuate) or a completely (didelphic) divided uterus and abnormal positioning of the urethral orifice. Affected males may have hypospadias. The genital defects are due to the fact that HOXA13 plays an important role in development of the cloaca into the urogenital sinus and anal canal (see Chapter 16). Mutations in HOXD13 result in a combination of syndactyly and polydactyly (synpolydactyly).

TBX5 mutations (chromosome 12q24.1) result in Holt-Oram syndrome, characterized by upper limb abnormalities and heart defects consistent with a role for this gene in upper limb and heart development. Virtually all types of limb defects affecting the upper limb have been observed, including absent digits, polydactyly, syndactyly, absent radius, and hypoplasia of any of the limb bones. Heart defects include atrial and ventricular septal defects and conduction abnormalities.

Osteogenesis imperfecta is characterized by shortening, bowing, and hypomineralization of the long bones of the limbs that can result in fractures and blue sclera (Fig. 12.14). Several types of osteogenesis imperfecta occur, ranging from persons with a mildly increased frequency of fractures to a severe form that is lethal in the neonatal period. In most cases, dominant mutations in the COL1A1 or COL1A2 genes that are involved in production of type I collagen cause the abnormalities.

Marfan syndrome is caused by mutations in the FIBRILLIN [FBN1] gene located on chromosome 15q21.1. Affected individuals are usually tall and slender with long thin limbs and a long thin face. Other characteristics include sternal defects (pectus excavatum or carinatum), joint hyperflexibility, dilatation and/or dissection of the ascending aorta, and dislocation of the lens of the eye.

Arthrogryposis [congenital joint contractures] (Fig. 12.15) usually involves more than one joint and may be caused by neurological defects (motor horn cell deficiency, meningomyelocele), muscular abnormalities (myopathies, muscle agenesis), and joint and contiguous tissue...
FIGURE 12.16 Digit amputations resulting from amniotic bands.

Problems [synostosis, abnormal development]. Clubfoot may be caused by arthrogryposis but is more commonly considered to be idiopathic in origin. The fact that 25% of cases are familial and that prevalence varies across ethnic populations suggests that many cases occur from genetic causes. In this regard, recent studies have linked clubfoot with mutations and microdeletions involving PITX1, a transcription factor important for hind limb development. Other causes include abnormal cartilage and bone formation.

Congenital absence or deficiency of the radius is usually a genetic abnormality observed with malformations in other structures, such as craniosynostosis-radial aplasia syndrome [Baller-Gerold syndrome]. These individuals have synostosis in one or more cranial sutures, absence of the radius, and other defects.

Amniotic bands may cause ring constrictions and amputations of the limbs or digits [Fig. 12.16; see also Fig. 8.17, p. 119]. The origin of the bands is not clear, but they may represent adhesions between the amnion and affected structures in the fetus. Other investigators believe that bands originate from tears in the amnion that detach and surround part of the fetus.

Transverse limb deficiencies are limb defects in which proximal structures are intact, but structures distal to a transverse plane are partially or completely absent [Fig. 12.17]. The defects may be due to disruption of the AER or its signaling or to vascular abnormalities, such as thromboses or vasoconstriction.

Congenital hip dislocation consists of underdevelopment of the acetabulum and head of the femur. It is rather common and occurs mostly in female newborns. Although dislocation usually occurs after birth, the abnormality of the bones develops prenatally. Because many babies with congenital hip dislocation are breech deliveries, it has been thought that breech posture may interfere with development of the hip joint. It is frequently associated with laxity of the joint capsule.

FIGURE 12.17 Transverse limb deficiency, which may be caused by disruptions to the AER or to vascular abnormalities.
SUMMARY

Limbs form at the end of the fourth week as buds along the body wall adjacent to specific spinal segments determined by HOX genes (upper limb, C5–T2; lower limb, L2–S2). The AER at the distal border of the limb regulates proximodistal limb outgrowth by secreting FGFs that maintain a region of rapidly dividing cells immediately adjacent to the ridge called the undifferentiated zone. As the limb grows, cells near the flank are exposed to retinoic acid that causes them to differentiate into the stylopod (humerus/femur). Next to differentiate is the zeugopod (radius/ulna and tibia/fibula), then the autopod (wrist and fingers, ankle and toes). The ZPA located at the posterior border of the limb secretes SHH and controls anterior-posterior patterning (thumb to little finger).

Bones of the limb form by endochondral ossification and are derived from the parietal layer of lateral plate mesoderm. Muscle cells migrate from somites in a segmental fashion and segregate into dorsal and ventral muscle groups. Later fusion and splitting of these groups into different muscles distorts the original segmental pattern. Muscles are innervated by ventral primary rami that split into dorsal and ventral branches. The dorsal and ventral branches eventually unite into dorsal and ventral nerves to innervate the dorsal (extensor) and ventral (flexor) compartments, respectively.

Digits form when apoptosis (programmed cell death) occurs in the AER to separate this structure into five separate ridges. Final separation of the digits is achieved by additional apoptosis in the interdigital spaces. Many digital defects occur that are related to these patterns of cell death, including polydactyly, syndactyly, and clefts (Fig 12.13).

Problems to Solve

1. If you observe congenital absence of the radius or digital defects, such as absent thumb or polydactyly, would you consider examining the infant for other malformations? Why?
The vascular system appears in the middle of the third week, when the embryo is no longer able to satisfy its nutritional requirements by diffusion alone. **Progenitor heart cells** lie in the epiblast, immediately adjacent to the cranial end of the primitive streak. From there, they migrate through the streak and into the splanchnic layer of lateral plate mesoderm where some form a horseshoe-shaped cluster of cells called the **primary heart field (PHF)** cranial to the neural folds (Fig. 13.1). These cells form the atria, left ventricle, and part of the right ventricle. The remainder of the right ventricle and outflow tract (conus cordis and truncus arteriosus) are derived from the **secondary heart field (SHF)**, which also contributes cells to formation of the atria at the caudal end of the heart (Fig. 13.2). This secondary field of cells resides in splanchnic mesoderm ventral to the pharynx (Fig. 13.2).

As progenitor heart cells migrate through the primitive streak on approximately day 16 of gestation, they are specified on both sides from lateral to medial to become the different parts of the heart (Fig. 13.1A). Patterning of these

Progenitor heart cells have migrated and formed the horseshoe-shaped PHF located in the splanchnic layer of lateral plate mesoderm. As they migrated, PHF cells were specified to form left and right sides of the heart and to form the atria (A), left ventricle (LV), and part of the right ventricle (RV). The remainder of the right ventricle and the outflow tract consisting of conus cordis and truncus arteriosus are formed by the SHF. B. Part II • Systems-Based Embryology

FIGURE 13.2 Drawing showing the SHF that lies in splanchnic mesoderm at the posterior of the pharynx. The SHF provides cells that lengthen the arterial and venous poles of the heart, which includes part of the right ventricle and the outflow tract [conus cordis and truncus arteriosus] and atria and sinus venosus, respectively. Disruption of the SHF causes shortening of the outflow tract region, resulting in outflow tract defects.

Cells in the SHF also exhibit laterality such that those on the right side contribute to the left of the outflow tract region and those on the left contribute to the right. This laterality is determined by the same signaling pathway that establishes laterality for the entire embryo (Fig. 13.3) and explains the spiraling nature of the pulmonary artery and aorta and ensures that the aorta exits from the left ventricle and the pulmonary artery from the right ventricle.

Once cells establish the PHF, they are induced by the underlying pharyngeal endoderm to form cardiac myoblasts and blood islands that will form blood cells and vessels by the process of vasculogenesis (Chapter 6, p. 83). With time, the islands unite and form a horseshoe-shaped endothelial-lined tube surrounded by myoblasts. This region is known as the cardiogenic region; the intraembryonic (primitive body) cavity over it later develops into the pericardial cavity (Fig. 13.1B,C).

In addition to the cardiogenic region, other blood islands appear bilaterally, parallel, and close to the midline of the embryonic shield. These islands form a pair of longitudinal vessels, the dorsal aortae.

FIGURE 13.3 Dorsal view of a drawing of a 16-day embryo showing the laterality pathway. The pathway is expressed in lateral plate mesoderm on the left side and involves a number of signaling molecules, including serotonin (5-HT), which result in expression of the transcription factor \textit{PITX2}, the master gene for left sidedness. This pathway specifies the left side of the body and also programs heart cells in the primary and SHFs. The right side is specified as well, but genes responsible for this patterning have not been completely determined. Disruption of the pathway on the left results in laterality abnormalities, including many heart defects (see Chapter 5, p. 63).
Clinical Correlates

Laterality and Heart Defects
Establishing laterality during gastrulation [see Chapter 5, p. 58] is essential for normal heart development because it specifies cells contributing to and patterning the right and left sides of the heart. The process requires a signaling cascade that includes serotonin (5-HT) as a key molecule in initiating the pathway [Fig. 13.3]. 5-HT is concentrated on the left side of the embryo and, by signaling through the transcription factor MAD3, restricts Nodal expression to the left where this gene initiates a signaling cascade culminating in expression of PITX2, the master gene for left sidedness [see Chapter 5, p. 62; Fig. 13.3]. The right side is also specified, but signals responsible for this event have not been as well established.

Cardiac progenitor cells are also specified at this time both for the parts of the heart they will form and their left-right sidedness by the laterality pathway. Thus, this period (days 16 to 18) is critical for heart development and individuals with laterality defects, such as heterotaxy often have many different types of heart defects, including dextrocardia (right-sided heart), ventricular septal defects (VSDs), atrial septal defects (ASDs), double outlet right ventricle (DORV; both the aorta and pulmonary artery exit the right ventricle), and outflow tract defects, such as transposition of the great vessels, pulmonary stenosis, and others. Laterality defects of the heart, such as atrial and ventricular isomerisms (both atria or both ventricles have similar characteristics instead of the normal left-right differences) and inversions (the characteristics of the atria or ventricles are reversed), also occur because of disruptions in specifying left and right sidedness in the progenitor heart cells. Even for individuals with isolated heart defects, the cause can be due to abnormalities in establishing laterality. There is also a strong genetic component to the defects as illustrated by the fact that heterotaxy can be familial and individuals within such families often have heart defects whether or not they exhibit other laterality abnormalities. Similarly, individuals with situs inversus [complete reversal of left-right asymmetry in all organs] have a slightly higher risk of having a heart defect, but the risk for their offspring is greatly increased.

The importance of laterality in normal heart development explains the teratogenic effects of antidepressants of the selective serotonin reuptake inhibitor (SSRIs) class that have been linked by epidemiology studies to an increase in heart defects. The mechanism for this effect appears to be a disruption of 5-HT signaling important in the laterality pathway [see Chapter 5, p. 69].

Formation and Position of the Heart Tube
Initially, the central portion of the cardiogenic area is anterior to the oropharyngeal membrane and the neural plate (Fig. 13.4A). With closure of the neural tube and formation of the brain vesicles, however, the central nervous system grows cranially so rapidly that it extends over the central cardiogenic region and the future pericardial cavity (Fig. 13.4). As a result of growth of the brain and cephalic folding of the embryo, the oropharyngeal membrane is pulled forward, while the heart and pericardial cavity move first to the cervical region and finally to the thorax (Fig. 13.4).

As the embryo grows and bends cephalocaudally, it also folds laterally (Fig. 13.5). As a result, the caudal regions of the paired cardiac tube merge except at their caudalmost ends (Fig. 13.6). Simultaneously, the central part of the horseshoe-shaped tube expands to form the future outflow tract and ventricular regions. Thus, the heart becomes a continuous expanded tube consisting of an inner endothelial lining, and an outer myocardial layer (Fig. 13.5C). It receives venous drainage at its caudal pole and begins to pump blood out of the first aortic arch into the dorsal aorta at its cranial pole (Figs. 13.6 and 13.7).

The developing heart tube bulges more and more into the pericardial cavity. Initially, however, the tube remains attached to the dorsal side of the pericardial cavity by a fold of mesodermal tissue, the dorsal mesocardium that is derived from the SHF (Figs. 13.5C; see also Fig. 13.16A, p. 186). No ventral mesocardium is ever formed. With further development, the middle section of
FIGURE 13.4 Figures showing effects of the rapid growth of the brain on positioning of the heart. Initially, the cardiogenic area and the pericardial cavity are in front of the oropharyngeal membrane. A. 18 days. B. 20 days. C. 21 days. D. 22 days.

Late presomite embryo [18 days]. C. Eight-somite stage [22 days]. Fusion occurs only in the caudal region of the horseshoe-shaped tube. The outflow tract and most of the ventricular region form by expansion and growth of the crescent portion of the horseshoe.
the dorsal mesocardium disappears, creating the transverse pericardial sinus, which connects both sides of the pericardial cavity. The heart is now suspended in the cavity by blood vessels at its cranial and caudal poles (Fig. 13.7D).

During these events, the myocardium thickens and secretes a layer of extracellular matrix, rich in hyaluronic acid called cardiac jelly, which separates it from the endothelium (Figs. 13.5C; see also Fig. 13.18, p. 188). In addition, formation of the proepicardial organ occurs in mesenchymal cells located at the caudal border of the dorsal mesocardium. Cells from this structure proliferate and migrate over the surface of the myocardium to form the epicardial layer (epicardium) of the heart. Thus, the heart tube consists of three layers: (1) the endocardium, forming the internal endothelial lining of the heart; (2) the myocardium, forming the muscular wall; and (3) the epicardium or visceral pericardium, covering the outside of the tube.

This outer layer is responsible for formation of the coronary arteries, including their endothelial lining and smooth muscle.

### FORMATION OF THE CARDIAC LOOP

The heart tube continues to elongate as cells are added from the SHF to its cranial end (Fig. 13.2). This lengthening process is essential for normal formation of part of the right ventricle and the outflow tract region (conus cordis and truncus arteriosus that form part of the aorta and pulmonary artery) and for the looping process. If this lengthening is inhibited, then a variety of outflow tract defects occur, including DORV (both the aorta and pulmonary artery arise from the right ventricle), VSDs, tetralogy of Fallot (see Fig. 13.34), pulmonary atresia (see Fig. 13.36B), and pulmonary stenosis.

As the outflow tract lengthens, the cardiac tube begins to bend on day 23. The cephalic portion of the tube bends ventrally, caudally, and to the right (Fig. 13.7); and the atrial (caudal) portion shifts dorsocranially and to the left (Figs. 13.7 and 13.8A). This bending, which may be due to cell shape changes, creates the cardiac loop. It is complete by day 28. While the cardiac loop is forming, local expansions become visible throughout the length of the tube. The atrial portion, initially a paired structure outside the pericardial cavity, forms a common atrium and is incorporated into the pericardial cavity (Fig. 13.7). The atrioventricular junction remains narrow and forms the atrioventricular canal, which connects the common atrium and the early embryonic ventricle (Fig. 13.9). The bulbus cordis is narrow except for its proximal third. This portion will form the trabeculated part of the right ventricle (Figs. 13.7 and 13.9). The midportion, the conus cordis, will form the outflow tracts of both ventricles. The distal part of the bulbus, the truncus arteriosus, will form the roots and proximal portion of the aorta and pulmonary artery (Fig. 13.9). The junction between the ventricle and the bulbus cordis, externally indicated by the bulboventricular sulcus (Fig. 13.7C), remains narrow. It is called the primary interventricular foramen (Fig. 13.9).

Thus, the cardiac tube is organized by regions along its craniocaudal axis from the conotruncus to the right ventricle to the left ventricle to

the atrial region, respectively (Fig. 13.7A–C). When looping is completed, the smooth-walled heart tube begins to form primitive trabeculae in two sharply defined areas just proximal and distal to the primary interventricular foramen (Fig. 13.9). The bulbus temporarily remains smooth-walled. The primitive ventricle, which is now trabeculated, is called the **primitive left ventricle**. Likewise, the trabeculated proximal third of the bulbus cordis is called the **primitive right ventricle** (Fig. 13.9).

The conotruncal portion of the heart tube, initially on the right side of the pericardial cavity, shifts gradually to a more medial position. This change in position is the result of formation of two transverse dilations of the atrium, bulging on each side of the bulbus cordis (Figs. 13.8B and 13.9).

**Clinical Correlates**

**Abnormalities of Cardiac Looping**

**Dextrocardia** is a condition where the heart lies on the right side of the thorax instead of the left and it occurs when the heart loops to the left instead of the right. The defect may be induced during gastrulation, when laterality is established, or slightly later when cardiac looping occurs. Dextrocardia occurs with **situs inversus**, a complete reversal of asymmetry in all organs, or may be associated with **laterality sequences** (heterotaxy) in which only some organ positions are reversed (see Chapter 5, p. 65).
Signals from anterior (cranial) endoderm induce a heart-forming region in overlying splanchnic mesoderm by inducing the transcription factor **NKX2.5**. The signals require secretion of bone morphogenetic proteins (BMPs) 2 and 4 secreted by the endoderm and lateral plate mesoderm. Concomitantly, the activity of WNT proteins (3a and 8), secreted by the neural tube, must be blocked because they normally inhibit heart development. Inhibitors (CRESCENT and CERBERUS) of the WNT proteins are produced by endoderm cells immediately adjacent to heart-forming mesoderm in the anterior half of the embryo. The combination of BMP activity and WNT inhibition by CRESCENT and CERBERUS causes expression of NKX2.5, the master gene for heart development (Figs. 13.1 and 13.10). BMP expression also upregulates expression of fibroblast growth factor 8 (FGF8) that is important for the expression of cardiac-specific proteins.

Once the cardiac tube is formed, the venous portion is specified by retinoic acid (RA) produced by mesoderm adjacent to the presumptive sinus venosus and atria. Following this initial exposure to RA, these structures express the gene for retinaldehyde dehydrogenase, which allows them to make their own RA and commits them to becoming caudal cardiac structures. Lower concentrations of RA in more anterior cardiac regions (ventricles and outflow tract) contribute to specification of these structures. The importance of RA in cardiac signaling explains why the compound can produce a variety of cardiac defects.

**NKX2.5** contains a homeodomain and is a homologue of the gene *tinman* that regulates heart development in *Drosophila*. **TBX5** is another transcription factor that contains a DNA-binding motif known as the T-box. Expressed later than **NKX2.5**, it plays an important role in septation.

Cardiac looping is dependent upon several factors, including the laterality pathway and expression of the transcription factor **PITX2** in lateral plate mesoderm on the left side. **PITX2** may play a role in the deposition and function of extracellular matrix molecules that assist in looping. In addition, **NKX2.5** upregulates expression of **HAND1** and **HAND2**, transcription factors that are expressed in the primitive heart tube and that later become restricted to the future left and right ventricles, respectively. Downstream effectors of these genes participate in the looping phenomenon. **HAND1** and **HAND2**, under the regulation of **NKX2.5**, also contribute to expansion and differentiation of the ventricles.

Lengthening of the outflow tract by the SHF is regulated in part by **SONIC HEDGEHOG (SHH)**. **SHH**, expressed by pharyngeal arch endoderm (see Chapter 17, p. 286), acts through its receptor patched (PTC; see Chapter 1, p. 8), expressed by

---

**FIGURE 13.10** Heart induction. BMPs secreted by the endoderm and lateral plate mesoderm in combination with inhibition of WNT expression by CRESCENT in the anterior half of the embryo induce expression of **NKX2.5** in the heart-forming region of the lateral plate mesoderm (splanchnic layer). **NKX2.5** is then responsible for heart induction.
SHF cells, to stimulate proliferation of cells in the SHF. Meanwhile, NOTCH signaling through its ligand JAG1 (see Chapter 1, p. 10) is responsible for upregulation of FGFs in the SHF that in turn regulate migration and differentiation of neural crest cells essential for outflow tract septation (see p. 195) and for development and patterning of the aortic arches (see p. 202). Mutations in SHH, Notch, and JAG1 are responsible for some outflow tract, aortic arch, and cardiac defects.

**DEVELOPMENT OF THE SINUS VENOSUS**

In the middle of the fourth week, the sinus venosus receives venous blood from the right and left sinus horns (Fig. 13.11A). Each horn receives blood from three important veins: (1) the vitelline or the omphalomesenteric vein, (2) the umbilical vein, and (3) the common cardinal vein. At first, communication between the sinus and the atrium is wide. Soon, however, the entrance of the sinus shifts to the right (Fig. 13.11B). This shift is caused primarily by left-to-right shunts of blood, which occur in the venous system during the fourth and fifth weeks of development.

With obliteration of the right umbilical vein and the left vitelline vein during the fifth week, the left sinus horn rapidly loses its importance (Fig. 13.11B). When the left common cardinal vein is obliterated at 10 weeks, all that remains of the left sinus horn is the **oblique vein of the left atrium** and the **coronary sinus** (Fig. 13.12).

As a result of left-to-right shunts of blood, the right sinus horn and veins enlarge greatly. The right horn, which now forms the only communication between the original sinus venosus and the atrium, is incorporated into the right atrium to form the smooth-walled part of the right atrium (Fig. 13.13). Its entrance, the **sinuatrial orifice**, is flanked on each side by a valvular fold, the **right and left venous valves** (Fig. 13.13A). Dorsocranially, the valves fuse, forming a ridge known as the **septum spurium** (Fig. 13.13A). Initially the valves are large, but when the right sinus horn is incorporated into the wall of the atrium, the left venous valve and the septum spurium fuse with the developing atrial septum.

![Figure 13.11](image-url) Dorsal view of two stages in the development of the sinus venosus at approximately 24 days [A] and 35 days [B]. Broken line, the entrance of the sinus venosus into the atrial cavity. Each drawing is accompanied by a scheme to show in transverse section the great veins and their relation to the atrial cavity. The major septa of the heart are formed between the 27th and 37th days of development, when the embryo grows in length from 5 mm to approximately 16 to 17 mm. One method by which a septum may be formed involves two actively growing masses of tissue that approach each other until they fuse, dividing the lumen into two separate canals (Fig. 13.14A,B). Such a septum may also be formed by active growth of a single tissue mass that continues to expand until it reaches the opposite side of the lumen (Fig. 13.14C). Formation of such tissue masses, called endocardial cushions, depends on synthesis and deposition of extracellular matrices and cell migration and proliferation. Thus, in regions where such cushions form, there is increased synthesis of extracellular matrix that produces endocardial cell covered protrusions into the lumen (Fig. 13.15A,B). These endocardial cushion protrusions develop in the atrioventricular and conotruncal regions, and in these locations, they assist in formation of the atrial and ventricular (membranous portion) septa, the atrioventricular canals and valves.
Chapter 13 • Cardiovascular System

Formation of septum by growth of opposite ridges

Such a septum never completely separates two cavities.

(Fig. 13.16), and the aortic and pulmonary channels (see Fig. 13.20). Eventually, cushions are populated by cells migrating and proliferating into the matrix: In atrioventricular cushions, cells are derived from overlying endocardial cells that detach from their neighbors and move into the matrix (Fig. 13.15C); in conotruncal cushions, cells are derived from neural crest cells migrating from the cranial neural folds to the outflow tract region (see p. 195 and FIGURE 13.15)

FIGURE 13.15 Drawings showing development of endocardial cushions. A. Initially, the heart tube consists of the myocardium and endocardium separated by a layer of extracellular matrix [ECM]. B. Endocardial cushions form in the atrioventricular canal and in the outflow tract as expansions of the ECM. C. Cells migrate into the cushions and proliferate: In the atrioventricular canal, these cells are derived from the endocardium; in the outflow tract, they are derived from neural crest cells (see p. 194).

Fig. 13.30, p. 197). Because of their key location, abnormalities in endocardial cushion formation may cause cardiac malformations, including ASDs and VSDs and defects involving the great vessels (i.e., transposition of the great vessels, common truncus arteriosus, and tetralogy of Fallot).

The other manner in which a septum is formed does not involve endocardial cushions. If, for example, a narrow strip of tissue in the wall of the atrium or ventricle should fail to grow while areas on each side of it expand rapidly, a narrow ridge forms between the two expanding portions (Fig. 13.14D,E). When growth of the expanding portions continues on either side of the narrow portion, the two walls approach each other and eventually merge, forming a septum (Fig. 13.14F). Such a septum never completely divides the original lumen but leaves a narrow communicating canal between the two expanded sections. It is usually closed secondarily by tissue contributed by neighboring proliferating tissues. Such a septum partially divides the atria and ventricles.

**Septum Formation in the Common Atrium**

At the end of the fourth week, a sickle-shaped crest grows from the roof of the common atrium into the lumen. This crest is the first portion of the septum primum (Figs. 13.13A and 13.16A,B). The two limbs of this septum extend toward the endocardial cushions in the atrioventricular canal. The opening between the lower rim of the septum primum and the endocardial cushions is the **ostium primum** (Fig. 13.16A,B). With further development, extensions of the superior and inferior endocardial cushions grow along the edge of the septum primum, closing the ostium primum (Fig. 13.16C,D). Before closure is complete, however, **cell death** produces perforations in the upper portion of the septum primum. Coalescence of these perforations forms the **ostium secundum**, ensuring free blood flow from the right to the left primitive atrium (Fig. 13.16B,D).

When the lumen of the right atrium expands as a result of incorporation of the sinus horn, a new crescent-shaped fold appears. This new fold, the **septum secundum** (Fig. 13.16C,D), never forms a complete partition in the atrial cavity (Fig. 13.16F,G). Its anterior limb extends downward to the septum in the atrioventricular canal. When the left venous valve and the septum spurium fuse with the right side of the septum secundum, the free concave edge of the septum secundum begins to overlap the ostium secundum (Fig. 13.16E,F). The opening left by the septum secundum is called the **oval foramen (foramen ovale)**. When the upper part of the septum primum gradually disappears, the remaining part becomes the **valve of the oval foramen**. The passage between the two atrial cavities consists of an obliquely elongated cleft (Fig. 13.16E–G) through which blood from the right atrium flows to the left side (arrows in Figs. 13.13B and 13.16E).

After birth, when lung circulation begins and pressure in the left atrium increases, the valve of the oval foramen is pressed against the septum secundum, obliterating the oval foramen and separating the right and left atria. In about 20% of cases, fusion of the septum primum and septum secundum is incomplete, and a narrow oblique cleft remains between the two atria. This condition is called **probe patency** of the oval foramen; it does not allow intracardiac shunting of blood.

**Formation of the Left Atrium and Pulmonary Vein**

While the primitive right atrium enlarges by incorporation of the right sinus horn, the primitive left atrium is likewise expanding. Meanwhile, mesenchyme at the caudal end of the dorsal mesocardium that suspends the heart tube in the pericardial cavity (Fig. 13.17A) begins to proliferate. Then, as the septum primum grows downward from the roof of the common atrium, this proliferating mesenchyme forms the **dorsal mesenchymal protrusion (DMP)**, and this tissue grows with the septum primum toward the atrioventricular canal (Fig. 13.17B,C). Within the DMP is the developing **pulmonary vein** that is positioned in the left atrium by the growth and movement of the DMP (Fig. 13.17C). Eventually, the remaining portion of the DMP at the tip of the septum primum contributes to endocardial cushion formation in the atrioventricular canal (Fig. 13.17D). The main stem of the pulmonary vein that opens into the left atrium sends two branches to each lung. Then, as expansion of the left atrium continues, the main stem is incorporated into the posterior wall until the point where branching of the vessel occurs, resulting in four separate openings for pulmonary veins into the atrial chamber (Fig. 13.17D and 13.18).
FIGURE 13.17 A. Drawing showing the heart tube suspended into the pericardial cavity by the dorsal mesocardium, a mesentery attached to mesoderm surrounding the gut tube, that is derived from the SHF (see Fig 13.5C). At this stage, the central portion of the mesocardium breaks down such that only the two ends of the heart tube remain attached. B,C. At the atrial pole, a portion of the dorsal mesocardium proliferates to form the dorsal mesenchymal protrusion [DMP] that penetrates the atrial wall to the left of the septum primum. The pulmonary vein forms within the mesenchyme of the DMP and becomes positioned in the posterior wall of the left atrium as the DMP grows downward with the septum primum. D. Initially, only the main stem of the pulmonary vein enters the left atrium, but, as the atrial walls expand, this stem is incorporated into the left atrium to the point where its four branches diverge to go to the lungs. Consequently, once the process of atrial expansion is complete, there are four openings for pulmonary veins into the left atrium. The remaining portion of the DMP remains at the tip of the septum primum and contributes to endocardial cushion formation around the atrioventricular canal.

FIGURE 13.18 Coronal sections through the heart to show development of the smooth-walled portions of the right and left atria. Both the wall of the right sinus horn [blue] and the pulmonary vein [red] are incorporated into the heart to form the smooth-walled parts of the atria.
Thus, each atrium develops by expansion (Fig. 13.14 D–F) and by incorporation of vascular structures: the sinus venosus in the right atrium and the stem of the pulmonary vein in the left (Fig. 13.18). In the fully developed heart, the original embryonic right atrium becomes the trabeculated right atrial appendage containing the pectinate muscles, whereas the smooth-walled sinus venarum originates from the right horn of the sinus venosus (Fig. 13.18A). The original embryonic left atrium is represented by little more than the trabeculated atrial appendage, whereas the smooth-walled part originates from the pulmonary vein (Fig. 13.18B).

**Septum Formation in the Atrioventricular Canal**

At the end of the fourth week, four atrioventricular endocardial cushions appear: one on each side plus one at the dorsal (superior) and one at the ventral (inferior) border of the atrioventricular canal (Figs. 13.19 and 13.20). Initially, the atrioventricular canal gives access only to the primitive left ventricle and is separated from the bulbus cordis by the bulbo (cono) ventricular flange (Fig. 13.9). Near the end of the fifth week, however, the posterior extremity of the flange terminates almost midway along the base of the dorsal endocardial cushion and is much less prominent than before (Fig. 13.20). Because the atrioventricular canal enlarges to the right, blood passing through the atrioventricular orifice now has direct access to the primitive left as well as the primitive right ventricle.

In addition to the dorsal and ventral endocardial cushions, two lateral atrioventricular cushions appear on the right and left borders of the canal (Figs. 13.19 and 13.20). The dorsal and ventral cushions, in the meantime, project further into the lumen and fuse, resulting in a complete division of the canal into right and left atrioventricular orifices by the end of the fifth week (Figs. 13.16B,D and 13.19).

**Atrioventricular Valves**

After the atrioventricular endocardial cushions fuse, each atrioventricular orifice is surrounded by local proliferations of mesenchymal tissue derived from the endocardial cushions (Fig. 13.21A). When the bloodstream hollows out and thins tissue on the ventricular surface of these proliferations, the mesenchymal tissue...
becomes fibrous and forms the atrioventricular valves, which remain attached to the ventricular wall by muscular cords (Fig. 13.21B,C). Finally, muscular tissue in the cords degenerates and is replaced by dense connective tissue. The valves then consist of connective tissue covered by endocardium. They are connected to thick muscular trabeculae in the wall of the ventricle, the papillary muscles, by means of chordae tendineae (Fig. 13.21C). In this manner, two valve leaflets, constituting the bicuspid (or mitral) valve, form in the left atrioventricular canal, and three, constituting the tricuspid valve, form on the right side.

FIGURE 13.20 Frontal section through the heart of a day-35 embryo. At this stage of development, blood from the atrial cavity enters the primitive left ventricle as well as the primitive right ventricle. Note development of the cushions in the atrioventricular canal. Cushions in the truncus and conus are also visible. Ring, primitive interventricular foramen; arrows, blood flow.

FIGURE 13.21 Formation of the atrioventricular valves and chordae tendineae. The valves are hollowed out from the ventricular side but remain attached to the ventricular wall by the chordae tendineae.
Heart and vascular abnormalities make up the largest category of human birth defects and are present in 1% of live born infants. The incidence among stillborns is 10 times as high. It is estimated that 12% of babies with heart defects have a chromosomal abnormality and, conversely, that 33% of babies with a chromosomal abnormality have a heart defect. Furthermore, 30% of heart defects occur in infants with other major malformations. Approximately 2% of heart defects are due to environmental agents, but most are caused by a complex interplay between genetic and environmental influences [multifactorial causes]. Classic examples of cardiovascular teratogens include rubella virus and thalidomide. Others include RA [Accutane], alcohol, and many other compounds. Maternal diseases, such as insulin-dependent diabetes, have also been linked to cardiac defects.

Targets for genetic or teratogen-induced heart defects include heart progenitor cells from the PHF and SHF, neural crest cells, endocardial cushions, and other cell types important for heart development [Table 13.1, p. 201]. The fact that the same malformation can result from disrupting different targets [e.g., transposition of the great arteries can result from disruption of the SHF or neural crest cells] means that heart defects are heterogeneous in origin and difficult to classify epidemiologically.

Genes regulating cardiac development are being identified and mapped, and mutations that result in heart defects are being discovered. For example, mutations in the heart-specifying gene *Nkx2.5*, on chromosome 5q35, can produce ASDs [secundum type], tetralogy of Fallot, and atrioventricular conduction delays in an autosomal dominant fashion. Mutations in the *Tbx5* gene result in Holt-Oram syndrome, characterized by preaxial [radial] limb abnormalities and ASDs. Defects in the muscular portion of the interventricular septum may also occur. Holt-Oram syndrome is one of a group of heart-hand syndromes illustrating that the same genes may participate in multiple developmental processes. For example, *Tbx5* regulates forelimb development and plays a role in septation of the heart. Holt-Oram syndrome is inherited as an autosomal dominant trait with a frequency of 1/100,000 live births.

Mutations in a number of genes regulating production of sarcomere proteins cause hypertrophic cardiomyopathy that may result in sudden death in athletes and the general population. The disease is inherited as an autosomal dominant, and most mutations [45%] target the β-myosin heavy-chain gene [14q11.2]. The result is cardiac hypertrophy due to disruption in the organization of cardiac muscle cells [myocardial disarray], which may adversely affect cardiac output and/or conduction.

Ventricular inversion is a defect in which the morphologic left ventricle is on the right and connects to the right atrium through a mitral valve. The morphologic right ventricle is on the left side and connects to the left atrium through the tricuspid valve. The defect is sometimes called L-transposition of the great arteries because the pulmonary artery exits the morphologic left ventricle and the aorta exits the morphologic right ventricle. However, the arteries are in their normal positions, but the ventricles are reversed. The abnormality arises during the establishment of laterality and specification of the left and right sides of the heart by the laterality pathway.

Hypoplastic right heart syndrome (HRHS) and hypoplastic left heart syndrome (HLHS; Fig. 13.22) are rare defects that cause an underdevelopment of the right or left sides of the heart, respectively. On the right, the ventricle is very small, the pulmonary artery is affected and may be atretic or stenosed, and the atrium may be small; on the left, the ventricle is very small, the aorta may be atretic or stenotic, and the atrium may be reduced in size. The laterality associated with these defects suggests an adverse effect on specification of the left and right cardiac progenitor cells at an early stage of cardiac morphogenesis.

ASD is a congenital heart abnormality with an incidence of 6.4/10,000 births and with a 2:1 prevalence in female to male infants. One of the most significant defects is the ostium secundum defect, characterized by a large opening between the left and right atria. It may be caused by excessive cell death and resorption of the septum primum [Fig. 13.23B,C] or by inadequate development of the septum secundum [Fig. 13.23D,E]. Depending on the
FIGURE 13.22  A. Hypoplastic right heart syndrome. B. Hypoplastic left heart syndrome. These are rare defects that cause an underdevelopment of the right or left sides of the heart, respectively. On the right, the ventricle is very small, the pulmonary artery is affected and may be atretic or stenosed and the atrium may be small; on the left, the ventricle is very small, the aorta may be atretic or stenotic, and the atrium may be reduced in size. The laterality associated with these defects suggests an adverse effect on specification of the left and right cardiac progenitor cells at an early stage of cardiac morphogenesis.

FIGURE 13.23  A. Normal atrial septum formation. B,C. Ostium secundum defect caused by excessive resorption of the septum primum. D,E. Similar defect caused by failure of development of the septum secundum. F. Common atrium, or cor triloculare biventriculare, resulting from complete failure of the septum primum and septum secundum to form.
size of the opening, considerable intracardiac shunting may occur from left to right. The most serious abnormality in this group is complete absence of the atrial septum (Fig. 13.23F). This condition, known as common atrium or cor triloculare biventriculare, is always associated with serious defects elsewhere in the heart.

Occasionally, the oval foramen closes during prenatal life. This abnormality, premature closure of the oval foramen, leads to massive hypertrophy of the right atrium and ventricle and underdevelopment of the left side of the heart. Death usually occurs shortly after birth.

Endocardial cushions of the atrioventricular canal not only divide this canal into a right and left orifice but also participate in formation of the membranous portion of the interventricular septum and in closure of the ostium primum (Fig 13.16). This region has the appearance of a cross, with the atrial and ventricular septa forming the post, and the atrioventricular cushions the crossbar (Fig. 13.16E). The integrity of this cross is an important sign in ultrasound scans of the heart. Whenever the atrioventricular cushions fail to fuse, the result is a persistent atrioventricular canal, combined with a defect in the cardiac septum (Fig. 13.24A).

**FIGURE 13.24** A. Persistent common atrioventricular canal. This abnormality is always accompanied by a septum defect in the atrial as well as in the ventricular portion of the cardiac partitions. B. Valves in the atrioventricular orifices under normal conditions. C. Split valves in a persistent atrioventricular canal. D,E. Ostium primum defect caused by incomplete fusion of the atrioventricular endocardial cushions. (continued)
This septal defect has an atrial and a ventricular component, separated by abnormal valve leaflets in the single atrioventricular orifice [Fig. 13.24B,C]. Occasionally, endocardial cushions in the atrioventricular canal partially fuse. The result is a defect in the atrial septum, but the interventricular septum is closed [Fig. 13.24D,E]. This defect, the **ostium primum defect**, is usually combined with a cleft in the anterior leaflet of the tricuspid valve [Fig. 13.24C].

**Tricuspid atresia**, which involves obliteration of the right atrioventricular orifice [Fig. 13.25], is characterized by the absence or fusion of the tricuspid valves. Tricuspid atresia is always associated with [1] patency of the oval foramen, [2] VSD, [3] underdevelopment of the right ventricle, and [4] hypertrophy of the left ventricle.

**Ebstein anomaly** is a condition where the tricuspid valve is displaced toward the apex of the right ventricle, and as a result, there is an expanded right atrium and a small right ventricle [Fig. 13.26]. The valve leaflets are abnormally positioned, and the anterior one is usually enlarged.
Septum Formation in the Truncus Arteriosus and Conus Cordis

During the fifth week, pairs of opposing ridges appear in the truncus. These ridges, the truncus swellings, or cushions, lie on the right superior wall (right superior truncus swelling) and on the left inferior wall (left inferior truncus swelling) (Fig. 13.20). The right superior truncus swelling grows distally and to the left, and the left inferior truncus swelling grows distally and to the right. Hence, while growing toward the aortic sac, the swellings twist around each other, foreshadowing the spiral course of the future septum (Fig. 13.27).

After complete fusion, the ridges form the aorticopulmonary septum, dividing the truncus into an aortic and a pulmonary channel.

When the truncus swellings appear, similar swellings (cushions) develop along the right dorsal and left ventral walls of the conus cordis (Figs. 13.20 and 13.27). The conus swellings grow toward each other and distally to unite with the truncus septum. When the two conus swellings have fused, the septum divides the conus into an anterolateral portion (the outflow tract of the right ventricle) (Fig. 13.28) and a posteromedial portion (the outflow tract of the left ventricle) (Fig. 13.29).

Cardiac neural crest cells, originating in the edges of the neural folds in the hindbrain region, migrate through pharyngeal arches 3, 4, and 6 to the outflow region of the heart, which they invade (Fig. 13.30). In this location, they contribute to endocardial cushion formation in both the conus cordis and truncus arteriosus. Migration and proliferation of cardiac neural crest cells is regulated by the SHF through the NOTCH signaling pathway.
FIGURE 13.28 Frontal section through the heart of a 7-week embryo. Note the conus septum and position of the pulmonary valves.

FIGURE 13.29 Frontal section through the heart of an embryo at the end of the seventh week. The conus septum is complete, and blood from the left ventricle enters the aorta. Note the septum in the atrial region.
pathway (see p. 10). Therefore, outflow tract defects may occur by insults to the SHF or insults to cardiac neural crest cells that disrupt formation of the conotruncal septum. Heart defects caused by these mechanisms include tetralogy of Fallot (Fig. 13.34), pulmonary stenoses, persistent (common) truncus arteriosus (Fig. 13.35), and transposition of the great vessels (Fig. 13.36). Because neural crest cells also contribute to craniofacial development, it is not uncommon to see facial and cardiac abnormalities in the same individual (see Chapter 17, p. 278).

**Septum Formation in the Ventricles**

By the end of the fourth week, the two primitive ventricles begin to expand. This is accomplished by continuous growth of the myocardium on the outside and continuous diverticulation and trabeculation on the inside (Figs. 13.20 and 13.29).

The medial walls of the expanding ventricles become apposed and gradually merge, forming the **muscular interventricular septum** (Fig. 13.29). Sometimes, the two walls do not merge completely, and a more or less deep apical cleft between the two ventricles appears. The space between the free rim of the muscular ventricular septum and the fused endocardial cushions permits communication between the two ventricles.

The **interventricular foramen**, above the muscular portion of the interventricular septum, shrinks on completion of the **conus septum** (Fig. 13.27). During further development, outgrowth of tissue from the anterior (inferior) endocardial cushion along the top of the muscular interventricular septum closes the foramen (Fig. 13.16E,F). This tissue fuses with the abutting parts of the conus septum. Complete closure of the interventricular foramen forms the **membranous part of the interventricular septum** (Fig. 13.16F).

**Semilunar Valves**

When partitioning of the truncus is almost complete, primordia of the semilunar valves become visible as small tubercles found on the main truncus swellings. One of each pair is assigned to the pulmonary and aortic channels, respectively (Fig. 13.31). A third tubercle appears in both channels opposite the fused truncus swellings. Gradually, the tubercles hollow out at their upper surface, forming the **semilunar valves** (Fig. 13.32). Recent evidence shows that neural crest cells contribute to formation of these valves.

Clinical Correlates

Heart Defects

VSDs involving the membranous or muscular portion of the septum [Fig. 13.33] are the most common congenital cardiac malformation, occurring as an isolated condition in 12/10,000 births. Most (80%) occur in the muscular region of the septum and resolve as the child grows. Membranous VSDs usually represent a more serious defect and are often associated with abnormalities in partitioning of the conotruncal region. Depending on the size of the opening, blood carried by the pulmonary artery may be 1.2 to 1.7 times as abundant as that carried by the aorta.

Tetralogy of Fallot, the most frequently occurring abnormality of the conotruncal region [Fig. 13.34], is due to an unequal division of the conus resulting from anterior displacement of the conotruncal septum. Displacement of the septum produces four cardiovascular alterations: [1] a narrow right ventricular outflow region, pulmonary infundibular stenosis; [2] a large defect of the interventricular septum; [3] an overriding aorta that arises directly above the septal defect; and [4] hypertrophy of the right ventricular wall because of higher pressure on the right side. Tetralogy of Fallot occurs in 9.6/10,000 births but occurs as a common feature in individuals with Alagille syndrome. In addition to the heart defect, these people have abnormalities in other organs, including the liver, and a characteristic face with a broad prominent forehead, deep set eyes, and a small pointed chin. In 90% of cases, there is a mutation in JAG1, the ligand for NOTCH signaling that regulates neural crest cells forming the conotruncal (outflow tract) septum [see Chapter 1, p. 10].

Persistent [common] truncus arteriosus results when the conotruncal ridges fail to form such that no division of the outflow tract occurs. [Fig. 13.35]. In such a case, which occurs

![Diagram](image-url)

**FIGURE 13.33** A. Normal heart. B. Isolated defect in the membranous portion of the interventricular septum. Blood from the left ventricle flows to the right through the interventricular foramen [arrows].
in 0.8/10,000 births, the pulmonary artery arises some distance above the origin of the undivided truncus. Because the ridges also participate in formation of the interventricular septum, the persistent truncus is always accompanied by a defective interventricular septum. The undivided truncus thus overrides both ventricles and receives blood from both sides.

Transposition of the great vessels occurs when the conotruncal septum fails to follow its normal spiral course and runs straight down (Fig. 13.36A). As a consequence, the aorta originates from the right ventricle, and the pulmonary artery originates from the left ventricle. This condition, which occurs in 4.8/10,000 births, sometimes is associated with a defect in the membranous part of the interventricular septum. It is usually accompanied by an open ductus arteriosus. Because the SHF and neural crest cells contribute to the formation and septation of the outflow tract, respectively, insults to these cells contribute to cardiac defects involving the outflow tract.

DiGeorge sequence is an example of the 22q11 deletion syndrome [see Chapter 17, p. 291] characterized by a pattern of malformations that have their origin in abnormal neural crest development. These children have facial defects, thymic hypoplasia, parathyroid dysfunction, and cardiac abnormalities involving the outflow tract, such as persistent truncus arteriosus and tetralogy of Fallot. Craniofacial malformations

FIGURE 13.34 Tetralogy of Fallot. A. Surface view. B. The four components of the defect: pulmonary stenosis, overriding aorta, interventricular septal defect, and hypertrophy of the right ventricle.

FIGURE 13.35 Persistent truncus arteriosus. The pulmonary artery originates from a common truncus. A. The septum in the truncus and conus has failed to form. B. This abnormality is always accompanied by an interventricular septal defect.
are often associated with heart defects because neural crest cells play important roles in the development of both the face and heart.

Valvular stenosis of the pulmonary artery or aorta occurs when the semilunar valves are fused for a variable distance. The incidence of the abnormality is similar for both regions, being approximately 3 to 4/10,000 births. In the case of a valvar stenosis of the pulmonary artery, the trunk of the pulmonary artery is narrow or even atretic [Fig. 13.36B]. The patent oval foramen then forms the only outlet for blood from the right side of the heart. The ductus arteriosus, always patent, is the only access route to the pulmonary circulation.

In **aortic valvular stenosis** (Fig. 13.37A), fusion of the thickened valves may be so complete that only a pinhole opening remains. The size of the aorta itself is usually normal.

When fusion of the semilunar aortic valves is complete—**aortic valvular atresia** (Fig. 13.37B)—the aorta, left ventricle, and left atrium are markedly underdeveloped. The abnormality is usually accompanied by an open ductus arteriosus, which delivers blood into the aorta.

**Ectopia cordis** is a rare anomaly in which the heart lies on the surface of the chest. It is caused by failure of the embryo to close the ventral body wall (see Chapter 7, p. 97).
FORMATION OF THE CONDUCTING SYSTEM OF THE HEART

Initially, the pacemaker for the heart lies in the caudal part of the left cardiac tube. Later, the sinus venosus assumes this function, and as the sinus is incorporated into the right atrium, pacemaker tissue lies near the opening of the superior vena cava. Thus, the sinusatrial node is formed.

The atrioventricular node and bundle (bundle of His) are derived from two sources: (1) myocardial cells in the left wall of the sinus venosus and (2) myocardial cells from the atrioventricular canal. Once the sinus venosus is incorporated into the right atrium, these cells lie in their final position at the base of the interatrial septum.

Clinical Correlates

As mentioned previously, heart defects are the most common birth defects, and this fact is probably related to the complexity of heart development that provides a number of targets for genetic mutations and/or environmental insults to disrupt normal embryological processes. Table 13.1 summarizes the target tissues and the birth defects that can be caused when different processes and stages of heart development are adversely affected. One of the key points of the table is the fact that heart development can be altered very early in gestation and that insults at different times can produce the same birth defects.

VASCULAR DEVELOPMENT

Blood vessel development occurs by two mechanisms: (1) vasculogenesis in which vessels arise by coalescence of angioblasts and (2) angiogenesis whereby vessels sprout from existing vessels. The major vessels, including the dorsal aorta and cardinal veins, are formed by vasculogenesis. The remainder of the vascular system then forms by angiogenesis. The entire system is patterned by guidance cues involving vascular endothelial growth factor (VEGF) and other growth factors (see Chapter 6, p. 83).

Arterial System

Aortic Arches

When pharyngeal arches form during the fourth and fifth weeks of development, each arch receives its own cranial nerve and its own artery (see Chapter 17). These arteries, the aortic arches, arise from the aortic sac, the most distal part of the truncus arteriosus (Figs. 13.9 and 13.38). The aortic arches are embedded in mesenchyme of the pharyngeal arches and terminate in the right and left dorsal aortae. (In the region of the arches, the dorsal aortae remain paired, but caudal to this region, they fuse to form a single vessel.) The pharyngeal arches and their vessels appear in a cranial-to-caudal sequence, so that they are not all present simultaneously. The aortic sac contributes a branch to each new arch as it forms, giving rise to a total of five pairs of arteries. (The fifth arch either never forms or forms incompletely and then regresses. Consequently, the five arches are numbered I, II, III, IV, and VI [Figs. 13.39 and 13.40A].) During further development, this arterial pattern becomes modified, and some vessels regress completely.

Neural crest cells in each pharyngeal arch contribute the coverings (smooth muscle and connective tissue) of the arch vessels and also regulate patterning of these vessels. Signals from endoderm and ectoderm lining the arches provide interactive signals to crest cells to regulate the patterning process. For example, FGF8 signaling in arch ectoderm is important for 4th arch development. Because patterning also involves left–right decisions, PITX2, the master gene for sidedness, expressed in the aortic sac, SHF, and arch mesoderm, regulates laterality during restructuring of the original aortic arch pattern.

Division of the truncus arteriosus by the aorticopulmonary septum divides the outflow channel of the heart into the ventral aorta and the pulmonary trunk. The aortic sac then forms right and left horns, which subsequently give rise to the brachiocephalic artery and the proximal segment of the aortic arch, respectively (Fig. 13.40B,C).

By day 27, most of the first aortic arch has disappeared (Fig. 13.39), although a small portion persists to form the maxillary artery. Similarly, the second aortic arch soon disappears. The remaining portions of this arch are the hyoid and stapedial arteries. The third arch is large; the fourth and sixth arches are in the

On the left, the nerve remains in place and hooks around the ligamentum arteriosum.
process of formation. Even though the sixth arch is not completed, the **primitive pulmonary artery** is already present as a major branch (Fig. 13.39A).

In the 29-day embryo, the first and second aortic arches have disappeared (Fig. 13.39B). The third, fourth, and sixth arches are large. The conotruncal region has divided so that the sixth arches are now continuous with the pulmonary trunk.

With further development, the aortic arch system loses its original symmetrical form, as shown in Figure 13.40A and establishes the definitive pattern illustrated in Figure 13.40B,C. This representation may clarify the transformation from the embryonic to the adult arterial system. The following changes occur:

The **third aortic arch** forms the **common carotid artery** and the first part of the **internal carotid artery**. The remainder of the internal carotid is formed by the cranial portion of the dorsal aorta. The **external carotid artery** is a sprout of the third aortic arch.

The **fourth aortic arch** persists on both sides, but its ultimate fate is different on the right and left sides. On the left, it forms part of the arch of the aorta, between the left common carotid and the left subclavian arteries. On the right, it forms the most proximal segment of the right subclavian artery, the distal part of which is formed by a portion of the right dorsal aorta and the seventh intersegmental artery (Fig. 13.40B).

The **fifth aortic arch** either never forms or forms incompletely and then regresses.

The **sixth aortic arch**, also known as the **pulmonary arch**, gives off an important branch that grows toward the developing lung bud (Fig. 13.40B). On the right side, the proximal part becomes the proximal segment of the right pulmonary artery. The distal portion of this arch loses its connection with the dorsal aorta and disappears. On the left, the distal part persists during intrauterine life as the **ductus arteriosus**. Table 13.2 summarizes the changes and derivatives of the aortic arch system.

A number of other changes occur along with alterations in the aortic arch system: (1) the dorsal aorta between the entrance of the third and fourth arches, known as the **carotid duct**, is obliterated (Fig. 13.41); (2) the right dorsal aorta disappears between the origin of the seventh intersegmental artery and the junction with the left dorsal aorta (Fig. 13.41); (3) cephalic folding, growth of the forebrain, and elongation of the neck push the heart into the thoracic cavity. Hence, the carotid and brachiocephalic arteries elongate considerably (Fig. 13.40C). As a further result of this caudal shift, the left subclavian artery, distally fixed in the arm bud, shifts its point of origin from the aorta at the level of the seventh intersegmental artery (Fig. 13.40B) to an increasingly higher point until it comes close to the origin of the left common carotid artery (Fig. 13.40C); and (4) as a result of the caudal shift of the heart and the disappearance of various portions of the aortic arches, the course of the **recurrent laryngeal nerves** becomes

| 3    | Common carotid and first part of the internal carotid arteries$^a$
|      | Arch of the aorta from the left common carotid to the left subclavian arteries$^b$
| Right side | Right subclavian artery (proximal portion)$^c$
| 6 Left side | Left pulmonary artery and ductus arteriosus |
| Right side | Right pulmonary artery |

$^a$Remainder of the internal carotid arteries are derived from the dorsal aorta; the external carotid arteries sprout from the third aortic arch.

$^b$The proximal portion of the aortic arch is derived from the left horn of the aortic sac; the right horn of this sac forms the brachiocephalic artery.

$^c$The distal portion of the right subclavian artery as well as the left subclavian artery form from the seventh intersegmental arteries on their respective sides.
different on the right and left sides. Initially, these nerves, branches of the vagus, supply the sixth pharyngeal arches. When the heart descends, they hook around the sixth aortic arches and ascend again to the larynx, which accounts for their recurrent course. On the right, when the distal part of the sixth aortic arch and the fifth aortic arch disappear, the recurrent laryngeal nerve moves up and hooks around the right subclavian artery. On the left, the nerve does not move up because the distal part of the sixth aortic arch persists as the ductus arteriosus, which later forms the ligamentum arteriosum (Fig. 13.40).

**Vitelline and Umbilical Arteries**

The *vitelline arteries*, initially a number of paired vessels supplying the yolk sac (Fig. 13.38), gradually fuse and form the arteries in the dorsal mesentery of the gut. In the adult, they are represented by the *celiac* and *superior mesenteric arteries*. The *inferior mesenteric arteries* are derived from the *umbilical arteries*. These three vessels supply derivatives of the *foregut*, *midgut*, and *hindgut*, respectively.

The *umbilical arteries*, initially paired ventral branches of the dorsal aorta, course to the placenta in close association with the allantois (Fig. 13.38). During the fourth week, however, each artery acquires a secondary connection with the dorsal branch of the aorta, the *common iliac artery*, and loses its earliest origin. After birth, the proximal portions of the umbilical arteries persist as the *internal iliac* and *superior vesical arteries*, and the distal parts are obliterated to form the *medial umbilical ligaments*.

**Coronary Arteries**

Coronary arteries are derived from the *epicardium*, which differentiated from the *proepicardial organ* located in the caudal portion of the dorsal mesocardium, a derivative of the SHF. Some epicardial cells undergo an epithelial-to-mesenchymal transition induced by the underlying myocardium. The newly formed mesenchymal cells then contribute to endothelial and smooth muscle cells of the coronary arteries. Neural crest cells also may contribute smooth muscle cells along the proximal segments of these arteries and may direct connection of the coronary arteries to the aorta. Connection occurs by ingrowth of arterial endothelial cells from the arteries into the aorta causing the coronary arteries to “invade” the aorta.
Arterial System Defects

Under normal conditions, the ductus arteriosus is functionally closed through contraction of its muscular wall shortly after birth to form the ligamentum arteriosum. Anatomical closure by means of intima proliferation takes 1 to 3 months. A patent ductus arteriosus (PDA), one of the most frequently occurring abnormalities of the great vessels (8/10,000 births), especially in premature infants, either may be an isolated abnormality or may accompany other heart defects [Figs. 13.34A and 13.36]. In particular, defects that cause large differences between aortic and pulmonary pressures may cause increased blood flow through the ductus, preventing its normal closure.

In coarctation of the aorta [Fig. 13.42A,B], which occurs in 3.2/10,000 births, the aortic lumen below the origin of the left subclavian artery is significantly narrowed. Because the constriction may be above or below the entrance of the ductus arteriosus, two types [preductal and postductal] may be distinguished. The cause of aortic narrowing is primarily an abnormality in the media of the aorta, followed by intima proliferations. In the preductal type, the ductus arteriosus persists, whereas in the post ductal type, which is more common, this channel is usually obliterated. In the latter case, collateral circulation between the proximal and distal parts of the aorta is established by way of large intercostal and internal thoracic arteries. In this manner, the lower part of the body is supplied with blood.

Classic clinical signs associated with this condition include hypertension in the right arm concomitant with lowered blood pressure in the legs.

Abnormal origin of the right subclavian artery [Fig. 13.43A,B] occurs when the artery is formed by the distal portion of the right dorsal aorta and the seventh intersegmental artery. The right fourth aortic arch and the proximal part of the right dorsal aorta are obliterated. With shortening of the aorta between the left common carotid and left subclavian arteries, the origin of the abnormal right subclavian artery finally settles just below that of the left subclavian artery. Because its stem is derived from the right dorsal aorta, it must cross the midline behind the esophagus to reach the right arm. This location does not usually cause problems with swallowing or breathing because neither the esophagus nor the trachea is severely compressed.

With a double aortic arch, the right dorsal aorta persists between the origin of the seventh intersegmental artery and its junction with the left dorsal aorta [Fig. 13.44]. A vascular ring surrounds the trachea and
esophagus and commonly compresses these structures, causing difficulties in breathing and swallowing.

In a right aortic arch, the left fourth arch and left dorsal aorta are obliterated and replaced by the corresponding vessels on the right side. Occasionally, when the ligamentum arteriosum lies on the left side and passes behind the esophagus, it causes complaints with swallowing.

An interrupted aortic arch (IAA) is a very rare defect [3/1,000,000 live births] caused by abnormal regression patterns in the right and left fourth aortic arches [Fig. 13.45A]. The result is an interruption between the aortic arch and descending aorta, and there are three types depending on where the break occurs: type A (3% to 40%), between the left subclavian artery and descending aorta [Fig. 13.45B]; type B (50% to 60%), between the left common carotid and left subclavian arteries [Fig. 13.45C]; and type C (4%), between the right and left common carotid arteries [Fig. 13.45D]. The defect is accompanied by a VSD and a PDA that allows blood to reach the lower part of the body. Although rare, the defect occurs in 50% of children with DiGeorge syndrome, part of the 22q11 deletion syndrome complex [see Chapter 17, p. 291].
Part II  •  Systems-Based Embryology

FIGURE 13.45  A. Abnormal regression patterns in the fourth aortic arch on the left result in three different types of interrupted aortic arch (IAA). These interruptions represent the ultimate expression of coarctation of the aorta where the vessel is split in two instead of simply constricted. B. Type A interrupted aortic arch (30% to 40% of cases). C. Type B interrupted aortic arch (40% to 50% of cases). D. Type C interrupted aortic arch (4% of cases). Note that a patent ductus arteriosus (PDA) is present to allow blood to reach the descending aorta to the lower parts of the body. A ventricular septal defect (VSD) is also present because the conotruncal septum responsible for septating the outflow tract fails to extend and fuse with the ventral endocardial cushion in the atroventricular canal (see Fig. 13.27, p. 195). Type B IAA is often present in children with DiGeorge syndrome, part of the 22q11 deletion syndrome complex. RSA, right subclavian artery; RCA, right common carotid artery; LCA, left common carotid artery; LSA, left subclavian artery.

Venous System

In the fifth week, three pairs of major veins can be distinguished: (1) the vitelline veins, or omphalomesenteric veins, carrying blood from the yolk sac to the sinus venosus; (2) the umbilical veins, originating in the chorionic villi and carrying oxygenated blood to the embryo; and (3) the cardinal veins, draining the body of the embryo proper (Fig. 13.46).

Vitelline Veins

Before entering the sinus venosus, the vitelline veins form a plexus around the duodenum and pass through the septum transversum. The liver cords growing into the septum interrupt the course of the veins, and an extensive vascular network, the hepatic sinusoids, forms (Fig. 13.47).

With reduction of the left sinus horn, blood from the left side of the liver is rechanneled toward the right, resulting in an enlargement of the right vitelline vein (right hepatocardiac channel). Ultimately, the right hepatocardiac channel forms the hepatic cardiac portion of the inferior vena cava. The proximal part of the left vitelline vein disappears (Fig. 13.48A,B).
FIGURE 13.46 Main components of the venous and arterial systems in a 4-mm embryo (end of the fourth week).

FIGURE 13.47 Development of the vitelline and umbilical veins during the [A] fourth and [B] fifth weeks. Note the plexus around the duodenum, formation of the hepatic sinusoids, and initiation of left-to-right shunts between the vitelline veins.

FIGURE 13.48 Development of vitelline and umbilical veins in the [A] second and [B] third months. Note formation of the ductus venosus, portal vein, and hepatic portion of the inferior vena cava. The splenic and superior mesenteric veins enter the portal vein.
The anastomotic network around the duodenum develops into a single vessel, the portal vein (Fig. 13.48A,B). The superior mesenteric vein, which drains the primary intestinal loop, derives from the right vitelline vein. The distal portion of the left vitelline vein also disappears (Fig. 13.48A,B).

**Umbilical Veins**

Initially, the umbilical veins pass on each side of the liver, but some connect to the hepatic sinusoids (Fig. 13.47A,B). The proximal part of both umbilical veins and the remainder of the right umbilical vein then disappear, so that the left vein is the only one to carry blood from the placenta to the liver (Fig. 13.48). With the increase of the placental circulation, a direct communication forms between the left umbilical vein and the right hepatocardiac channel, the ductus venosus (Fig. 13.48A,B). This vessel bypasses the sinusoidal plexus of the liver. After birth, the left umbilical vein and ductus venosus are obliterated and form the ligamentum teres hepatitis and ligamentum venosum, respectively.

**Cardinal Veins**

Initially, the cardinal veins form the main venous drainage system of the embryo. This system consists of the anterior cardinal veins, which drain the cephalic part of the embryo, and the posterior cardinal veins, which drain the rest of the embryo. The anterior and posterior veins join before entering the sinus horn and form the short common cardinal veins. During the fourth week, the cardinal veins form a symmetrical system (Fig. 13.46).

During the fifth to the seventh weeks, a number of additional veins are formed: (1) the subcardinal veins, which mainly drain the kidneys; (2) the sacrocardinal veins, which drain the lower extremities; and (3) the supracardinal veins, which drain the body wall by way of the intercostal veins, taking over the functions of the posterior cardinal veins (Fig. 13.49).

Formation of the vena cava system is characterized by the appearance of anastomoses between left and right in such a manner that the blood from the left is channeled to the right side.

**FIGURE 13.49** Development of the inferior vena cava, azygos vein, and superior vena cava. A. Seventh week. The anastomosis lies between the subcardinals, supracardinals, sacrocardinals, and anterior cardinals. B. The venous system at birth showing the three components of the inferior vena cava.
The anastomosis between the anterior cardinal veins develops into the left brachiocephalic vein (Fig. 13.49A,B). Most of the blood from the left side of the head and the left upper extremity is then channeled to the right. The terminal portion of the left posterior cardinal vein entering into the left brachiocephalic vein is retained as a small vessel, the left superior intercostal vein (Fig. 13.49B). This vessel receives blood from the second and third intercostal spaces. The superior vena cava is formed by the right common cardinal vein and the proximal portion of the right anterior cardinal vein. The anterior cardinal veins provide the primary venous drainage of the head during the fourth week of development and ultimately form the internal jugular veins (Fig. 13.49). External jugular veins are derived from a plexus of venous vessels in the face and drain the face and side of the head to the subclavian veins.

The anastomosis between the subcardinal veins forms the left renal vein. When this communication has been established, the left subcardinal vein disappears, and only its distal portion remains as the left gonadal vein.

Hence, the right subcardinal vein becomes the main drainage channel and develops into the renal segment of the inferior vena cava (Fig. 13.49B).

The anastomosis between the sacrocardinal veins forms the left common iliac vein (Fig. 13.49B). The right sacrocardinal vein becomes the sacrocardinal segment of the inferior vena cava. When the renal segment of the inferior vena cava connects with the hepatic segment, which is derived from the right viteline vein, the inferior vena cava, consisting of hepatic, renal, and sacrocardinal segments, is complete.

With obliteration of the major portion of the posterior cardinal veins, the supracardinal veins assume a greater role in draining the body wall. The 4th to 11th right intercostal veins empty into the right supracardinal vein, which together with a portion of the posterior cardinal vein forms the azygos vein (Fig. 13.49). On the left, the 4th to 7th intercostal veins enter into the left supracardinal vein, and the left supracardinal vein, then known as the hemiazygos vein, empties into the azygos vein (Fig. 13.49B).

### Clinical Correlates

**Venous System Defects**

The complicated development of the vena cava may account for the fact that deviations from the normal pattern are common. Also, the fact that the original pattern of venous return is established bilaterally and then shifts to the right probably accounts for the fact that vena cava abnormalities are often observed in individuals with laterality [sidedness] defects.

A **double inferior vena cava** occurs when the left sacrocardinal vein fails to lose its connection with the left subcardinal vein [Fig. 13.50A]. The left common iliac vein may or may not be present, but the left gonadal vein remains as in normal conditions.

**Absence of the inferior vena cava** arises when the right subcardinal vein fails to make its connection with the liver and shunts its blood directly into the right supracardinal vein [Figs. 13.49 and 13.50B]. Hence, the bloodstream from the caudal part of the body reaches the heart by way of the azygos vein and superior vena cava. The hepatic vein enters into the right atrium at the site of the inferior vena cava. Usually, this abnormality is associated with other heart malformations.

**Left superior vena cava** is caused by persistence of the left anterior cardinal vein and obliteration of the common cardinal and proximal part of the anterior cardinal veins on the right [Fig. 13.51A]. In such a case, blood from the right is channeled toward the left by way of the brachiocephalic vein. The left superior vena cava drains into the right atrium by way of the left sinus horn, that is, the coronary sinus.

A **double superior vena cava** is characterized by the persistence of the left anterior cardinal vein and failure of the left brachiocephalic vein to form [Fig. 13.51B]. The persistent left anterior cardinal vein, the left superior vena cava, drains into the right atrium by way of the coronary sinus.

[continued]
CIRCULATION BEFORE AND AFTER BIRTH

Fetal Circulation

Before birth, blood from the placenta, about 80% saturated with oxygen, returns to the fetus by way of the umbilical vein. On approaching the liver, most of this blood flows through the ductus venosus directly into the inferior vena cava, short-circuiting the liver. A smaller amount enters the liver sinusoids and mixes with blood from the portal circulation (Fig. 13.52).

A sphincter mechanism in the ductus venosus, close to the entrance of the umbilical vein, regulates flow of umbilical blood through the liver sinusoids. This sphincter closes when a uterine contraction renders the venous return too high, preventing a sudden overloading of the heart.

After a short course in the inferior vena cava, where placental blood mixes with deoxygenated blood returning from the lower limbs, it enters the right atrium. Here, it is guided toward the oval foramen by the valve of the inferior vena cava, and most of the blood passes directly into
the left atrium. A small amount is prevented from doing so by the lower edge of the septum secundum, the crista dividens, and remains in the right atrium. Here, it mixes with desaturated blood returning from the head and arms by way of the superior vena cava.

From the left atrium, where it mixes with a small amount of desaturated blood returning from the lungs, blood enters the left ventricle and ascending aorta. Because the coronary and carotid arteries are the first branches of the ascending aorta, the heart musculature and the brain are supplied with well-oxygenated blood. Desaturated blood from the superior vena cava flows by way of the right ventricle into the pulmonary trunk. During fetal life, resistance in the pulmonary vessels is high, such that most of this blood passes directly through the ductus arteriosus into the descending aorta, where it mixes with blood from the proximal aorta. After coursing through the descending aorta, blood flows toward the placenta by way of the two umbilical arteries. The oxygen saturation in the umbilical arteries is approximately 58%.

During its course from the placenta to the organs of the fetus, blood in the umbilical vein gradually loses its high oxygen content as it mixes with desaturated blood. Theoretically, mixing may occur in the following places (Fig. 13.52, I to V):

I. Liver, by mixture with a small amount of blood returning from the portal system
II. Inferior vena cava, which carries deoxygenated blood returning from the lower extremities, pelvis, and kidneys
III. Right atrium, by mixture with blood from the head and upper limbs
IV. Left atrium, by mixture with blood returning from the lungs
V. The entrance of the ductus arteriosus into the descending aorta

Circulatory Changes at Birth

Changes in the vascular system at birth are caused by cessation of placental blood flow and the beginning of respiration. Because the ductus arteriosus closes by muscular contraction of its wall, the amount of blood flowing through the lung vessels increases rapidly. This, in turn, raises pressure in the left atrium. Simultaneously, pressure in the right atrium decreases as a result of interruption of placental blood flow. The septum primum is then apposed to the septum secundum, and functionally, the oval foramen closes.

To summarize, the following changes occur in the vascular system after birth (Fig. 13.53):

**Closure of the umbilical arteries**, accomplished by contraction of the smooth musculature in their walls, is probably caused by thermal and mechanical stimuli and a change in oxygen tension. Functionally, the arteries close a few minutes after birth, although the actual obliteration of the lumen by fibrous proliferation may take 2 to 3 months. Distal parts of the umbilical arteries form the **medial umbilical ligaments**, and the proximal portions remain open as the **superior vesical arteries** (Fig. 13.53).

**FIGURE 13.53** Human circulation after birth. Note the changes occurring as a result of the beginning of respiration and interruption of placental blood flow. Arrows, direction of blood flow.
Closure of the umbilical vein and ductus venosus occurs shortly after that of the umbilical arteries. Hence, blood from the placenta may enter the newborn for some time after birth. After obliteration, the umbilical vein forms the ligamentum teres hepatitis in the lower margin of the falciform ligament. The ductus venosus, which courses from the ligamentum teres to the inferior vena cava, is also obliterated and forms the ligamentum venosum.

Closure of the ductus arteriosus by contraction of its muscular wall occurs almost immediately after birth; it is mediated by bradykinin, a substance released from the lungs during initial inflation. Complete anatomical obliteration by proliferation of the intima is thought to take 1 to 3 months. In the adult, the obliterated ductus arteriosus forms the ligamentum arteriosum.

Closure of the oval foramen is caused by an increased pressure in the left atrium, combined with a decrease in pressure on the right side. The first breath presses the septum primum against the septum secundum. During the first days of life, however, this closure is reversible. Crying by the baby creates a shunt from right to left, which accounts for cyanotic periods in the newborn. Constant apposition gradually leads to fusion of the two septa in about 1 year. In 20% of individuals, however, perfect anatomical closure may never be obtained (probe patent foramen ovale).

Lymphatic System

The lymphatic system begins its development later than the cardiovascular system, not appearing until the fifth week of gestation. Lymphatic vessels arise as sac-like outgrowths from the endothelium of veins. Six primary lymph sacs are formed: two jugular, at the junction of the subclavian and anterior cardinal veins; two iliac, at the junction of the iliac and posterior cardinal veins; one retroperitoneal, near the root of the mesentry; and one cisterna chyli, dorsal to the retroperitoneal sac. Numerous channels connect the sacs with each other and drain lymph from the limbs, body wall, head, and neck. Two main channels, the right and left thoracic ducts, join the jugular sacs with the cisterna chyli, and soon, an anastomosis forms between these ducts. The thoracic duct then develops from the distal portion of the right thoracic duct, the anastomosis, and the cranial portion of the left thoracic duct. The right lymphatic duct is derived from the cranial portion of the right thoracic duct. Both ducts maintain their original connections with the venous system and empty into the junction of the internal jugular and subclavian veins. Numerous anastomoses produce many variations in the final form of the thoracic duct.

Specification of the lymphatic lineage is regulated by the transcription factor PROX1 that upregulates lymphatic vessel genes and down-regulates blood vessel genes. A critical gene that is upregulated is VEGFR3 that is the receptor for the paracrine factor VEGFC. This protein causes PROX1 expressing endothelial cells to sprout from existing veins to initiate growth of lymphatic vessels.

SUMMARY

On approximately day 16, heart progenitor cells migrate through the primitive streak to a position cranial to the neural folds where they establish a horseshoe-shaped region in the splanchnic layer of lateral plate mesoderm called the primary heart field (PHF) (Fig. 13.1). As they migrate, these cells are specified by the laterality pathway (Fig. 13.3) to contribute to right and left sides of the heart and to form specific heart regions, including part of the atria, left ventricle, and part of the right ventricle (Fig. 13.1A). The remainder of the heart, including part of the atria, part of the right ventricle, conus cordis, and truncus arteriosus (the outflow tract), is derived from cells in the secondary heart field (SHF) (Fig. 13.2). The SHF arises from cells that migrate through the primitive streak and then reside in splanchnic mesoderm near the floor of the posterior part of the pharynx. These cells are also patterned by laterality signaling and regulate neural crest cell contributions to septation of the outflow tract, including the spiraling of the conotruncal septum. (Figs. 13.2 and 13.30). Disruption of the laterality pathway results in many different types of heart defects, whereas disruption of the SHF results in defects of the outflow tract, including transposition of the great arteries, pulmonary stenosis, double outlet right ventricle (DORV), and others (see Table 13.1, p. 201).

Induction of the cardiogenic region is initiated by anterior endoderm underlying progenitor heart cells and causes the cells to become myoblasts and vessels. BMPs secreted by this endoderm in combination with inhibition of WNT expression induces expression of NKX2.5,
the master gene for heart development. Some cells in the PHF become endothelial cells and form a horseshoe-shaped tube, whereas others form myoblasts surrounding the tube. By the 22nd day of development, lateral body wall folds bring the two sides of the horseshoe (Fig. 13.5) toward the midline where they fuse (except for their caudal [atrial] ends) to form a single, slightly bent heart tube (Fig. 13.7) consisting of an inner endocardial tube and a surrounding myocardial mantle (Figs. 13.5C and 13.15). During the fourth week, the heart undergoes cardiac looping. This process causes the heart to fold on itself and assume its normal position in the left part of the thorax with the atria posteriorly and the ventricles in a more anterior position. Failure of the heart to loop properly results in dextrocardia and the heart lies on the right side. Dextrocardia can also be induced at an earlier time when laterality is established.

Septum formation in the heart in part arises from development of endocardial cushion tissue in the atrioventricular canal (atrioventricular cushions) and in the conotruncal region (conotruncal swellings). Because of the key location of cushion tissue, many cardiac malformations are related to abnormal cushion morphogenesis.

Atrial development is dependent upon expansion of the original atrial region and incorporation of additional structures. On the right, the sinus venosus is incorporated and forms the smooth-walled portion of the right atrium (Figs. 13.11 and 13.13), which is separated from the trabeculated portion by the crista terminalis (Fig. 13.13). On the left, the pulmonary vein, which forms in the dorsal mesocardium, is positioned into the posterior wall of the left atrium when cells in the dorsal mesenchymal protrusion (DMP) proliferate and accompany the septum primum as this structure grows toward the floor of the atrium (Fig. 13.17). Later, the root of the pulmonary vein is incorporated into the left atrium by atrial expansion until the vein’s four branches enter the atrium on its posterior wall. This portion constitutes the smooth-walled region of the left atrium (Fig. 13.18). Development of the pulmonary vein begins in the midline and then shifts to the left, a result of laterality signaling. Total anomalous pulmonary venous return (TAPVR) in which the vein is shifted to the right and enters the right atrium or even the superior vena cava or brachiocephalic vein, arises in cases of heterotaxy where left–right patterning is disrupted.

Septum Formation in the Atrium. The septum primum, a sickle-shaped crest descending from the roof of the atrium, begins to divide the atrium in two but leaves a lumen, the ostium primum, for communication between the two sides (Fig. 13.16). Later, when the ostium primum is obliterated by fusion of the septum primum with the endocardial cushions, the ostium secundum is formed by cell death that creates an opening in the septum primum. Finally, a septum secundum forms, but an interatrial opening, the oval foramen, persists. Only at birth, when pressure in the left atrium increases, do the two septa press against each other and close the communication between the two. Abnormalities in the atrial septum may vary from total absence (Fig. 13.23) to a small opening known as probe patency of the oval foramen.

Septum Formation in the Atrioventricular Canal. Four endocardial cushions surround the atrioventricular canal. Fusion of the opposing superior and inferior cushions divides the orifice into right and left atrioventricular canals (Fig. 13.16B–D). Cushion tissue then becomes fibrous and forms the mitral (bicuspid) valve on the left and the tricuspid valve on the right (Fig. 13.16F). Persistence of the common atrioventricular canal (Fig. 13.24) and abnormal formation of the valves are defects that occur due to abnormalities in this endocardial cushion tissue.

Septum Formation in the Ventricles. The interventricular septum consists of a thick muscular part and a thin membranous portion (Figs. 13.16F and 13.29) formed by (1) the inferior endocardial atrioventricular cushion, (2) the right conus swelling, and (3) the left conus swelling (Fig. 13.27). In many cases, these three components fail to fuse, resulting in an open interventricular foramen. Although this abnormality may be isolated, it is commonly combined with other compensatory defects (Figs. 13.33 and 13.34).

Septum Formation in the Bulbus. The bulbus is divided into the smooth-walled portion of the right ventricle and the conus and truncus arteriosus. The truncus region is divided by the spiral aorticopulmonary septum into the proximal segments of the aorta and pulmonary artery (Fig. 13.27). Conus cushions divide the
outflow tract regions of the aortic and pulmonary channels from the left and right ventricles, respectively and also, together with tissue from the inferior endocardial cushion, close the interventricular foramen (Fig. 13.27). Many vascular abnormalities, such as transposition of the great vessels and pulmonary valvular atresia, result from abnormal division of the conotruncal region; their origin may involve neural crest cells that contribute to septum formation in the conotruncal region (Fig. 13.30).

The aortic arches lie in each of the five pharyngeal arches (Figs. 13.38 and 13.40). Four important derivatives of the original aortic arch system are (1) the carotid arteries (third arches); (2) the arch of the aorta (left fourth aortic arch); (3) the pulmonary artery (sixth aortic arch), which during fetal life is connected to the aorta through the ductus arteriosus; and (4) the right subclavian artery formed by the right fourth aortic arch, distal portion of the right dorsal aorta, and the seventh intersegmental artery (Fig. 13.40B). The most common vascular aortic arch abnormalities include (1) open ductus arteriosus and coarctation of the aorta (Fig. 13.42) and (2) persistent right aortic arch and abnormal right subclavian artery (Figs. 13.43 and 13.44), which may cause respiratory and swallowing complaints.

The vitelline arteries initially supply the yolk sac but later form the celiac and superior mesenteric arteries. The inferior mesenteric arteries are derived from the umbilical arteries. These three arteries supply the foregut, midgut, and hindgut regions, respectively.

The paired umbilical arteries arise from the common iliac arteries. After birth, the distal portions of these arteries are obliterated to form the medial umbilical ligaments, whereas the proximal portions persist as the internal iliac and vesicular arteries.

Venous System. Three systems can be recognized: (1) the vitelline system, which develops into the portal system; (2) the cardinal system, which forms the caval system; and (3) the umbilical system, which disappears after birth. The complicated caval system is characterized by many abnormalities, such as double inferior and superior vena cava and left superior vena cava (Fig. 13.51), which are also associated with laterality defects.

Changes at Birth. During prenatal life, the placental circulation provides the fetus with its oxygen, but after birth, the lungs take on gas exchange. In the circulatory system, the following changes take place at birth and in the first postnatal months: (1) The ductus arteriosus closes, (2) the oval foramen closes, (3) the umbilical vein and ductus venosus close and remain as the ligamentum teres hepatitis and ligamentum venosum, and (4) the umbilical arteries form the medial umbilical ligaments.

Lymphatic System. The lymphatic system develops later than the cardiovascular system, originating from the endothelium of veins as five sacs: two jugular, two iliac, one retroperitoneal, and one cisterna chyli. Numerous channels form to connect the sacs and provide drainage from other structures. Ultimately, the thoracic duct forms from anastomosis of the right and left thoracic ducts, the distal part of the right thoracic duct, and the cranial part of the left thoracic duct. The right lymphatic duct develops from the cranial part of the right thoracic duct.

Problems to Solve

1. A prenatal ultrasound of a 35-year-old woman in her 12th week of gestation reveals an abnormal image of the fetal heart. Instead of a four-chambered view provided by the typical cross, a portion just below the crosspiece is missing. What structures constitute the cross, and what defect does this infant probably have?
2. A child is born with severe craniofacial defects and transposition of the great vessels. What cell population may play a role in both abnormalities, and what type of insult might have produced this effect?
3. What type of tissue is critical for dividing the heart into four chambers and the outflow tract into pulmonary and aortic channels?
4. A patient complains about having difficulty swallowing. What vascular abnormality or abnormalities might produce this complaint? What is its embryological origin?
When the embryo is approximately 4 weeks old, the respiratory diverticulum (lung bud) appears as an outgrowth from the ventral wall of the foregut (Fig. 14.1A). The appearance and location of the lung bud are dependent upon an increase in retinoic acid (RA) produced by adjacent mesoderm. This increase in RA causes upregulation of the transcription factor \textit{TBX4} expressed in the endoderm of the gut tube at the site of the respiratory diverticulum. \textit{TBX4} induces formation of the bud and the continued growth and differentiation of the lungs. Hence, epithelium of the internal lining of the larynx, trachea, and bronchi, as well as that of the lungs, is entirely of endodermal origin. The cartilaginous, muscular, and connective tissue components of the trachea and lungs are derived from \textit{splanchnic mesoderm} surrounding the foregut.

Initially, the lung bud is in open communication with the foregut (Fig. 14.1B). When the diverticulum expands caudally, however, two longitudinal ridges, the tracheoesophageal ridges, separate it from the foregut (Fig. 14.2A). Subsequently, when these ridges fuse to form the \textit{tracheoesophageal septum}, the foregut is divided into a dorsal portion, the \textit{esophagus}, and a ventral portion, the \textit{trachea} and \textit{lungs} (Fig. 14.2B,C). The respiratory primordium maintains its communication with the pharynx through the laryngeal orifice (Fig. 14.2D).

\textbf{FIGURE 14.1} A. Embryo of approximately 25 days' gestation showing the relation of the respiratory diverticulum to the heart, stomach, and liver. B. Sagittal section through the cephalic end of a 5-week embryo showing the openings of the pharyngeal pouches and the laryngotracheal orifice.
Abnormalities in partitioning of the esophagus and trachea by the tracheoesophageal septum result in **esophageal atresia** with or without **tracheoesophageal fistulas (TEFs)**. These defects occur in approximately 1/3,000 births, and 90% result in the upper portion of the esophagus ending in a blind pouch and the lower segment forming a fistula with the trachea (Fig. 14.3A). Isolated esophageal atresia (Fig. 14.3B) and H-type TEF without esophageal atresia (Fig. 14.3C) each account for 4% of these defects. Other variations...
Part II • Systems-Based Embryology

[Fig. 14.3D,E] each account for approximately 1% of these defects. These abnormalities are associated with other birth defects, including cardiac abnormalities, which occur in 33% of these cases. In this regard, TEFs are a component of the VACTERL association (Vertebral anomalies, Anal atresia, Cardiac defects, Tracheoesophageal fistula, Esophageal atresia, Renal anomalies, and Limb defects), a collection of defects of unknown causation, but occurring more frequently than predicted by chance alone.

A complication of some TEFs is polyhydramnios because in some types of TEF, amniotic fluid, when swallowed does not pass to the stomach and intestines. Also, gastric contents and/or amniotic fluid at birth may enter the trachea through a fistula, causing pneumonitis and pneumonia.

**LARYNX**

The internal lining of the larynx originates from endoderm, but the cartilages and muscles originate from mesenchyme of the fourth and sixth pharyngeal arches. As a result of rapid proliferation of this mesenchyme, the laryngeal orifice changes in appearance from a sagittal slit to a T-shaped opening (Fig. 14.4A). Subsequently, when mesenchyme of the two arches transforms into the thyroid, cricoid, and arytenoid cartilages, the characteristic adult shape of the laryngeal orifice can be recognized (Fig. 14.4B).

At about the time that the cartilages are formed, the laryngeal epithelium also proliferates rapidly, resulting in a temporary occlusion of the lumen. Subsequently, vacuolization and recanalization produce a pair of lateral recesses, the laryngeal ventricles. These recesses are bounded by folds of tissue that differentiate into the false and true vocal cords.

Because musculature of the larynx is derived from mesenchyme of the fourth and sixth pharyngeal arches, all laryngeal muscles are innervated by branches of the tenth cranial nerve, the **vagus nerve**: The superior laryngeal nerve innervates derivatives of the fourth pharyngeal arch, and the recurrent laryngeal nerve innervates derivatives of the sixth pharyngeal arch. (For further details on the laryngeal cartilages, see Chapter 17, p. 283.)

**TRACHEA, BRONCHI, AND LUNGS**

During its separation from the foregut, the lung bud forms the trachea and two lateral outpocketings, the bronchial buds (Fig. 14.2B,C). At the beginning of the fifth week, each of these buds enlarges to form right and left main bronchi. The right then forms three secondary bronchi, and the left, two (Fig. 14.5A), thus foreshadowing the three lobes of the lung on the right side and two on the left (Fig. 14.5B,C).

With subsequent growth in caudal and lateral directions, the lung buds expand into the body cavity (Fig. 14.6). The spaces for the lungs, the pericardioperitoneal canals, are narrow. They lie on each side of the foregut and are gradually

**FIGURE 14.4** Laryngeal orifice and surrounding swellings at successive stages of development. A. 6 weeks. B. 12 weeks.
filled by the expanding lung buds. Ultimately, the pleuroperitoneal and pleuropericardial folds separate the pericardioperitoneal canals from the peritoneal and pericardial cavities, respectively, and the remaining spaces form the **primitive pleural cavities** (see Chapter 7). The mesoderm, which covers the outside of the lung, develops into the **visceral pleura**. The somatic mesoderm layer, covering the body wall from the inside, becomes the **parietal pleura** (Fig. 14.6A). The space between the parietal and visceral pleura is the **pleural cavity** (Fig. 14.7).

During further development, secondary bronchi divide repeatedly in a dichotomous fashion, forming 10 tertiary (segmental) bronchi in the right lung and 8 in the left, creating the **bronchopulmonary segments** of the adult lung. By the end of the sixth month, approximately 17 generations of subdivisions have formed. Before the bronchial tree reaches its final shape, however, **an additional six divisions form during postnatal life**. Branching is regulated by epithelial–mesenchymal interactions between the endoderm of the lung buds and splanchnic mesoderm that surrounds them. Signals for branching, which emit from the mesoderm, involve members of the fibroblast growth factor family. While all of these new subdivisions are occurring and the bronchial tree is developing, the lungs assume a more caudal position, so that by the time of birth, the bifurcation of the trachea is opposite the fourth thoracic vertebra.

Part II • Systems-Based Embryology

Maturation of the Lungs

Up to the seventh prenatal month, the bronchioles divide continuously into more and smaller canals (canalicular phase) and the vascular supply increases steadily (Fig. 14.8A). Terminal bronchioles divide to form respiratory bronchioles, and each of these divides into three to six alveolar ducts (Fig. 14.8B). The ducts end in terminal sacs (primitive alveoli) that are surrounded by flat alveolar cells in close contact with neighboring capillaries (Fig. 14.8B). By the end of the seventh month, sufficient numbers of mature alveolar sacs and capillaries are present to guarantee adequate gas exchange, and the premature infant is able to survive (Fig. 14.9) (Table 14.1).

During the last 2 months of prenatal life and for several years thereafter, the number of terminal sacs increases steadily. In addition, cells lining the sacs, known as type I alveolar epithelial cells, become thinner, so that surrounding capillaries protrude into the alveolar sacs (Fig. 14.9). This intimate contact between epithelial and endothelial cells makes up the blood–air barrier. Mature alveoli are not present before birth. In addition to endothelial cells and flat alveolar epithelial cells, another cell type develops at the end of the sixth month. These cells, type II alveolar epithelial cells, produce surfactant, a phospholipid-rich fluid capable of lowering surface tension at the air–alveolar interface.

Before birth, the lungs are full of fluid that contains a high chloride concentration, little protein, some mucus from the bronchial glands, and surfactant from the alveolar epithelial cells (type II). The amount of surfactant in the fluid increases, particularly during the last 2 weeks before birth.

As concentrations of surfactant increase during the 34th week of gestation, some of this...
phospholipid enters the amniotic fluid and acts on macrophages in the amniotic cavity. Once “activated,” evidence suggests that these macrophages migrate across the chorion into the uterus where they begin to produce immune system proteins, including interleukin-1β (IL-1β). Upregulation of these proteins results in increased production of prostaglandins that cause uterine contractions. Thus, there may be signals from the fetus that participate in initiating labor and birth.

Fetal breathing movements begin before birth and cause aspiration of amniotic fluid. These movements are important for stimulating lung development and conditioning respiratory muscles. When respiration begins at birth, most of the lung fluid is rapidly resorbed by the blood and lymph capillaries, and a small amount is probably expelled via the trachea and bronchi during delivery. When the fluid is resorbed from alveolar sacs, surfactant remains deposited as a thin phospholipid coat on alveolar cell membranes. With air entering alveoli during the first breath, the surfactant coat prevents development of an air-water (blood) interface with high surface tension. Without the fatty surfactant layer, the alveoli would collapse during expiration (atelectasis).

Respiratory movements after birth bring air into the lungs, which expand and fill the pleural cavity. Although the alveoli increase somewhat in size, growth of the lungs after birth is due primarily to an increase in the number of respiratory bronchioles and alveoli. It is estimated that only one-sixth of the adult number of alveoli are present at birth. The remaining alveoli are formed during the first 10 years of postnatal life through the continuous formation of new primitive alveoli.

**SUMMARY**

The respiratory system is an outgrowth of the ventral wall of the foregut, and the epithelium of the larynx, trachea, bronchi, and alveoli originates in the endoderm. The cartilaginous, muscular, and connective tissue components arise in the mesoderm. In the fourth week of development, the tracheoesophageal septum separates the trachea from the foregut, dividing the foregut into the lung bud anteriorly and the esophagus posteriorly. Contact between the two is maintained through the larynx, which is formed by tissue of the fourth and sixth pharyngeal arches. The lung bud develops into two main bronchi: The right forms three secondary bronchi and three lobes; the left forms two secondary bronchi and two lobes. Faulty partitioning of the

Surfactant is particularly important for survival of the premature infant. When surfactant is insufficient, the air-water (blood-surface) membrane tension becomes high, bringing great risk that alveoli will collapse during expiration. As a result, respiratory distress syndrome (RDS) develops. This is a common cause of death in the premature infant. In these cases, the partially collapsed alveoli contain a fluid with a high protein content, many hyaline membranes, and lamellar bodies, probably derived from the surfactant layer. RDS, which was previously known as hyaline membrane disease, accounts for approximately 20% of deaths among newborns. Treatment of preterm babies with artificial surfactant as well as treatment of mothers with premature labor with glucocorticoids to stimulate surfactant production have reduced the mortality associated with RDS.

Although many abnormalities of the lung and bronchial tree have been described (e.g., blind-ending trachea with absence of lungs and agenesis of one lung), most of these gross abnormalities are rare. Abnormal divisions of the bronchial tree are more common; some result in supernumerary lobules. These variations of the bronchial tree have little functional significance, but they may cause unexpected difficulties during bronchoscopies.

More interesting are ectopic lung lobes arising from the trachea or esophagus. It is believed that these lobes are formed from additional respiratory buds of the foregut that develop independent of the main respiratory system.

Most important clinically are congenital cysts of the lung, which are formed by dilation of terminal or larger bronchi. These cysts may be small and multiple, giving the lung a honeycomb appearance on radiograph, or they may be restricted to one or more larger ones. Cystic structures of the lung usually drain poorly and frequently cause chronic infections.

Problems to Solve
1. A prenatal ultrasound revealed polyhydramnios, and at birth, the baby had excessive fluids in its mouth. What type of birth defect might be present, and what is its embryological origin? Would you examine the child carefully for other birth defects? Why?
2. A baby born at 6 months’ gestation is having trouble breathing. Why?
DIVISIONS OF THE GUT TUBE

As a result of cephalocaudal and lateral folding of the embryo, a portion of the endoderm derived from gastrulation is incorporated into the embryo to form the primitive gut. The yolk sac and the allantois, remain outside the embryo (Fig. 15.1A–D).

In the cephalic and caudal parts of the embryo, the primitive gut forms a blind-ending tube, the foregut and hindgut, respectively.

The middle part, the midgut, remains temporarily connected to the yolk sac by means of the vitelline duct, or yolk stalk (Fig. 15.1D).

Development of the primitive gut and its derivatives is usually discussed in four sections: (1) The pharyngeal gut, or pharynx, extends from the oropharyngeal membrane to the respiratory diverticulum and is part of the foregut; this section is particularly important for development of the head and neck and is

FIGURE 15.1 Sagittal sections through embryos at various stages of development demonstrating the effect of cephalocaudal and lateral folding on the position of the endoderm-lined cavity. Note formation of the foregut, midgut, and hindgut.

discussed in Chapter 17. (2) The remainder of the **foregut** lies caudal to the pharyngeal tube and extends as far caudally as the liver outgrowth. (3) The **midgut** begins caudal to the liver bud and extends to the junction of the right two-thirds and left third of the transverse colon in the adult. (4) The **hindgut** extends from the left third of the transverse colon to the cloacal membrane (Fig. 15.1). **Endoderm** forms the epithelial lining of the digestive tract and gives rise to the specific cells (the **parenchyma**) of glands, such as hepatocytes and the exocrine and endocrine cells of the pancreas. The **stroma** (connective tissue) for the glands is derived from visceral mesoderm. Muscle, connective tissue, and peritoneal components of the wall of the gut also are derived from visceral mesoderm.

**MOLECULAR REGULATION OF GUT TUBE DEVELOPMENT**

Regional specification of the gut tube into different components occurs during the time that the lateral body folds are bringing the two sides of the tube together (Figs. 15.2 and 15.3). Specification is initiated by a concentration gradient of retinoic acid (RA) from the pharynx, which is exposed to little or no RA, to the colon, that sees the highest concentration of RA. This RA gradient causes

**FIGURE 15.2** Diagrams showing molecular regulation of gut development. **A.** Color-coded diagram that indicates genes responsible for initiating regional specification of the gut into esophagus, stomach, duodenum, etc. **B-D.** Drawings showing an example from the midgut and hindgut regions indicating how early gut specification is stabilized. Stabilization is effected by epithelial-mesenchymal interactions between gut endoderm and surrounding visceral (splanchnic) mesoderm. Endoderm cells initiate the stabilization process by secreting sonic hedgehog ([SHH](#)), which establishes a nested expression of **HOX** genes in the mesoderm. This interaction results in a genetic cascade that regulates specification of each gut region as is shown for the small and large intestine regions in these diagrams.
transcription factors to be expressed in different regions of the gut tube. Thus, SOX2 "specifies" the esophagus and stomach; PDX1, the duodenum; CDX2, the small intestine; and CDX2, the large intestine and rectum (Fig. 15.2A). This initial patterning is stabilized by reciprocal interactions between the endoderm and visceral mesoderm adjacent to the gut tube (Fig. 15.2B–D). This epithelial–mesenchymal interaction is initiated by SONIC HEDGEHOG (SHH) expression throughout the gut tube. SHH expression upregulates factors in the mesoderm that then determine the type of structure that forms from the gut tube, such as the stomach, duodenum, small intestine, etc. For example, in the region of the caudal limit of the midgut and all of the hindgut, SHH expression establishes a nested expression of the HOX genes in the mesoderm (Fig. 15.2D). Once the mesoderm is specified by this code, then it instructs the endoderm to form the various components of the mid- and hindgut regions, including part of the small intestine, cecum, colon, and cloaca (Fig. 15.2).

**MESENTERIES**

Portions of the gut tube and its derivatives are suspended from the dorsal and ventral body wall by mesenteries, double layers of peritoneum that enclose an organ and connect it to the body wall. Such organs are called intraperitoneal, whereas organs that lie against the posterior body wall and are covered by peritoneum on their anterior surface only (e.g., the kidneys) are considered retroperitoneal. Peritoneal ligaments are double layers of peritoneum (mesenteries) that pass from one organ to another or from an organ to the body wall. Mesenteries and ligaments provide pathways for vessels, nerves, and lymphatics to and from abdominal viscera (Figs. 15.3 and 15.4).

Initially, the foregut, midgut, and hindgut are in broad contact with the mesenchyme of the posterior abdominal wall (Fig. 15.3). By the fifth week, however, the connecting tissue bridge has narrowed, and the caudal part of the foregut, the midgut, and a major part of the hindgut are suspended from the abdominal wall by the **dorsal mesentery** (Figs. 15.3C and 15.4), which extends from the lower end of the esophagus to the cloacal region of the hindgut. In the region of the stomach, it forms the **dorsal mesogastrium** or greater omentum; in the region of the duodenum, it forms the dorsal mesoduodenum; and in the region of the colon, it forms the **dorsal mesocolon**. Dorsal mesentery of the jejunal and ileal loops forms the **mesentery proper**. **Ventral mesentery**, which exists only in the region of the terminal part of the esophagus, the stomach, and the upper part of the duodenum (Fig. 15.4), is derived from the **septum transversum**. Growth of the liver into the mesenchyme of the septum transversum divides the ventral mesentery into (1) the lesser omentum, extending from the lower portion of the esophagus, the stomach, and the upper portion of the
Part II • Systems-Based Embryology

duodenum to the liver and (2) the falciform ligament, extending from the liver to the ventral body wall (Fig. 15.4).

**FOREGUT**

**Esophagus**

When the embryo is approximately 4 weeks old, the respiratory diverticulum (lung bud) appears at the ventral wall of the foregut at the border with the pharyngeal gut (Fig. 15.5). The tracheoesophageal septum gradually partitions this diverticulum from the dorsal part of the foregut (Fig. 15.6). In this manner, the foregut divides into a ventral portion, the respiratory primordium (see Chapter 14), and a dorsal portion, the esophagus.

At first, the esophagus is short (Fig. 15.5A), but with descent of the heart and lungs, it lengthens rapidly (Fig. 15.5B). The muscular coat, which is formed by surrounding splanchnic mesenchyme, is striated in its upper two-thirds and innervated by the vagus; the muscle coat is smooth in the lower third and is innervated by the splanchnic plexus.
**Clinical Correlates**

**Esophageal Abnormalities**

*Esophageal atresia* and/or *tracheoesophageal fistula* results either from spontaneous posterior deviation of the *tracheoesophageal septum* or from some mechanical factor pushing the dorsal wall of the foregut anteriorly. In its most common form, the proximal part of the esophagus ends as a blind sac, and the distal part is connected to the trachea by a narrow canal just above the bifurcation (Fig. 15.7A). Other types of defects in this region occur much less frequently (Fig. 15.7B-E) [see Chapter 14].

![Variations of esophageal atresia and/or tracheoesophageal fistula in order of their frequency of appearance: (A) 90%, (B) 4%, (C) 4%, (D) 1%, and (E) 1%.](continued)
Atresia of the esophagus prevents normal passage of amniotic fluid into the intestinal tract, resulting in accumulation of excess fluid in the amniotic sac (polyhydramnios). In addition to atresias, the lumen of the esophagus may narrow, producing esophageal stenosis, usually in the lower third. Stenosis may be caused by incomplete recanalization, vascular abnormalities, or accidents that compromise blood flow. Occasionally, the esophagus fails to lengthen sufficiently, and the stomach is pulled up into the esophageal hiatus through the diaphragm. The result is a congenital hiatal hernia.

Stomach

The stomach appears as a fusiform dilation of the foregut in the fourth week of development (Fig. 15.5A). During the following weeks, its appearance and position change greatly as a result of the different rates of growth in various regions of its wall and the changes in position of surrounding organs. Positional changes of the stomach are most easily explained by assuming that it rotates around a longitudinal and an anteroposterior axis (Fig. 15.8).

The stomach rotates 90° clockwise around its longitudinal axis, causing its left side to face anteriorly and its right side to face posteriorly (Fig. 15.8A–C). Hence, the left vagus nerve, initially innervating the left side of the stomach, now innervates the anterior wall; similarly, the right nerve innervates the posterior wall. During this rotation, the original posterior wall of the stomach grows faster than the anterior portion, forming the greater and lesser curvatures (Fig. 15.8C).

The cephalic and caudal ends of the stomach originally lie in the midline, but during further growth, the stomach rotates around an anteroposterior axis, such that the caudal or pyloric part moves to the right and upward, and the cephalic or cardiac portion moves to the left and slightly downward (Fig. 15.8D,E). The stomach thus assumes its final position, its axis running from above left to below right.

Because the stomach is attached to the dorsal body wall by the dorsal mesogastrium and

![Figure 15.8](image-url)
to the ventral body wall by the ventral mesogastrium (Figs. 15.4 and 15.9A), its rotation and disproportionate growth alter the position of these mesenteries. Rotation about the longitudinal axis pulls the dorsal mesogastrium to the left, creating a space behind the stomach called the omental bursa (lesser peritoneal sac) (Figs. 15.9 and 15.10). This rotation also pulls the ventral mesogastrium to the right. As this process continues in the fifth week of development, the spleen primordium appears as a mesodermal proliferation between the two leaves of the dorsal mesogastrium (Figs. 15.10 and 15.11). With continued rotation of the stomach, the dorsal mesogastrium lengthens, and the portion between the spleen and dorsal midline swings to the left and fuses with the peritoneum of the posterior abdominal wall (Figs. 15.10 and 15.11). The posterior leaf of the dorsal mesogastrium and the peritoneum along this line of fusion degenerate. The spleen, which remains intra-peritoneal, is then connected to the body wall in the region of the left kidney by the lienorenal ligament and to the stomach by the gastrolenal ligament (Figs. 15.10 and 15.11). Lengthening and fusion of the dorsal mesogastrium to the posterior body wall also determine the final position of the pancreas. Initially, the organ grows into the dorsal mesoduodenum, but eventually, its tail extends into the dorsal mesogastrium.

**FIGURE 15.9** A. Transverse section through a 4-week embryo showing intercellular clefts appearing in the dorsal mesogastrium. B,C. The clefts have fused, and the omental bursa is formed as an extension of the right side of the intraembryonic cavity behind the stomach.

**FIGURE 15.10** A. The positions of the spleen, stomach, and pancreas at the end of the fifth week. Note the position of the spleen and pancreas in the dorsal mesogastrium. B. Position of spleen and stomach at the 11th week. Note formation of the omental bursa (lesser peritoneal sac).
FIGURE 15.11 Transverse sections through the region of the stomach, liver, and spleen, showing formation of the omental bursa [lesser peritoneal sac], rotation of the stomach, and position of the spleen and tail of the pancreas between the two leaves of the dorsal mesogastrium. With further development, the pancreas assumes a retroperitoneal position.

(FIG. 15.10A). Because this portion of the dorsal mesogastrium fuses with the dorsal body wall, the tail of the pancreas lies against this region (Fig. 15.11). Once the posterior leaf of the dorsal mesogastrium and the peritoneum of the posterior body wall degenerate along the line of fusion, the tail of the pancreas is covered by peritoneum on its anterior surface only and therefore lies in a retroperitoneal position. (Organs, such as the pancreas, that are originally covered by peritoneum, but later fuse with the posterior body wall to become retroperitoneal, are said to be secondarily retroperitoneal.)

As a result of rotation of the stomach about its anteroposterior axis, the dorsal mesogastrium bulges down (Fig. 15.12). It continues to grow down and forms a double-layered sac extending over the transverse colon and small intestinal loops like an apron (Fig. 15.13A). This double-leaved apron is the greater omentum; later, its layers fuse to form a single sheet hanging from the greater curvature of the stomach (Fig. 15.13B). The posterior layer of the greater omentum also fuses with the mesentery of the transverse colon (Fig. 15.13B).

The lesser omentum and falciform ligament form from the ventral mesogastrium, which

FIGURE 15.12 A. Derivatives of the dorsal mesentery at the end of the third month. The dorsal mesogastrium bulges out on the left side of the stomach, where it forms part of the border of the omental bursa. B. The greater omentum hangs down from the greater curvature of the stomach in front of the transverse colon.
itself is derived from mesoderm of the septum transversum. When liver cords grow into the septum, it thins to form (1) the peritoneum of the liver; (2) the falciform ligament, extending from the liver to the ventral body wall; and (3) the lesser omentum, extending from the stomach and upper duodenum to the liver (Figs. 15.14 and 15.15). The free margin of the falciform ligament contains the umbilical vein (Fig. 15.10A), which is obliterated after birth to form the round ligament of the liver (ligamentum teres hepatis). The free margin of the lesser omentum connecting the duodenum and liver (hepatoduodenal ligament) contains the bile duct, portal vein, and hepatic artery (portal triad). This free margin also forms the roof of the epiploic foramen of Winslow, which is the opening connecting the omental bursa (lesser sac) with the rest of the peritoneal cavity (greater sac) (Fig. 15.16).

FIGURE 15.13 A. Sagittal section showing the relation of the greater omentum, stomach, transverse colon, and small intestinal loops at 4 months. The pancreas and duodenum have already acquired a retroperitoneal position. B. Similar section as in [A] in the newborn. The leaves of the greater omentum have fused with each other and with the transverse mesocolon. The transverse mesocolon covers the duodenum, which fuses with the posterior body wall to assume a retroperitoneal position.

FIGURE 15.14 A. A 3-mm embryo (approximately 25 days) showing the primitive gastrointestinal tract and formation of the liver bud. The bud is formed by endoderm lining the foregut. B. A 5-mm embryo (approximately 32 days). Epithelial liver cords penetrate the mesenchyme of the septum transversum.
Duodenum

The terminal part of the foregut and the cephalic part of the midgut form the duodenum. The junction of the two parts is directly distal to the origin of the liver bud (Figs. 15.14 and 15.15).

As the stomach rotates, the duodenum takes on the form of a C-shaped loop and rotates to the right. This rotation, together with rapid growth of the head of the pancreas, swings the duodenum from its initial midline position to the right side.
of the abdominal cavity (Figs. 15.10A and 15.17). The duodenum and head of the pancreas press against the dorsal body wall, and the right surface of the dorsal mesoduodenum fuses with the adjacent peritoneum. Both layers subsequently disappear, and the duodenum and head of the pancreas become fixed in a retroperitoneal position. The entire pancreas thus obtains a retroperitoneal position. The dorsal mesoduodenum disappears entirely except in the region of the pylorus of the stomach, where a small portion of the duodenum (duodenal cap) retains its mesentery and remains intraperitoneal.

During the second month, the lumen of the duodenum is obliterated by proliferation of cells in its walls. However, the lumen is recanalized shortly thereafter (Fig. 15.18A,B). Because the foregut is supplied by the celiac artery and the midgut is supplied by the superior mesenteric artery, the duodenum is supplied by branches of both arteries (Fig. 15.14).

![Figure 15.17](image1)

**FIGURE 15.17** Transverse sections through the region of the duodenum at various stages of development. At first, the duodenum and head of the pancreas are located in the median plane (A), but later, they swing to the right and acquire a retroperitoneal position (B).

![Figure 15.18](image2)

**FIGURE 15.18** Upper portion of the duodenum showing the solid stage (A) and cavity formation (B) produced by recanalization.

**Clinical Correlates**

**Stomach Abnormalities**

**Pyloric stenosis** occurs when the circular and, to a lesser degree, the longitudinal musculature of the stomach in the region of the pylorus hypertrophies. One of the most common abnormalities of the stomach in infants, pyloric stenosis was previously believed to develop only during fetal life, despite the fact that most cases present 3 to 5 days after birth. However, recent data indicate that a postnatal exposure (e.g., treatment with erythromycin in the newborn period) substantially increases the risk for pyloric stenosis, suggesting that in some cases the defect may develop later. Pyloric stenosis is characterized by an extreme narrowing of the pyloric lumen, and the passage of food is obstructed, resulting in severe projectile vomiting. In a few cases, the pylorus is atretic. Other malformations of the stomach, such as duplications and a prepyloric septum, are rare.
Liver and Gallbladder

The liver primordium appears in the middle of the third week as an outgrowth of the endodermal epithelium at the distal end of the foregut (Figs. 15.14 and 15.15). This outgrowth, the hepatic diverticulum, or liver bud, consists of rapidly proliferating cells that penetrate the septum transversum, that is, the mesodermal plate between the pericardial cavity and the stalk of the yolk sac (Figs. 15.14 and 15.15). While hepatic cells continue to penetrate the septum, the connection between the hepatic diverticulum and the foregut (duodenum) narrows, forming the bile duct. A small ventral outgrowth is formed by the bile duct, and this outgrowth gives rise to the gallbladder and the cystic duct (Figs. 15.15). During further development, epithelial liver cords intermingle with the vitelline and umbilical veins, which form hepatic sinusoids. Liver cords differentiate into the parenchyma (liver cells) and form the lining of the biliary ducts. Hematopoietic cells, Kupffer cells, and connective tissue cells are derived from mesoderm of the septum transversum.

When liver cells have invaded the entire septum transversum, so that the organ bulges caudally into the abdominal cavity, mesoderm of the septum transversum lying between the liver and the foregut and the liver and the ventral abdominal wall becomes membranous, forming the lesser omentum and falciform ligament, respectively. Together, having formed the peritoneal connection between the foregut and the ventral abdominal wall, they are known as the ventral mesentery (Fig. 15.15).

Mesoderm on the surface of the liver differentiates into visceral peritoneum except on its cranial surface (Fig. 15.15B). In this region, the liver remains in contact with the rest of the original septum transversum. This portion of the septum, which consists of densely packed mesoderm, will form the central tendon of the diaphragm. The surface of the liver that is in contact with the future diaphragm is never covered by peritoneum; it is the bare area of the liver (Fig. 15.15).

In the 10th week of development, the weight of the liver is approximately 10% of the total body weight. Although this may be attributed partly to the large numbers of sinusoids, another important factor is its hematopoietic function. Large nests of proliferating cells, which produce red and white blood cells, lie between hepatic cells and walls of the vessels. This activity gradually subsides during the last 2 months of intrauterine life, and only small hematopoietic islands remain at birth. The weight of the liver is then only 5% of the total body weight.

Another important function of the liver begins at approximately the 12th week, when bile is formed by hepatic cells. Meanwhile, because the gallbladder and cystic duct have developed and the cystic duct has joined the hepatic duct to form the bile duct (Fig. 15.15), bile can enter the gastrointestinal tract. As a result, its contents take on a dark green color. Because of positional changes of the duodenum, the entrance of the bile duct gradually shifts from its initial anterior position to a posterior one, and consequently, the bile duct passes behind the duodenum (Figs. 15.19 and 15.20).

Molecular Regulation of Liver Induction

All of the foregut endoderm has the potential to express liver-specific genes and to differentiate into liver tissue. However, this expression is
blocked by factors produced by surrounding tissues, including ectoderm, noncardiac mesoderm, and particularly the notochord (Fig. 15.21). The action of these inhibitors is blocked in the prospective hepatic region by fibroblast growth factors (FGF2) secreted by cardiac mesoderm and by blood vessel-forming endothelial cells adjacent to the gut tube at the site of liver bud outgrowth. Thus, the cardiac mesoderm together with neighboring vascular endothelial cells “instructs” gut endoderm to express liver-specific genes by inhibiting an inhibitory factor of these same genes. Other factors participating in this “instruction” are bone morphogenetic proteins (BMPs) secreted by the septum transversum. BMPs appear to enhance the competence of prospective liver endoderm to respond to FGF2. Once this “instruction” is received, cells in the liver field differentiate into both hepatocytes and biliary cell lineages, a process that is at least partially regulated by HEPATOCYTE NUCLEAR TRANSCRIPTION FACTORS (HNF3 and HNF4).
Liver and Gallbladder Abnormalities

Variations in liver lobulation are common but not clinically significant. Accessory hepatic ducts and duplication of the gallbladder [Fig. 15.22] are also common and usually asymptomatic. However, they become clinically important under pathological conditions. In some cases the ducts, which pass through a solid phase in their development, fail to recanalize [Fig. 15.22]. This defect, extrahepatic biliary atresia, occurs in 1/15,000 live births. Among patients with extrahepatic biliary atresia, 15% to 20% have patent proximal ducts and a correctable defect, but the remainder usually die unless they receive a liver transplant. Another problem with duct formation lies within the liver itself; it is intrahepatic biliary duct atresia and hypoplasia. This rare abnormality (1/100,000 live births) may be caused by fetal infections. It may be lethal but usually runs an extended benign course.

![FIGURE 15.22 A. Obliteration of the bile duct resulting in distention of the gallbladder and the hepatic ducts distal to the obliteration. B. Duplication of the gallbladder.](image)

---

**PANCREAS**

The pancreas is formed by two buds, dorsal and ventral, originating from the endodermal lining of the duodenum (Fig. 15.19). Whereas the dorsal pancreatic bud is in the dorsal mesentery, the ventral pancreatic bud is close to the bile duct (Fig. 15.19). When the duodenum rotates to the right and becomes C-shaped, the ventral pancreatic bud moves dorsally in a manner similar to the shifting of the entrance of the bile duct (Fig. 15.19). Finally, the ventral bud comes to lie immediately below and behind the dorsal bud (Fig. 15.20). Later, the parenchyma and the duct systems of the dorsal and ventral pancreatic buds fuse (Fig. 15.20B). The ventral bud forms the uncinate process and inferior part of the head of the pancreas. The remaining part of the gland is derived from the dorsal bud. The main pancreatic duct (of Wirsung) is formed by the distal part of the dorsal pancreatic duct and the entire ventral pancreatic duct (Fig. 15.20B). The proximal part of the dorsal pancreatic duct either is obliterated or persists as a small channel, the accessory pancreatic duct (of Santorini). The main pancreatic duct, together with the bile duct, enters the duodenum at the site of the major papilla; the entrance of the accessory duct (when present) is at the site of the minor papilla. In about 10% of cases, the duct system fails to fuse, and the original double system persists.

In the third month of fetal life, pancreatic islets (of Langerhans) develop from the parenchymatous pancreatic tissue and scatter throughout the pancreas. Insulin secretion begins at approximately the fifth month. Glucagon- and somatostatin-secreting cells also develop from
parenchymal cells. Visceral mesoderm surrounding the pancreatic buds forms the pancreatic connective tissue.

**Molecular Regulation of Pancreas Development**

FGF2 and ACTIVIN (a TGF-β family member) produced by the notochord and endothelium of the dorsal aorta repress SHH expression in gut endoderm destined to form the dorsal pancreatic bud. The ventral bud is induced by visceral mesoderm. As a result, expression of the **PANCREATIC AND DUODENAL HOMEBOX 1 (PDX) gene** is upregulated. Although all of the downstream effectors of pancreas development have not been determined, it appears that expression of the paired homeobox genes **PAX4** and **PAX6** specifies the endocrine cell lineage, such that cells expressing both genes become β (insulin), δ (somatostatin), and γ (pancreatic polypeptide) cells; whereas those expressing only PAX6 become a (glucagon) cells.

**Clinical Correlates**

**Pancreatic Abnormalities**

The ventral pancreatic bud consists of two components that normally fuse and rotate around the duodenum so that they come to lie below the dorsal pancreatic bud. Occasionally, however, the right portion of the ventral bud migrates along its normal route, but the left migrates in the opposite direction. In this manner, the duodenum is surrounded by pancreatic tissue, and an annular pancreas is formed [Fig. 15.23]. The malformation sometimes constricts the duodenum and causes complete obstruction.

**Accessory pancreatic tissue** may be anywhere from the distal end of the esophagus to the tip of the primary intestinal loop. Most frequently, it lies in the mucosa of the stomach and in Meckel diverticulum, where it may show all of the histological characteristics of the pancreas itself.

**MIDGUT**

In the 5-week embryo, the midgut is suspended from the dorsal abdominal wall by a short mesentery and communicates with the yolk sac by way of the **vitelline duct** or **yolk stalk** (Figs. 15.1 and 15.24). In the adult, the midgut begins immediately distal to the entrance of the bile duct into the duodenum (Fig. 15.15) and terminates at the junction of the proximal two-thirds of the transverse colon with the distal third. Over its entire length, the midgut is supplied by the **superior mesenteric artery** (Fig. 15.24).

Development of the midgut is characterized by rapid elongation of the gut and its mesentery, resulting in formation of the **primary intestinal loop** (Figs. 15.24 and 15.25). At its apex, the loop remains in open connection with the yolk sac by way of the narrow **vitelline duct** (Fig. 15.24). The cephalic limb of the loop develops into the distal part of the duodenum, the jejunum, and part of the ileum. The caudal
limb becomes the lower portion of the ileum, the cecum, the appendix, the ascending colon, and the proximal two-thirds of the transverse colon.

**Physiological Herniation**

Development of the primary intestinal loop is characterized by rapid elongation, particularly of the cephalic limb. As a result of the rapid growth and expansion of the liver, the abdominal cavity temporarily becomes too small to contain all the intestinal loops, and they enter the extraembryonic cavity in the umbilical cord during the sixth week of development (physiological umbilical herniation) (Fig. 15.26).

**Rotation of the Midgut**

Coincident with growth in length, the primary intestinal loop rotates around an axis formed by the superior mesenteric artery (Fig. 15.25). When viewed from the front, this rotation is counterclockwise, and it amounts to approximately 270° when it is complete (Figs. 15.25 and 15.27). Even during rotation, elongation of the small intestinal loop continues, and the jejunum and ileum form a number of coiled loops (Fig. 15.26). The large intestine likewise lengthens considerably but does not participate in the coiling phenomenon. Rotation occurs during herniation (about 90°) as well as during return of the intestinal...
loops into the abdominal cavity (remaining 180°) (Fig. 15.27).

Retraction of Herniated Loops
During the 10th week, herniated intestinal loops begin to return to the abdominal cavity. Although the factors responsible for this return are not precisely known, it is thought that regression of the mesonephric kidney, reduced growth of the liver, and expansion of the abdominal cavity play important roles.

FIGURE 15.26 Umbilical herniation of the intestinal loops in an embryo of approximately 8 weeks (crown-rump length, 35 mm). Coiling of the small intestinal loops and formation of the cecum occur during the herniation. The first 90° of rotation occurs during herniation; the remaining 180° occurs during the return of the gut to the abdominal cavity in the third month.

FIGURE 15.27 A. Anterior view of the intestinal loops after 270° counterclockwise rotation. Note the coiling of the small intestinal loops and the position of the cecal bud in the right upper quadrant of the abdomen. B. Similar view as in [A] with the intestinal loops in their final position. Displacement of the cecum and appendix caudally places them in the right lower quadrant of the abdomen.
The proximal portion of the jejunum, the first part to reenter the abdominal cavity, comes to lie on the left side (Fig. 15.27A). The later returning loops gradually settle more and more to the right. The cecal bud, which appears at about the sixth week as a small conical dilation of the caudal limb of the primary intestinal loop, is the last part of the gut to reenter the abdominal cavity. Temporarily, it lies in the right upper quadrant directly below the right lobe of the liver (Fig. 15.27A). From here, it descends into the right iliac fossa, placing the ascending colon and hepatic flexure on the right side of the abdominal cavity (Fig. 15.27B). During this process, the distal end of the cecal bud forms a narrow diverticulum, the appendix (Fig. 15.28).

Because the appendix develops during descent of the colon, its final position frequently is posterior to the cecum or colon. These positions of the appendix are called retrocecal or retrocolic, respectively (Fig. 15.29).

**Mesenteries of the Intestinal Loops**

The mesentery of the primary intestinal loop, the *mesentery proper*, undergoes profound changes with rotation and coiling of the bowel. When the caudal limb of the loop moves to the right side of the abdominal cavity, the dorsal mesentery twists around the origin of the *superior mesenteric artery* (Fig. 15.24). Later, when the ascending and descending portions of the colon obtain their definitive positions, their mesenteries press against the peritoneum of the posterior abdominal wall (Fig. 15.30). After fusion of these layers, the ascending and descending colons are permanently anchored in a retroperitoneal position. The appendix, lower end of the cecum, and sigmoid colon, however, retain their free mesenteries (Fig. 15.30B).

The fate of the transverse mesocolon is different. It fuses with the posterior wall of the greater omentum (Fig. 15.30) but maintains its mobility. Its line of attachment finally extends from the hepatic flexure of the ascending colon to the splenic flexure of the descending colon (Fig. 15.30B).

The mesentery of the jejunoileal loops is at first continuous with that of the ascending colon (Fig. 15.30A). When the mesentery of the ascending mesocolon fuses with the posterior abdominal wall, the mesentery of the jejunoileal loops obtains a new line of attachment that extends from the area where the duodenum becomes intraperitoneal to the ileocecal junction (Fig. 15.30B).
Abnormalities of the Mesenteries

Normally, the ascending colon, except for its most caudal part (approximately 1 in.), fuses to the posterior abdominal wall and is covered by peritoneum on its anterior surface and sides. Persistence of a portion of the mesocolon gives rise to a mobile cecum. In the most extreme form, the mesentery of the ascending colon fails to fuse with the posterior body wall. Such a long mesentery allows abnormal movements of the gut or even volvulus of the cecum and colon. Similarly, incomplete fusion of the mesentery with the posterior body wall may give rise to retrocolic pockets behind the ascending mesocolon. A retrocolic hernia is entrapment of portions of the small intestine behind the mesocolon.

Body Wall Defects

Omphalocele [Fig. 15.31A,B] involves herniation of abdominal viscera through an enlarged umbilical ring. The viscera, which may include liver, small and large intestines, stomach, spleen, or gallbladder, are covered by amnion. The origin of the defect is a failure of the bowel to return to the body cavity from its physiological herniation during the 6th to 10th weeks. It can be diagnosed in utero later in gestation by ultrasound [Fig. 15.31D]. Omphalocele occurs in 2.5/10,000 births and is associated with a high rate of mortality [25%] and severe malformations, such as cardiac anomalies [50%] and neural tube defects [40%]. Approximately 15% of live-born infants with omphalocele have chromosomal abnormalities.

Gastrochisis [Fig. 15.31C] refers to a protrusion of abdominal contents through the body wall directly into the amniotic cavity. It occurs lateral to the umbilicus usually on the right, and the defect is most likely due to abnormal closure of the body wall around the connecting stalk [see Chapter 7]. Viscera are not covered by peritoneum or amnion, and the bowel may be damaged by exposure to amniotic fluid. Like omphalocele, it can be diagnosed later in pregnancy by ultrasound [Fig. 15.31E]. Gastrochisis occurs in 1/10,000 births but is increasing in frequency, especially among young women (<20 years old). The reason for this increase and why the defect is more prevalent in babies born to younger women is not known. Unlike omphalocele, gastrochisis is not associated with chromosome abnormalities or other severe defects, so the survival rate is excellent. Volvulus [rotation of the bowel] resulting in a compromised blood supply may, however, kill large regions of the intestine and lead to fetal death.

[continued]
FIGURE 15.31 A. Omphalocele showing failure of the intestinal loops to return to the body cavity after physiological herniation. The herniated loops are covered by amnion. B. Omphalocele in a newborn. C. Newborn with gastrochisis. Loops of bowel extend through a closure defect in the ventral body wall and are not covered by amnion (see Chapter 7). D. Ultrasound at 22 weeks showing a fetus with an omphalocele (O) protruding from the abdominal wall (A). The spherical nature of the defect is due to the fact that there is a covering of amnion that holds the loops of bowel in place. E. Ultrasound at 16 weeks of a fetus with gastrochisis (G). Loops of bowel protrude through the abdominal wall (A) and are not covered by amnion and so have a more ragged appearance. In both (D) and (E), the red and blue colors indicate blood flow in the umbilical circulation.
Vitelline Duct Abnormalities

In 2% to 4% of people, a small portion of the vitelline duct persists, forming an outpocketing of the ileum, Meckel diverticulum or ileal diverticulum [Fig. 15.32A]. In the adult, this diverticulum, approximately 40 to 60 cm from the ileocecal valve on the antimesenteric border of the ileum, does not usually cause any symptoms. However, when it contains heterotopic pancreatic tissue or gastric mucosa, it may cause ulceration, bleeding, or even perforation. Sometimes, both ends of the vitelline duct transform into fibrous cords, and the middle portion forms a large cyst, an enterocystoma, or a vitelline cyst [Fig. 15.32B]. Because the fibrous cords traverse the peritoneal cavity, intestinal loops may twist around the fibrous strands and become obstructed, causing strangulation or volvulus. In another variation, the vitelline duct remains patent over its entire length, forming a direct communication between the umbilicus and the intestinal tract. This abnormality is known as an umbilical fistula, or a vitelline fistula [Fig. 15.32C]. A fecal discharge may then be found at the umbilicus.

Gut Rotation Defects

Malrotation of the intestinal loop may result in twisting of the intestine (volvulus) and a compromise of the blood supply. Normally, the primary intestinal loop rotates 270° counterclockwise. Occasionally, however, rotation amounts to 90° only. When this occurs, the colon and cecum are the first portions of the gut to return from the umbilical cord, and they settle on the left side of the abdominal cavity [Fig. 15.33A]. The later returning loops then move more and more to the right, resulting in a left-sided colon.

Reversed rotation of the intestinal loop occurs when the primary loop rotates 90° clockwise. In this abnormality, the transverse colon passes behind the duodenum [Fig. 15.33B] and lies behind the superior mesenteric artery.

Duplications of intestinal loops and cysts may occur anywhere along the length of the gut tube. They are most frequently found in the region of the ileum, where they may vary from a long segment to a small diverticulum. Symptoms usually occur early in life, and 33% are associated with other defects, such as intestinal

**FIGURE 15.33** A. Abnormal rotation of the primary intestinal loop. The colon is on the left side of the abdomen, and the small intestinal loops are on the right. The ileum enters the cecum from the right. B. The primary intestinal loop is rotated 90° clockwise (reversed rotation). The transverse colon passes behind the duodenum. (continued)
Gut Atresias and Stenoses

Atresias and stenoses may occur anywhere along the intestine. Most occur in the duodenum, fewest occur in the colon, and equal numbers occur in the jejunum and ileum (1/1,500 births). Atresias in the upper duodenum are probably due to a lack of recanalization [Fig. 15.18]. From the distal portion of the duodenum caudally, however, stenoses and atresias were thought to be caused by vascular “accidents” that resulted in compromised blood flow and tissue necrosis in a section of the gut resulting in the defects. It was suggested that these accidents could be caused by malrotation, volvulus, gastroschisis, omphalocele, and other factors. However, new evidence suggests that problems with gut differentiation can also cause these defects. Thus, misexpression of some HOX genes and of genes and receptors in the FGF family result in gut atresias. In 50% of cases, a region of the bowel is lost, and in 20%, a fibrous cord remains [Fig. 15.34A,B]. In another 20%, there is narrowing, with a thin diaphragm separating the larger and smaller pieces of bowel [Fig. 15.34C]. Stenoses and multiple atresias account for the remaining 10% of these defects, with a frequency of 5% each [Fig. 15.34D]. Apple peel atresia accounts for 10% of atresias. The atresia is in the proximal jejunum, and the intestine is short, with the portion distal to the lesion coiled around a mesenteric remnant [Fig. 15.35]. Effects of atresias on newborns depend on the amount of bowel that has been damaged and its location. Some babies with extensive gut involvement have low birth weight and other abnormalities.

**FIGURE 15.34** The most commonly occurring bowel atresias and stenoses. (A). The most common, occurs in 50% of cases; (B) and (C) occur in 20% each of cases, and (D) occurs in 5% of cases. They may be caused by problems with expression of HOX and FGFs and certain FGF receptors during gut differentiation or by vascular accidents; those in the upper duodenum may be caused by a lack of recanalization. Atresias (A–C) occur in 95% of cases, and stenoses (D) in only 5%.
**HINDGUT**

The hindgut gives rise to the distal third of the transverse colon, the descending colon, the sigmoid, the rectum, and the upper part of the anal canal. The endoderm of the hindgut also forms the internal lining of the bladder and urethra (see Chapter 16).

The terminal portion of the hindgut enters into the posterior region of the cloaca, the primitive anorectal canal; the allantois enters into the anterior portion, the primitive urogenital sinus (Fig. 15.36A). The cloaca itself is an endoderm-lined cavity covered at its ventral boundary by surface ectoderm. This boundary between the endoderm and the ectoderm forms the cloacal membrane (Fig. 15.36). A layer of mesoderm, the urorectal septum, separates the region between the allantois and hindgut. This septum is derived from a wedge of mesoderm between the allantois and hindgut (Fig. 15.36). As the embryo grows and caudal folding continues, the tip of the urorectal septum comes to lie close to the cloacal membrane (Fig. 15.36B,C). At the end of the seventh week, the cloacal membrane ruptures, creating the anal opening for the hindgut and a ventral opening for the urogenital sinus. Between the two, the tip of the urorectal septum forms the perineal body (Fig. 15.36C). The upper part (two-thirds) of the anal canal is derived from endoderm of the hindgut; the lower part (one-third) is derived from ectoderm around the proctodeum (Fig. 15.36B,C). Ectoderm in the region of the proctodeum on the surface of part of the cloaca proliferates and invaginates to create the anal pit (Fig. 15.37D). Subsequently, degeneration of the cloacal membrane (now called the anal membrane) establishes continuity between the upper and lower parts of the anal canal. Because the caudal part of the anal canal originates from ectoderm, it is supplied by the inferior rectal arteries, branches of the internal pudendal arteries. However, the cranial part of the anal canal originates from endoderm and is therefore supplied by the superior rectal artery, a continuation of the inferior mesenteric artery, the artery of the hindgut. The junction between the endodermal and ectodermal regions of the anal canal is delineated by the pectinate line, just below the anal columns. At this line, the epithelium changes from columnar to stratified squamous epithelium.

---

**Clinical Correlates**

**Hindgut Abnormalities**

Rectourethral and rectovaginal fistulas, which occur in 1/5,000 live births, may be caused by abnormalities in formation of the cloaca and/or the urorectal septum. For example, if the cloaca is too small, or if the urorectal septum does not extend far enough caudally, then opening of the hindgut shifts anteriorly leading to an opening of the hindgut into the urethra or vagina (Fig. 15.37A,B). Rectoanal fistulas and atresias vary in severity and may leave a narrow tube or fibrous remnant connected to the perineal surface (Fig. 15.37C). These defects are probably due to misexpression of genes during epithelial–mesenchymal signaling. **Imperforate anus** occurs when the anal membrane fails to break down (Fig. 15.37D).

**Congenital megacolon** is due to an absence of parasympathetic ganglia in the bowel wall (aganglionic megacolon or Hirschsprung disease). These ganglia are derived from neural crest cells that migrate from the neural folds to the wall of the bowel. Mutations in the RET gene, a tyrosine kinase receptor involved in crest cell migration (see Chapter 18), can result in congenital megacolon. In most cases, the rectum is involved, and in 80%, the defect extends to the midpoint of the sigmoid. In only 10% to 20% are the transverse and right-side colonic segments involved, and in 3%, the entire colon is affected.

---

**SUMMARY**

The epithelium of the digestive system and the parenchyma of its derivatives originate in the endoderm; connective tissue, muscular components, and peritoneal components originate in the mesoderm. Different regions of the gut tube such as the esophagus, stomach, duodenum, etc. are specified by a RA gradient that causes transcription factors unique to each region to be expressed (Fig. 15.2A). Then, differentiation of the gut and its derivatives depends upon reciprocal interactions between the gut endoderm (epithelium) and its surrounding mesoderm (an epithelial–mesenchymal interaction). HOX genes in the mesoderm are induced by SHH secreted by gut endoderm and regulate the

The hindgut enters the posterior portion of the cloaca, the future anorectal canal; the allantois enters the anterior portion, the future urogenital sinus. The urorectal septum is formed by a wedge of mesoderm between the allantois and the hindgut. The cloacal membrane, which forms the ventral boundary of the cloaca, is composed of ectoderm and endoderm. B. As caudal folding of the embryo continues, the urorectal septum moves closer to the cloacal membrane. C. Lengthening of the genital tubercle pulls the urogenital portion of the cloaca anteriorly; breakdown of the cloacal membrane creates an opening for the hindgut and one for the urogenital sinus. The tip of the urorectal septum forms the perineal body.

FIGURE 15.37 Urorectal [A] and rectovaginal [B] fistulas that result from incomplete separation of the hindgut from the urogenital sinus by the urorectal septum. These defects may also arise if the cloaca is too small, which causes the opening of the hindgut to shift anteriorly. C. Rectoperineal (fistula). These defects probably result from misexpression of genes during epithelial–mesenchymal signaling in this region. D. Imperforate anus resulting from failure of the anal membrane to break down.
craniocaudal organization of the gut and its derivatives. The gut system extends from the oropharyngeal membrane to the cloacal membrane (Fig. 15.5) and is divided into the pharyngeal gut, foregut, midgut, and hindgut. The pharyngeal gut gives rise to the pharynx and related glands (see Chapter 17).

The **foregut** gives rise to the esophagus, the trachea and lung buds, the stomach, and the duodenum proximal to the entrance of the bile duct. In addition, the liver, pancreas, and biliary apparatus develop as outgrowths of the endodermal epithelium of the upper part of the duodenum (Fig. 15.15). Because the upper part of the foregut is divided by a septum (the **tracheoesophageal septum**) into the esophagus posteriorly and the trachea and lung buds anteriorly, deviation of the septum may result in abnormal openings between the trachea and esophagus. The epithelial liver cords and biliary system growing out into the septum transversum (Fig. 15.15) differentiate into parenchyma. **Hematopoietic cells** (present in the liver in greater numbers before birth than afterward), the Kupffer cells, and connective tissue cells originate in the mesoderm. The **pancreas** develops from a **ventral bud** and a **dorsal bud** that later fuse to form the definitive pancreas (Figs. 15.19 and 15.20). Sometimes, the two parts surround the duodenum (annular pancreas), causing constriction of the gut (Fig. 15.23).

The **midgut** forms the **primary intestinal loop** (Fig. 15.24), gives rise to the duodenum distal to the entrance of the bile duct, and continues to the junction of the proximal two-thirds of the transverse colon with the distal third. At its apex, the primary loop remains temporarily in open connection with the yolk sac through the **vitelline duct**. During the sixth week, the loop grows so rapidly that it protrudes into the umbilical cord (**physiological herniation**) (Fig. 15.26). During the 10th week, it returns into the abdominal cavity. While these processes are occurring, the midgut loop rotates 270° counterclockwise (Fig. 15.27). Remnants of the vitelline duct, failure of the midgut to return to the abdominal cavity, malrotation, stenosis, and duplication of parts of the gut are common abnormalities.

The **hindgut** gives rise to the region from the distal third of the transverse colon to the upper part of the **anal canal**; the distal part of the anal canal originates from ectoderm. The hindgut enters the posterior region of the cloaca (future anorectal canal), and the **allantois** enters the anterior region (future urogenital sinus). The **urorectal septum** will divide the two regions (Fig. 15.36) and breakdown of the cloacal membrane covering this area will provide communication to the exterior for the anus and urogenital sinus. Abnormalities in the size of the posterior region of the cloaca shift the entrance of the anus anteriorly, causing rectovaginal and rectourethral fistulas and atresias (Fig. 15.37).

The anal canal itself is derived from endoderm (cranial part) and ectoderm (caudal part). The caudal part is formed by invaginating ectoderm around the **proctodeum**. Vascular supply to the anal canal reflects its dual origin. Thus, the cranial part is supplied by the **superior rectal artery** from the inferior mesenteric artery, the artery of the hindgut, whereas the caudal part is supplied by the **inferior rectal artery**, a branch of the internal pudendal artery.

### Problems to Solve

1. Prenatal ultrasound showed polyhydramnios at 36 weeks, and at birth, the infant had excessive fluids in its mouth and difficulty breathing. What birth defect might cause these conditions?
2. Prenatal ultrasound at 20 weeks revealed a midline mass that appeared to contain intestines and was membrane-bound. What diagnosis would you make, and what would be the prognosis for this infant?
3. At birth, a baby girl has meconium in her vagina and no anal opening. What type of birth defect does she have, and what was its embryological origin?
functionally, the urogenital system can be divided into two entirely different components: the **urinary system** and the **genital system**. Embryologically and anatomically, however, they are intimately interwoven. Both develop from a common mesodermal ridge (**intermediate mesoderm**) along the posterior wall of the abdominal cavity, and initially, the excretory ducts of both systems enter a common cavity, the cloaca.

### URINARY SYSTEM

**Kidney Systems**

Three slightly overlapping kidney systems are formed in a cranial-to-caudal sequence during intrauterine life in humans: the **pronephros**, **mesonephros**, and **metanephros**. The first of these systems is rudimentary and nonfunctional; the second may function for a short time during the early fetal period; the third forms the permanent kidney.

**Pronephros**

At the beginning of the fourth week, the pronephros is represented by 7 to 10 solid cell groups in the cervical region (Figs. 16.1 and 16.2). These groups form vestigial excretory units, nephromes, that regress before more caudal ones are formed. By the end of the fourth week, all indications of the pronephric system have disappeared.

**Mesonephros**

The mesonephros and mesonephric ducts are derived from intermediate mesoderm from upper thoracic to upper lumbar (L3) segments (Fig. 16.2). Early in the fourth week of development, during regression of the pronephric system, the first excretory tubules of the mesonephros appear. They lengthen rapidly, form an S-shaped loop, and acquire a tuft of capillaries.

![Figure 16.1](image-url) Transverse sections through embryos at various stages of development showing formation of nephric tubules. **A.** 21 days. **B.** 25 days. Note formation of external and internal glomeruli and the open connection between the intraembryonic cavity and the nephric tubule.
that will form a glomerulus at their medial extremity (Fig. 16.3A). Around the glomerulus, the tubules form Bowman’s capsule, and together these structures constitute a renal corpuscle. Laterally, the tubule enters the longitudinal collecting duct known as the mesonephric or Wolffian duct (Figs. 16.2 and 16.3).

In the middle of the second month, the mesonephros forms a large ovoid organ on each side of the midline (Fig. 16.3). Because the developing gonad is on its medial side, the ridge formed by both organs is known as the urogenital ridge (Fig. 16.3). While caudal tubules are still differentiating, cranial tubules and glomeruli show degenerative changes, and by the end of the second month, the majority have disappeared. In the male, a few of the caudal tubules and the mesonephric duct persist and participate in formation of the genital system, but they disappear in the female.

**Metanephros: The Definitive Kidney**

The third urinary organ, the **metanephros** or **permanent kidney**, appears in the fifth week. Its excretory units develop from **metanephric mesoderm** (Fig. 16.4) in the same manner as in the mesonephric system. The development of the duct system differs from that of the other kidney systems.

**Collecting System**

Collecting ducts of the permanent kidney develop from the **ureteric bud**, an outgrowth of the mesonephric duct close to its entrance to the cloaca (Fig. 16.4). The bud penetrates the metanephric tissue, which is molded over its distal end as a cap (Fig. 16.4). Subsequently, the bud dilates, forming the primitive **renal pelvis**, and splits into cranial and caudal portions, the future **major calyces** (Fig. 16.5A,B).

Each calyx forms two new buds while penetrating the metanephric tissue. These buds continue to subdivide until 12 or more generations of tubules have formed (Fig. 16.5). Meanwhile, at the periphery, more tubules form until the end of the fifth month. The tubules of the second order enlarge and absorb those of the third and fourth generations, forming the **minor calyces** of the renal pelvis. During further development, collecting tubules of the fifth and successive generations elongate considerably and converge on the minor calyces.
**FIGURE 16.3** A. Transverse section through the urogenital ridge in the lower thoracic region of a 5-week embryo showing formation of an excretory tubule of the mesonephric system. Note the appearance of Bowman’s capsule and the gonadal ridge. The mesonephros and gonad are attached to the posterior abdominal wall by a broad urogenital mesentery. B. Relation of the gonad and the mesonephros. Note the size of the mesonephros. The mesonephric duct (Wolffian duct) runs along the lateral side of the mesonephros.

**FIGURE 16.4** Relation of the hindgut and cloaca at the end of the fifth week. The ureteric bud penetrates the metanephric mesoderm (blastema).
calyx, forming the renal pyramid (Fig. 16.5D). The ureteric bud gives rise to the ureter, the renal pelvis, the major and minor calyces, and approximately 1 to 3 million collecting tubules.

**Excretory System**

Each newly formed collecting tubule is covered at its distal end by a metanephric tissue cap (Fig. 16.6A). Under the inductive influence of the tubule, cells of the tissue cap form small vesicles, the renal vesicles, which in turn give rise to small S-shaped tubules (Fig. 16.6B,C). Capillaries grow into the pocket at one end of the S and differentiate into glomeruli. These tubules, together with their glomeruli, form nephrons, or excretory units. The proximal end of each nephron forms Bowman’s capsule, which is deeply indented by a glomerulus (Fig. 16.6C,D). The distal end forms an open connection with one of the collecting tubules, establishing a passageway from Bowman’s capsule to the collecting unit. Continuous lengthening of the excretory tubule results in formation of the proximal convoluted tubule, loop of Henle, and distal convoluted tubule (Fig. 16.6E,F). Hence, the kidney develops from two sources: (1) metanephric mesoderm, which provides excretory units, and (2) the ureteric bud, which gives rise to the collecting system.

Nephrons are formed until birth, at which time there are approximately 1 million in each kidney. Urine production begins early in gestation, soon after differentiation of the glomerular capillaries, which start to form by the 10th week. At birth, the kidneys have a lobulated appearance, but the lobulation disappears during infancy as a result of further growth of the nephrons, although there is no increase in their number.

**Molecular Regulation of Kidney Development**

As with most organs, differentiation of the kidney involves epithelial-mesenchymal interactions. In this example, epithelium of the ureteric bud from the mesonephros interacts with mesenchyme of the metanephric blastema (Fig. 16.7). The mesenchyme expresses WT1, a transcription factor that makes this tissue competent to respond to induction by the ureteric bud. WT1 also regulates production of GLIAL-DERIVED NEUROTROPHIC FACTOR (GDNF) and HEPATOCYTE GROWTH FACTOR (HGF, or SCATTER FACTOR) by the mesenchyme, and these proteins stimulate branching and growth of the ureteric buds (Fig. 16.7A). The tyrosine kinase receptors RET, for GDNF, and MET, for HGF, are synthesized by the epithelium of the ureteric buds, establishing signaling pathways between the two tissues. In turn, the buds induce the mesenchyme via FIBROBLAST GROWTH FACTOR 2 (FGF2) and BONE MORPHOGENETIC PROTEIN 7 (BMP7) (Fig. 16.7A). Both of these growth factors block apoptosis and stimulate proliferation in the metanephric mesenchyme while maintaining production of WT1. Conversion of the mesenchyme to an epithelium for nephron formation is also mediated by the ureteric buds through expression of WNT9B and WNT6, which upregulate PAX2 and WNT4 in the metanephric mesenchyme. PAX2 promotes condensation of the mesenchyme preparatory to tubule formation, whereas WNT4 causes the
**FIGURE 16.6** A–F. Development of a metanephric excretory unit. Arrows, the place where the excretory unit (blue) establishes an open communication with the collecting system (yellow), allowing flow of urine from the glomerulus into the collecting ducts.

**FIGURE 16.7** Genes involved in differentiation of the kidney. A. WT1, expressed by the mesenchyme, enables this tissue to respond to induction by the ureteric bud. Glial-derived neurotrophic factor (GDNF) and hepatocyte growth factor (HGF), also produced by the mesenchyme, interact through their receptors, RET and MET, respectively, in the ureteric bud epithelium, to stimulate growth of the bud and maintain the interactions. The growth factors fibroblast growth factor 2 (FGF2) and bone morphogenetic protein 7 (BMP7) stimulate proliferation of the mesenchyme and maintain WT1 expression. B. WNT9B and WNT6 secreted by branches of the ureteric bud epithelium cause upregulation of PAX2 and WNT4 in the surrounding mesenchyme. In turn, these genes cause the mesenchyme to epithelialize (PAX2) and to then form tubules (WNT4). Changes in the extracellular matrix also occur, such that laminin and type IV collagen form a basement membrane (orange) for the epithelial cells.
condensed mesenchyme to epithelialize and form tubules (Fig. 16.7B). Because of these interactions, modifications in the extracellular matrix also occur. Thus, fibronectin, collagen I, and collagen III are replaced with laminin and type IV collagen, characteristic of an epithelial basal lamina (Fig. 16.7B). In addition, the cell adhesion molecules syndecan and E-cadherin, which are essential for condensation of the mesenchyme into an epithelium, are synthesized.

Clinical Correlates

Renal Tumors and Defects

Wilms tumor is a cancer of the kidneys that usually affects children by 5 years of age but may also occur in the fetus. Wilms tumor is due to mutations in the WT1 gene on 11p13, and it may be associated with other abnormalities and syndromes. For example, WAGR syndrome is characterized by Wilms tumor, aniridia, gonadoblastomas [tumors of the gonads], and mental retardation [intellectual disability]. The constellation of defects is due to a microdeletion in chromosome 11 that includes both the PAX6 [aniridia] and WT1 genes that are only 700 kb apart. Similarly, Denys-Drash syndrome consists of renal failure, ambiguous genitalia, and Wilms tumor.

Renal dysplasias and agenesis are a spectrum of severe malformations that represent the primary diseases requiring dialysis and transplantation in the first years of life. Multicystic dysplastic kidney is one example of this group of abnormalities in which numerous ducts are surrounded by undifferentiated cells. Nephrons fail to develop, and the ureteric bud fails to branch, so that the collecting ducts never form. In some cases, these defects cause involution of the kidneys and renal agenesis. Renal agenesis may also arise if the interaction between the metanephric mesoderm and the ureteric bud fails to occur. Normally, during the interaction, GDNF produced by the metanephric mesoderm produces branching and growth of the ureteric bud. Thus, mutations in genes that regulate GDNF expression of signaling may result in renal agenesis. Examples include the gene SALL1, responsible for Townes-Brock syndrome; PAX2 that causes renal coloboma syndrome; and EYA1 that results in branchiootorenal syndrome. Bilateral renal agenesis, which occurs in 1/10,000 births, results in renal failure. The baby presents with Potter sequence, characterized by anuria, oligohydramnios [decreased volume of amniotic fluid], and hypoplastic lungs secondary to the oligohydramnios. In 85% of cases, other severe defects, including absence

or abnormalities of the vagina and uterus, vas deferens, and seminal vesicles, accompany this condition. Common associated defects in other systems include cardiac anomalies, tracheal and duodenal atresias, cleft lip and palate, and brain abnormalities. Because of the oligohydramnios, the uterine cavity is compressed resulting in a characteristic appearance of the fetus, including a flattened face [Potter facies] and club feet.

In congenital polycystic kidney disease [Fig. 16.8], numerous cysts form. It may be inherited as an autosomal recessive or autosomal dominant disorder or may be caused by other factors. Autosomal recessive polycystic kidney disease (ARPKD), which occurs in 1/5,000 births, is a progressive disorder in which cysts form from collecting ducts. The kidneys become very large, and renal failure occurs in infancy or childhood. In autosomal dominant polycystic kidney disease (ADPKD), cysts form from all segments of the nephron and usually do not cause renal failure until adulthood. The autosomal dominant disease is more common [1/500 to 1/1,000 births] but less progressive than the autosomal recessive disease. Both types of disease are linked to mutations in genes that encode proteins localized in cilia and that are important for ciliary function. These abnormalities belong to a growing group of diseases called the ciliopathies that are due to mutations

![Surface view of a fetal kidney with multiple cysts characteristic of polycystic kidney disease.](continued)
Part II • Systems-Based Embryology

in cilia-related proteins. These disorders include **Bardet-Biedl syndrome**, characterized by renal cysts, obesity, intellectual disability, and limb defects, and **Meckel-Gruber syndrome**, characterized by renal cysts, hydrocephalus, microphthalmia, cleft palate, absence of the olfactory tract, and polydactyly. Because cilia are present on most cell types and in most tissues, many organ systems can be affected by abnormalities in ciliary structure and function.

Duplication of the ureter results from early splitting of the ureteric bud [Fig. 16.9]. Splitting may be partial or complete, and metanephric tissue may be divided into two parts, each with its own renal pelvis and ureter. More frequently, however, the two parts have a number of lobes in common as a result of intermingling of collecting tubules. In rare cases, one ureter opens into the bladder, and the other is ectopic, entering the vagina, urethra, or vestibule [Fig. 16.9C]. This abnormality results from development of two ureteric buds. One of the buds usually has a normal position, whereas the abnormal bud moves down together with the mesonephric duct. Thus, it has a low, abnormal entrance in the bladder, urethra, vagina, or epididymal region.

**FIGURE 16.9** A,B. A complete and a partial double ureter. C. Possible sites of ectopic ureteral openings in the vagina, urethra, and vestibule. D,E. Photomicrographs of complete and partial duplications of the ureters [U]. Arrows, duplicated hilum; B, bladder; K, kidneys; ML, median umbilical ligament.
**Position of the Kidney**

The kidney, initially in the pelvic region, later shifts to a more cranial position in the abdomen. This **ascent of the kidney** is caused by diminution of body curvature and by growth of the body in the lumbar and sacral regions (Fig. 16.10). In the pelvis, the metanephros receives its arterial supply from a pelvic branch of the aorta. During its ascent to the abdominal level, it is vascularized by arteries that originate from the aorta at continuously higher levels. The lower vessels usually degenerate, but some may remain.

**Function of the Kidney**

The definitive kidney formed from the metanephros becomes functional near the 12th week. Urine is passed into the amniotic cavity and mixes with the amniotic fluid. The fluid is swallowed by the fetus and recycles through the kidneys. During fetal life, the kidneys are not responsible for excretion of waste products because the placenta serves this function.

**Bladder and Urethra**

During the fourth to seventh weeks of development, the **cloaca** divides into the **urogenital sinus** anteriorly and the **anal canal** posteriorly (Fig. 16.12) (see Chapter 15, p. 247). The **urorectal septum** is a layer of mesoderm between the primitive anal canal and the urogenital sinus. The tip of the septum will form the **perineal body**, a site of insertion of several perineal muscles (Fig. 16.12C). Three portions of the urogenital sinus can be distinguished; the upper and largest part is the **urinary bladder** (Fig. 16.13A). Initially, the bladder is continuous with the allantois, but when the lumen of the allantois is obliterated, a thick fibrous cord, the **urachus** (Fig. 16.13B), remains and
connects the apex of the bladder with the umbilicus (Fig. 16.13B). In the adult, it forms the **median umbilical ligament**. The next part is a rather narrow canal, the **pelvic part of the urogenital sinus**, which in the male gives rise to the **prostatic** and **membranous** parts of the **urethra**. The last part is the **phallic part** of the urogenital sinus. It is flattened from side to side, and as the genital tubercle grows, this part of the sinus will be pulled ventrally (Fig. 16.13A). (Development of the phallic part of the urogenital sinus differs greatly between the two sexes.)

During differentiation of the cloaca, the caudal portions of the mesonephric ducts are absorbed into the wall of the urinary bladder (Fig. 16.14). Consequently, the ureters, initially outgrowths from the mesonephric ducts, enter the bladder separately (Fig. 16.14B). As a result of ascent of the kidneys, the orifices of the ureters move farther cranially; those of the mesonephric ducts move close together to enter the prostatic urethra and in the male become the **ejaculatory ducts** (Fig. 16.14C,D). Because both the mesonephric ducts and ureters originate in the

FIGURE 16.13 A. Development of the urogenital sinus into the urinary bladder and definitive urogenital sinus. B. In the male, the definitive urogenital sinus develops into the penile urethra. The prostate gland is formed by buds from the urethra, and seminal vesicles are formed by budding from the ductus deferens.

FIGURE 16.14 Dorsal views of the bladder showing the relation of the ureters and mesonephric ducts during development. Initially, the ureters are formed by an outgrowth of the mesonephric duct [A], but with time, they assume a separate entrance into the urinary bladder [B–D]. Note the trigone of the bladder formed by incorporation of the mesonephric ducts [C,D].
mesoderm, the mucosa of the bladder formed by incorporation of the ducts (the trigone of the bladder) is also mesodermal. With time, the mesodermal lining of the trigone is replaced by endodermal epithelium, so that finally, the inside of the bladder is completely lined with endodermal epithelium.

The epithelium of the urethra in both sexes originates in the endoderm; the surrounding connective and smooth muscle tissue is derived from visceral mesoderm. At the end of the third month, epithelium of the prostatic urethra begins to proliferate and forms a number of outgrowths that penetrate the surrounding mesenchyme. In the male, these buds form the prostate gland (Fig. 16.13B). In the female, the cranial part of the urethra gives rise to the urethral and paraurethral glands.

**Clinical Correlates**

**Bladder Defects**

When the lumen of the intraembryonic portion of the allantois persists, a urachal fistula may cause urine to drain from the umbilicus (Fig. 16.15A). If only a local area of the allantois persists, secretory activity of its lining results in a cystic dilation, a urachal cyst [Fig. 16.15B]. When the lumen in the upper part persists, it forms a urachal sinus. This sinus is usually continuous with the urinary bladder [Fig. 16.15C].

**Exstrophy of the bladder** [Fig. 16.16A] is a ventral body wall defect in which the bladder mucosa is exposed. Epispadias is a constant feature [Fig. 16.34], and the open urinary tract extends along the dorsal aspect of the penis through the bladder to the umbilicus. Exstrophy of the bladder is probably due to failure of the lateral body wall folds to close in the midline in the pelvic region [see Chapter 7, p. 99]. This anomaly is rare, occurring in 2/10,000 live births.

**Exstrophy of the cloaca** [Fig. 16.16B] is a more severe ventral body wall defect in which progression and closure of the lateral body wall folds are disrupted to a greater degree than is observed in bladder exstrophy [see Chapter 7, p. 99]. In addition to the closure defect, normal development of the urorectal septum is altered, such that anal canal malformations and imperforate anus occur [see Chapter 15, p. 247]. Furthermore, because the body folds do not fuse, the genital swellings are widely spaced resulting in defects in the external genitalia [Fig. 16.16B]. Occurrence of the defect is rare (1/30,000).

**FIGURE 16.15** A. Urachal fistula. B. Urachal cyst. C. Urachal sinus. The sinus may or may not be in open communication with the urinary bladder.
GENITAL SYSTEM

Sex differentiation is a complex process that involves many genes, including some that are autosomal. The key to sexual dimorphism is the Y chromosome, which contains the testis-determining gene called the SRY (sex-determining region on Y) gene on its short arm (Yp11). The protein product of this gene is a transcription factor initiating a cascade of downstream genes that determine the fate of rudimentary sexual organs. The SRY protein is the testis-determining factor; under its influence, male development occurs; in its absence, female development is established.

Gonads

Although the sex of the embryo is determined genetically at the time of fertilization, the gonads do not acquire male or female morphological characteristics until the seventh week of development.

Gonads appear initially as a pair of longitudinal ridges, the genital or gonadal ridges (Fig. 16.17). They are formed by proliferation of the epithelium and a condensation of underlying mesenchyme. Germ cells do not appear in the genital ridges until the sixth week of development.

Primordial germ cells originate in the epiblast, migrate through the primitive streak, and by the third week reside among endoderm cells in the wall of the yolk sac close to the allantois (Fig. 16.18A). During the fourth week, they migrate by ameboid movement along the dorsal mesentery of the hindgut (Fig. 16.18A,B), arriving at the primitive gonads at the beginning of the fifth week and invading the genital ridges in

FIGURE 16.16 A. Exstrophy of the bladder. B. Cloacal extrophy in a newborn.

FIGURE 16.17 A. Relation of the genital ridge and the mesonephros showing location of the mesonephric duct. B. Transverse section through the mesonephros and genital ridge at the level indicated in [A].
Part II • Systems-Based Embryology

the sixth week. If they fail to reach the ridges, the gonads do not develop. Hence, the primordial germ cells have an inductive influence on development of the gonad into ovary or testis.

Shortly before and during arrival of primordial germ cells, the epithelium of the genital ridge proliferates, and epithelial cells penetrate the underlying mesenchyme. Here they form a number of irregularly shaped cords, the **primitive sex cords** (Fig. 16.19). In both male and female embryos, these cords are connected to surface epithelium, and it is impossible to differentiate between the male and female gonad. Hence, the gonad is known as the **indifferent gonad**.

**Testis**

If the embryo is genetically male, the primordial germ cells carry an XY sex chromosome complex. Under influence of the SRY gene on the Y chromosome, which encodes the testis-determining factor, the primitive sex cords continue to proliferate and penetrate deep into the medulla to form the **testis** or **medullary cords** (Figs. 16.20A and 16.21). Toward the hilum of the gland, the cords break up into a network of tiny cell strands that later give rise to tubules of the **rete testis** (Fig. 16.20A,B). During further development, a dense layer of fibrous connective tissue, the **tunica albuginea**, separates the testis cords from the surface epithelium (Fig. 16.20).

In the fourth month, the testis cords become horseshoe-shaped, and their extremities are continuous with those of the rete testis (Fig. 16.20B). Testis cords are now composed of primitive germ cells and **sustentacular cells of Sertoli** derived from the surface epithelium of the gland.

**Interstitial cells of Leydig**, derived from the original mesenchyme of the gonadal ridge, lie between the testis cords. They begin development shortly after onset of differentiation of these cords. By the eighth week of gestation, Leydig cells begin production of **testosterone** and the testis is able to influence sexual differentiation of the genital ducts and external genitalia.
Testis cords remain solid until puberty, when they acquire a lumen, thus forming the **spermiferous tubules**. Once the spermiferous tubules are canalized, they join the rete testis tubules, which in turn enter the **ductuli efferentes**. These efferent ductules are the remaining parts of the excretory tubules of the mesonephric system. They link the rete testis and the mesonephric or Wolffian duct, which becomes the **ductus deferens** (Fig. 16.20B).

**Ovary**

In female embryos with an XX sex chromosome complement and no Y chromosome, primitive sex cords dissociate into irregular cell clusters (Figs. 16.21 and 16.22A). These clusters, containing groups of primitive germ cells, occupy the medullary part of the ovary. Later, they disappear and are replaced by a vascular stroma that forms the **ovarian medulla** (Fig. 16.22).

The surface epithelium of the female gonad, unlike that of the male, continues to proliferate. In the seventh week, it gives rise to a second generation of cords, **cortical cords**, which penetrate the underlying mesenchyme but remain close to the surface (Fig. 16.22A). In the third month, these cords split into isolated cell clusters. Cells in these clusters continue to proliferate and begin to surround each oogonium with a layer of epithelial cells called **follicular cells**. Together, the oogonia and follicular cells constitute a **primordial follicle** (Fig. 16.22B; see Chapter 2, p. 26).

It may thus be stated that the genetic sex of an embryo is determined at the time of fertilization, depending on whether the spermatocyte carries an X or a Y chromosome. In embryos with an

The cortical zone of the ovary contains groups of oogonia surrounded by follicular cells.

XX sex chromosome configuration, medullary cords of the gonad regress, and a secondary generation of cortical cords develops (Figs. 16.21 and 16.22). In embryos with an XY sex chromosome complex, medullary cords develop into testis cords, and secondary cortical cords fail to develop (Figs. 16.20 and 16.21).

Genital Ducts

Indifferent Stage

Initially, both male and female embryos have two pairs of genital ducts: mesonephric (Wolffian) ducts and paramesonephric (Müllerian) ducts. The paramesonephric duct arises as a longitudinal invagination of the epithelium on the anterolateral surface of the urogenital ridge (Fig. 16.23).

Cranially, the duct opens into the abdominal cavity with a funnel-like structure. Caudally, it first runs lateral to the mesonephric duct, then crosses it ventrally to grow caudomedially (Fig. 16.23). In the midline, it comes in close contact with the paramesonephric duct from the opposite side. The caudal tip of the combined ducts projects into the posterior wall of the urogenital sinus, where it causes a small swelling, the sinus tubercle (Fig. 16.24A). The mesonephric ducts open into the urogenital sinus on either side of the sinus tubercle.

Genital Ducts in the Male

Genital ducts in the male are stimulated to develop by testosterone and are derived from parts of the mesonephric kidney system (Fig. 16.25). Some of

FIGURE 16.23 Genital ducts in the sixth week in the male [A] and female [B]. The mesonephric and paramesonephric ducts are present in both. Note the excretory tubules of the mesonephros and their relation to the developing gonad in both sexes.
FIGURE 16.24 A. Genital ducts in the female at the end of the second month. Note the paramesonephric (Müllerian) tubercle and formation of the uterine canal. B. Genital ducts after descent of the ovary. The only parts remaining from the mesonephric system are the epoophoron, paroophoron, and Gartner cyst. Note the suspensory ligament of the ovary, ligament of the ovary proper, and round ligament of the uterus.

FIGURE 16.25 Influence of the sex glands on further sex differentiation.
the original excretory tubules, the epigenital tubules, establish contact with cords of the rete testis and form the efferent ductules of the testis (Fig. 16.26). Excretory tubules along the caudal pole of the testis, the paragenital tubules, do not join the cords of the rete testis (Fig. 16.26). Their vestiges are collectively known as the paradidymis.

Except for the most cranial portion, the appendix epididymis, the mesonephric ducts persist and form the main genital ducts (Fig. 16.26). Immediately below the entrance of the efferent ductules, the mesonephric ducts elongate and become highly convoluted, forming the (ductus) epididymis. From the tail of the epididymis to the outbudding of the seminal vesicle, the mesonephric ducts obtain a thick muscular coat and form the ductus deferens. The region of the ducts beyond the seminal vesicles is the ejaculatory duct. Under the influence of anti-Müllerian hormone (AMH; also called Müllerian inhibiting substance [MIS]) produced by Sertoli cells, paramesonephric ducts in the male degenerate except for a small portion at their cranial ends, the appendix testis (Figs. 16.25 and 16.26B).

**Genital Ducts in the Female**

In the presence of estrogen and the absence of testosterone and AMH (MIS), paramesonephric ducts develop into the main genital ducts of the female (Fig. 16.25). Initially, three parts can be recognized in each duct: (1) a cranial vertical portion that opens into the abdominal cavity, (2) a horizontal part that crosses the mesonephric duct, and (3) a caudal vertical part that fuses with its partner from the opposite side (Fig. 16.24A). With descent of the ovary, the first two parts develop into the uterine tube (Fig. 16.24B), and the caudal parts fuse to form the uterine canal. When the second part of the paramesonephric ducts moves mediocaudally, the urogenital ridges gradually come to lie in a transverse plane (Fig. 16.27A,B). After the ducts fuse in the midline, a broad transverse pelvic fold is established (Fig. 16.27C). This fold, which extends from the lateral sides of the fused paramesonephric ducts toward the wall of the pelvis, is the broad ligament of the uterus. The uterine tube lies in its upper border, and the ovary lies on its posterior surface (Fig. 16.27C). The uterus and broad ligaments divide the pelvic cavity into the uterorectal pouch and the uterovesical pouch. The fused paramesonephric ducts give rise to the corpus and cervix of the uterus and the upper portion of the vagina. The uterus is surrounded by a layer of mesenchyme that forms both its muscular coat, the myometrium, and its peritoneal covering, the perimetrium. In the absence of testosterone, mesonephric ducts in the female degenerate.
**Molecular Regulation of Genital Duct Development**

*SRY* is a transcription factor and the master gene for testes development. It appears to act in conjunction with the *autosomal gene SOX9*, a transcriptional regulator, that can also induce testes differentiation (see Fig. 16.28 for a potential pathway for these genes). SOX9 is known to bind to the promoter region of the gene for AMH (MIS) and probably regulates this gene’s expression. Initially, *SRY* and/or *SOX9* induce the testes to secrete *FGF9* that acts as a chemotactic factor that causes tubules from the mesonephric duct to penetrate the gonadal ridge. Without penetration by these tubules, differentiation of the testes does not continue. Next, *SRY* either directly or indirectly (through *SOX9*) upregulates production of *STEROIDOGENESIS FACTOR 1* (*SFl*) that stimulates differentiation of Sertoli and Leydig cells. *SFl* working with *SOX9* elevates the concentration of AMH leading to regression of the paramesonephric (Müllerian) ducts. In Leydig cells, *SFl* upregulates the genes for enzymes that synthesize testosterone. Testosterone enters cells of target tissues where it may remain intact or be converted to dihydrotestosterone by a 5-α reductase enzyme. Testosterone and dihydrotestosterone bind to a specific high-affinity

![FIGURE 16.28](image-url) Schematic showing genes responsible for differentiation of the testes and ovaries. In both males and females, *SOX9* and *WNT4* are expressed in the gonadal ridges. In males, the expression of *SRY* upregulates *SOX9*, which in turn activates expression of *SFl* and other genes responsible for testes differentiation, while inhibiting expression of *WNT4*. In females, the uninhibited expression of *WNT4* upregulates *DAX1* that in turn inhibits *SOX9* expression. Then, under the continued influence of *WNT4*, other downstream target genes (perhaps *TAFII105*) induce ovarian differentiation.
intracellular receptor, and this hormone receptor complex is transported to the nucleus where it binds to DNA to regulate transcription of tissue-specific genes and their protein products. Testosterone receptor complexes mediate differentiation of the mesonephric ducts to form the vas deferens, seminal vesicles, efferent ductules, and epididymis. Dihydrotestosterone receptor complexes modulate differentiation of the male external genitalia (Fig. 16.25).

WNT4 is the ovary-determining gene. This gene upregulates DAX1, a member of the nuclear hormone receptor family, that inhibits the function of SOX9. In addition, WNT4 regulates expression of other genes responsible for ovarian differentiation, but these target genes have not been identified. One target may be the TAFII105 gene, whose protein product is a subunit for the TATA-binding protein for RNA polymerase in ovarian follicular cells. Female mice that do not synthesize this subunit do not form ovaries.

Estrogens are also involved in sexual differentiation, and under their influence, the paramesonephric (Müllerian) ducts are stimulated to form the uterine tubes, uterus, cervix, and upper vagina. In addition, estrogens act on the external genitalia at the indifferent stage to form the labia majora, labia minora, clitoris, and lower vagina (Fig. 16.25).

**Vagina**

Shortly after the solid tip of the paramesonephric ducts contacts the urogenital sinus (Figs. 16.29A and 16.30A), two solid evaginations grow out from the pelvic part of the sinus (Figs. 16.29B and 16.30B). These evaginations, the sinovaginal bulbs, proliferate and form a solid vaginal plate. Proliferation continues at the cranial end of the plate, increasing the distance between the uterus and the urogenital sinus. By the fifth month, the vaginal outgrowth is entirely canalized. The wing-like expansions of the vagina around the end of the uterus, the vaginal fornices, are of paramesonephric origin (Fig. 16.30C). Thus, the vagina has a dual origin, with the upper portion derived from the uterine canal and the lower portion derived from the urogenital sinus.

The lumen of the vagina remains separated from that of the urogenital sinus by a thin tissue plate, the hymen (Figs. 16.29C and 16.30C), which consists of the epithelial lining of the sinus and a thin layer of vaginal cells. It usually develops a small opening during perinatal life.

The female may retain some remnants of the cranial and caudal excretory tubules in the mesovarium, where they form the epoophoron and paroophoron, respectively (Fig. 16.24B). The mesonephric duct disappears except for a small cranial portion found in the epoophoron and occasionally a small caudal portion that may be found in the wall of the uterus or vagina. Later in life, it may form Gartner cyst (Fig. 16.24B).

---

**Figure 16.29** Formation of the uterus and vagina. **A.** 9 weeks. Note the disappearance of the uterine septum. **B.** At the end of the third month. Note the tissue of the sinovaginal bulbs. **C.** Newborn. The fornices and the upper portion of the vagina are formed by vacuolization of the paramesonephric tissue, and the lower portion of the vagina is formed by vacuolization of the sinovaginal bulbs.
Chapter 16 • Urogenital System

Clinical Correlates

Uterine and Vaginal Defects

Duplications of the uterus result from lack of fusion of the paramepnephric ducts in a local area or throughout their normal line of fusion. In its extreme form, the uterus is entirely double (uterus didelphys) [Fig. 16.31A]; in the least severe form, it is only slightly indented in the middle (uterus arcuatus) [Fig. 16.31B]. One of the relatively common anomalies is the uterus bicornis, in which the uterus has two horns entering a common vagina [Fig. 16.31C]. This condition is normal in many mammals below the primates.

In patients with complete or partial atresia of one of the paramepnephric ducts, the rudimentary part lies as an appendage to the well-developed side. Because its lumen usually does not communicate with the vagina, complications are common [uterus bicornis unicollis with one rudimentary horn] (Fig. 16.31D). If the atresia involves both sides, an atresia of the cervix may result [Fig. 16.31E]. If the sinovaginal bulbs fail to fuse or do not develop at all, a double vagina or atresia of the vagina, respectively, results [Fig. 16.31F]. In the latter case, a small vaginal pouch originating from the paramepnephric ducts usually surrounds the opening of the cervix.

FIGURE 16.31 Main abnormalities of the uterus and vagina, caused by persistence of the uterine septum or obliteration of the lumen of the uterine canal.
External Genitalia

Indifferent Stage

In the third week of development, mesenchyme cells originating in the region of the primitive streak migrate around the cloacal membrane to form a pair of slightly elevated cloacal folds (Fig. 16.32A). Cranial to the cloacal membrane, the folds unite to form the genital tubercle. Caudally, the folds are subdivided into urethral folds anteriorly and anal folds posteriorly (Fig. 16.32B).

In the meantime, another pair of elevations, the genital swellings, becomes visible on each side of the urethral folds. These swellings later form the scrotal swellings in the male (Fig. 16.33A) and the labia majora in the female (Fig. 16.35B). At the end of the sixth week, however, it is impossible to distinguish between the two sexes.

External Genitalia in the Male

Development of the external genitalia in the male is under the influence of androgens secreted by the fetal testes and is characterized by rapid elongation of the genital tubercle, which is now called the phallus (Figs. 16.33A). During this elongation, the phallus pulls the urethral folds forward so that they form the lateral walls of the urethral groove. This groove extends along the caudal aspect of the elongated phallus but does not reach the most distal part, the glans. The epithelial lining of the groove, which originates in the endoderm, forms the urethral plate (Fig. 16.33B).

At the end of the third month, the two urethral folds close over the urethral plate, forming the penile urethra (Figs. 16.33B). This canal does not extend to the tip of the phallus. This most
distal portion of the urethra is formed during the fourth month, when ectodermal cells from the tip of the glans penetrate inward and form a short epithelial cord. This cord later obtains a lumen, thus forming the external urethral meatus (Fig. 16.33C).

The genital swellings, known in the male as the scrotal swellings, arise in the inguinal region. With further development, they move caudally, and each swelling then makes up half of the scrotum. The two are separated by the scrotal septum (Figs. 16.33D).

**Clinical Correlates**

**Defects in the Male Genitalia**

In hypospadias, fusion of the urethral folds is incomplete, and abnormal openings of the urethra occur along the inferior aspect of the penis, usually near the glans, along the shaft, or near the base of the penis [Fig. 16.34]. In rare cases, the urethral meatus extends along the scrotal raphe. When fusion of the urethral folds fails entirely, a wide sagittal slit is found along the entire length of the penis.
and the scrotum. The two scrotal swellings then closely resemble the labia majora. The incidence of hypospadias is 3–5/1,000 births, and this rate represents a doubling over the past 15 to 20 years. Reasons for the increase are not known, but one hypothesis suggests it could be a result of a rise in environmental estrogens (endocrine disruptors; see Chapter 9).

Epispadias is a rare abnormality [1/30,000 births] in which the urethral meatus is found on the dorsum of the penis [Fig. 16.34D]. Although epispadias may occur as an isolated defect, it is most often associated with exstrophy of the bladder and abnormal closure of the ventral body wall [Fig. 16.16].

Micropenis occurs when there is insufficient androgen stimulation for growth of the external genitalia. Micropenis is usually caused by primary hypogonadism or hypothalamic or pituitary dysfunction. By definition, the penis is 2.5 standard deviations below the mean in length as measured along the dorsal surface from the pubis to the tip with the penis stretched to resistance. Bifid penis or double penis may occur if the genital tubercle splits.

External Genitalia in the Female
Estrogens stimulate development of the external genitalia of the female. The genital tubercle elongates only slightly and forms the clitoris (Fig. 16.35A); urethral folds do not fuse, as in the male, but develop into the labia minora. Genital swellings enlarge and form the labia majora. The urogenital groove is open and forms the vestibule (Fig. 16.35B). Although the genital tubercle does not elongate extensively in the female, it is larger than in the male during the early stages of development. In fact, using tubercle length as a criterion (as monitored by ultrasound) has resulted in mistakes in identification of the sexes during the third and fourth months of gestation.

Descent of the Testes
The testes develop retroperitoneally in the abdominal region and must move caudally and pass through the abdominal wall to reach the scrotum. Passage through the abdominal wall is via the inguinal canal, which is about 4 cm long and lies just superiorly to the medial half of the inguinal ligament. Entry to the canal is by the deep (internal) inguinal ring, and exit is by the superficial (external) ring near the pubic tubercle.

Toward the end of the second month, the urogenital mesentery attaches the testis and mesonephros to the posterior abdominal wall (Fig. 16.3A). With degeneration of the mesonephros, the attachment serves as a mesentery for the gonad (Fig. 16.27B). Caudally, it becomes ligamentous and is known as the caudal genital ligament. Also extending from the caudal pole of the testis is a mesenchymal condensation rich in extracellular matrices, the gubernaculum (Fig. 16.37). Prior to descent of the testis, this band of mesenchyme terminates in the inguinal region between the differentiating internal and external abdominal oblique muscles. Later, as the testis begins to descend toward the internal

FIGURE 16.35  Development of the external genitalia in the female at 5 months [A] and in the newborn [B].
Disorders of Sexual Development

Because sexual development of males and females begins in an identical fashion, it is not surprising that abnormalities in differentiation and sex determination occur. **Ambiguous genitalia** [Fig. 16.36] may appear as a large clitoris or a small penis. Thus, a child may be born with a typically female appearance, but with a large clitoris (clitoral hypertrophy) or typically male with a small penis that is open on its ventral surface [hypospadias]. In some cases, these abnormalities result in individuals with characteristics of both sexes, and they may be called hermaphrodites. However, true hermaphrodites have both male and female gonadal tissues, and such individuals have not been described in humans. Instead, these individuals have ovotestes that have both testicular and ovarian tissue. They may be typically female or typically male or in between in terms of genital development. In 70% of cases, the karyotype is 46,XX, and there is usually a uterus. External genitalia are ambiguous or predominantly female, and most of these individuals are raised as females.

Sometimes, the genotypic [chromosomal] sex does not match the phenotype [physical appearance]. For example, the most common cause of sexual ambiguity is **congenital adrenal hyperplasia (CAH)**. Biochemical abnormalities in the adrenal glands result in decreased steroid hormone production and an increase in adrenocorticotropic hormone (ACTH). In most cases, 21-hydroxylase is inhibited. Females with this condition can have a range of sexual characteristics varying from partial masculinization with a large clitoris to virilization and a male appearance. In a rarer form of CAH, there is a 17α-hydroxylase deficiency resulting in females having female internal and external anatomy at birth but failure of secondary sex characteristics to appear at puberty due to an inability of the adrenals or ovaries to produce sex hormones. Consequently, there is no breast development or growth of pubic hair. In males with 17α-hydroxylase deficiency, virilization is inhibited.

Another cause of sexual ambiguity is the **androgen insensitivity syndrome (AIS)**. Individuals with AIS are males [have a Y chromosome and testes], but there is a lack of androgen receptors or failure of tissues to respond to receptor-dihydrotestosterone complexes. Consequently, androgens produced by the testes are ineffective in inducing differentiation of male genitalia. Because these patients have testes and MIS is present, the paramesonephric system is suppressed, and uterine tubes and uterus are absent. In patients with **complete androgen insensitivity syndrome (CAIS)**, a vagina is present but usually short or poorly developed. The testes are frequently found in the inguinal or labial regions, but spermatogenesis does not occur. Furthermore, there is an increased risk of testicular tumors, and 33% of these individuals develop malignancies prior to age 50 years. Other patients have **mild androgen insensitivity syndrome (MAIS)** or **partial androgen insensitivity syndrome (PAIS)** forms of the disorder. With the mild form, there is virilization to varying degrees, but with the partial form, ambiguous genitalia may be present, including clitoromegaly or a small penis with hypospadias. Testes are usually undescended in these cases.

5α-Reductase deficiency (5-ARD) is another condition that causes ambiguous genitalia in males and is due to an inability to convert testosterone to dihydrotestosterone because of a lack of the reductase enzyme. Without dihydrotestosterone, external genitalia do not develop normally and may appear male but be underdeveloped with hypospadias, or they may appear to be female with clitoromegaly.

Other conditions may be associated with abnormal sexual differentiation. For example, **Klinefelter syndrome**, with a karyotype of

![FIGURE 16.36 Male [46,XY] infant with ambiguous genitalia. Note partial fusion of the scrotal swellings and a small penis with hypospadias.](image-url)
47,XXY (or other variants, e.g., XXXY), is the most common sex chromosome disorder, occurring with a frequency of 1 per 1,000 males. Patients may have decreased fertility, small testes, and decreased testosterone levels. Gynecomastia (enlarged breasts) is present in approximately 33% of affected individuals. Nondisjunction of the XX homologues is the most common causative factor.

In gonadal dysgenesis, oocytes are absent, and the ovaries appear as streak gonads. Individuals are phenotypically female but may have a variety of chromosomal complements, including XY. **XY female gonadal dysgenesis (Swyer syndrome)** results from point mutations or deletions of the SRY gene. Individuals appear to be normal females but do not menstruate and do not develop secondary sexual characteristics at puberty. Patients with Turner syndrome also have gonadal dysgenesis. They have a 45,X karyotype and short stature, high-arched palate, webbed neck, shield-like chest, cardiac and renal anomalies, and inverted nipples (see Chapter 2, p. 21).

Inguinal ring, an extra-abdominal portion of the gubernaculum forms and grows from the inguinal region toward the scrotal swellings. When the testis passes through the inguinal canal, this extra-abdominal portion contacts the scrotal floor (the gubernaculum forms in females also, but in normal cases, it remains rudimentary).

Factors controlling descent of the testis are not entirely clear. It appears, however, that outgrowth of the extra-abdominal portion of the gubernaculum produces intra-abdominal migration, that an increase in intra-abdominal pressure due to organ growth produces passage through the inguinal canal, and that regression of the extra-abdominal portion of the gubernaculum completes movement of the testis into the scrotum. Normally, the testes reach the inguinal region by approximately 12 weeks’ gestation, migrate through the inguinal canal by 28 weeks, and reach the scrotum by 33 weeks (Fig. 16.37). The process is influenced by hormones, including androgens and MIS. During descent, blood supply to the testis from the aorta is retained, and testicular vessels extend from their original lumbar position to the testis in the scrotum.

**FIGURE 16.37** Descent of the testis. A. During the second month. B. In the middle of the third month. Peritoneum lining the body cavity evaginates into the scrotal swelling, where it forms the vaginal process (tunica vaginalis). C. In the seventh month. D. Shortly after birth.
Independently from descent of the testis, the peritoneum of the abdominal cavity forms an evagination on each side of the midline into the ventral abdominal wall. This evagination, the processus vaginalis, follows the course of the gubernaculum testis into the scrotal swellings (Fig. 16.37B). Hence, the processus vaginalis, accompanied by the muscular and fascial layers of the body wall, evaginates into the scrotal swelling, forming the **inguinal canal** (Fig. 16.38).

The testis descends through the inguinal ring and over the rim of the pubic bone and is present in the scrotum at birth. The testis is then covered by a reflected fold of the processus vaginalis (Fig. 16.37D). The peritoneal layer covering the testis is the **visceral layer of the tunica vaginalis**; the remainder of the peritoneal sac forms the **parietal layer of the tunica vaginalis** (Fig. 16.37D). The narrow canal connecting the lumen of the vaginal process with the peritoneal cavity is obliterated at birth or shortly thereafter.

In addition to being covered by peritoneal layers derived from the processus vaginalis, the testis becomes ensheathed in layers derived from the anterior abdominal wall through which it passes. Thus, the **transversalis fascia** forms the **internal spermatic fascia**, the **internal abdominal oblique muscle** gives rise to the **cremasteric fascia and muscle**, and the **external abdominal oblique muscle** forms the **external spermatic fascia** (Fig. 16.38). The transversus abdominis muscle does not contribute a layer because it arches over this region and does not cover the path of migration.

[Hernias and Cryptorchidism](#)

The connection between the abdominal cavity and the processus vaginalis through the inguinal canal and into the scrotal sac normally closes in the first year after birth (Fig. 16.37D). If this passageway remains open, intestinal loops may descend into the scrotum, causing a **congenital indirect inguinal hernia** (Fig. 16.39A). Sometimes, obliteration of this passageway is irregular, leaving small cysts along its course. Later, these cysts may secrete fluid, forming a **hydrocele of the testis and/or spermatic cord** (Fig. 16.39B).

In 97% of male newborns, testes are present in the scrotum before birth. In most

---

**FIGURE 16.38** Drawing showing the coverings of the testes that are derived from constituents of the abdominal wall. These coverings are formed as the testes migrate through the wall in route from their retroperitoneal location in the abdominal cavity to the scrotum.
of the remainder, descent will be completed during the first 3 months postnatally. However, in <1% of infants, one or both testes fail to descend. The condition is called cryptorchidism and may be caused by decreased androgen (testosterone) production. The undescended testes fail to produce mature spermatozoa, and the condition is associated with a 3% to 5% incidence of renal anomalies.

**Descent of the Ovaries**

Descent of the gonads is considerably less in the female than in the male, and the ovaries finally settle just below the rim of the true pelvis. The cranial genital ligament forms the suspensory ligament of the ovary, whereas the caudal genital ligament forms the ligament of the ovary proper and the round ligament of the uterus (Fig. 16.24). The latter extends into the labia majora.

**SUMMARY**

The urinary and genital systems both develop from mesodermal tissue. Three urinary systems develop in a temporal sequence from cranial to caudal segments:

The **pronephros**, which forms in the cervical region, is vestigial.

The **mesonephros**, which forms in the thoracic and lumbar regions, is large and is characterized by excretory units (nephrons) and its own collecting duct, the mesonephric or Wolffian duct. In the human, it may function briefly, but most of the system disappears. Ducts and tubules from the mesonephros form the conduit for sperm from the testes to the urethra. In the female, these ducts regress.

The **metanephros**, or permanent kidney, develops from two sources. It forms its own excretory tubules or nephrons like the mesonephros, but its collecting system originates from the **ureteric bud**, an outgrowth of the mesonephric duct. This bud gives rise to the **ureter**, **renal pelvis**, **calyces**, and the entire **collecting system** (Fig. 16.5). Connection between the collecting and excretory tubule systems is essential for normal development (Fig. 16.6). **WT1**, expressed by the mesenchyme, makes this tissue competent to respond to induction by the ureteric bud. Interactions between the bud and mesenchyme occur through production of GDNF and HGF by the mesenchyme with their tyrosine kinase receptors RET and MET, respectively, produced by the ureteric epithelium. **PAX2** and **WNT4**, produced by metanephric mesenchyme, cause epithelialization and excretory tubule differentiation (Fig. 16.7).

Early division of the ureteric bud may lead to bifid or supernumerary kidneys with **ectopic ureters** (Fig. 16.9). Because the kidneys develop in the pelvic region and then “ascend” to their location in the lumbar area, abnormal positions of the kidney, such as **pelvic** and **horseshoe kidney**, occur (Fig. 16.11).

The **bladder** forms during the 4th to 7th weeks as the **cloaca**, the common repository for the primitive kidneys and gut system, is subdivided into the **urogenital sinus** anteriorly and the **anal canal** posteriorly by the **urorectal septum** (Fig. 16.12). The anterior portion of this sinus then differentiates into the bladder. The remaining portion of the sinus differentiates into the **prostatic** and **membranous** parts of the **urethra** in the male and the urethra in the female (Fig. 16.13).
The **genital system** consists of (1) gonads or primitive sex glands, (2) genital ducts, and (3) external genitalia. All three components go through an **indifferent stage** in which they may develop into either a male or a female. The **SRY gene** on the Y chromosome produces **testes-determining factor** and regulates male sexual development. Genes downstream from SRY include **SOX9** and **SFl** that stimulate differentiation of **Sertoli** and **Leydig cells** in the testes. Expression of the SRY gene causes (1) development of the **medullary (testis) cords**, (2) formation of the **tunica albuginea**, and (3) **failure of the cortical (ovarian) cords to develop**.

Ovarian development occurs in the absence of the SRY gene and in the presence of **WNT4**, the master gene for this differentiation process. WNT4 upregulates **DAX1** that inhibits the expression of SOX9, and then, WNT4, together with other downstream genes, causes **formation of ovaries** with (1) **typical cortical cords**, (2) **disappearance of the medullary (testis) cords**, and (3) **failure of the tunica albuginea to develop** (Fig. 16.21). Development of both testes and ovaries is dependent upon induction by **primordial germ cells** that migrate from the yolk sac to the genital ridges during the 4th to 6th weeks. If these cells fail to reach the indifferent gonad, the gonad remains indifferent or is absent.

The indifferent duct system and external genitalia develop under the influence of hormones. During the **indifferent stage**, there are two duct systems: the **mesonephric duct** and **paramesonephric duct**. **Testosterone**, produced by **Leydig cells** in the testes, stimulates development of the mesonephric ducts to form the **efferent ducts, epididymis, vas deferens**, and **ejaculatory duct**. **Müllerian inhibiting substance** (MIS; also called, **antimüllerian hormone** [AMH]), produced by **Sertoli cells** in the testes, causes regression of the paramesonephric ducts. **Dihydrotestosterone** stimulates development of the external genitalia, including the **penis and scrotum** (Fig. 16.25). **Estrogens** (together with the absence of testosterone) regulate development of the paramesonephric ducts, which form the **uterine tube, uterus, cervix**, and **upper portion of the vagina**. Because there is no testosterone production to stimulate development of the mesonephric ducts, these structures regress. Estrogens also stimulate differentiation of the external genitalia, including the **clitoris, labia, and lower portion of the vagina** (Fig. 16.25). Errors in production of or sensitivity to hormones of the testes lead to a predominance of female characteristics under influence of the maternal and placental estrogens.

External genitalia also begin in an indifferent stage. Initially, a **genital tubercle**, two **genital swellings**, and two **cloacal folds** form on the exterior of the floor of the pelvis. When the urorectal septum reaches the interior of this floor to separate the anal canal from the primitive urogenital sinus (soon to form the bladder), the cloacal folds are now called the **urethral folds** (Fig. 16.32). In the male, the genital tubercle grows and is called the **phallus**. As it grows, it pulls the urethral folds together and these fuse forming the shaft of the penis. Meanwhile, the genital swellings become larger to form the **scrotal swellings**, and these also come together and fuse in the midline. In females, the genital tubercle forms the **clitoris**, the urethral folds the **labia minora**, and the genital swellings the **labia majora**. Note that in the female there is a lack of fusion of the primordial structures. Also note the **analogous structures** in the two sexes: penis=clitoris and scrotum=labia majora.

### Problems to Solve

1. **During development of the urinary system, three systems form. What are they, and what parts of each, if any, remain in the newborn?**
2. **At birth, an apparently male baby has no testicles in the scrotum. Later, it is determined that both are in the abdominal cavity. What is the term given to this condition? Explain the embryological origin of this defect.**
3. **It is said that male and female external genitalia have homologies. What are they, and what are their embryological origins?**
4. **After several years of trying to become pregnant, a young woman seeks consultation. Examination reveals a bicorneate uterus. How could such an abnormality occur?**
mesenchyme for formation of the head region is derived from paraxial and lateral plate mesoderm, neural crest, and thickened regions of ectoderm known as ectodermal placodes. Paraxial mesoderm (somites and somitomeres) forms a large portion of the membranous and cartilaginous components of the neurocranium (skull) (Fig. 17.1; see also Chapter 10 and Fig. 10.6), all voluntary muscles of the craniofacial region (see Table 17.1, p. 279), the dermis and connective tissues in the dorsal region of the head, and the meninges caudal to the prosencephalon. Lateral plate mesoderm forms the laryngeal cartilages (arytenoid and cricoid) and connective tissue in this region. Neural crest cells originate in the neuroectoderm of forebrain, midbrain, and hindbrain regions and migrate ventrally into the pharyngeal arches and rostrally around the forebrain and optic cup into the facial region (Fig. 17.2). In these locations, they form the entire viscerocranium (face) and parts of the membranous and cartilaginous regions of the neurocranium (skull) (Fig. 17.1; see also Chapter 10 and Fig. 10.6). They also form all other tissues in these regions, including cartilage, bone, dentin, tendon, dermis, pia and arachnoid, sensory neurons, and glandular connective tissue. Cells from ectodermal placodes (epipharyngeal placodes), together with neural crest, form neurons of the 5th, 7th, 9th, and 10th cranial sensory ganglia (Fig. 17.2).

The most distinctive feature in development of the head and neck is the presence of pharyngeal arches (the old term for these structures is branchial arches because they somewhat resemble the gills [branchia] of a fish). These arches...

appear in the fourth and fifth weeks of development and contribute to the characteristic external appearance of the embryo (Table 17.1 and Fig. 17.3). Initially, they consist of bars of mesenchymal tissue separated by deep clefts known as pharyngeal clefts (Fig. 17.3C; see also Fig. 17.6). Simultaneously, with development of the arches and clefts, a number of outpocketings, the pharyngeal pouches, appear along the lateral walls of the pharynx, the most cranial part of the foregut (Fig. 17.4; see also Fig. 17.6). The pouches penetrate the surrounding mesenchyme but do not establish an open communication with the external clefts (Fig. 17.6). Hence, although development of pharyngeal arches, clefts, and pouches resemble formation of gills.
in fishes and amphibians, in the human embryo, real gills are never formed. Therefore, the term pharyngeal (arches, clefts, and pouches) has been adopted for the human embryo.

Pharyngeal arches not only contribute to formation of the neck but also play an important role in formation of the face. At the end of the fourth week, the center of the face is formed by the stomodeum, surrounded by the first pair of pharyngeal arches (Fig. 17.5). When the embryo is 42 days old, five mesenchymal prominences can be recognized: the mandibular prominences (first pharyngeal arch), caudal to the stomodeum; the maxillary prominences (dorsal portion of the first pharyngeal arch), lateral to the stomodeum; and the frontonasal prominence, a slightly rounded elevation cranial to the stomodeum. Development of the face is later complemented by formation of the nasal prominences (Fig. 17.5). In all cases, differentiation of structures derived from arches, pouches, clefts, and prominences is dependent on epithelial-mesenchymal interactions.

**PHARYNGEAL ARCHES**

Each pharyngeal arch consists of a core of mesenchymal tissue covered on the outside by surface ectoderm and on the inside by epithelium of endodermal origin (Fig. 17.6). In addition to mesenchyme derived from paraxial and lateral plate mesoderm, the core of each arch receives substantial numbers of neural crest cells, which migrate into the arches to contribute to skeletal components of the face. The original mesoderm of the arches gives rise to the musculature of the face and neck. Thus, each pharyngeal arch is characterized by its own muscular components. The muscular components of each arch have their own cranial nerve, and wherever the muscle cells migrate, they carry their nerve component with them (Figs. 17.6 and 17.7). In addition, each arch has its own arterial component (Figs. 17.4 and 17.6). (Derivatives of the pharyngeal arches and their nerve supply are summarized in Table 17.1.)

**First Pharyngeal Arch**

The first pharyngeal arch consists of a dorsal portion, the maxillary process, which extends forward beneath the region of the eye, and a ventral portion, the mandibular process, which contains Meckel’s cartilage (Figs. 17.5 and 17.8A). During further development, Meckel’s cartilage disappears except for two small portions at its dorsal end that persist and form the incus and malleus (Figs. 17.8B and 17.9). Mesenchyme of the maxillary process gives rise to the premaxilla, maxilla, zygomatic bone, and part of the temporal bone through membranous ossification (Fig. 17.8B). The mandible is also formed by membranous ossification of mesenchymal tissue surrounding Meckel’s cartilage. In addition, the first arch contributes to formation of the bones of the middle ear (see Chapter 19).
Musculature of the first pharyngeal arch includes the muscles of mastication (temporalis, masseter, and pterygoids), anterior belly of the digastric, mylohyoid, tensor tympani, and tensor palatini. The nerve supply to the muscles of the first arch is provided by the mandibular branch of the trigeminal nerve (Fig. 17.7). Because mesenchyme from the first arch also contributes to the dermis of the face, sensory supply to the skin of the face is provided by ophthalmic, maxillary, and mandibular branches of the trigeminal nerve.

Muscles of the arches do not always attach to the bony or cartilaginous components of their own arch but sometimes migrate into surrounding regions. Nevertheless, the origin of these muscles can always be traced because their nerve supply is derived from the arch of origin.

**Second Pharyngeal Arch**

The cartilage of the second or hyoid arch (Reichert’s cartilage) (Fig. 17.8B) gives rise to the stapes, styloid process of the temporal bone, stylohyoid ligament, and ventrally, the lesser horn and upper part of the body of the hyoid bone (Fig. 17.9). Muscles of the hyoid arch are the stapedius, stylohyoid, posterior belly of the digastric, auricular, and muscles of facial expression. The facial nerve, the nerve of the second arch, supplies all of these muscles.

Frontal view of an embryo at approximately 30 days showing rupture of the oropharyngeal membrane and formation of the nasal placodes on the frontonasal prominence. C. Photograph of a human embryo at a stage [28 days] similar to that shown in (B).
Part II • Systems-Based Embryology

FIGURE 17.6 Drawing shows the pharyngeal arches cut in cross section. Each arch consists of a mesenchymal core derived from mesoderm and neural crest cells and each is lined internally by endoderm and externally by ectoderm. Each arch also contains an artery [one of the aortic arches] and a cranial nerve and each will contribute specific skeletal and muscular components to the head and neck. Between the arches are pouches on the inner surface and clefts externally.

FIGURE 17.7 Each pharyngeal arch is supplied by its own cranial nerve. The trigeminal nerve supplying the first pharyngeal arch has three branches: the ophthalmic, maxillary, and mandibular. The nerve of the second arch is the facial nerve; that of the third is the glossopharyngeal nerve. The musculature of the fourth arch is supplied by the superior laryngeal branch of the vagus nerve, and that of the sixth arch, by the recurrent branch of the vagus nerve.
Third Pharyngeal Arch

The cartilage of the third pharyngeal arch produces the lower part of the body and greater horn of the hyoid bone (Fig. 17.9). The musculature is limited to the stylopharyngeus muscles. These muscles are innervated by the glossopharyngeal nerve, the nerve of the third arch (Fig. 17.7).

Fourth and Sixth Pharyngeal Arches

Cartilaginous components of the fourth and sixth pharyngeal arches fuse to form the thyroid, cricoid, arytenoid, corniculate, and cuneiform cartilages of the larynx (Fig. 17.9). Muscles of the fourth arch (cricothyroid, levator palatini, and constrictors of the pharynx) are innervated by...
the superior laryngeal branch of the vagus, the nerve of the fourth arch. Intrinsic muscles of the larynx are supplied by the recurrent laryngeal branch of the vagus, the nerve of the sixth arch.

**PHARYNGEAL POUCHES**

The human embryo has four pairs of pharyngeal pouches; the fifth is rudimentary (Figs. 17.6 and 17.10). Because the epithelial endodermal lining of the pouches gives rise to a number of important organs, the fate of each pouch is discussed separately. Derivatives of the pharyngeal pouches are summarized in Table 17.2, p. 285.

**First Pharyngeal Pouch**

The first pharyngeal pouch forms a stalk-like diverticulum, the tubotympanic recess, which comes in contact with the epithelial lining of the first pharyngeal cleft, the future external auditory meatus. Foramen cecum

**FIGURE 17.10** A. Development of the pharyngeal clefts and pouches. The second arch grows over the third and fourth arches, burying the second, third, and fourth pharyngeal clefts. B. Remnants of the second, third, and fourth pharyngeal clefts form the cervical sinus, which is normally obliterated. Note the structures formed by the various pharyngeal pouches.
TABLE 17.2 Derivatives of the Pharyngeal Pouches

</tr>
</tbody>
</table>

The distal portion of the diverticulum widens into a sac-like structure, the **primitive tympanic or middle ear cavity**, and the proximal part remains narrow, forming the **auditory (eustachian) tube**. The lining of the tympanic cavity later aids in formation of the **tympanic membrane** or **eardrum** (see Chapter 19).

**Second Pharyngeal Pouch**

The epithelial lining of the second pharyngeal pouch proliferates and forms buds that penetrate into the surrounding mesenchyme. The buds are secondarily invaded by mesodermal tissue, forming the primordium of the **palatine tonsils** (Fig. 17.10). During the third and fifth months, the tonsil is infiltrated by lymphatic tissue. Part of the pouch remains and is found in the adult as the **tonsillar fossa**.

**Third Pharyngeal Pouch**

The third and fourth pouches are characterized at their distal extremity by a dorsal and a ventral wing (Fig. 17.10). In the fifth week, epithelium of the dorsal region of the third pouch differentiates into the **inferior parathyroid gland**, whereas the ventral region forms the **thymus** (Fig. 17.10). Both gland primordia lose their connection with the pharyngeal wall, and the thymus then migrates in a caudal and a medial direction, pulling the **inferior parathyroid** with it (Fig. 17.11). Although the main portion of the thymus moves rapidly to its final position in the anterior part of the thorax, where it fuses with its counterpart from the opposite side, its tail portion sometimes persists either embedded in the thyroid gland or as isolated thymic nests.

Growth and development of the thymus continue until puberty. In the young child, the thymus occupies considerable space in the thorax and lies behind the sternum and anterior to the pericardium and great vessels. In older persons, it is difficult to recognize because it is atrophied and replaced by fatty tissue.

The parathyroid tissue of the third pouch finally comes to rest on the dorsal surface of the thyroid gland and forms the **inferior parathyroid gland** (Fig. 17.11).
Fourth Pharyngeal Pouch

Epithelium of the dorsal region of the fourth pharyngeal pouch forms the **superior parathyroid gland**. When the parathyroid gland loses contact with the wall of the pharynx, it attaches itself to the dorsal surface of the caudally migrating thyroid as the **superior parathyroid gland** (Fig. 17.11). The ventral region of the fourth pouch gives rise to the **ultimobranchial body**, which is later incorporated into the thyroid gland. Cells of the ultimobranchial body give rise to the **parafollicular, or C, cells** of the thyroid gland. These cells secrete **calcitonin**, a hormone involved in regulation of the calcium level in the blood (Table 17.2).

**PHARYNGEAL CLEFTS**

The 5-week embryo is characterized by the presence of four pharyngeal clefts (Fig. 17.6), of which only one contributes to the definitive structure of the embryo. The dorsal part of the first cleft penetrates the underlying mesenchyme and gives rise to the **external auditory meatus** (Figs. 17.10 and 17.11). The epithelial lining at the bottom of the meatus participates in formation of the **eardrum** (see Chapter 19).

Active proliferation of mesenchymal tissue in the second arch causes it to overlap the third and fourth arches. Finally, it merges with the **epicardial ridge** in the lower part of the neck (Fig. 17.10), and the second, third, and fourth clefts lose contact with the outside (Fig. 17.10B). The clefts form a cavity lined with ectodermal epithelium, the **cervical sinus**, but with further development, this sinus disappears.

**MOLECULAR REGULATION OF FACIAL DEVELOPMENT**

Neural crest cells arise from neuroepithelial cells adjacent to the surface ectoderm all along the edges of the neural folds. Bone morphogenetic protein (BMP) signaling is important in establishing this edge region and then regulates **WNT1** expression to cause prospective crest cells to undergo an epithelial-to-mesenchymal transition and begin their migration into the surrounding mesenchyme (see Chapter 6, p. 75). In the hindbrain, crest cells originate in a specific pattern from segments called **rhombomeres** (Fig. 17.12). There are eight of these segments in the hindbrain (R1–R8), and neural crest cells

![FIGURE 17.12](image_url)

**FIGURE 17.12** Drawing showing the pathways of neural crest cell migration from the cranial neural folds into the face and pharyngeal arches. From the hindbrain region, crest cells migrate from segments called rhombomeres. Rhombomeres express a specific pattern of HOX genes [the midbrain and rhombomeres 1 and 2 express the homeodomain-containing transcription factor OTX2; see also Fig. 18.31], and neural crest cells carry these expression patterns into the pharyngeal arches. Also, notice that there are three streams of crest cells and that rhombomeres 3 and 5 do not contribute many [if any] cells to these streams. The three streams are important because they provide guidance cues for cranial nerves growing back from their ganglia to establish connections in the hindbrain [see also Fig. 18.40].
from specific segments migrate to populate specific pharyngeal arches. These crest cells migrate in three streams: Those from R1 and R2 migrate to the first arch along with crest cells from the caudal midbrain region; crest from R4 migrate to the second arch; and cells from R6 and R7 migrate to arches 4 to 6 (Fig. 17.12). Segregation of the three streams is assisted by the fact that very few crest cells form from R3 and R5 segments and those that do enter adjoining streams of cells to migrate. Three distinct streams are important because they provide axonal guidance cues for axons from ganglia forming in the head and neck region, including the trigeminal, geniculate, vestibuloacoustic, petrosal, and nodose ganglia. These ganglia are formed from a combination of crest cells and cells from placodes in this region (see Chapter 18). Axons from the trigeminal ganglion enter the hindbrain at R2; those from the geniculate and vestibuloacoustic at R4; and those from the petrosal and nodose at R6 and R7, thus accounting for three streams of crest cells. No axons project to R3 or R5.

Neural crest cells that populate the pharyngeal arches form the skeletal components characteristic of each arch. Previously, it was thought that neural crest cells regulated patterning of these skeletal elements, but now, it is clear that this process is controlled by pharyngeal pouch endoderm. Formation of the pharyngeal pouches occurs prior to neural crest migration and takes place even in the absence of crest cells. Pouches are formed by migration of endoderm cells laterally, and this migration is stimulated by fibroblast growth factors (FGFs). As pouches form, they express a very characteristic pattern of genes (Fig. 17.13). BMP7 is expressed in the posterior endoderm of each pouch; FGF8 lies in the anterior endoderm; and PAX1 expression is restricted to the dorsalmost endoderm of

![Figure 17.13](image)

**FIGURE 17.13 A,B.** Drawings showing the gene expression patterns in pharyngeal arch endoderm and mesenchyme. Endoderm is responsible for patterning the skeletal derivatives of the arches, but the response of the mesenchyme to these signals is dictated by the genes that the mesenchyme expresses. Gene expression in the endoderm of the pouches shows a specific pattern: Fibroblast growth factor 8 (FGF8) is expressed in the anterior region of each pouch with bone morphogenetic protein 7 (BMP7) expressed in the posterior region; sonic hedgehog (SHH) is expressed in the posterior region of pouches 2 and 3, whereas PAX1 is expressed in the dorsalmost area of each pouch [A,B]. Mesenchymal expression patterns are established by neural crest cells that migrate into the arches and carry the genetic code from their rhombomeres of origin [or also from the midbrain in the case of the first arch] to the arches [B] [see also Figs. 17.12 and 18.31].
each pouch. In addition, SONIC HEDGEHOG (SHH) is expressed in the posterior endoderm of the second and third pouches. These expression patterns then regulate differentiation and patterning of pharyngeal arch mesenchyme into specific skeletal structures. This process, however, is also dependent on the mesenchyme and represents another example of an epithelial-mesenchymal interaction. In this case, the response of the mesenchyme to endodermal signals is dependent on transcription factors expressed in that mesenchyme. These transcription factors include HOX genes and others carried by neural crest cells into the arches. Crest cells acquire their specific gene expression patterns from the rhombomeres of their origin (Fig. 17.12). The pattern of rhombomeres itself is established by a nested code of patterns from the rhombomeres of origin expressed in that mesenchyme. These transcription factors allow each arch to respond differently to signals emanating from pouch endoderm, such that the first arch forms the maxilla and mandible, the second arch, the hyoid bone, etc.

The remainder of the skeleton of the face, the mid and upper facial regions, also is derived from neural crest cells that migrate into the frontonasal prominence (Fig. 17.12). In this region, signals emanating from the surface ectoderm and the underlying areas of the neuroepithelium dictate the fate of the mesenchyme. Again, it appears that SHH and FGF8 play major roles in patterning this area, but the specific genetic interactions are not known.

**Clinical Correlates**

**Birth Defects Involving the Pharyngeal Region**

**Ectopic Thymic and Parathyroid Tissue**

Because glandular tissue derived from the pouches undergoes migration, it is not unusual for accessory glands or remnants of tissue to persist along the pathway. This is true particularly for thymic tissue, which may remain in the neck, and for the parathyroid glands. The inferior parathyroids are more variable in position than the superior ones and are sometimes found at the bifurcation of the common carotid artery.

**Branchial Fistulas**

Branchial fistulas occur when the second pharyngeal arch fails to grow caudally over the third and fourth arches, leaving remnants of the second, third, and fourth clefts in contact with the surface by a narrow canal [Fig. 17.14A]. Such a fistula, found on the lateral aspect of the neck directly anterior to the sternocleidomastoid muscle, usually provides drainage for a lateral cervical cyst [Fig. 17.14B]. These cysts, remnants of the cervical sinus, are most often just below the angle of the jaw [Fig. 17.15], although they may be found anywhere along the anterior border of the sternocleidomastoid muscle. Frequently, a lateral cervical cyst is not visible at birth but becomes evident as it enlarges during childhood.

**Internal branchial fistulas** are rare; they occur when the cervical sinus is connected to the lumen of the pharynx by a small canal, which usually opens in the tonsillar region [Fig. 17.14C]. Such a fistula results from a rupture of the membrane between the second pharyngeal cleft and pouch at some time during development.

**Neural Crest Cells and Craniofacial Defects**

**Neural crest cells** [Fig. 17.2] are essential for formation of much of the craniofacial region. Consequently, disruption of crest cell development results in craniofacial malformations. Because neural crest cells also contribute to the conotruncal endocardial cushions, which septate the outflow tract of the heart into pulmonary and aortic channels, many infants with craniofacial defects also have cardiac abnormalities, including persistent truncus arteriosus, tetralogy of Fallot, and transposition of the great vessels. Unfortunately, crest cells...
The cysts appear to be a particularly vulnerable cell population and are easily killed by compounds such as alcohol and retinoic acid. Examples of craniofacial defects involving crest cells include the following.

**Treacher Collins syndrome (mandibulofacial dysostosis)** is a rare autosomal dominant disorder occurring in 1/50,000 live births with 60% of cases arising as new mutations. The syndrome is characterized by hypoplasia of the maxilla, mandible, and zygomatic arches, which may be absent. Cleft palate is common as are external ear defects accompanied by atresia of the auditory canals and abnormalities of the middle ear ossicles, such that bilateral conductive hearing loss is often present. The eyes are usually involved with down-slanting palpebral fissures and lower eyelid colobomas. Mutations in the **TCOF1** gene (5q32) are responsible for most cases. The product of this gene is a nucleolar protein called **treacle** that appears to be necessary for preventing apoptosis and maintaining proliferation in neural crest cells but not for regulating their migration, which occurs normally. Although most cases of the syndrome are [continued]
due to genetic mutations, phenocopies can be produced in laboratory animals following exposure to teratogenic doses of retinoic acid, suggesting that some cases in humans may be caused by teratogens.

Robin sequence may occur independently or in association with other syndromes and malformations. Like Treacher Collins syndrome, Robin sequence alters first-arch structures, with development of the mandible most severely affected. Infants usually have a triad of micrognathia, cleft palate, and glossoptosis (posteriorly placed tongue) [Fig. 17.16A]. Robin sequence may be due to genetic or
22q11.2 Deletion syndrome is the most common deletion syndrome in humans and has several presentations, including DiGeorge syndrome [Fig. 17.16B], DiGeorge anomaly, velocardio-facial syndrome [Fig. 17.16C], Shprintzen syndrome, conotruncal anomaly face syndrome, and congenital thymic aplasia and hypoplasia. The defects are the result of a deletion on the long arm of chromosome 22 and occur in approximately 1 per 4,000 births. Recent evidence shows that mutations in one of the genes in the deletion interval, TBX1 [T-box DNA binding transcription factor 1], result in the same syndrome without a deletion. Furthermore, variability in regulation of the TBX1 gene may explain the wide range of observed phenotypes. The syndrome is characterized by a variety of malformations and degrees of severity, but infants most often present with congenital heart and aortic arch defects, mild facial dysmorphism, learning disabilities, and frequent infections due to thymic hypoplasia or aplasia that disrupts the immune system's T cell-mediated response. Many of the infants also have seizures due to hypocalcemia caused by abnormal development of the parathyroid glands. Later in life, these individuals are more likely to have mental illnesses, including schizophrenia and depression. In part origin of the defects is due to disruption of neural crest cells that contribute to many of the affected structures. Even the thymus and parathyroid defects are related to neural crest cells because these cells contribute the mesenchyme into which endoderm from the pharyngeal pouches migrates. Endoderm cells from the pouches make the thymus and parathyroid cells [see Fig. 17.10] and neural crest derived mesenchyme makes the connective tissue. Without this mesenchyme, the normal epithelial endodermal-mesenchymal interaction essential for differentiation of the glands does not occur.

Oculoauriculovertebral spectrum [Goldenhar syndrome] includes a number of craniofacial abnormalities that usually involve the maxillary, temporal, and zygomatic bones, which are small and flat. Ear [anotia, microtia, eye [tumors and dermoids in the eyelid], and vertebral [fused and hemivertebrae, spina bifida] defects are commonly observed in these patients [Fig. 17.16D]. Asymmetry is present in 65% of the cases, which occur in 1/5,600 births. Other malformations, which occur in 50% of cases, include cardiac abnormalities, such as tetralogy of Fallot and ventricular septal defects. Causes of hemifacial microsomia are unknown.

### TONGUE

The tongue appears in embryos of approximately 4 weeks in the form of two lateral lingual swellings and one medial swelling, the tuberculum impar (Fig. 17.17A). These three swellings originate from the first pharyngeal arch. A second median swelling, the copula, or hypobranchial eminence, is formed by mesoderm of the second, third, and part of the fourth arch. Finally, a third median swelling, formed by the posterior part of the fourth arch, marks development of the epiglottis. Immediately behind this swelling is the laryngeal orifice, which is flanked by the arytenoid swellings (Fig. 17.17).

As the lateral lingual swellings increase in size, they overgrow the tuberculum impar and merge, forming the anterior two-thirds, or body, of the tongue (Fig. 17.17). Because the mucosa covering the body of the tongue originates from the first pharyngeal arch, sensory innervation to this area is by the mandibular branch of the trigeminal nerve. The body of the tongue is separated from the posterior third by a V-shaped groove, the terminal sulcus (Fig. 17.17B).

The posterior part, or root, of the tongue originates from the second, third, and parts of the fourth pharyngeal arch. The fact that sensory innervation to this part of the tongue is supplied by the glossopharyngeal nerve indicates that tissue of the third arch overgrows that of the second.

The epiglottis and the extreme posterior part of the tongue are innervated by the superior laryngeal nerve, reflecting their development from the fourth arch. Some of the tongue muscles probably differentiate in situ, but most are derived from myoblasts originating in
occipital somites. Thus, tongue musculature is innervated by the hypoglossal nerve.

The general sensory innervation of the tongue is easy to understand. The body is supplied by the trigeminal nerve, the nerve of the first arch; that of the root is supplied by the glossopharyngeal and vagus nerves, the nerves of the third and fourth arches, respectively. Special sensory innervation (taste) to the anterior two-thirds of the tongue is provided by the chorda tympani branch of the facial nerve, whereas the posterior third is supplied by the glossopharyngeal nerve.

THYROID GLAND

The thyroid gland appears as an epithelial proliferation in the floor of the pharynx between the tuberculum impar and the copula at a point later indicated by the foramen cecum (Figs. 17.17 and 17.18A). Subsequently, the thyroid descends in front of the pharyngeal gut as a bilobed diverticulum (Fig. 17.18). During this migration, the thyroid remains connected to the tongue by a narrow canal, the thyroglossal duct. This duct later disappears.

With further development, the thyroid gland descends in front of the hyoid bone and the laryngeal cartilages. It reaches its final position in front of the trachea in the seventh week (Fig. 17.18B). By then, it has acquired a small median isthmus and two lateral lobes. The thyroid begins to function at approximately the end of the third month, at which time the first follicles containing colloid become visible. Follicular cells produce the colloid that serves as a source of thyroxine and triiodothyronine. Parafollicular, or C, cells derived from the ultimobranchial body (Fig. 17.10) serve as a source of calcitonin.

FACE

At the end of the fourth week, facial prominences consisting primarily of neural crest–derived mesenchyme and formed mainly by the first pair of pharyngeal arches appear. Maxillary prominences can be distinguished lateral to the stomodeum, and mandibular prominences can be distinguished caudal to this structure (Fig. 17.21). The frontonasal prominence, formed by proliferation of mesenchyme ventral to the brain vesicles, constitutes the upper border of the stomodeum. On both sides of the frontonasal prominence, local thickenings of the surface ectoderm, the nasal (olfactory) placodes, originate under inductive influence of the ventral portion of the forebrain (Fig. 17.21).

Clinical Correlates

Tongue-Tie

In ankyloglossia (tongue-tie), the tongue is not freed from the floor of the mouth. Normally, extensive cell degeneration occurs, and the frenulum is the only tissue that anchors the tongue to the floor of the mouth. In the most common form of ankyloglossia, the frenulum extends to the tip of the tongue.
**Clinical Correlates**

*Thyroglossal Duct and Thyroid Abnormalities*

A **thyroglossal cyst** may lie at any point along the migratory pathway of the thyroid gland but is always near or in the midline of the neck. As indicated by its name, it is a cystic remnant of the thyroglossal duct. Although approximately 50% of these cysts are close to or just inferior to the body of the hyoid bone (Figs. 17.19 and 17.20), they may also be found at the base of the tongue or close to the thyroid cartilage. Sometimes, a thyroglossal cyst is connected to the outside by a fistulous canal, a **thyroglossal fistula**. Such a fistula usually arises secondarily after rupture of a cyst but may be present at birth.

**Aberrant thyroid tissue** may be found anywhere along the path of descent of the thyroid gland. It is commonly found in the base of the tongue, just behind the foramen cecum, and is subject to the same diseases as the thyroid gland itself.

**FIGURE 17.19** Thyroglossal cysts. These cysts, most frequently found in the hyoid region, are always close to the midline.
**FIGURE 17.20** Thryroglossal cyst. These cysts, which are remnants of the thyroglossal duct, may be any-where along the migration pathway of the thyroid gland. They are commonly found behind the arch of the hyoid bone. An important diagnostic characteristic is their midline location.

**FIGURE 17.21** A. Lateral view of an embryo at the end of the fourth week, showing position of the pharyngeal arches. B. Frontal view of a 4.5-week embryo showing the mandibular and maxillary prominences. The nasal placodes are visible on either side of the frontonasal prominence. C. Photograph of a human embryo at a stage [4.5 weeks] similar to that of (B).
During the fifth week, the nasal placodes invaginate to form nasal pits. In so doing, they create a ridge of tissue that surrounds each pit and forms the nasal prominences. The prominences on the outer edge of the pits are the lateral nasal prominences; those on the inner edge are the medial nasal prominences (Fig. 17.22).

During the following 2 weeks, the maxillary prominences continue to increase in size. Simultaneously, they grow medially, compressing the medial nasal prominences toward the midline. Subsequently, the cleft between the medial nasal prominence and the maxillary prominence is lost, and the two fuse (Fig. 17.23). Hence, the upper lip is formed by the two medial nasal prominences and the two maxillary prominences. The lateral nasal prominences do not participate in formation of the upper lip. The lower lip and jaw form from the mandibular prominences that merge across the midline.

Initially, the maxillary and lateral nasal prominences are separated by a deep furrow, the nasolacrimal groove (Figs. 17.22 and 17.23). Ectoderm in the floor of this groove forms a solid epithelial cord that detaches from the overlying ectoderm. After canalization, the cord forms the nasolacrimal duct; its upper end widens to form the lacrimal sac. Following detachment of the cord, the maxillary and lateral nasal prominences merge with each other. The nasolacrimal duct then runs from the medial corner of the eye to the inferior meatus of the nasal cavity, and the maxillary prominences enlarge to form the cheeks and maxillae.

The nose is formed from five facial prominences (Fig. 17.23): the frontal prominence gives rise to the bridge, the merged medial nasal prominences

⁹The frontonasal prominence is a single unpaired structure; the other prominences are paired.

prominences provide the crest and tip, and the lateral nasal prominences form the sides (alae) (Table 17.3).

**INTERMAXILLARY SEGMENT**

As a result of medial growth of the maxillary prominences, the two medial nasal prominences merge not only at the surface but also at a deeper level. The structure formed by the two merged prominences is the intermaxillary segment. It is composed of (1) a labial component, which forms the philtrum of the upper lip; (2) an upper jaw component, which carries the four incisor teeth; and (3) a palatal
component, which forms the triangular primary palate (Fig. 17.24). The intermaxillary segment is continuous with the rostral portion of the nasal septum, which is formed by the frontal prominence.

### SECONDARY PALATE

Although the primary palate is derived from the intermaxillary segment (Fig. 17.24), the main part of the definitive palate is formed by two shelf-like outgrowths from the maxillary prominences. These outgrowths, the palatine shelves, appear in the sixth week of development and are directed obliquely downward on each side of the tongue (Fig. 17.25). In the seventh week, however, the palatine shelves ascend to attain a horizontal position above the tongue and fuse, forming the secondary palate (Figs. 17.26 and 17.27).

Anteriorly, the shelves fuse with the triangular primary palate, and the incisive foramen is the midline landmark between the primary and secondary palates (Fig. 17.27B). At the same time as the palatine shelves fuse, the nasal septum grows down and joins with the cephalic aspect of the newly formed palate (Fig. 17.27).

### NASAL CAVITIES

During the sixth week, the nasal pits deepen considerably, partly because of growth of the surrounding nasal prominences and partly because of their penetration into the underlying mesenchyme (Fig. 17.31A). At first, the oronasal membrane separates the pits from the primitive oral cavity by way of the newly formed foramina, the primitive choanae (Fig. 17.31C).
Clinical Correlates

**Facial Clefts**

Cleft lip and cleft palate are common defects that result in abnormal facial appearance and difficulties with speech. The **incisive foramen** is considered the dividing landmark between anterior and posterior cleft deformities. Those anterior to the incisive foramen include **lateral cleft lip, cleft upper jaw, and cleft** between the **primary and secondary palates** (Figs. 17.28B–D and 17.29A). Such defects are due to a partial or complete lack of fusion of the maxillary prominence with the medial nasal prominence on one or both sides. Those that lie posterior to the incisive foramen include **cleft (secondary) palate and cleft uvula** (Figs. 17.28E and 17.29B). Cleft palate results from a lack of fusion of the palatine shelves, which may be due to smallness of the shelves, failure of the shelves to elevate, inhibition of the fusion process itself, or failure of the tongue to drop from between the shelves because of micrognathia. The third category is formed by a combination of clefts lying anterior as well as posterior to the incisive foramen [Fig. 17.28F]. Anterior clefts vary in severity from a barely visible defect in the vermilion of the lip to extension into the nose. In severe cases, the cleft extends to a deeper level, forming a cleft of the upper jaw, and the maxilla is split between the lateral incisor and the canine tooth (Fig. 17.29A). Frequently, such a cleft extends to the incisive foramen [Fig. 17.28C,F]. Likewise, posterior clefts vary in severity from clefting of the entire secondary palate [Fig. 17.28E and 17.29B] to clefting of the uvula only.

**Van der Woude syndrome** is the most common syndrome associated with cleft lip
FIGURE 17.28  Ventral view of the palate, gum, lip, and nose. A. Normal. B. Unilateral cleft lip extending into the nose. C. Unilateral cleft involving the lip and jaw and extending to the incisive foramen. D. Bilateral cleft involving the lip and jaw. E. Isolated cleft palate. F. Cleft palate combined with unilateral anterior cleft lip.

FIGURE 17.29  A. Bilateral cleft lip [compare to Fig. 17.28D]. B. Cleft palate [compare to Fig. 17.28E]. C. Oblique facial cleft [see nasolacrimal groove, Fig. 17.23A and 17.23C]. D. Midline cleft lip.

[continued]
The syndrome is inherited as an autosomal dominant and is due to mutations in *INTERFERON REGULATORY FACTOR 6* (IRF6; 1p32-41) that is expressed in the medial (fusing) edge of the palatal shelves. Interestingly, 88% of affected infants will have pits in their lower lip, and in 64% of these individuals, this will be the only abnormality.

**Oblique facial clefts** are produced by failure of the maxillary prominence to merge with its corresponding lateral nasal prominence along the line of the nasolacrimal groove [Figs. 17.23A and C]. When this occurs, the nasolacrimal duct is usually exposed to the surface [Fig. 17.29C].

**Median (midline) cleft lip**, a rare abnormality, is caused by incomplete merging of the two medial nasal prominences in the midline [Fig. 17.29D and Fig. 17.30A and B]. Infants with midline clefts are often **cognitively impaired** and may have brain abnormalities that include varying degrees of loss of midline structures. Loss of midline tissue may be so extensive that the lateral ventricles fuse (**holoprosencephaly**) [Fig. 17.30C]. These defects are induced very early in development, at the beginning of neurulation [days 19 to 21] when the midline of the forebrain is being established (see Chapter 18).

Most cases of cleft lip with or without cleft palate are multifactorial. These conditions are usually classified as [1] cleft lip with or without cleft palate and [2] cleft palate and are thought to be etiologically and pathogenetically distinct. Cleft lip with or without cleft palate [approximately 1/700 births] occurs more frequently in males (65%) than in females, and its incidence varies among populations. Asians and Native Americans have some of the highest rates [3.5/1,000], whereas African Americans have the lowest ([1/1,000).

The frequency of isolated **cleft palate** is lower than that of cleft lip ([1/1,500 births]), occurs more often in females (55%) than in males. In females, the palatal shelves fuse approximately 1 week later than in males, which may be related to why isolated cleft palate occurs more frequently in females than in males.

Causes of cleft lip with or without cleft palate are not well defined. Some cases are syndromic and associated with certain syndromes and genes. Others are nonsyndromic but associated with some of the same genes that cause syndromes, such as *IRF6* (van der Woude syndrome) and *MSX1*. Still, other cases are caused by exposure to teratogenic compounds, such as anticonvulsant medications, particularly valproic acid. Cigarette smoking during pregnancy also increases the risk for having a baby with orofacial clefts.

**FIGURE 17.30** Photographs demonstrating normal and abnormal development involving the midline of the face and brain. **A.** Normal face of an embryo at the beginning of the seventh week. Note the distance between the nasal openings (vertical lines) and between the medial nasal prominences. **B.** Face of a newborn with a midline cleft lip. In this case, there is insufficient tissue in the midline to fill in the space between the medial nasal prominences.
These choanae lie on each side of the midline and immediately behind the primary palate. Later, with formation of the secondary palate and further development of the primitive nasal chambers (Fig. 17.31D), the definitive choanae lie at the junction of the nasal cavity and the pharynx. Paranasal air sinuses develop as diverticula of the lateral nasal wall and extend into the maxilla, ethmoid, frontal, and sphenoid bones. They reach their maximum size during
puberty and contribute to the definitive shape of the face.

**TEETH**

The shape of the face is determined not only by expansion of the paranasal sinuses but also by growth of the mandible and maxilla to accommodate the teeth. Teeth themselves arise from an epithelial-mesenchymal interaction between overlying oral epithelium and underlying mesenchyme derived from neural crest cells. By the sixth week of development, the basal layer of the epithelial lining of the oral cavity forms a C-shaped structure, the **dental lamina**, along the length of the upper and lower jaws. This lamina subsequently gives rise to a number of **dental buds** (Fig. 17.32A), 10 in each jaw, which form the primordia of the ectodermal components of the teeth. Soon, the deep surface of the buds invaginates, resulting in the **cap stage of tooth development** (Fig. 17.32B). Such a cap consists of an outer layer, the **outer dental epithelium**, an inner layer, the **inner dental epithelium**, and a central core of loosely woven tissue, the **stellate reticulum**. The **mesenchyme**, which originates in the **neural crest** in the indentation, forms the **dental papilla** (Fig. 17.32B).

As the dental cap grows and the indentation deepens, the tooth takes on the appearance of a bell (bell stage) (Fig. 17.32C). Mesenchyme cells of the papilla adjacent to the inner dental layer differentiate into **odontoblasts**, which later produce **dentin**. With thickening of the dentin layer, odontoblasts retreat into the dental papilla, leaving a thin cytoplasmic process (dental process) behind in the dentin (Fig. 17.32D). The odontoblast layer persists throughout the life of the tooth and continuously provides predentin. The remaining cells of the dental papilla form the **pulp** of the tooth (Fig. 17.32D).

In the meantime, epithelial cells of the inner dental epithelium differentiate into **ameloblasts** (enamel formers). These cells produce long enamel prisms that are deposited over the dentin (Fig. 17.32D). Furthermore, a cluster of these cells in the inner dental epithelium forms the **enamel knot** that regulates early tooth development (Fig. 17.32B).

Enamel is first laid down at the apex of the tooth and from here spreads toward the neck. When the enamel thickens, the ameloblasts retreat into the stellate reticulum. Here they regress, temporarily leaving a thin membrane (dental cuticle) on the surface of the enamel. After eruption of the tooth, this membrane gradually sloughs off.

Formation of the root of the tooth begins when the dental epithelial layers penetrate

---

**FIGURE 17.32** Formation of the tooth at successive stages of development. **A.** Bud stage [8 weeks]. **B.** Cap stage [10 weeks]. **C.** Bell stage [3 months]. **D.** 6 months.
into the underlying mesenchyme and form the **epithelial root sheath** (Fig. 17.32D). Cells of the dental papilla lay down a layer of dentin continuous with that of the crown (Fig. 17.33). As more and more dentin is deposited, the pulp chamber narrows and finally forms a canal containing blood vessels and nerves of the tooth.

Mesenchymal cells on the outside of the tooth and in contact with dentin of the root differentiate into **cementoblasts** (Fig. 17.33A). These cells produce a thin layer of specialized bone, the **cementum**. Outside of the cement layer, mesenchyme gives rise to the **periodontal ligament** (Fig. 17.33), which holds the tooth firmly in position and functions as a shock absorber.

With further lengthening of the root, the crown is gradually pushed through the overlying tissue layers into the oral cavity (Fig. 17.33B). The eruption of **deciduous** or **milk teeth** occurs 6 to 24 months after birth.

**Buds** for the **permanent teeth**, which lie on the lingual aspect of the milk teeth, are formed during the third month of development. These buds remain dormant until approximately the sixth year of postnatal life (Fig. 17.34). Then they begin to grow, pushing against the underside of the milk teeth and aiding in the shedding of them. As a permanent tooth grows, the root of the overlying deciduous tooth is resorbed by osteoclasts.

![Left anterolateral view](image)
Teeth are present only in vertebrates and parallel the evolutionary appearance of the neural crest. Tooth development represents a classic example of an epithelial–mesenchymal interaction, in this case between the overlying epithelium and underlying neural crest–derived mesenchyme. Regulation of tooth patterning from incisors to molars is generated by a combinatorial expression of HOX genes expressed in the mesenchyme. With respect to each tooth’s individual development, the epithelium governs differentiation to the bud stage, at which time this regulatory function is transferred to the mesenchyme.Signals for development involve growth factors including WNTs, BMPs, and FGFs; the secreted factor SHH; and transcription factors, such as MSX1 and MSX2, that interact in a complex pathway to produce cell differentiation and patterning for each tooth. Teeth also appear to have a signaling center that represents the “organizer” for tooth development much like the activity of the node during gastrulation (see Chapter 5). This organizer region is called the enamel knot, and it appears in a circumscribed region of the dental epithelium at the tips of the tooth buds. It then enlarges at the cap stage into a tightly packed group of cells but undergoes apoptosis (cell death) and disappears by the end of this stage (Fig. 17.32B). While it is present, it expresses FGF4, SHH, and BMP2 and 4. FGF4 may regulate outgrowth of cusps much as it participates in limb outgrowth produced by the apical ectodermal ridge, whereas BMP4 may regulate the timing of apoptosis in knot cells.

### SUMMARY

**Pharyngeal (branchial) arches**, consisting of bars of mesenchymal tissue separated by pharyngeal pouches and clefts, give the head and neck their typical appearance in the fourth week (Fig. 17.3). Each arch contains its own artery (Fig. 17.4), cranial nerve (Fig. 17.7), muscle element, and cartilage bar or skeletal element (Figs. 17.8 and 17.9; Table 17.1, p. 279). Endoderm of the pharyngeal pouches gives rise to a number of endocrine glands and part of the middle ear. In subsequent order, the pouches give rise to (1) the middle ear cavity and auditory tube (pouch 1), (2) the stroma of the palatine tonsil (pouch 2), (3) the inferior parathyroid glands and thymus (pouch 3), and (4) the superior parathyroid glands and ultimobranchial body (pouches 4 and 5) (Fig. 17.10).

**Pharyngeal clefts** give rise to only one structure, the external auditory meatus.

Patterning of the skeletal elements of the pharyngeal arches is regulated by gene expression in pharyngeal pouch endoderm. The process involves epithelial–mesenchymal signaling with endoderm of the pouches sending signals to the responding tissue, the mesenchyme. Mesenchymal gene expression is initially determined by homeodomain-containing transcription factors (OTX2 and HOX genes) carried by pharyngeal arches by migrating neural crest cells. Crest cells originate from the caudal midbrain and from segments in the hindbrain called rhombomeres. These genes respond to endodermal signals and dictate the type of skeletal elements that form.

The **thyroid gland** originates from an epithelial proliferation in the floor of the tongue and descends to its level in front of the tracheal rings in the course of development.

The paired maxillary and mandibular prominences and the frontonasal prominence are the first prominences of the facial region. Later, medial and lateral nasal prominences form around the nasal placodes on the frontonasal prominence. All of these structures are important because they determine, through fusion and specialized growth, the size and integrity of the mandible, upper lip, palate, and nose (Table 17.3, p. 296). Formation of the upper lip
occurs by fusion of the two maxillary prominences with the two medial nasal prominences (Figs. 17.22 and 17.23). The intermaxillary segment is formed by merging of the two medial nasal prominences in the midline. This segment is composed of (1) the philtrum; (2) the upper jaw component, which carries the four incisor teeth; and (3) the palatal component, which forms the triangular primary palate. The nose is derived from (1) the frontonasal prominence, which forms the bridge; (2) the medial nasal prominences, which provide the crest and tip; and (3) the lateral nasal prominences, which form the alae (Fig. 17.23). Fusion of the palatal shelves, which form from the maxillary prominences, creates the hard (secondary) and soft palate. A series of cleft deformities may result from partial or incomplete fusion of these mesenchymal tissues, which may be caused by hereditary factors and drugs (diphenylhydantoin).

The adult form of the face is influenced by development of paranasal sinuses, nasal conchae, and teeth. Teeth develop from epithelial–mesenchymal interactions between oral epithelium and neural crest–derived mesenchyme. Enamel is made by ameloblasts (Figs. 17.32 and 17.33). It lies on a thick layer of dentin produced by odontoblasts, a neural crest derivative. Cementum is formed by cementoblasts, another mesenchymal derivative found in the root of the tooth. The first teeth (deciduous teeth or milk teeth) appear 6 to 24 months after birth, and the definitive or permanent teeth, which supplant the milk teeth, are formed during the third month of development (Fig. 17.34).

### Problems to Solve

1. Why are neural crest cells considered such an important cell population for craniofacial development?
2. You are called as a consultant for a child with a very small mandible and ears that are represented by small protuberances bilaterally. The baby has had numerous episodes of pneumonia and is small for its age. What might your diagnosis be, and what might have caused these abnormalities?
3. A child is born with a median cleft lip. Should you be concerned about any other abnormalities?
4. A child presents with a midline swelling beneath the arch of the hyoid bone. What might this swelling be, and what is its basis embryologically?
The central nervous system (CNS) appears at the beginning of the third week as a slipper-shaped plate of thickened ectoderm, the neural plate (actually a large placode; see definition and poem, p. xi) in the mid-dorsal region in front of the primitive node. Its lateral edges soon elevate to form the neural folds (Fig. 18.1).

With further development, the neural folds continue to elevate, approach each other in the midline, and finally fuse, forming the neural tube (Figs. 18.2 and 18.3). Fusion begins in the cervical region and proceeds in cephalic and caudal directions (Fig. 18.3A). Once fusion is initiated, the open ends of the neural tube form the cranial and caudal neuropores that communicate with the overlying amniotic cavity (Fig. 18.3B). Closure of the cranial neuropore occurs cranially from the initial closure site in the cervical region (Fig. 18.3A) and from a site in the forebrain that forms later. This latter site proceeds cranially, to close the rostral-most region of the neural tube, and caudally to meet advancing closure from the cervical site (Fig. 18.3B). Final closure of the cranial neuropore occurs at the 18- to 20-somite stage (25th day); closure of the caudal neuropore occurs approximately 3 days later.

The cephalic end of the neural tube shows three dilations, the primary brain vesicles: (1) the prosencephalon, or forebrain; (2) the mesencephalon, or midbrain; and (3) the rhombencephalon, or hindbrain (Fig. 18.4). Simultaneously, it forms two flexures: (1) the cervical flexure at the junction of the hindbrain and the spinal cord and (2) the cephalic flexure in the midbrain region (Fig. 18.4).

By five weeks of development, the primary brain vesicles have differentiated into five secondary vesicles: The prosencephalon forms the telencephalon and diencephalon, the mesencephalon remains, and the rhombencephalon forms the metencephalon and myelencephalon (Fig. 18.5). A deep furrow, the rhombencephalic isthmus separates the mesencephalon from the metencephalon and the pontine flexure marks the boundary between the metencephalon and myelencephalon (Fig. 18.5). Each of the secondary vesicles will contribute a different part of the brain.
The main derivatives of these vesicles are indicated in Figure 18.5 and include telencephalon (cerebral hemispheres), diencephalon (optic vesicle, thalamus, hypothalamus, pituitary), mesencephalon (anterior [visual] and posterior [auditory] colliculi), metencephalon (cerebellum, pons), and myelencephalon (medulla oblongata).

The lumen of the spinal cord, the central canal, is continuous with that of the brain vesicles. The cavity of the rhombencephalon is the fourth ventricle, that of the diencephalon is the third ventricle, and those of the cerebral hemispheres are the lateral ventricles (Fig. 18.5).

The lumen of the mesencephalon connects the third and fourth ventricles. This lumen becomes very narrow and is then known as the aqueduct of Sylvius. Each lateral ventricle communicates with the third ventricle through the interventricular foramina of Monro (Fig. 18.5).

### SPINAL CORD

**Neuroepithelial, Mantle, and Marginal Layers**

The wall of a recently closed neural tube consists of neuroepithelial cells. These cells extend...
Part II  Systems-Based Embryology

FIGURE 18.3 A. Dorsal view of a human embryo at approximately day 22. Seven distinct somites are visible on each side of the neural tube. B. Dorsal view of a human embryo at approximately day 23. The nervous system is in connection with the amniotic cavity through the cranial and caudal neuropores.

over the entire thickness of the wall and form a thick pseudostratified epithelium (Fig. 18.6). Junctional complexes at the lumen connect them. During the neural groove stage and immediately after closure of the tube, they divide rapidly, producing more and more neuroepithelial cells. Collectively, they constitute the neuroepithelial layer or neuroepithelium.

Once the neural tube closes, neuroepithelial cells begin to give rise to another cell type characterized by a large round nucleus with pale nucleoplasm and a dark-staining nucleolus. These are the primitive nerve cells, or neuroblasts (Fig. 18.7). They form the mantle layer, a zone around the neuroepithelial layer (Fig. 18.8). The mantle layer later forms the gray matter of the spinal cord.

The outermost layer of the spinal cord, the marginal layer, contains nerve fibers emerging from neuroblasts in the mantle layer. As a result of myelination of nerve fibers, this layer takes on a white appearance and therefore is called the white matter of the spinal cord (Fig. 18.8).

Basal, Alar, Roof, and Floor Plates
As a result of continuous addition of neuroblasts to the mantle layer, each side of the neural tube shows a ventral and a dorsal thickening. The ventral thickenings, the basal plates, which contain ventral motor horn cells, form the motor areas of the spinal cord; the dorsal thickenings, the alar plates, form the sensory areas (Fig. 18.8A). A longitudinal groove, the sulcus limitans, marks the boundary between the two. The dorsal and ventral midline portions of the neural tube, known as the roof and floor plates, respectively, do not contain neuroblasts; they serve primarily as pathways for nerve fibers crossing from one side to the other.

In addition to the ventral motor horn and the dorsal sensory horn, a group of neurons accumulates between the two areas and forms a small intermediate horn (Fig. 18.8B). This horn, containing neurons of the sympathetic portion of the autonomic nervous system (ANS), is present only at thoracic (T1–T12) and upper lumbar levels (L2 or L3) of the spinal cord.

The major derivatives of each of these divisions are also indicated.

Histological Differentiation

Nerve Cells

Neuroblasts, or primitive nerve cells, arise exclusively by division of the neuroepithelial cells. Initially, they have a central process extending to the lumen (transient dendrite), but when they migrate into the mantle layer, this process disappears, and neuroblasts are temporarily round and apolar (Fig. 18.9A). With further differentiation, two new cytoplasmic processes appear on opposite sides of the cell body, forming a bipolar neuroblast (Fig. 18.9B). The process at one end of the cell elongates rapidly to form the primitive axon, and the process at the other end shows a number of cytoplasmic arborizations, the primitive dendrites (Fig. 18.9C).

FIGURE 18.6 A. Section of the wall of the recently closed neural tube showing neuroepithelial cells, which form a pseudostatified epithelium extending over the full width of the wall. Note the dividing cells at the lumen of the tube. B. Scanning electron micrograph of a section of the neural tube of a chick embryo similar to that in (A).
FIGURE 18.7 Section of the neural tube at a slightly more advanced stage than in Figure 18.6. The major portion of the wall consists of neuroepithelial cells. On the periphery, immediately adjacent to the external limiting membrane, neuroblasts form. These cells, which are produced by the neuroepithelial cells in ever-increasing numbers, will form the mantle layer.

FIGURE 18.8 A,B. Two successive stages in the development of the spinal cord. Note formation of ventral motor and dorsal sensory horns and the intermediate column.
The cell is then known as a multipolar neuroblast and with further development becomes the adult nerve cell or neuron. Once neuroblasts form, they lose their ability to divide. Axons of neurons in the basal plate break through the marginal zone and become visible on the ventral aspect of the cord. Known collectively as the ventral motor root of the spinal nerve, they conduct motor impulses from the spinal cord to the muscles (Fig. 18.10).

Axons of neurons in the dorsal sensory horn (alar plate) behave differently from those in the ventral horn. They penetrate into the marginal layer of the cord, where they ascend to either higher or lower levels to form association neurons.

**Glial Cells**

The majority of primitive supporting cells, the glia blasts, are formed by neuroepithelial cells after production of neuroblasts ceases. Glia blasts migrate from the neuroepithelial layer to the mantle and marginal layers. In the mantle layer, they differentiate into protoplasmic astrocytes and fibrillar astrocytes (Fig. 18.11). These cells are situated between blood vessels and neurons where they provide support and serve metabolic functions.

Another type of supporting cell possibly derived from glia blasts is the oligodendroglial cell. This cell, which is found primarily in the marginal layer, forms myelin sheaths around the ascending and descending axons in the marginal layer.

In the second half of development, a third type of supporting cell, the microglial cell, appears in the CNS. This highly phagocytic cell type is derived from vascular mesenchyme when blood vessels grow into the nervous system (Fig. 18.11). When neuroepithelial cells cease to produce neuroblasts and glia blasts, they differentiate into ependymal cells lining the central canal of the spinal cord.

**Neural Crest Cells**

During elevation of the neural plate, a group of cells appears along each edge (the crest) of the neural folds (Fig. 18.2). These neural crest cells are ectodermal in origin and extend throughout the length of the neural tube. Crest cells migrate laterally and give rise to sensory ganglia (dorsal root ganglia) of the spinal nerves and other cell types (Fig. 18.2).

During further development, neuroblasts of the sensory ganglia form two processes (Fig. 18.10A). The centrally growing processes penetrate the dorsal portion of the neural tube. In the spinal cord, they either end in the dorsal horn or ascend through the marginal layer to one of the higher brain centers. These processes are known collectively as the dorsal sensory root of the spinal nerve (Fig. 18.10B). The peripherally growing processes join fibers of the ventral motor roots and thus participate in formation of the trunk of the spinal nerve. Eventually, these processes terminate in the sensory receptor organs. Hence, neuroblasts of the sensory ganglia derived from neural crest cells give rise to the dorsal root neurons.

In addition to forming sensory ganglia, cells of the neural crest differentiate into sympathetic neuroblasts, Schwann cells, pigment cells, odontoblasts, meninges, and mesenchyme of the pharyngeal arches (see Table 6.1, p. 77).

**Spinal Nerves**

Motor nerve fibers begin to appear in the fourth week, arising from nerve cell bodies in the...
basal plates (ventral horns) of the spinal cord. These fibers collect into bundles known as ventral nerve roots (Fig. 18.10). Dorsal nerve roots carrying sensory fibers originate from nerve cell bodies positioned outside of the spinal cord in dorsal root ganglia (spinal ganglia) derived from neural crest cells. Processes from these ganglia form bundles that grow into the dorsal horns of the spinal cord. Distal processes join the ventral nerve roots to form a spinal nerve (Fig. 18.10). Thus, dorsal root fibers carry sensory innervation, whereas ventral root fibers carry motor innervation and, therefore, spinal nerves contain both sensory and motor fibers. Almost immediately, spinal nerves divide into dorsal and ventral primary rami, which contain both motor and sensory fibers. Dorsal primary rami innervate dorsal axial musculature,
vertebral joints, and the skin of the back. Ventral primary rami innervate the limbs and ventral body wall and form the major nerve plexuses (brachial plexus and lumbosacral plexus).

**Myelination**

Schwann cells myelinate the peripheral nerves with each cell myelinating only a single axon. These cells originate from neural crest, migrate peripherally, and wrap themselves around axons, forming the neurilemma sheath (Fig. 18.12). Beginning at the fourth month of fetal life, many nerve fibers take on a whitish appearance as a result of deposition of myelin, which is formed by repeated coiling of the Schwann cell membrane around the axon (Fig. 18.12C).

The myelin sheath surrounding nerve fibers in the spinal cord has a completely different origin, the oligodendroglial cells (Fig. 18.12B,C). Unlike Schwann cells, a single oligodendrocyte can myelinate up to 50 axons. Although myelination of nerve fibers in the spinal cord begins in approximately the fourth month of intrauterine life, some of the motor fibers descending from higher brain centers to the spinal cord do not become myelinated until the first year of postnatal life. Tracts in the nervous system become myelinated at about the time they start to function.

**Positional Changes of the Cord**

In the third month of development, the spinal cord extends the entire length of the embryo, and spinal nerves pass through the intervertebral foramina at their level of origin (Fig. 18.13A). With increasing age, however, the vertebral column and dura lengthen more rapidly than the

![FIGURE 18.11](image-url) Origin of the nerve cell and the various types of glial cells. Neuroblasts, fibrillar and protoplasmic astrocytes, and ependymal cells originate from neuroepithelial cells. Microglia develop from mesenchyme cells of blood vessels as the CNS becomes vascularized.

![FIGURE 18.12](image-url) A. Motor horn cell with naked rootlet. B. In the spinal cord, oligodendroglia cells surround the ventral rootlet; outside the spinal cord, Schwann cells begin to surround the rootlet. C. In the spinal cord, the myelin sheath is formed by oligodendroglial cells; outside the spinal cord, the sheath is formed by Schwann cells.
neural tube, and the terminal end of the spinal cord gradually shifts to a higher level. At birth, this end is at the level of the third lumbar vertebra (Fig. 18.13C). As a result of this disproportionate growth, dorsal and ventral roots of spinal nerves run obliquely from their segment of origin in the spinal cord to the corresponding level of the vertebral column where the appropriate roots unite to form spinal nerves. The dura remains attached to the vertebral column at the coccygeal level.

In the adult, the spinal cord terminates at the level of L2–L3, whereas the dural sac and subarachnoid space extend to S2. At the end of the cord, a threadlike extension of pia mater passes caudally, goes through the dura, which provides a covering layer at S2 and extends to the first coccygeal vertebra. This structure is called the filum terminale, and it marks the tract of regression of the spinal cord as well as providing support for the cord (the part covered by dura and extending from S2, to the coccyx is also called the coccygeal ligament). Dorsal and ventral roots of spinal nerves below the terminal end of the cord at L2–L3 collectively constitute the cauda equina (horse’s tail). When cerebrospinal fluid is tapped during a lumbar puncture, the needle is inserted at the lower lumbar level (L4–L5), avoiding the lower end of the cord.

Molecular Regulation of Nerve Differentiation in the Spinal Cord

Dorsal (sensory) and ventral (motor) regions of the developing spinal cord are dependent upon concentration gradients between members of the transforming growth factor β (TGF-β) family of growth factors secreted in the dorsal neural tube and sonic hedgehog (SHH) secreted by the notochord and floor plate (Fig. 18.14A). Initially, bone morphogenetic proteins (BMP) 4 and 7 are secreted by ectoderm overlying the neural tube, and the presence of these proteins establishes a second signaling center in the roof plate. Then, BMP4 in the roof plate induces a cascade of TGF-β proteins, including BMP5, BMP7, activin, and dorsalin in the roof plate and surrounding area. This cascade is organized in time and space such that a concentration gradient of these factors is established. As a result, cells near the roof plate are exposed to the highest concentrations with more ventrally positioned cells seeing less and less of these factors.

Similar events occur in the ventral region of the neural tube, only the signaling molecule is SHH. This factor is first expressed in the notochord followed by the establishment of a second signaling center in the floor plate (Fig. 18.14A). As a result, there is a diminishing concentration of SHH from the ventral to the dorsal region of the neural tube.

**FIGURE 18.13** Terminal end of the spinal cord in relation to that of the vertebral column at various stages of development. A. Approximately the third month. B. End of the fifth month. C. Newborn.
FIGURE 18.14 A,B. Drawings illustrating the molecular regulation of neuron differentiation in the spinal cord. A. Initially, bone morphogenetic protein 4 and 7 [BMP4 and 7] secreted in the ectoderm overlying the neural tube establish a signaling center in the roof plate. Then, BMP4 in the roof plate upregulates a cascade of TGF-β proteins, including BMP5 and 7, activin, and dorsalin in this region. Similarly, sonic hedgehog [SHH] secreted by the notochord establishes additional SHH signaling in the floor plate. In this manner, an overlapping gradient involving the dorsal and ventral factors is established in the neural tube. B. The gradient established by TGF-β proteins and SHH activates transcription factors that regulate neuronal differentiation. For example, high concentrations of TGF-β in the dorsal neural tube activate PAX3 and 7 that control sensory neuron differentiation. High concentrations of SHH and very low concentrations of TGF-β near the floor plate activate NKX2.2 and NKX6.1 and ventral neuron formation. Slightly higher concentrations of TGF-β and slightly lower concentrations of SHH activate NKX6.1 and PAX6 and differentiation of ventral motor neurons and so on. S, somite; N, notochord; F, floorplate.

Thus, two overlapping concentrations are established between TGF-β family members and SHH. These gradients then activate transcription factors that regulate differentiation of sensory and motor neurons. For example, high concentrations of TGF-β factors and very low concentrations of SHH in the dorsal neural tube activate PAX3 and 7 that controls sensory neuron differentiation (Fig. 18.14B). Likewise, high concentrations of SHH and very low concentrations of TGF-β molecules in the ventral-most region result in activation of NKX2.2 and NKX6.1 and ventral neuron formation. Immediately dorsal to this region, where slightly lower concentrations of SHH and higher concentrations of TGF-β molecules occur, expression of NKX6.1 and PAX6 is initiated, and these transcription factors induce differentiation of ventral motor horn cells. These interactions continue to produce all the different types of neurons in the spinal cord.

Clinical Correlates

Neural Tube Defects
Most defects of the spinal cord result from abnormal closure of the neural folds in the third and fourth weeks of development. The resulting abnormalities, neural tube defects [NTDs], may involve the meninges, vertebrae, muscles, and skin. The birth prevalence of NTDs, including spina bifida and anencephaly, varies among different populations and may be as high as 1/200 births in some areas, such as Northern China. The birth prevalence of NTDs in the United States has decreased by approximately 25% to 1/1,500 births since fortification of flour with folic acid was instituted in 1998.

Spina bifida is a general term for NTDs affecting the spinal region. It consists of a splitting of the vertebral arches and may or may not involve underlying neural tissue. Spina bifida occulta is a defect in the vertebral arches that is covered by skin and normally does not involve underlying neural tissue [Fig. 18.15A]. Most often, the defect occurs in the sacral region (S1–S2) and is sometimes marked by a patch of hair overlying the affected region. The defect, which is due to a lack of fusion of the vertebral arches, affects about 10% of otherwise normal people. The malformation is not usually detected at [continued]
Part II • Systems-Based Embryology

FIGURE 18.15 A–E. Drawings illustrating a variety of NTDs involving the spinal cord. The term *spina bifida* applies to all of the defects because the bony arch of one or more vertebrae has failed to fuse dorsal to the spinal cord. In some cases, the bony defect is covered by skin [spina bifida occulta [A]], but the spinal cord is intact. Often, this defect is noticeable because of a patch of dark hair that grows over the area. In cases of meningoceles [B], only a fluid-filled sac of meninges protrudes from the defect, whereas myelomeningoceles include neural tissue in the sac [C]. *Rachischisis* refers to NTDs in which the neural tube fails to close, resulting in spina bifida and exposure of neural tissue that often becomes necrotic [D,E]. Rachischisis may occur in the spinal cord or brain regions of the neural tube and represents the most severe type of abnormality. Most spinal cord defects occur in the lumbosacral area, and 50% to 70% of all NTDs can be prevented by maternal use of folic acid [400 μg daily] prior to and during pregnancy.

Birth and does not cause disability. Often, the defect is first noticed as an incidental finding diagnosed when an x-ray of the back is performed.

Other types of spina bifida include meningocele and myelomeningocele. These are severe NTDs in which neural tissue and/or meninges protrude through a defect in the vertebral arches and skin to form a cyst-like sac [Fig. 18.15B]. Most lie in the lumbosacral region and result in neurological deficits, but they are usually not associated with intellectual disability. In some cases, only fluid-filled meninges protrude through the defect [meningocele] [Fig. 18.15B]; in others, neural tissue is included in the sac [myelomeningocele] [Fig. 18.15C]. Occasionally, the neural folds do not elevate but remain as a flattened mass of neural tissue [spina bifida with myeloschisis or rachischisis] [Figs. 18.15D,E and 18.16]. *Hydrocephaly* requiring intervention develops in 80% to 90% of children born with severe NTDs and is often related to the presence of an *Arnold–Chiari malformation* [herniation of part of the cerebellum into the foramen magnum], which obstructs the flow of cerebrospinal fluid and causes the hydrocephalus. Herniation of the cerebellum occurs because the spinal cord is tethered to the vertebral column due to its abnormal development. As the vertebral column lengthens, tethering of the cord pulls the cerebellum into the foramen magnum, cutting off the flow of cerebrospinal fluid. Hydrocephalus can be treated by inserting a ventriculoperitoneal shunt, which allows drainage of the cerebrospinal fluid from one of the cerebral ventricles to the peritoneal cavity.

Spina bifida can be diagnosed prenatally by ultrasound and by determination of α-fetoprotein levels in maternal serum and amniotic fluid. The vertebra can be visualized by 12 weeks of gestation, and defects in closure of the vertebral arches can be detected. Experimental treatment for the defect is to perform surgery in utero as early as 22 weeks
of gestation. The fetus is exposed by an incision into the uterus, the defect is repaired, and the infant is placed back in the uterus.

Hyperthermia, valproic acid, and hypervitaminosis A produce NTDs, as do a large number of other teratogens. The origin of most NTDs is multifactorial, and the likelihood of having a child with such a defect increases significantly once one affected offspring is born. Prevention of many NTDs is possible if women take folic acid [400µg/day] starting at least 1 month prior to conception and then throughout their pregnancy. Such a protocol reduces the occurrence of NTDs by as much as 50% to 70%. Folic acid may also reduce the incidence of autism spectrum disorder (ASD). Because approximately 50% of all pregnancies are unplanned, it is recommended that all women of childbearing age take a multivitamin containing 400 µg of folic acid daily. Furthermore, women who have had a child with an NTD or who have a family history of NTDs should take 400 µg of folic acid daily and then 4,000 µg (4 mg) per day starting at least 1 month before conception through the first 3 months of pregnancy.

BRAIN

The brain is sometimes divided into the brain stem (consisting of the myelencephalon, pons from the metencephalon, and the mesencephalon) and the higher centers (cerebellum and cerebral hemispheres). The brain stem is a direct continuation of the spinal cord and has a similar organization. Thus, distinct basal and alar plates, representing motor and sensory areas, respectively, are found on each side of the midline. However, the higher centers reflect almost none of this basic pattern and, instead, show accentuation of the alar plates and regression of the basal plates.

Rhombencephalon: Hindbrain

The rhombencephalon consists of the myelencephalon, the most caudal of the brain vesicles, and the metencephalon, which extends from the pontine flexure to the rhombencephalic isthmus (Figs. 18.5 and 18.17).

Myelencephalon

The myelencephalon gives rise to the medulla oblongata, a transitional zone between the brain and spinal cord. It differs from the spinal cord in that its lateral walls are everted (Fig. 18.18). Alar and basal plates separated by the sulcus limitans can be clearly distinguished. The basal plate, similar to that of the spinal cord, contains motor nuclei. These nuclei are divided into three groups: (1) a medial somatic efferent group, (2) an intermediate special visceral efferent group, and (3) a lateral general visceral efferent group (Fig. 18.18C; Table 18.1, p. 319).

The somatic efferent group contains motor neurons, which form the cephalic continuation of the anterior horn cells. Because this group continues rostrally into the mesencephalon, it is called the somatic efferent motor column. In the myelencephalon, it includes neurons of the hypoglossal (XII) nerve that supply the tongue musculature. In the metencephalon
and the mesencephalon, the column contains neurons of the abducens (VI) (Fig. 18.19), trochlear (IV), and oculomotor (III) nerves (Fig. 18.23), respectively. These nerves supply the eye musculature.

The special visceral efferent group extends into the metencephalon, forming the special visceral efferent motor column. Its motor neurons supply striated muscles of the pharyngeal arches. In the myelencephalon, the column is

represented by neurons of the accessory (XI), vagus (X), and glossopharyngeal (IX) nerves.

The general visceral efferent group contains motor neurons that supply involuntary musculature of the respiratory tract, intestinal tract, and heart.

The alar plate contains three groups of sensory relay nuclei (Fig. 18.18C; Table 18.1). The most lateral of these, the somatic afferent (general sensory) group, receives sensations of pain, temperature, and touch from the pharynx by way of the glossopharyngeal nerve (IX). The intermediate, or special afferent, group receives impulses from taste buds of the tongue, palate, oropharynx, and epiglottis and from the vestibulocochlear nerve (VIII) for hearing and balance. The medial, or general visceral afferent, group receives interoceptive

information from the gastrointestinal tract and heart.

The roof plate of the myelencephalon consists of a single layer of ependymal cells covered by vascular mesenchyme, the pia mater (Fig. 18.18C). The two combined are known as the tela choroidea. Because of active proliferation of the vascular mesenchyme, a number of sac-like invaginations project into the underlying ventricular cavity (Figs. 18.18C). These tuft-like invaginations form the choroid plexus, which produces cerebrospinal fluid.

**Metencephalon**

The metencephalon, similar to the myelencephalon, is characterized by basal and alar plates (Fig. 18.19). Two new components form (1) the cerebellum, a coordination center for posture and movement (Fig. 18.20), and (2) the pons, the pathway for nerve fibers between the spinal cord and the cerebral and cerebellar cortices.

Each basal plate of the metencephalon (Fig. 18.19; Table 18.1) contains three groups of motor neurons: (1) the medial somatic efferent group, which gives rise to the nucleus of the abducens nerve; (2) the special visceral efferent group, containing nuclei of the trigeminal and facial nerves, which innervate the musculature of the first and second pharyngeal arches; and (3) the general visceral efferent group, with axons that supply the submandibular and sublingual glands.

The marginal layer of the basal plates of the metencephalon expands as it makes a bridge for nerve fibers connecting the cerebral cortex and cerebellar cortex with the spinal cord. Hence, this portion of the metencephalon is known as the pons (bridge). In addition to nerve fibers, the pons contains the pontine nuclei, which originate in the alar plates of the metencephalon and myelencephalon (Fig. 18.19, arrows).

The alar plates of the metencephalon contain three groups of sensory nuclei: (1) a lateral somatic afferent group, which contains neurons of the trigeminal nerve; (2) the special afferent group; and (3) the general visceral afferent group (Fig. 18.19; Table 18.1).

**Cerebellum**

The dorsolateral parts of the alar plates bend medially and form the rhombic lips (Fig. 18.18). In the caudal portion of the metencephalon, the rhombic lips are widely separated, but immediately below the mesencephalon, they approach each other in the midline (Fig. 18.20). As a result of a further deepening of the pontine flexure, the rhombic lips compress cephalocaudally and form the cerebellar plate (Fig. 18.20). In a 12-week embryo, this plate shows a small midline portion, the vermis, and two lateral portions, the hemispheres. A transverse fissure soon separates the nodule from the vermis and the lateral flocculus from the hemispheres (Fig. 18.20B). This flocculonodular lobe is phylogenetically the most primitive part of the cerebellum.

Initially, the cerebellar plate consists of neuroepithelial, mantle, and marginal layers (Fig. 18.21A). During further development, a number of cells formed by the neuroepithelium migrate to the surface of the cerebellum to form the external granular layer. Cells of this layer retain their ability to divide and form a proliferative zone on the surface of the cerebellum (Fig. 18.21B,C).

---

**FIGURE 18.20** A. Dorsal view of the mesencephalon and rhombencephalon in an 8-week embryo. The roof of the fourth ventricle has been removed, allowing a view of its floor. B. Similar view in a 4-month embryo. Note the choroidal fissure and the lateral and medial apertures in the roof of the fourth ventricle.
In the sixth month of development, the external granular layer gives rise to various cell types. These cells migrate toward the differentiating Purkinje cells (Fig. 18.22) and give rise to granule cells. Basket and stellate cells are produced by proliferating cells in the cerebellar white matter. The cortex of the cerebellum, consisting of Purkinje cells, Golgi II neurons, and neurons produced by the external granular layer, reaches its definitive size after birth (Fig. 18.22B). The deep cerebellar nuclei, such as the dentate nucleus, reach their final position before birth (Fig. 18.21D).

### Mesencephalon: Midbrain

In the mesencephalon (Fig. 18.23), each basal plate contains two groups of motor nuclei: (1) a medial somatic efferent group, represented by the oculomotor and trochlear nerves, which innervate the eye musculature, and (2) a small general visceral efferent group, represented by the nucleus of Edinger-Westphal, which innervates...
the sphincter pupillary muscle (Fig. 18.23B). The marginal layer of each basal plate enlarges and forms the crus cerebri. These crura serve as pathways for nerve fibers descending from the cerebral cortex to lower centers in the pons and spinal cord. Initially, the alar plates of the mesencephalon appear as two longitudinal elevations separated by a shallow midline depression (Fig. 18.23). With further development, a transverse groove divides each elevation into an anterior (superior) and a posterior (inferior) colliculus (Fig. 18.23B). The posterior colliculi serve as synaptic relay stations for auditory reflexes; the anterior colliculi function as correlation and reflex centers for visual impulses. The colliculi are formed by waves of neuroblasts migrating into the overlying marginal zone. Here they are arranged in layers (Fig. 18.23B).

**Prosencephalon: Forebrain**

The prosencephalon consists of the telencephalon, which forms the cerebral hemispheres, and the diencephalon, which forms the optic cup and stalk, pituitary, thalamus, hypothalamus, and epiphysis.

**Diencephalon**

**ROOF PLATE AND EPIPHYSIS**

The diencephalon, which develops from the median portion of the prosencephalon (Figs. 18.5 and 18.17), is thought to consist of a roof plate and two alar plates but to lack floor and basal plates (interestingly, SHH, a ventral midline marker, is expressed in the floor of the diencephalon, suggesting that a floor plate does exist). The roof plate of the diencephalon consists of a single layer of ependymal cells covered by vascular mesenchyme. Together, these layers give rise to the choroid plexus of the third ventricle (Fig. 18.30). The most caudal part of the roof plate develops into the pineal body, or epiphysis. This body initially appears as an epithelial thickening in the midline, but by the seventh week, it begins to evaginate (Figs. 18.24 and 18.25). Eventually,

**FIGURE 18.23** A, B. Position and differentiation of the basal and alar plates in the mesencephalon at various stages of development. Arrows in [A] indicate the path followed by cells of the alar plate to form the nucleus ruber and substantia nigra. Note the various motor nuclei in the basal plate.

**FIGURE 18.24** A. Medial surface of the right half of the prosencephalon in a 7-week embryo. B. Transverse section through the prosencephalon at the level of the broken line in [A]. The corpus striatum bulges out in the floor of the lateral ventricle and the foramen of Monro.
it becomes a solid organ on the roof of the mesencephalon (Fig. 18.30) that serves as a channel through which light and darkness affect endocrine and behavioral rhythms. In the adult, calcium is frequently deposited in the epiphysis and then serves as a landmark on radiographs of the skull.

**ALAR PLATE, THALAMUS, AND HYPOTHALAMUS**

The alar plates form the lateral walls of the diencephalon. A groove, the **hypothalamic sulcus**, divides the plate into a dorsal and a ventral region, the **thalamus** and **hypothalamus**, respectively (Figs. 18.24 and 18.25).

As a result of proliferative activity, the thalamus gradually projects into the lumen of the diencephalon. Frequently, this expansion is so great that thalamic regions from the right and left sides fuse in the midline, forming the **massa intermedia**, or **interthalamic connexus**.

The hypothalamus, forming the lower portion of the alar plate, differentiates into a number of nuclear areas that regulate the visceral functions, including sleep, digestion, body temperature, and emotional behavior. One of these groups, the **mamillary body**, forms a distinct protuberance on the ventral surface of the hypothalamus on each side of the midline (Figs. 18.24A and 18.25A).

**HYPOPHYSIS OR PITUITARY GLAND**

The hypophysis, or pituitary gland, develops from two completely different parts: (1) an ectodermal outpocketing of the **stomodeum** (primitive oral cavity) immediately in front of the oropharyngeal membrane, known as **Rathke’s pouch**, and
Part II • Systems-Based Embryology

FIGURE 18.26 A. Sagittal section through the cephalic part of a 6-week embryo showing Rathke’s pouch as a dorsal outpocketing of the oral cavity and the infundibulum as a thickening in the floor of the diencephalon. B.C. Sagittal sections through the developing hypophysis in the 11th and 16th weeks of development, respectively. Note formation of the pars tuberalis encircling the stalk of the pars nervosa.

(2) a downward extension of the diencephalon, the **infundibulum** (Fig. 18.26).

When the embryo is approximately 3 weeks old, Rathke’s pouch appears as an evagination of the oral cavity and subsequently grows dorsally toward the infundibulum. By the end of the second month, it loses its connection with the oral cavity and is then in close contact with the infundibulum.

During further development, cells in the anterior wall of Rathke’s pouch increase rapidly in number and form the **anterior lobe of the hypophysis**, or **adenohypophysis** (Fig. 18.26B). A small extension of this lobe, the **pars tuberalis**, grows along the stalk of the infundibulum and eventually surrounds it (Fig. 18.26C). The posterior wall of Rathke’s pouch develops into the **pars intermedia**, which in humans seems to have little significance.

The infundibulum gives rise to the **stalk** and the **pars nervosa**, or **posterior lobe of the hypophysis** (neurohypophysis) (Fig. 18.26C). It is composed of neuroglial cells. In addition, it contains a number of nerve fibers from the hypothalamic area.

**Clinical Correlates**

Hypophyseal Defects
Occasionally, a small portion of Rathke’s pouch persists in the roof of the pharynx as a **pharyngeal hypophysis**. Craniopharyngiomas arise from remnants of Rathke’s pouch. They may form within the sella turcica or along the stalk of the pituitary but usually lie above the sella. They may cause hydrocephalus and pituitary dysfunction (e.g., diabetes insipidus, growth failure).

**Telencephalon**

The telencephalon, the most rostral of the brain vesicles, consists of two lateral outpocketings, the **cerebral hemispheres**, and a median portion, the **lamina terminales** (Figs. 18.5, 18.24, and 18.25). The cavities of the hemispheres, the **lateral ventricles**, communicate with the lumen of the diencephalon through the **interventricular foramina of Monro** (Fig. 18.24).

**Cerebral Hemispheres**

The cerebral hemispheres arise at the beginning of the fifth week of development as bilateral evaginations of the lateral wall of the prosencephalon (Fig. 18.24). By the middle of the second month, the basal part of the hemispheres (i.e., the part that initially formed the forward extension of the thalamus) (Fig. 18.24A) begins to grow and bulges into the lumen of the lateral ventricle and into the floor of the foramen of Monro (Figs. 18.24B and 18.25A,B). In transverse sections, the rapidly growing region has a striated appearance and is therefore known as the **corpus striatum** (Fig. 18.25B).

In the region where the wall of the hemisphere is attached to the roof of the diencephalon, the wall fails to develop neuroblasts and remains very thin (Fig. 18.24B). Here the hemisphere wall consists of a single layer of ependymal cells covered by vascular mesenchyme, and together, they form the **choroid plexus**. The choroid plexus should have formed the roof of the hemisphere, but as a result of the disproportionate growth of the various parts of the hemisphere, it protrudes into the lateral ventricle along the **choroidal fissure** (Figs. 18.25 and 18.27). Immediately above the choroidal fissure, the wall of the hemisphere thickens, forming the
hippocampus (Figs. 18.24B and 18.25B). This structure’s primary function is olfaction, and it bulges into the lateral ventricle.

With further expansion, the hemispheres cover the lateral aspect of the diencephalon, mesencephalon, and cephalic portion of the metencephalon (Figs. 18.27 and 18.28). The corpus striatum (Fig. 18.24B), being a part of the wall of the hemisphere, likewise expands posteriorly and is divided into two parts: (1) a dorsomedial portion, the caudate nucleus, and (2) a ventrolateral portion, the lentiform nucleus (Fig. 18.27B). This division is accomplished by axons passing to and from the cortex of the hemisphere and breaking through the nuclear mass of the corpus striatum. The fiber bundle thus formed is known as the internal capsule (Fig. 18.27B). At the same time, the medial wall of the hemisphere and the lateral wall of the diencephalon fuse, and the caudate nucleus and thalamus come into close contact (Fig. 18.27B).

Continuous growth of the cerebral hemispheres in anterior, dorsal, and inferior directions results in the formation of frontal, temporal, and occipital lobes, respectively. As growth in the region overlying the corpus striatum slows, however, the area between the frontal and temporal lobes becomes depressed and is known as the insula (Fig. 18.28A). This region

FIGURE 18.27 A. Medial surface of the right half of the telencephalon and diencephalon in a 10-week embryo. B. Transverse section through the hemisphere and diencephalon at the level of the broken line in [A].
is later overgrown by the adjacent lobes and at the time of birth is almost completely covered. During the final part of fetal life, the surface of the cerebral hemispheres grows so rapidly that a great many convolutions (gyri) separated by fissures and sulci appear on its surface (Fig. 18.28B).

Cortex Development
The cerebral cortex develops from the pallium (Fig. 18.24B), which has two regions: (1) the paleopallium, or archipallium, immediately lateral to the corpus striatum (Fig. 18.25B), and (2) the neopallium, between the hippocampus and the paleopallium (Figs. 18.25B and 18.27B).

In the neopallium, waves of neuroblasts migrate to a subpial position and then differentiate into fully mature neurons. When the next wave of neuroblasts arrives, they migrate through the earlier formed layers of cells until they reach the subpial position. Hence, the early formed neuroblasts obtain a deep position in the cortex, whereas those formed later obtain a more superficial position.

At birth, the cortex has a stratified appearance due to differentiation of the cells in layers. The motor cortex contains a large number of pyramidal cells, and the sensory areas are characterized by granular cells.

Differentiation of the olfactory system is dependent on epithelial–mesenchymal interactions. These occur between neural crest cells and ectoderm of the frontonasal prominence to form the olfactory placodes (see Chapter 17, p. 292) and between these same crest cells and the floor of the telencephalon to form the olfactory bulbs (Fig. 18.29). Cells in the nasal placodes differentiate into primary sensory neurons of the nasal epithelium, which has axons that grow and make contact with secondary neurons in the developing olfactory bulbs (Fig. 18.29). By the seventh week, these contacts are well established. As growth of the brain continues, the olfactory bulbs and the olfactory tracts of the secondary neurons lengthen, and together they constitute the olfactory nerve (Fig. 18.30).

Commissures
In the adult, a number of fiber bundles, the commissures, which cross the midline, connect the right and left halves of the hemispheres. The most important fiber bundles make use of the lamina terminalis (Figs. 18.24A and 18.25A). The first of the crossing bundles to appear is the anterior commissure. It consists of fibers connecting the olfactory bulb and related brain areas of one hemisphere to those of the opposite side (Figs. 18.27A and 18.30).

The second commissure to appear is the hippocampal commissure, or fornix commissure. Its fibers arise in the hippocampus and converge on the lamina terminalis close to the roof plate of the diencephalon. From here, the fibers continue, forming an arching system immediately outside the choroid fissure, to the mamillary body and the hypothalamus.

Another important commissure is the corpus callosum. It appears by the 10th week of development and connects the nonolfactory areas of the right and the left cerebral cortices. Initially, it forms a small bundle in the lamina terminalis (Fig. 18.27A). As a result of continuous expansion
FIGURE 18.29 A. Sagittal section through the nasal pit and lower rim of the medial nasal prominence of a 6-week embryo. The primitive nasal cavity is separated from the oral cavity by the oronasal membrane. B. Similar section as in (A) toward the end of the sixth week, showing breakdown of the oronasal membrane. C. At 7 weeks, neurons in the nasal epithelium have extended processes that contact the floor of the telencephalon in the region of the developing olfactory bulbs. D. By 9 weeks, definitive oronasal structures have formed, neurons in the nasal epithelium are well differentiated, and secondary neurons from the olfactory bulbs to the brain begin to lengthen. Together, the olfactory bulbs and tracts of the secondary neurons constitute the olfactory nerve [Fig. 18.30].

FIGURE 18.30 Medial surface of the right half of the brain in a 4-month embryo showing the various commissures. Broken line, future site of the corpus callosum. The hippocampal commissure is not indicated.
of the neopallium, however, it extends first ante-
riorly and then posteriorly, arching over the thin
roof of the diencephalon (Fig. 18.30).

In addition to the three commissures develop-
ing in the lamina terminalis, three more ap-
pear. Two of these, the posterior and habenular
commissures, are just below and rostral to the
stalk of the pineal gland. The third, the optic
chiasma, which appears in the rostral wall of the
diencephalon, contains fibers from the medial
halves of the retinae (Fig. 18.30).

CEREBROSPINAL FLUID

Cerebrospinal fluid (CSF) is secreted by the
choroid plexuses in the brain ventricles. These
plexuses are modifications of the ependymal
layer and produce approximately 400 to 500 mL
of CSF per day. The fluid circulates through the
brain ventricles leaving the lateral ventricles,
for example, through the interventricular for-
amina, entering the third ventricle, and then
passing through the cerebral aqueduct into the
fourth ventricle (Fig. 18.30). Some CSF enters
the spinal canal, and some exits the fourth ven-
tricle through its median and lateral apertures
to enter the subarachnoid space that surrounds
the CNS. CSF is absorbed into the venous sys-
tem from the subarachnoid space through
arachnoid granulations, especially those that
project into the superior sagittal sinus. CSF “floats” the brain and, thus, provides a cushion
for the brain and gives it buoyancy so that its
weight does not compress cranial nerves against
the inside of the skull.

MOLECULAR REGULATION OF
BRAND DEVELOPMENT

Anteroposterior (craniocaudal) patterning of the
CNS begins early in development, during gas-
trulation and neural induction (see Chapters 5
and 6). Once the neural plate is established, sig-
als for segregation of the brain into forebrain,
midbrain, and hindbrain regions are derived from
homeobox genes expressed in the notochord,
prechordal plate, and neural plate. The hindbrain
has eight segments, the rhombomeres, that have
variable expression patterns of the Antennapedia
class of homeobox genes, the HOX genes (see
Chapter 6, p. 88). These genes are expressed in
overlapping (nested) patterns, with genes at
the most 3' end of a cluster having more ante-
rior boundaries and paralogous genes having
identical expression domains (Fig. 18.31). Genes
at the 3' end are also expressed earlier than those
at the 5' end, so that a temporal relation to the
expression pattern is established. These genes,
then, confer positional value along the antero-
posterior axis of the hindbrain, determine the
identity of the rhombomeres, and specify their
derivatives. How this regulation occurs is not
clear, although retinoids (retinoic acid) play a
critical role in regulating HOX expression. For
example, excess retinoic acid shifts HOX gene
expression anteriorly and causes more cranial
rhombomeres to differentiate into more caudal
types. Retinoic acid deficiency results in a small
hindbrain. There is also a differential response to
retinoic acid by the HOX genes; those at the 3'
end of the cluster are more sensitive than those
at the 5' end.

Specification of the forebrain and midbrain
areas is also regulated by genes containing a
homeodomain. However, these genes are not
of the Antennapedia class, whose most anterior
boundary of expression stops at rhombomere 3.
Thus, new genes have assumed the pattern-
ing role for these regions of the brain, which
evolutionarily constitute the “new head.” At the
neural plate stage, LIM1, expressed in the pre-
chordal plate, and OTX2, expressed in the neural

![FIGURE 18.31 Patterns of HOX gene expression in the hindbrain. HOX genes are expressed in overlapping patterns ending at specific rhombomere boundaries. Genes at the 3' end of a cluster have the most anterior boundaries, and paralogous genes have identical expression domains. These genes confer positional value along the anterior-posterior axis of the hindbrain, determine the identity of the rhombomeres, and specify their derivatives.]
plate, are important for designating the forebrain and midbrain areas, with LIM1 supporting OTX2 expression. (These genes are also expressed at the earliest stages of gastrulation, and they assist in specifying the entire cranial region of the epiblast.) Once the neural folds and pharyngeal arches appear, additional homeobox genes, including OTX1, EMX1, and EMX2, are expressed in specific and in overlapping (nested) patterns in the mid- and forebrain regions and specify the identity of these areas. Once these boundaries are established, two additional organizing centers appear: the anterior neural ridge (ANR) at the junction of the cranial border of the neural plate and nonneural ectoderm (Fig. 18.32) and the isthmus (Fig. 18.33) between the hindbrain and midbrain. In both locations, fibroblast growth factor 8 (FGF8) is the key signaling molecule, inducing subsequent gene expression that regulates differentiation. In the ANR at the four-somite stage, FGF8 induces expression of FOXG1, a transcription factor (Fig. 18.32). FOXG1 then regulates development of the telencephalon (cerebral hemispheres) and regional specification within the forebrain, including the basal telencephalon and the retina. In the isthmus at the junction between the midbrain and hindbrain territories, FGF8 is expressed in a ring around the circumference of this location (Fig. 18.33). FGF8 induces expression of ENGRAILED 1 and 2 (EN1 and EN2), two homeobox-containing genes, expressed in gradients radiating anteriorly and posteriorly from the isthmus. EN1 regulates development throughout its expression domain, including the dorsal midbrain (tectum) and anterior hindbrain (cerebellum), whereas EN2 is involved only in cerebellar development. FGF8 also induces WNT1 expression in a circumferential band anterior to the region of FGF8 expression (Fig. 18.33). WNT1 interacts with EN1 and EN2 to regulate development of this region, including the cerebellum. In fact, WNT1 may assist in early specification of the midbrain area since it is expressed in this region at the neural plate stage. FGF8 is also expressed at this early time in mesoderm underlying the midbrain–hindbrain junction and may therefore regulate WNT1 expression and initial patterning of this region. The constriction for the isthmus is slightly posterior to the actual

**FIGURE 18.32** A. Dorsal view of a late presomite stage embryo at approximately 18 days showing development of the neural plate in the cranial region [blue area]. B. Diagram of the cranial neural plate region shown in [A] [blue area] illustrating the organizing center known as the anterior neural ridge [ANR]. This area lies in the most anterior region of the neural plate and secretes fibroblast growth factor 8 [FGF8], which induces expression of FOXG1 in adjacent neuroectoderm. FOXG1 regulates development of the telencephalon [cerebral hemispheres] and regional specification within the prosencephalon [PR]. Sonic hedgehog [SHH], secreted by the prechordal plate [P] and notochord [N], ventralizes the brain and induces expression of NKX2.1, which regulates development of the hypothalamus. Bone morphogenetic protein 4 and 7 [BMP4 and 7], secreted by the adjacent nonneural ectoderm, control dorsal patterning of the brain. M, mesencephalon; R, rhombencephalon.
midbrain–hindbrain junction, which lies at the caudal limit of OTX2 expression.

Dorsoventral (mediolateral) patterning also occurs in the forebrain and midbrain areas. Ventral patterning is controlled by SHH just as it is throughout the CNS. SHH, secreted by the prechordal plate, induces expression of \textit{NKK2.1}, a homeodomain-containing gene that regulates development of the hypothalamus. Importantly, SHH signaling requires cleavage of the protein, and the carboxy-terminal portion executes this process. Following cleavage of the SHH protein, cholesterol is covalently linked to the carboxy-terminus of the amino-terminal product. The amino-terminal portion retains all of the signaling properties of SHH, and its association with cholesterol assists in its distribution.

Dorsal (lateral) patterning of the neural tube is controlled by BMP4 and BMP7 expressed in the nonneural ectoderm adjacent to the neural plate. These proteins induce expression of \textit{MSX1} in the midline and repress expression of \textit{FOXG1} (Fig. 18.32). Once the neural tube is closed, BMP2 and 4 are expressed in the roof plate, and these proteins regulate expression of the transcription factor \textit{LHX2} in the cortex. This expression then initiates a cascade of genes to pattern this region.

Expression patterns of genes regulating anterior–posterior (craniocaudal) and dorsoventral (mediolateral) patterning of the brain overlap and interact at the borders of these regions. Furthermore, various brain regions are competent to respond to specific signals and not to others. For example, only the cranial part of the neural plate expresses \textit{NKK2.1} in response to SHH. Likewise, only the anterior neural plate expresses \textit{FOXG1} in response to FGF8; midbrain levels express \textit{EN2} in response to the same FGF8 signal. Thus, a \textbf{competence to respond} also assists in specifying regional differences.

**Clinical Correlates**

**Cranial Defects**

\textbf{Holoprosencephaly (HPE)} refers to a spectrum of abnormalities in which a loss of midline structures results in malformations of the brain and face. In severe cases, the lateral ventricles merge into a single \textit{teiencephalic vesicle} (alobar HPE), the eyes are fused, and there is a single nasal chamber along with other midline facial defects (Fig. 18.34). In less severe cases, some division of the prosencephalon into two cerebral hemispheres occurs, but there is incomplete development of midline structures. Usually, the olfactory bulbs and tracts and the corpus callosum are hypoplastic or absent. In very mild cases, sometimes the only indication that some degree of HPE has occurred is the presence of a single central incisor. HPE occurs in 1/15,000 live births but is present in 1/250 pregnancies that end in early miscarriage. Mutations in \textit{SHH}, the gene that regulates establishment of the ventral midline in the CNS, result in some forms of HPE. Another cause is
defective cholesterol biosynthesis leading to Smith-Lemli-Opitz syndrome. These children have craniofacial and limb defects, and 5% have HPE. Smith-Lemli-Opitz syndrome is an autosomal recessive condition due to abnormalities in 7-dehydrocholesterol reductase, which metabolizes 7-dehydrocholesterol to cholesterol. Many of the defects, including those of the limbs and brain, may be due to abnormal SHH signaling, as cholesterol is necessary for this gene to exert its effects. Other genetic causes include mutations in the transcription factors SINE OCCULIS HOMEBOX 3 (SIX3), TG-INTERACTING FACTOR (TGIF), and the ZINC FINGER PROTEIN (ZIC2).

Schizencephaly is a rare disorder in which large clefts occur in the cerebral hemispheres, sometimes causing a loss of brain tissue. Mutations in the homeobox gene EMX2 appear to account for some of these cases.

Ossification defects in bones of the skull can result in meningoceles, meningoencephaloceles, and meningoencephalocele. The most frequently affected bone is the squamous part of the occipital bone, which may be partially or totally lacking. If the opening of the occipital bone is small, only meninges bulge through it (meningocele), but if the defect is large, part of the brain and even part of the ventricle may penetrate through the opening into the meningeal sac (Figs. 18.35 and 18.36).

[continued]
The latter two malformations are known as meningoecephalocele and meningohydroencephalocele, respectively. These defects occur in 1/12,000 births.

Exencephaly is characterized by failure of the cephalic part of the neural tube to close. As a result, the vault of the skull does not form, leaving the malformed brain exposed. Later, this tissue degenerates, leaving a mass of necrotic tissue. This defect is called anencephaly, although the brain stem remains intact (Fig. 18.37A). In some cases, the closure defect of the neural tube extends caudally into the spinal cord, and the abnormality is called craniorachischisis (Fig. 18.37B). Again, there is anencephaly but with a large defect involving the spine. Because anencephalic fetuses lack a swallowing reflex, the last 2 months of pregnancy are characterized by polyhydramnios. The abnormality can be recognized on ultrasound, as the vault of the skull is absent. Anencephaly occurs in 1 per 5,000 births and is more common in females than in males. Like spina bifida, many of these cases can be prevented by having women

FIGURE 18.36 Fetus with a large occipital meningoecephalocele. Some infants with smaller defects can survive with surgery, and their degree of neurological deficits depends on the amount of neural tissue that is abnormal or lost.

FIGURE 18.37 A. Fetus with anencephaly [absent brain] due to a lack of closure of the cranial neural folds. Once the folds fail to close, neural tissue is disorganized and is exposed to amniotic fluid, which causes necrosis and loss of tissue. This defect is always fatal, and most pregnancies with such cases are terminated. B. Fetus with anencephaly and craniorachischisis. The neural tube has failed to close in cranial and upper spinal cord regions resulting in massive necrosis of neural tissue. The defects illustrated in (A) and (B) can be prevented by maternal use of folic acid [400 μg daily] prior to and during pregnancy.
take 400 μg of folic acid per day before and during early pregnancy.

Hydrocephalus is characterized by an abnormal accumulation of CSF within the ventricular system. In most cases, hydrocephalus in the newborn is due to an obstruction of the aqueduct of Sylvius [aqueductal stenosis]. This prevents the CSF of the lateral and third ventricles from passing into the fourth ventricle and from there into the subarachnoid space, where it would be resorbed. As a result, fluid accumulates in the lateral ventricles and presses on the brain and bones of the skull. Because the cranial sutures have not yet fused, spaces between them widen as the head expands. In extreme cases, brain tissue and bones become thin and the head may be very large [Fig. 18.38].

Microcephaly describes a cranial vault that is smaller than normal [Fig. 18.39]. Because the size of the cranium depends on growth of the brain, the underlying defect is in brain development. Causation of the abnormality is varied; it may be genetic (autosomal recessive) or caused by prenatal insults, such as infection or exposure to drugs or other teratogens. Intellectual disability occurs in more than half the cases.

Fetal infection by toxoplasmosis may result in cerebral calcification, intellectual disability, hydrocephalus, or microcephaly. Likewise, exposure to radiation during the early stages of development may produce microcephaly. Hyperthermia [fever] produced by maternal infection or by sauna baths and hot tubs may cause spina bifida and anencephaly.

The aforementioned abnormalities are the most serious ones, and they may be incompatible with life. A great many other defects of the CNS may occur without much external manifestation. For example, the corpus callosum may be partially or completely absent without much functional disturbance. Likewise, partial or complete absence of the cerebellum may result in only a slight disturbance of coordination. On the other hand, cases of severe intellectual disability may not be associated with morphologically detectable brain abnormalities. Intellectual disability may result from genetic abnormalities [e.g., Down syndrome] or from exposures to teratogens, including infectious agents (rubella, cytomegalovirus, toxoplasmosis). The leading cause of intellectual disability is, however, maternal alcohol abuse.
## CRANIAL NERVES

By the fourth week of development, nuclei for all 12 cranial nerves are present. All except the olfactory (I) and optic (II) nerves arise from the brain stem, and of these, only the oculomotor (III) arises outside the region of the hindbrain. In the hindbrain, proliferation centers in the neuroepithelium establish eight distinct segments, the rhombomeres. These rhombomeres give rise to motor nuclei of cranial nerves (CN) IV, V, VI, VII, IX, X, XI, and XII (Figs. 18.17 and 18.40). Establishment of this segmental pattern appears to be directed by mesoderm collected into somitomeres beneath the overlying neuroepithelium.

Motor neurons for cranial nuclei are within the brainstem, whereas sensory ganglia are outside of the brain. Thus, the organization of cranial nerves is homologous to that of spinal nerves, although not all cranial nerves contain both motor and sensory fibers (Table 18.2).

Cranial nerve sensory ganglia originate from a series of **ectodermal placodes** and **neural crest cells**. Ectodermal placodes include the nasal, otic, and four epiphyseal placodes represented by ectodermal thickenings dorsal to the pharyngeal (branchial) arches (Table 18.3; see also Fig. 17.2). Epiphyseal placodes contribute to ganglia for nerves of the pharyngeal arches (V, VII, IX, and X). Parasympathetic (visceral efferent) ganglia are derived from neural crest cells, and their fibers are carried by CNs III, VII, IX, and X (Table 18.2).

---

## AUTONOMIC NERVOUS SYSTEM

The autonomic nervous system (ANS) is composed of motor (efferent) fibers that innervate smooth and cardiac muscle and secretory glands, and therefore, it is sometimes called the visceral motor system. The system is divided into two parts: a **sympathetic** portion and a **parasympathetic** portion, and both parts rely on two neurons to provide innervation, a preganglionic and a postganglionic neuron. Preganglionic neurons have their cell bodies in the gray matter of the CNS; postganglionic neurons have their cell bodies located outside of the CNS in **autonomic ganglia** and their fibers terminate on target organs. In general, **norepinephrine** is the neurotransmitter employed by the sympathetic system, whereas **acetylcholine** is employed by the parasympathetic system.

### Sympathetic Nervous System

Cell bodies of preganglionic neurons of the sympathetic nervous system are located in the intermedialateral cell columns (horns) of the spinal cord at the levels of T1–L2 (Fig. 18.42A). Cell bodies for postganglionic neurons are located in **paravertebral ganglia** on each side of the vertebral column and in **prevertebral (pauriotic ganglia** located around major vessels branching from the aorta (celiac, superior mesenteric, and inferior mesenteric arteries; Fig. 18.42A). Paravertebral ganglia are linked by fibers and form the right and left **sympathetic trunks (chain ganglia)**. All of these ganglia originate from neural crest.

cells of the thoracic region that migrate during the fifth week of development (Fig. 18.41). Crest cells forming the sympathetic trunk ganglia also migrate cranially and caudally to extend these trunks into cervical and pelvic regions. Migration and positioning of these crest cells is regulated by BMPs secreted by the dorsal aorta that act as chemoattractants for the migrating cells.

**FIGURE 18.41** Formation of the sympathetic ganglia. Neural crest cells (light blue) migrate from the neural tube and form the dorsal root ganglia, all of the sympathetic ganglia, and the adrenal medulla.

Preganglionic sympathetic fibers originating from cell bodies in the spinal cord from T1 to L2 exit via ventral roots (because they are motor fibers), enter a spinal nerve, then a ventral primary ramus, and, almost immediately, enter a white ramus communicans to reach the sympathetic trunk (Fig. 18.42). Once in the trunk, they can synapse at the seg-
FIGURE 18.42 Diagram of the sympathetic component of the ANS. The system originates in the intermediolateral cell columns [horns] of the spinal cord from segments T1–L2, which house the preganglionic nerve cell bodies. Fibers from these cells enter the ventral roots of spinal nerves, then ventral primary rami, then white rami communicans to reach the sympathetic trunks. Once in the trunks, they may synapse at the segment they entered, ascend or descend to synapse at other levels, or pass through without synapsing to travel to prevertebral ganglia as abdominopelvic splanchnic nerves.
Part II • Systems-Based Embryology

ment they entered, ascend or descend to synapse on cranial or caudal neurons, or they can pass through the trunks without synapsing and travel to prevertebral ganglia to synapse. Preganglionic fibers traveling to prevertebral ganglia are collected into groups called abdominopelvic splanchnic nerves: These include the greater (T5–T9), lesser (T10–T11), least (T12), and lumbar splanchnic nerves (Fig. 18.42). Postganglionic fibers from the sympathetic trunk ganglia to blood vessels, arrector pili muscles (goose bumps), and sweat glands in the head and neck, body wall, and limbs travel from the sympathetic trunk through gray rami communicantes to ventral rami of all 31 spinal nerves and travel on blood vessels to reach their destinations (Fig. 18.42). Postganglionic fibers from lower cervical and upper thoracic trunk ganglia exit the trunks as collections of fibers called the cardiopulmonary splanchnic nerves on their way to innervate the heart and lungs (Fig. 18.42). Postganglionic fibers from prevertebral (preaortic) ganglia travel via blood vessels to innervate the abdominal organs and genitalia. Note that because cell bodies of preganglionic neurons are located in spinal cord segments T1–L2, these segments will be the only ones to have white rami communicantes. However, because each spinal nerve receives fibers from postganglionic neurons, every ventral primary rami of every spinal nerve will be connected to a gray rami communicantes.

Parasympathetic Nervous System

Preganglionic parasympathetic neuron cell bodies are located in the brainstem and the sacral region (S2–S4) of the spinal cord and consequently are sometimes called the craniosacral portion of the ANS (Fig.18.43). Preganglionic parasympathetic fibers from nuclei in the brainstem travel via the oculomotor (CN III), facial (CN VII), glossopharyngeal (CN IX), and vagus (CN X) nerves to structures in the head and neck. The vagus nerve also supplies parasympathetic innervation to most of the visceral organs down to the region of the proximal third of the transverse colon (Fig. 18.43). Preganglionic fibers from the sacral component of the system exit the spinal cord via the ventral roots of spinal nerves from S2 to S4 and then leave the ventral primary rami of these nerves as the pelvic splanchnic nerves to provide innervation to the remaining portion of the gastrointestinal tract from the distal two-thirds of the transverse colon to the rectum (Fig. 18.43). Some of these fibers also travel to the bladder and erectile tissue of the genitalia. Postganglionic parasympathetic neuron cell bodies in the cranial region reside in four ganglia: the ciliary (CN III), pterygopalatine and submandibular (CN VII), and otic (CN IX; Fig.18.43). Postganglionic neurons in the thorax and abdomen associated with the vagus nerve (CN X) are usually located in or on the organ innervated. This arrangement is also true for postganglionic cell bodies of pelvic splanchnic nerves in the pelvic region, which exist individually or as smaller ganglia in the walls of target organs, such as the enteric ganglia of the gut. As in the sympathetic system, postganglionic neurons throughout the parasympathetic system are derived from neural crest cells.

Suprarenal (Adrenal) Gland

The suprarenal (adrenal) gland develops from two components: (1) a mesodermal portion, which forms the cortex, and (2) an ectodermal portion, which forms the medulla. During the fifth week of development, mesothelial cells between the root of the mesentery and the developing gonad begin to proliferate and penetrate the underlying mesenchyme (Fig. 18.41). Here, they differentiate into large acidophilic cells, which form the fetal cortex, or primitive cortex, of the suprarenal gland (Fig. 18.44A). Shortly afterward, a second wave of cells from the mesothelium penetrates the mesenchyme and surrounds the original acidophilic cell mass. These cells, smaller than those of the first wave, later form the definitive cortex of the gland (Fig. 18.44). These are steroid-producing cells and in the second trimester begin secreting dehydroepiandrosterone (DHEA) that is converted to estrogen by the placenta. Evidence suggests that hormone production by the fetal cortex is important for maintaining the placenta and pregnancy. Soon after birth, the fetal cortex regresses rapidly, whereas the remaining cells differentiate into the three definitive layers of the cortex: the zona glomerulosa, zona fasciculata, and zona reticularis (Fig. 18.44B). The cortex primarily secretes cortisol, aldosterone, and androgens.
Chapter 18 • Central Nervous System

Parasympathetic fibers

--- Presynaptic
--- Postsynaptic

FIGURE 18.43 Diagram of the parasympathetic component of the ANS. The system has a craniosacral origin with preganglionic cell bodies originating in the brainstem and the spinal cord at segments S2–S4. Preganglionic fibers from the brainstem travel through CN III, CN VII, CN IX, and CN X and synapse on postganglionic neurons in the ciliary [CN III], pterygopalatine [CN VII], and otic [CN IX] ganglia. Postganglionic neurons associated with the vagus nerve [CN X] are usually located in the organ innervated. Preganglionic fibers from sacral segments leave the ventral primary rami of spinal nerves S2–S4 as pelvic splanchnic nerves and innervate the gastrointestinal tract from the distal two thirds of the transverse colon to the rectum.
While the fetal cortex is being formed, neural crest cells invade its medial aspect, where they are arranged in cords and clusters to form the medulla of the gland (Figs. 18.41 and 18.44A). Signals that regulate migration of these cells and their specification to the adrenal medulla emanate from the dorsal aorta and include BMPs. When differentiated, these cells stain yellow-brown with chrome salts and hence are called chromaffin cells (Fig. 18.44B). These cells represent modified postganglionic sympathetic neurons that are innervated by preganglionic sympathetic fibers and when stimulated produce epinephrine (adrenaline) and norepinephrine (noradrenaline) that are released directly into the bloodstream. During embryonic life, chromaffin cells are scattered widely throughout the embryo, but in the adult, the only persisting group is in the medulla of the adrenal glands.

**Clinical Correlates**

**Pheochromocytomas**

Pheochromocytomas are rare tumors involving chromaffin cells that result in excessive production and release of epinephrine and norepinephrine causing paroxysmal episodes of hypertension, increased heart rate, headaches, and other associated symptoms. Most occur in the adrenal medulla, but approximately 10% occur in other sites, usually the abdomen. Twenty-five percent are familial and have been associated with mutations in the *RET* gene that plays a role in neural crest cell migration.

**Congenital Megacolon (Hirschsprung Disease)**

Congenital megacolon (Hirschsprung disease) results from a failure of parasympathetic ganglia to form in the wall of a part or all of the colon and rectum because the neural crest cells fail to migrate. Most familial cases of Hirschsprung disease are caused by mutations in the *RET* gene, which codes for a cell membrane tyrosine kinase receptor. This gene on chromosome 10q11 is essential for neural crest cell migration. The ligand for the receptor is GLIAL CELL-DERIVED NEUROTROPHIC GROWTH FACTOR secreted by mesenchyme cells through which crest cells migrate. Receptor ligand interactions then regulate crest cell migration. Consequently, if there are abnormalities in the receptor, migration is inhibited, and no parasympathetic ganglia form in affected areas. The rectum is involved in nearly all cases, and the rectum and sigmoid are involved in 80% of affected infants. The transverse and ascending portions of the colon are involved in only 10% to 20%. The colon is dilated above the affected region, which has a small diameter because of tonic contraction of noninnervated musculature.
SUMMARY

The central nervous system (CNS) originates in the ectoderm and appears as the neural plate at the middle of the third week (Fig. 18.1). After the edges of the plate fold, the neural folds approach each other in the midline to fuse into the neural tube (Figs. 18.2 and 18.3). The cranial end closes at approximately day 25, and the caudal end closes at day 28. The CNS then forms a tubular structure with a broad cephalic portion, the brain, and a long caudal portion, the spinal cord. Failure of the neural tube to close results in defects such as spina bifida (Figs. 18.15 and 18.16) and anencephaly (Fig. 18.37), defects that can be prevented by folic acid.

The spinal cord, which forms the caudal end of the CNS, is characterized by the basal plate containing the motor neurons, the alar plate for the sensory neurons, and a floor plate and a roof plate as connecting pathways between the two sides (Fig. 18.8). Spinal nerves form from each segment of the spinal cord. These nerves have their motor nuclei in the basal plate (inside the cord) and their sensory cell bodies in spinal ganglia derived from neural crest cells (outside the cord). SHH ventralizes the neural tube in the spinal cord region and induces the floor and basal plates. BMP4 and BMP7, expressed in nonneural ectoderm, maintain and upregulate expression of PAX3 and PAX7 in the alar and roof plates.

The brain can be divided into the brain stem, which is a continuation of the spinal cord and resembles that structure in its organization of basal and alar plates, and the higher centers, the cerebellum and cerebral hemispheres, which accentuate the alar plates. After closure of the neural tube, the brain consists of three vesicles: the rhombencephalon (hindbrain), mesencephalon (midbrain), and prosencephalon (forebrain). Later, these primary vesicles subdivide into five different regions (Fig. 18.5). The rhombencephalon is divided into (1) the myelencephalon, which forms the medulla oblongata (this region has a basal plate for somatic and visceral efferent neurons and an alar plate for somatic and visceral afferent neurons) (Fig. 18.18), and (2) the metencephalon, with its typical basal (efferent) and alar (afferent) plates (Fig. 18.19). This brain vesicle is also characterized by formation of the cerebellum (Fig. 18.20), a coordination center for posture and movement, and the pons, the pathway for nerve fibers between the spinal cord and the cerebral and the cerebellar cortices (Fig. 18.19).

The mesencephalon, or midbrain, does not subdivide and resembles the spinal cord with its basal efferent and alar afferent plates. The mesencephalon’s alar plates form the anterior and posterior colliculi as relay stations for visual and auditory reflex centers, respectively (Fig. 18.23). The prosencephalon also subdivides into the diencephalon posteriorly and the telencephalon anteriorly. The diencephalon consists of a thin roof plate and a thick alar plate in which the thalamus and hypothalamus develop (Figs. 18.24 and 18.25). It participates in formation of the pituitary gland, which also develops from Rathke’s pouch (Fig. 18.26). Rathke’s pouch forms the adenohypophysis, the intermediate lobe, and pars tuberalis, and the diencephalon forms the posterior lobe, the neurohypophysis, which contains neuroglia and receives nerve fibers from the hypothalamus.

The telencephalon consists of two lateral outpocketings, the cerebral hemispheres, and a median portion, the lamina terminalis (Fig. 18.27). The lamina terminalis is used by the commissures as a connection pathway for fiber bundles between the right and left hemispheres (Fig. 18.30). The cerebral hemispheres, originally two small outpocketings (Figs. 18.24 and 18.25), expand and cover the lateral aspect of the diencephalon, mesencephalon, and metencephalon (Figs. 18.26 to 18.28). Eventually, nuclear regions of the telencephalon come in close contact with those of the diencephalon (Fig. 18.27).

The ventricular system, containing cerebrospinal fluid (CSF), extends from the lumen in the spinal cord to the fourth ventricle in the rhombencephalon through the narrow aqueduct in the mesencephalon (aqueduct of Sylvius) and to the third ventricle in the diencephalon. By way of the foramina of Monro, the ventricular system extends from the third ventricle into the lateral ventricles of the cerebral hemispheres. CSF is produced in the choroid plexuses of the third, fourth, and lateral ventricles. Blockage of CSF in the ventricular system or subarachnoid space results in hydrocephalus.

The brain is patterned along the anteroposterior (craniocaudal) and dorsoventral (mediolateral) axes. HOX genes pattern the anteroposterior axis in the hindbrain and specify rhombomere
identity. Other transcription factors containing a homeodomain pattern the anteroposterior axis in the forebrain and midbrain regions, including LIM1 and OTX2. Two other organizing centers, the anterior neural ridge (ANS) and the rhombencephalic isthmus, secrete FGF8, which serves as the inducing signal for these areas. In response to this growth factor, the cranial end of the forebrain expresses FOXG1, which regulates development of the telencephalon, and the isthmus expresses ENGRAILED genes that regulate differentiation of the cerebellum and the roof of the midbrain. As it does throughout the CNS, SHH, secreted by the prechordal plate and notochord, ventralizes the forebrain and midbrain areas. BMP4 and BMP7, secreted by nonneural ectoderm, induce and maintain expression of dorsalizing genes.

There are 12 cranial nerves, and most of these originate from the hindbrain. Motor neurons for each of the nerves are located within the brain, whereas sensory neurons originate outside of the brain from ectodermal placodes and neural crest cells (Tables 18.2 and 18.3). In this regard, organization of the sensory and motor cell bodies for these nerves is similar to that for spinal nerves.

The autonomic nervous system (ANS) consists of sympathetic and parasympathetic components. This is a two-neuron system with preganglionic and postganglionic fibers. Preganglionic neurons for the sympathetic system lie in the intermediate (lateral) horns of the spinal cord from T1 to L2; its postganglionic neurons lie in the sympathetic trunks and paravertebral (preaortic) ganglia along the aorta. Parasympathetic preganglionic neurons have their nuclei in the brainstem (associated with CNs III, VII, IX, and X) and in the sacral region of the spinal cord (S2–S4); postganglionic nuclei reside in ganglia that usually lie close to the organs they innervate. Neural crest cells form all of the ganglia for the ANS.

The suprarenal (adrenal) gland is derived from two sources: (1) mesoderm from the posterior body wall that proliferates to form the fetal cortex that is replaced by a second proliferation of these cells that form the definitive cortex. This part of the gland produces steroids and plays a role in maintaining pregnancy by secreting DHEA that is converted by the placenta to estrogen; (2) neural crest cells that migrate from the neural folds and form the medulla of the gland. These cells differentiate into chromaffin cells and represent modified postganglionic sympathetic neurons. When stimulated by preganglionic neurons, they secrete epinephrine (adrenalin) and norepinephrine (noradrenaline) directly into the bloodstream.

### Problems to Solve

1. How are cranial nerves and spinal nerves similar? How are they different?
2. What components come together to form a spinal nerve? What is the difference between a dorsal root, ventral root, dorsal primary ramus, and ventral primary ramus? What types of fibers (sensory or motor) are found in each of these structures?
3. At what level is a spinal tap performed? From an embryological standpoint, why is this possible?
4. What is the embryological basis for most NTDs? Can they be diagnosed prenatally? Are there any means of prevention?
5. Prenatal ultrasound reveals an infant with an enlarged head and expansion of both lateral ventricles. What is this condition called, and what might have caused it?
6. What are the two parts of the ANS? Where are their respective preganglionic neurons located? What cells give rise embryologically to their postganglionic neurons?
In the adult, the ear forms one anatomic unit serving both hearing and equilibrium. In the embryo, however, it develops from three distinctly different parts: (1) the external ear, the sound-collecting organ; (2) the middle ear, a sound conductor from the external to the internal ear; and (3) the internal ear, which converts sound waves into nerve impulses and registers changes in equilibrium.

**INTERNAL EAR**

The first indication of the developing ear can be found in embryos of approximately 22 days as a thickening of the surface ectoderm on each side of the rhombencephalon (Fig. 19.1). These thickenings, the otic placodes, invaginate rapidly and form the otic or auditory vesicles (otocysts) (Fig. 19.2). Cells from the otocyst differentiate and form ganglion cells for the statoacoustic (vestibulocochlear) ganglia (Fig. 19.2C). During later development, each vesicle divides into (1) a ventral component that gives rise to the saccule and cochlear duct and (2) a dorsal component that forms the utricle, semicircular canals, and endolymphatic duct (Figs. 19.3 to 19.6). Together, these epithelial structures form the membranous labyrinth.

**Saccule, Cochlea, and Organ of Corti**

In the sixth week of development, the saccule forms a tubular outpocketing at its lower pole (see Fig. 19.3C–E). This outgrowth, the cochlear duct, penetrates the surrounding mesenchyme in a spiral fashion until the end of the eighth week, when it has completed 2.5 turns...

FIGURE 19.2 Transverse sections through the region of the rhombencephalon showing formation of the otic vesicles. A, 24 days. B, 27 days. C, 4.5 weeks. Neurons derived from the otic vesicle [otocyst] form the statoacoustic (vestibulocochlear) ganglia.

FIGURE 19.3 A,B. Development of the otocyst showing a dorsal utricular portion with the endolymphatic duct and a ventral saccular portion. C-E. Cochlear duct at 6, 7, and 8 weeks, respectively. Note formation of the ductus reuniens and the utriculosaccular duct.

(Fig. 19.3D,E). In the seventh week, cells of the cochlear duct differentiate into the spiral organ of Corti that transduces sound vibrations into electrical signals for hearing. A connection between the cochlear duct and the remaining portion of the saccule is maintained but confined to a narrow pathway, the ductus reuniens (Fig. 19.3E; see also Fig. 19.8).

Mesenchyme surrounding the cochlear duct soon differentiates into cartilage (Fig. 19.4A). In the 10th week, this cartilaginous shell undergoes vacuolization, and two perilymphatic spaces, the scala vestibuli and scala tympani, are formed (Fig. 19.4B, C). The cochlear duct is then separated from the scala vestibuli by the vestibular membrane and from the scala tympani by the basilar membrane (Fig. 19.4C). The lateral wall of the cochlear duct remains attached to the surrounding cartilage by the spiral ligament, whereas its median angle is connected to and partly supported by a long cartilaginous process, the modiolus, the future axis of the bony cochlea (Fig. 19.4B).

Initially, epithelial cells of the cochlear duct are alike (Fig. 19.4A). With further development, however, they form two ridges: the inner ridge, the future spiral limbus, and the outer ridge (Fig. 19.4B). The outer ridge forms one row of inner and three or four rows of outer hair cells, the sensory cells of the auditory system (Fig. 19.5). They are covered by the tectorial membrane, a fibrillar gelatinous substance attached to the spiral limbus that rests with its tip on the hair cells (Fig. 19.5). The sensory cells and tectorial membrane together constitute the organ of Corti. Impulses received by this organ are transmitted to the spiral ganglion and then to the nervous system by the auditory fibers of cranial nerve VIII (Figs. 19.4 and 19.5).
Figure 19.4 Development of the scala tympani and scala vestibuli. **A.** The cochlear duct is surrounded by a cartilaginous shell. **B.** During the 10th week, large vacuoles appear in the cartilaginous shell. **C.** The cochlear duct (scala media) is separated from the scala tympani and the scala vestibuli by the basilar and vestibular membranes, respectively. Ganglion cells from the vestibulocochlear nerve (cranial nerve VIII) form the spiral ganglion and extend processes to innervate the hair cells.

Figure 19.5 Development of the organ of Corti. **A.** 10 weeks. **B.** Approximately 5 months. **C.** Full-term infant.
Utricle and Semicircular Canals

During the sixth week of development, semicircular canals appear as flattened outpocketings of the utricular part of the otic vesicle (Fig. 19.6A,B). Central portions of the walls of these outpocketings eventually appose each other (Fig. 19.6B,C) and disappear, giving rise to three semicircular canals (Fig. 19.6; see also Fig. 19.8). Whereas one end of each canal dilates to form the crus ampullare, the other, the crus nonampullare, does not widen (Fig. 19.6). Because two of the latter type fuse, however, only five crura enter the utricle, three with an ampulla and two without.

Cells in the ampullae form a crest, the crista ampullaris, containing sensory cells for maintenance of equilibrium. Similar sensory areas, the maculae acusticae, develop in the walls of the utricle and saccule. Impulses generated in sensory cells of the crista and maculae as a result of a change in position of the body are carried to the brain by vestibular fibers of cranial nerve VIII.

During formation of the otic vesicle, a small group of cells breaks away from its wall and forms the statoacoustic ganglion (Fig. 19.2C). Other cells of this ganglion are derived from the neural crest. The ganglion subsequently splits into cochlear and vestibular portions, which supply sensory cells of the organ of Corti and those of the saccule, utricle, and semicircular canals, respectively.

MIDDLE EAR

Tympanic Cavity and Auditory Tube

The tympanic cavity, which originates in the endoderm, is derived from the first pharyngeal pouch (Figs. 19.2 and 19.7). This pouch expands in a lateral direction and comes in contact with the floor of the first pharyngeal cleft. The distal part of the pouch, the tubotympanic recess, widens and gives rise to the primitive tympanic cavity, and the proximal part remains narrow and forms the auditory tube (eustachian tube) (Figs. 19.7B and 19.8), through which the tympanic cavity communicates with the nasopharynx.

Ossicles

The malleus and incus are derived from cartilage of the first pharyngeal arch, and the stapes is derived from that of the second arch (Fig. 19.9A). Although the ossicles appear during the first half of fetal life, they remain embedded in mesenchyme until the eighth month (Fig. 19.9B), when the surrounding tissue dissolves (Figs. 19.7, 19.8, and 19.9B). The endodermal epithelial lining of the primitive tympanic cavity then extends along the wall of the newly developing space. The tympanic cavity is now at least twice as large as before. When the ossicles are entirely free of surrounding mesenchyme, the endodermal epithelium connects them in a mesentery-like fashion to the wall of the cavity.
FIGURE 19.7 A. Transverse section of a 7-week embryo in the region of the rhombencephalon, showing the tubotympanic recess, the first pharyngeal cleft, and mesenchymal condensation, foreshadowing development of the ossicles. B. Middle ear showing the cartilaginous precursors of the auditory ossicles. Thin yellow line in mesenchyme indicates future expansion of the primitive tympanic cavity.

FIGURE 19.8 Ear showing the external auditory meatus, the middle ear with its ossicles, and the inner ear.

FIGURE 19.9 A. Derivatives of the first three pharyngeal arches. The malleus and incus form at the dorsal tip of the first arch and the stapes at that of the second arch. B. Middle ear showing the handle of the malleus in contact with the eardrum. The stapes will establish contact with the membrane in the oval window. The wall of the tympanic cavity is lined with endodermal epithelium.
Because the malleus is derived from the first pharyngeal arch, its muscle, the tensor tympani, is innervated by the mandibular branch of the trigeminal nerve. The stapedius muscle, which is attached to the stapes, is innervated by the facial nerve, the nerve to the second pharyngeal arch.

During late fetal life, the tympanic cavity expands dorsally by vacuolization of surrounding tissue to form the tympanic antrum. After birth, the epithelium of the tympanic cavity invades the bone of the developing mastoid process, and epithelium-lined air sacs are formed (pneumatization). Later, most of the mastoid air sacs come in contact with the antrum and tympanic cavity. Expansion of inflammations of the middle ear into the antrum and mastoid air cells is a common complication of middle ear infections.

### EXTERNAL EAR

#### External Auditory Meatus

The external auditory meatus develops from the dorsal portion of the first pharyngeal cleft (Fig. 19.7A). At the beginning of the third month, epithelial cells at the bottom of the meatus proliferate, forming a solid epithelial plate, the meatal plug (Fig. 19.7B). In the seventh month, this plug dissolves, and the epithelial lining of the floor of the meatus participates in formation of the definitive eardrum. Occasionally, the meatal plug persists until birth, resulting in congenital deafness.

#### Eardrum or Tympanic Membrane

The eardrum is made up of (1) an ectodermal epithelial lining at the bottom of the auditory meatus, (2) an endodermal epithelial lining of the tympanic cavity, and (3) an intermediate layer of connective tissue (Fig. 19.9B) that forms the fibrous stratum. The major part of the eardrum is firmly attached to the handle of the malleus (Figs. 19.8 and 19.9B), and the remaining portion forms the separation between the external auditory meatus and the tympanic cavity.

#### Auricle

The auricle develops from six mesenchymal proliferations at the dorsal ends of the first and second pharyngeal arches, surrounding the first pharyngeal cleft (Fig. 19.10). These swellings (auricular hillocks), three on each side of the external meatus, later fuse and form the definitive auricle (Fig. 19.10). Because formation and fusion of the auricular hillocks is complicated, developmental abnormalities of the auricle are common. Furthermore, because the hillocks are derived from neural crest cells, external ear defects are often associated with malformations in other organs derived from neural crest cells, such as the face, skull, and heart. Initially, the external ears are in the lower neck region (Fig. 19.10A,B), but growth of the mandible posteriorly and cranially, moves the external ears to the side of the head at the level of the eyes.

### HEARING

Hearing is dependent on sound waves that cause vibrations in the tympanic membrane, which is held tightly like the surface of a drum by the tensor tympani muscle. If too loud a sound, causing potentially damaging vibrations, occurs, the tensor tympani together with the stapedius muscle stretches the membrane even tighter to prevent it from vibrating too forcefully. Once the tympanic membrane vibrates, it causes movement of the ear ossicles, the malleus, incus, and stapes that serve to amplify the force of the sound wave and to transmit the pressure of the wave to the cochlea through the oval window (Fig. 19.8). Amplification results from two factors: (1) The large size difference between the tympanic membrane \((55 \text{ mm}^2)\) and the oval window \((3.2 \text{ mm}^2)\), where the stapes attaches, results in greater energy produced by the membrane to be transferred and amplified at the oval window; (2) because of its shape, the malleus acts like a lever to increase the force received by the stapes (Fig. 19.8 and 19.9B). Pressure produced by movement of the stapes at the oval window creates a fluid wave in the cochlea that is balanced by movement of the round window (Fig. 19.8). The fluid wave moves small regions of the basilar membrane (Fig. 19.4) and the location of these regions is determined in part by the amplitude (loudness) and frequency (pitch) of the wave. Near the oval window, the basilar membrane is attached by shorter stiffer fibers to the side of the cochlea; farther along the cochlea, the fibers are longer and more flexible. Based on these fiber characteristics and the frequency of the wave, the wave reaches a point where it resonates with
the fibers and moves the basilar membrane. This movement is sensed by adjacent hair cells that send impulses back through nerve fibers of the acoustic segment of the statoacoustic nerve (Fig. 19.4C and 19.5C). High frequencies (high pitch) are heard near the oval window where fibers connecting the basilar membrane are shorter and stiffer; lower frequencies are heard farther up the cochlea where the fibers are longer and more flexible.

**Clinical Correlates**

**Hearing Loss and External Ear Abnormalities**

Congenital hearing loss may be due to abnormalities of the hair cells or auditory nerve ganglia (sensorineural loss) or to structural defects in the external ear canal, eardrum, or ear ossicles (conductive hearing loss). Fifty percent of cases are genetic and may involve autosomal dominant or recessive or X-linked genes. In Treacher Collins syndrome, malformations in the external ear and ear canal and the ear ossicles can all be involved in causing (continued)
varying degrees of conductive hearing loss. In Down syndrome, hearing loss may be caused by sensorineural and/or conductive abnormalities. Most cases caused by other factors are characterized by sensorineural defects. These factors include prenatal infections (rubella, cytomegalovirus, herpes simplex), prematurity, and maternal diabetes. Accutane (retinoids) can cause both types of deafness.

The most common ear ossicle to be involved in conductive hearing loss is the **stapes**, and this fact may be due to its unique origin because its footplate is derived from neural crest cells and paraxial mesoderm. Neural crest cells direct formation of the footplate and of the oval window. Without directive signals from the neural crest, neither the footplate nor the oval window develops properly. Stapes fixation (ankylosis) is the most common abnormality and usually involves both ears.

**External ear defects** are common; they include minor and severe abnormalities [Fig. 19.11]. They are significant from the standpoint of the psychological and emotional trauma they may cause and for the fact that they are often associated with other malformations. This association is due in part to the fact that external ears are derived from neural crest cells and this cell type contributes to development of many other structures, including the face, skull, and heart. Thus, external ear defects serve as clues to examine infants

![Figure 19.11](image-url)
carefully for other abnormalities. All of the frequently occurring chromosomal syndromes and most of the less common ones have ear anomalies as one of their characteristics.

Preauricular appendages and pits (Fig. 19.11 C,D) are skin tags and shallow depressions, respectively, anterior to the ear. Pits may indicate abnormal development of the auricular hillocks, whereas appendages may be caused by accessory hillocks. Like other external ear defects, both are sometimes associated with other malformations.

**SUMMARY**

The ear consists of three parts that have different origins but that function as one unit. The internal ear originates from the otic vesicle, which in the fourth week of development detaches from surface ectoderm. This vesicle divides into a ventral component, which gives rise to the sacculus and cochlear duct and a dorsal component, which gives rise to the utricle, semicircular canals, and endolymphatic duct (Figs. 19.3, 19.6, and 19.8). The epithelial structures thus formed are known collectively as the membranous labyrinth. Except for the cochlear duct, which forms the organ of Corti, all structures derived from the membranous labyrinth are involved with equilibrium.

The middle ear, consisting of the tympanic cavity and auditory tube, is lined with epithelium of endodermal origin and is derived from the first pharyngeal pouch. The auditory tube extends between the tympanic cavity and nasopharynx. The ossicles, which transfer sound from the tympanic membrane to the oval window, are derived from the first (malleus and incus) and second (stapes) pharyngeal arches (Fig. 19.9).

The external auditory meatus develops from the first pharyngeal cleft and is separated from the tympanic cavity by the tympanic membrane (eardrum). The eardrum consists of (1) an ectodermal epithelial lining, (2) an intermediate layer of mesenchyme, and (3) an endodermal lining from the first pharyngeal pouch.

The auricle develops from six mesenchymal hillocks (Fig. 19.10) along the first and second pharyngeal arches. Defects in the auricle are often associated with other congenital malformations.

### Problems to Solve

1. The otic placode plays a major role in formation of the internal (inner ear). What is a placode, and where does the otic placode form? What structures does it contribute to the inner ear?
2. What is the embryologic origin of the tympanic (middle ear) cavity, auditory tube, and tympanic membrane (eardrum)?
3. A newborn has bilateral microtia. Should you be concerned about other malformations? What cell population might be involved in the embryologic origin of the defect?
The developing eye appears in the 22-day embryo as a pair of shallow grooves on the sides of the forebrain (Fig. 20.1). With closure of the neural tube, these grooves form outpocketings of the forebrain, the optic vesicles. These vesicles subsequently come in contact with the surface ectoderm and induce changes in the ectoderm necessary for lens formation (Fig. 20.1). Shortly thereafter, the optic vesicle begins to

**FIGURE 20.1** A. Embryo at the end of 4 weeks of development showing the otic and optic vesicles. B. Transverse section through the forebrain of a 22-day embryo (~14 somites) showing the optic grooves. C. Transverse section through the forebrain of a 4-week embryo showing the optic vesicles in contact with the surface ectoderm. Note the slight thickening of the ectoderm (lens placode). D. Transverse section through the forebrain of a 5-mm embryo showing invagination of the optic vesicle and the lens placode.
invaginate and forms the double-walled optic cup (Figs. 20.1 and 20.2A). The inner and outer layers of this cup are initially separated by a lumen, the intraretinal space (Fig. 20.2B), but soon this lumen disappears, and the two layers appose each other (Fig. 20.2D,E). Invagination is not restricted to the central portion of the cup but also involves a part of the inferior surface (Fig. 20.2A) that forms the choroid fissure. Formation of this fissure allows the hyaloid artery to reach the inner chamber of the eye (Fig. 20.3; see also Fig. 20.7). During the seventh week, the lips of the choroid fissure fuse, and the mouth of the optic cup becomes a round opening, the future pupil.

During these events, cells of the surface ectoderm, initially in contact with the optic vesicle, begin to elongate and form the lens placode (Fig. 20.1). This placode subsequently invaginates
and develops into the lens vesicle. During the fifth week, the lens vesicle loses contact with the surface ectoderm and lies in the mouth of the optic cup (Figs. 20.2C–E and 20.3).

**RETINA, IRIS, AND CILIARY BODY**

The outer layer of the optic cup, which is characterized by small pigment granules, is known as the pigmented layer of the retina (Fig. 20.2D,E; see also Fig. 20.6). Development of the inner (neural) layer of the optic cup is more complicated. The posterior four-fifths, the pars optica retinæ, contains cells bordering the intraretinal space (Fig. 20.3) that differentiate into the photoreceptive rods and cones (Fig. 20.4). Rods are more numerous (120 million) and more sensitive than cones (6 to 7 million) but do
not detect color like the cones. Adjacent to this photoreceptive layer is the mantle layer, which, as in the brain, gives rise to neurons and supporting cells, including the outer nuclear layer, inner nuclear layer, and ganglion cell layer (Fig. 20.4). On the surface is a fibrous layer that contains axons of nerve cells of the deeper layers. Nerve fibers in this zone converge toward the optic stalk, which develops into the optic nerve (Fig. 20.3). Hence, light impulses pass through most layers of the retina before they reach the rods and cones.

The anterior fifth of the inner layer, the pars ceca retinae, remains one cell layer thick. It later divides into the pars iridica retinae, which forms the inner layer of the iris, and the pars ciliaris retinae, which participates in formation of the ciliary body (Figs. 20.5 and 20.6).

Meanwhile, the region between the optic cup and the overlying surface epithelium is filled with loose mesenchyme (Figs. 20.2C and 20.6). The sphincter and dilator pupillae muscles form in this tissue (Fig. 20.5). These muscles develop from the underlying ectoderm of the optic cup. In the adult, the iris is formed by the pigment-containing external layer, the unpigmented internal layer of the optic cup, and a layer of richly vascularized connective tissue that contains the pupillary muscles (Fig. 20.5).

The pars ciliaris retinae is easily recognized by its marked folding (Figs. 20.5B and 20.6). Externally, it is covered by a layer of mesenchyme (Figs. 20.2C and 20.6). The primary lens fibers reach the anterior wall of the lens vesicle. Growth of the lens is not finished at this stage, however, because new (secondary) lens fibers are continuously added to the central core.

**LENS**

Shortly after formation of the lens vesicle (Fig. 20.2C), cells of the posterior wall begin to elongate anteriorly and form long fibers that gradually fill the lumen of the vesicle (Fig. 20.3). By the end of the seventh week, these primary lens fibers reach the anterior wall of the lens vesicle. Growth of the lens is not finished at this stage, however, because new (secondary) lens fibers are continuously added to the central core.

**CHOROID, SCLERA, AND CORNEA**

At the end of the fifth week, the eye primordium is completely surrounded by loose mesenchyme (Fig. 20.3). This tissue soon differentiates into an inner layer comparable with the pia mater of the brain and an outer layer comparable with the dura mater. The inner layer later forms a highly vascularized pigmented layer known as the choroid; the outer layer develops into the sclera and is continuous with the dura mater around the optic nerve (Fig. 20.6).

Differentiation of mesenchymal layers overlying the anterior aspect of the eye is different. The anterior chamber forms through vacuolization and splits the mesenchyme into an inner layer in front of the lens and iris, the iridopupillary membrane, and an outer layer continuous with the sclera, the substantia propria of the cornea (Fig. 20.6). The anterior chamber itself is lined by flattened mesenchymal cells. Hence, the cornea is formed by (1) an epithelial layer derived from the surface ectoderm, (2) the substantia propria or stroma, which is continuous with the sclera, and (3) an epithelial layer, which borders the anterior chamber. The iridopupillary membrane in front of the lens disappears completely. The posterior chamber is the space between the iris anteriorly and the lens and ciliary body posteriorly. The anterior and posterior chambers communicate with each other through the pupil and are filled with fluid called the aqueous humor produced by the ciliary process of the ciliary body. The clear aqueous humor circulates from the posterior chamber into the anterior chamber providing nutrients for the avascular cornea and lens. From the anterior chamber, the fluid passes through the scleral venous sinus (canal of Schlemm) at the iridocorneal angle where it is resorbed into the bloodstream. Blockage of the flow of fluid at the canal of Schlemm is one cause of glaucoma.

**VITREOUS BODY**

Mesenchyme not only surrounds the eye primordium from the outside but also invades the inside of the optic cup by way of the choroid fissure. Here, it forms the hyaloid vessels, which during intrauterine life supply the lens and form the vascular layer on the inner surface of the retina (Fig. 20.6). In addition, it forms a delicate...
FIGURE 20.5 Development of the iris and ciliary body. The rim of the optic cup is covered by mesenchyme, in which the sphincter and dilator pupillae develop from the underlying ectoderm.

FIGURE 20.6 Section through the eye of a 15-week fetus showing the anterior chamber, iridopupillary membrane, inner and outer vascular layers, choroid, and sclera.
network of fibers between the lens and retina. The interstitial spaces of this network later fill with a transparent gelatinous substance, forming the vitreous body (Fig. 20.6). The hyaloid vessels in this region are obliterated and disappear during fetal life, leaving behind the hyaloid canal.

### OPTIC NERVE

The optic cup is connected to the brain by the optic stalk, which has a groove, the choroid fissure, on its ventral surface (Figs. 20.2 and 20.3). In this groove are the hyaloid vessels. The nerve fibers of the retina returning to the brain lie among cells of the inner wall of the stalk (Fig. 20.7). During the seventh week, the choroid fissure closes, and a narrow tunnel forms inside the optic stalk (Fig. 20.7B). As a result of the continuously increasing number of nerve fibers, the inner wall of the stalk grows, and the inside and outside walls of the stalk fuse (Fig. 20.7C). Cells of the inner layer provide a network of neuroglia that supports the optic nerve fibers.

The optic stalk is thus transformed into the optic nerve. Its center contains a portion of the hyaloid artery, later called the central artery of the retina. On the outside, a continuation of the choroid and sclera, the pia arachnoid and dura layer of the nerve, respectively, surround the optic nerve.

### MOLECULAR REGULATION OF EYE DEVELOPMENT

PAX6 is the key regulatory gene for eye development. It is a member of the PAX (paired box) family of transcription factors and contains two DNA-binding motifs that include a paired domain and a paired-type homeodomain. Initially, this transcription factor is expressed in a band in the anterior neural ridge of the neural plate before neurulation begins (Fig. 20.8A,B; see also Fig. 18.32). At this stage, there is a single eye field that later separates into two optic primordia (Fig. 20.8B). The signal for separation of this field is SONIC HEDGEHOG (SHH) expressed in the prechordal plate. SHH expression upregulates PAX2 in the center of the eye field and downregulates PAX6 (Fig. 20.8C). Later, this pattern is maintained so that PAX2 is expressed in the optic stalks and PAX6 is expressed in the optic cup and overlying surface ectoderm that forms the lens. As development proceeds, it appears that PAX6 is not essential for optic cup formation. Instead, this process is regulated by interactive signals between the optic vesicle and surrounding mesenchyme and the overlying surface ectoderm in the lens-forming region (Fig. 20.9). Thus, fibroblast growth factors (FGFs) from the surface ectoderm promote differentiation of the neural (inner layer) retina, whereas transforming growth factor β (TGF-β), secreted by surrounding mesenchyme, directs formation of the pigmented (outer) retinal layer. Downstream from these gene products, the transcription factors MITF and CHX10 are expressed and direct differentiation of the pigmented and neural layer, respectively (Fig. 20.9). Thus, the lens ectoderm is essential for proper formation of the optic cup, such that without a lens placode, no cup invagination occurs.

Differentiation of the lens depends on PAX6, although the gene is not responsible for inductive activity by the optic vesicle. Instead, PAX6 acts in the surface ectoderm to regulate lens
development (Fig. 20.9C). This expression up-regulates the transcription factor SOX2 and also maintains PAX6 expression in the prospective lens ectoderm. In turn, the optic vesicle secretes BMP4, which also upregulates and maintains SOX2 expression as well as expression of LMAF, another transcription factor (Fig. 20.9C). Next, the expression of two homeobox genes, SIX3 and PROX1, is regulated by PAX6. The combined expression of PAX6, SOX2, and LMAF initiates expression of genes responsible for lens crystallin formation, including PROX1. SIX3 also acts as a regulator of crystallin production by inhibiting the crystallin gene. Finally, PAX6, acting through FOX3, regulates cell proliferation in the lens.
FIGURE 20.9 Drawing showing molecular regulation of epithelial–mesenchymal interactions responsible for patterning eye development. **A.** Once PAX6 establishes the eye field, fibroblast growth factors (FGFs), secreted by surface ectoderm in the prospective lens-forming region overlying the optic vesicle, promote differentiation of the neural retinal layer, whereas members of the transforming growth factor β (TGF-β) family, secreted by surrounding mesenchyme, promote differentiation of the pigmented retinal layer. These external signals cause regionalization of the inner and outer layers of the optic cup and upregulate downstream genes, including CHX10 and MITF, that regulate continued differentiation of these structures. **B,C.** In addition to its role in determining the eye fields, PAX6 regulates lens development. Thus, PAX6 upregulates SOX2 expression in the prospective lens, whereas BMP4 secreted by the outer vesicle upregulates the transcription factor LMAF. Once this gene is activated, PAX6 induces expression of the homeodomain–containing genes SIX3 and PROX1. The combined expression of PAX6, SOX2, LMAF, and PROX1 leads to crystallin formation. SIX3 assists in regulating this process by inhibiting the crystallin gene.

**Clinical Correlates**

**Eye Abnormalities**

**Coloboma** may occur if the choroid fissure fails to close. Normally, this fissure closes during the seventh week of development [Fig. 20.7]. When it does not, a cleft persists. Although such a cleft is usually in the iris only—coloboma iridis [Fig. 20.10A]—it may extend into the ciliary body, the retina, the choroid, and the optic nerve. Coloboma is a common eye abnormality frequently associated with other eye defects. Colobomas [clefts] of the eyelids may also occur. Mutations in the PAX2 gene have been linked with optic nerve colobomas and may play a role in the other types as well. Renal defects also occur with mutations in PAX2 as part of the renal coloboma syndrome [see Chapter 16].

The **iridopupillary membrane** [Fig. 20.10B] may persist instead of being resorbed during formation of the anterior chamber.

**Congenital cataracts** cause the lens to become opaque during intrauterine life. Although this anomaly is usually genetically determined, many children born to mothers who had rubella [German measles] between the fourth and seventh weeks of pregnancy had cataracts. If the mother is infected after the seventh week of pregnancy, the lens escapes damage, but the child may have hearing loss as a result of cochlear abnormalities. Because of the MMR [measles, mumps, and rubella] vaccine, congenital rubella syndrome has been nearly eradicated in the United States.
Part II • Systems-Based Embryology

The **hyaloid artery** may persist to form a cord or cyst. Normally, the distal portion of this vessel degenerates, leaving the proximal part to form the central artery of the retina.

In **microphthalmia**, the eye is too small; the eyeball may be only two-thirds of its normal volume. Usually associated with other ocular abnormalities, microphthalmia can result from intrauterine infections, such as cytomegalovirus and toxoplasmosis.

**Anophthalmia** is absence of the eye. In some cases, histological analysis reveals some ocular tissue. The defect is usually accompanied by severe cranial abnormalities.

**Congenital aphakia** (absence of the lens) and **aniridia** (absence of the iris; Fig. 20.11) are rare anomalies that result from disturbances in induction and development of tissues responsible for formation of these structures. Mutations in **PAX6** result in aniridia and may also contribute to anophthalmia and microphthalmia.

**Cyclopia** (single eye) and **synophthalmia** (fusion of the eyes) comprise a spectrum of defects in which the eyes are partially or completely fused [Fig. 20.12]. The defects are caused by a loss of midline tissue that may occur as early as days 19 to 21 of gestation or at later stages when facial development is initiated. This loss results in underdevelopment of the forebrain and frontonasal prominence.

These defects are invariably associated with a brain defect called **holoprosencephaly**, in which the cerebral hemispheres are partially or completely merged into a single telencephalic vesicle. Factors associated with holoprosencephaly include alcohol, maternal diabetes, mutations in **SHH**, and abnormalities in cholesterol metabolism that may disrupt **SHH** signaling [see Chapter 18].

**FIGURE 20.10** A. Coloboma iris. B. Persistence of the iridopupillary membrane.

**FIGURE 20.11** Patient with aniridia (absence of the iris), which can be due to mutations in PAX6.

**FIGURE 20.12** Synophthalmia. The eyes are fused because loss of midline structures prevented the eye fields from separating. Such babies also have severe cranial defects, including holoprosencephaly [see Chapter 18].
SUMMARY
The eyes begin to develop as a pair of outpocketings that will become the **optic vesicles** on each side of the forebrain at the end of the fourth week of development (Fig. 20.1). The optic vesicles contact the surface ectoderm and induce **lens** formation. When the optic vesicle begins to invaginate to form the pigment and neural layers of the retina, the lens placode invaginates to form the lens vesicle. Through a groove at the inferior aspect of the optic vesicle, the **choroid fissure**, the **hyaloid artery** (later the central artery of the retina) enters the eye (Fig. 20.3). Nerve fibers of the eye also occupy this groove to reach the optic areas of the brain. The cornea is formed by (1) a layer of surface ectoderm; (2) the stroma, which is continuous with the sclera; and (3) an epithelial layer bordering the anterior chamber (Fig. 20.6).

**PAX6**, the master gene for eye development, is expressed in the single eye field at the neural plate stage. The eye field is separated into two optic primordia by **SHH**, which upregulates **PAX2** expression in the optic stalks while downregulating **PAX6**, restricting this gene’s expression to the optic cup and lens. Epithelial–mesenchymal interactions between prospective lens ectoderm, optic vesicle, and surrounding mesenchyme then regulate lens and optic cup differentiation (Figs. 20.8 and 20.9).

### Problems to Solve
1. A newborn has unilateral aphakia (absent lens). What is the embryological origin of this defect?
2. In taking a history of a young woman in her 10th week of gestation, you become concerned that she may have contracted rubella sometime during the fourth to eighth weeks of her pregnancy. What types of defects might be produced in her offspring?
3. Physical examination of a newborn reveals clefts in the lower portion of the iris bilaterally. What is the embryological basis for this defect? What other structures might be involved?
The skin is the largest organ in the body and has a dual origin: (1) A superficial layer, the **epidermis**, develops from the surface ectoderm. (2) A deep layer, the **dermis**, develops from the underlying mesenchyme.

**Epidermis**

Initially, the embryo is covered by a single layer of ectodermal cells (Fig. 21.1A). In the beginning of the second month, this epithelium divides, and a layer of flattened cells, the **periderm** or **epitrichium**, is laid down on the surface (Fig. 21.1B). With further proliferation of cells in the basal layer, a third, intermediate zone is formed (Fig. 21.1C). Finally, at the end of the fourth month, the epidermis acquires its definitive arrangement, and four layers can be distinguished (Fig. 21.1D):

- **The basal layer**, or **germinative layer**, is responsible for production of new cells. This layer later forms ridges and hollows, which are reflected on the surface of the skin in the fingerprint.
- A thick **spinous layer** consists of large polyhedral cells containing fine tonofibrils.
- The **granular layer** contains small keratohyalin granules in its cells.
- The **horny layer**, forming the tough scale-like surface of the epidermis, is made up of closely packed dead cells containing keratin.

Cells of the periderm are usually cast off during the second part of intrauterine life and can be found in the amniotic fluid. During the first 3 months of development, the epidermis is invaded by cells arising from the neural crest. These cells synthesize melanin pigment in melanosomes. As melanosomes accumulate, they are transported down dendritic processes of melanocytes and are transferred intercellularly to keratinocytes of the skin and hair bulb. In this manner, pigmentation of the skin and hair is acquired.

**Dermis**

Dermis is derived from mesenchyme that has three sources: (1) lateral plate mesoderm supplying cells for dermis in the limbs and body...
Pigmentary Disorders
A large number of pigmentary disorders occur, and these can be classified as diseases of melanocyte development, function, and survival. Examples of abnormalities of melanocyte function include piebaldism (patchy absence of hair pigment) and Waardenburg syndrome (WS), which feature patches of white skin and hair. There are several types of WS, but they share some common characteristics, including patches of white hair (usually a forelock), heterochromia irides (eyes of different colors), white patches of skin, and deafness. The defects arise because of faulty migration or proliferation of neural crest cells (absence of melanocytes derived from these cells in the stria vascularis in the cochlea accounts for deafness in these diseases). Some types of WS result from mutations in PAX3, including WS1 and WS3.

Diseases of melanocyte function include the various forms of albinism characterized by globally reduced or absent pigmentation in the skin, hair, and eyes. These cases are classified as different types of oculocutaneous albinism (OCA). In most cases, abnormalities of melanin synthesis or processing produce the abnormalities.

Vitiligo results from a loss of melanocytes due to an autoimmune disorder. There is patchy loss of pigment from affected areas, including the skin and overlying hair and the oral mucosa. Vitiligo is also associated with other autoimmune diseases, particularly of the thyroid.

Fingerprints
The epidermal ridges that produce typical patterns on the surface of the fingertips, palms of the hand, and soles of the feet are genetically determined. They form the basis for many studies in medical genetics and criminal investigations (dermatoglyphics). In children with chromosomal abnormalities, the epidermal pattern on the hand and fingers is sometimes used as a diagnostic tool.

Clinical Correlates

Keratinization of the Skin
Ichthyosis, excessive keratinization of the skin, is characteristic of a group of hereditary disorders that are usually inherited as an autosomal recessive trait but may also be X-linked. In severe cases, ichthyosis may result in a grotesque appearance, as in the case of a harlequin fetus (Fig. 21.2).

FIGURE 21.2 Ichthyosis in a harlequin fetus with massive thickening of the keratin layer, which cracks to form fissures between thickened plaques.
wall, (2) paraxial mesoderm supplying cells for dermis in the back, and (3) neural crest cells supplying cells for dermis in the face and neck. During the third and fourth months, this tissue, the corium (Fig. 21.1D), forms many irregular papillary structures, the dermal papillae, which project upward into the epidermis. Most of these papillae contain a small capillary or a sensory nerve end organ. The deeper layer of the dermis, the subcutaneous layer, contains large amounts of fatty tissue.

At birth, the skin is covered by a whitish paste, the vernix caseosa, formed by secretions from sebaceous glands and degenerated epidermal cells and hairs. It protects the skin against the macerating action of amniotic fluid.

**HAIR**

Hairs begin development as solid epidermal proliferations from the germinative layer that penetrates the underlying dermis (Fig. 21.3A). At their terminal ends, hair buds invaginate. The invaginations, the hair papillae, are rapidly filled with mesoderm in which vessels and nerve endings develop (Fig. 21.3B,C). Soon, cells in the center of the hair buds become spindle-shaped and keratinized, forming the hair shaft, whereas peripheral cells become cuboidal, giving rise to the epithelial hair sheath (Fig. 21.3B,C).

The dermal root sheath is formed by the surrounding mesenchyme. A small smooth muscle, also derived from mesenchyme, is usually attached to the dermal root sheath. The muscle is the arrector pili muscle. Continuous proliferation of epithelial cells at the base of the shaft pushes the hair upward, and by the end of the third month, the first hairs appear on the surface in the region of the eyebrow and upper lip. The first hair that appears, lanugo hair, is shed at about the time of birth and is later replaced by coarser hairs arising from new hair follicles.

The epithelial wall of the hair follicle usually shows a small bud penetrating the surrounding mesoderm (Fig. 21.3C). Cells from these buds form the sebaceous glands. Cells from the central region of the gland degenerate, forming a fat-like substance (sebum) secreted into the hair follicle, and from there, they reach the skin.

![Figure 21.3](image.png)  Development of a hair and a sebaceous gland. **A.** 4 months. **B.** 6 months. **C.** Newborn.
Abnormalities of Hair Distribution

**Hypertrichosis** (excessive hairiness) is caused by an unusual abundance of hair follicles. It may be localized to certain areas of the body, especially the lower lumbar region covering a spina bifida occulta defect or may cover the entire body (Fig. 21.4).

**Atrichia**, the congenital absence of hair, is usually associated with abnormalities of other ectodermal derivatives, such as teeth and nails.

---

**FINGERNAILS AND TOENAILS**

By the end of the third month, thickenings in the epidermis appear at the tips of the digits to form the **nail fields**. From this location, these fields migrate to the dorsal side of each digit and grow proximally, forming the **nail root**, whereas proliferation of tissue surrounding each nail field creates a shallow depression for each nail. From the nail root, epidermis differentiates into fingernails and toenails that do not reach the tips of the digits until the ninth month of development.

---

**SWEAT GLANDS**

There are two types of sweat glands: **eccrine** and **apocrine**. Eccrine sweat glands form in the skin over most parts of the body beginning as buds from the germinative layer of the epidermis. These buds grow into the dermis, and their end coils to form the secretory parts of the glands. Smooth muscle cells associated with the glands also develop from the epidermal buds. These glands function by merocrine mechanisms (exocytosis) and are involved in temperature control.

Apocrine sweat glands develop anywhere there is body hair, including the face, axillae, and pubic region. They begin to develop during puberty and arise from the same epidermal buds that produce hair follicles. Hence, these sweat glands open onto hair follicles instead of skin. The sweat produced by these glands contains lipids, proteins, and pheromones, and odor originating from this sweat is due to bacteria that break down these products. It should be noted that these glands classified as apocrine because a portion of the secretory cells is shed and incorporated into the secretion.

---

**MAMMARY GLANDS**

Mammary glands are modified sweat glands and first appear as bilateral bands of thickened epidermis called the **mammary lines** or
mammary ridges. In a 7-week embryo, these lines extend on each side of the body from the base of the forelimb to the region of the hind limb (Fig. 21.5C). Although the major part of each mammary line disappears shortly after it forms, a small portion in the thoracic region persists and penetrates the underlying mesenchyme (see Fig. 21.5A). Here it forms 16 to 24 sprouts, which in turn give rise to small, solid buds. By the end of prenatal life, the epithelial sprouts are canalized and form the lactiferous ducts. Initially, the lactiferous ducts open into a small epithelial pit (Fig. 21.5B). Shortly after birth, this pit is transformed into the nipple by proliferation of the underlying mesenchyme. At birth, lactiferous ducts have no alveoli and therefore no secretory apparatus. At puberty, however, increased concentrations of estrogen and progesterone stimulate branching from the ducts to form alveoli and secretory cells.

Clinical Correlates

Mammary Gland Abnormalities

Polythelia is a condition in which accessory nipples have formed resulting from the persistence of fragments of the mammary line (Fig. 21.5C). Accessory nipples may develop anywhere along the original mammary line (Fig. 21.6) but usually appear in the axillary region.

Polymastia occurs when a remnant of the mammary line develops into a complete breast.

Inverted nipple is a condition in which the lactiferous ducts open into the original epithelial pit that has failed to evert.
SUMMARY
The skin and its associated structures, hair, nails, and glands are derived from surface ectoderm. Melanocytes, which give the skin its color, are derived from neural crest cells, which migrate into the epidermis. The production of new cells occurs in the germinative layer. After moving to the surface, cells are sloughed off in the horny layer (Fig. 21.1). The dermis, the deep layer of the skin, is derived from lateral plate mesoderm (limbs and body wall), from dermatomes that form from somites in paraxial mesoderm (back), and from neural crest cells (face and neck).

Hairs develop from downgrowth of epidermal cells into the underlying dermis. By about 20 weeks, the fetus is covered by downy hair, lanugo hair, which is shed at the time of birth. Sebaceous glands, sweat glands, and mammary glands all develop from epidermal proliferations. Supernumerary nipples (polythelia) and breasts (polymastia) are relatively common (Figs. 21.5 and 21.6).

Problems to Solve
1. A woman appears to have accessory nipples in her axilla and on her abdomen bilaterally. What is the embryological basis for these additional nipples, and why do they occur in these locations?
Appendix
1. During the process of induction, one group of cells or tissues (the inducer) causes another group (the responder) to change its fate. The responding cells must have the competence to respond, which is conferred by a competency factor. Most inductive processes during embryo development involve epithelial–mesenchymal interactions, and these include the kidneys, gut derivatives, limbs, and many others.

2. Signaling by fibroblast growth factors (FGFs), which are part of the family of growth and differentiation factors, is by paracrine mechanisms, and it can be disrupted at many levels. For example, even subtle alterations of the ligand and/or its receptor can alter signaling because of the high degree of specificity between these proteins. Such alterations might be caused by gene mutations, as, in fact, has happened with the FGF receptors, resulting in skull defects (see Chapter 10). Also, if any of the proteins in the signaling cascade downstream from receptor activation have been altered, then normal signaling may be disrupted. Similarly, modifications of the transcription factors or their DNA-binding sites can alter the quality or quantity of protein products. Fortunately, there is redundancy built into the system that can circumvent alterations in the pathways. The simplest example is the fact that in some cases, one FGF protein can substitute for another.

1. The most common cause for abnormal chromosome number is nondisjunction during either meiosis or mitosis. For unknown reasons, chromosomes fail to separate during cell division. Nondisjunction during meiosis I or II results in half of the gametes having no copy and half having two copies of a chromosome. If fertilization occurs between a gamete lacking a chromosome and a normal one, monosomy results; if it occurs between a gamete with two copies and a normal one, trisomy results. Trisomy 21 (Down syndrome), the most common numerical abnormality resulting in birth defects (intellectual disability, abnormal facies, heart malformations), is usually caused by nondisjunction in the mother and occurs most frequently in children born to women older than 35 years of age, reflecting the fact that the risk of meiotic nondisjunction increases with increasing maternal age. Other trisomies that result in syndromes of abnormal development involve chromosomes 8, 9, 13, and 18. Monosomies involving autosomal chromosomes are fatal, but monosomy of the X chromosome (Turner syndrome) is compatible with life. This condition is usually (80%) a result of nondisjunction during meiosis of paternal chromosomes and is characterized by infertility, short stature, webbing of the neck, and other defects. Karyotyping of embryonic cells obtained by amniocentesis or chorionic villus biopsy (see “Prenatal Diagnosis” in Chapter 9, p. 136) can detect chromosome abnormalities prenatally.

2. Chromosomes sometimes break and the pieces may create partial monosomies or trisomies or become attached (translocated) to other chromosomes. Translocation of part of chromosome 21 onto chromosome 14, for example, accounts for approximately 4% of cases of Down syndrome. Chromosomes may also be altered by mutations in single genes. The risk of chromosomal abnormalities is increased by maternal and paternal age over 35 years.

3. Mosaicism occurs when an individual has two or more cell lines that are derived from a single zygote but that have different genetic characteristics. The different cell lines may arise by mutation or by mitotic nondisjunction during cleavage, as in some cases of Down syndrome.
Answers to Problems

2. The three phases of fertilization are (1) penetration of the corona radiata, (2) penetration of the zona pellucida, and (3) fusion of the oocyte and sperm cell membranes. Once fusion occurs, the egg undergoes cortical and zona reactions to prevent polyspermy. Cortical granules next to the oocyte plasma membrane release lysosomal enzymes that alter the cell membrane and the zona pellucida, such that additional sperms cannot enter the egg.

3. Infertility occurs in approximately 20% of married couples. A major cause of infertility in women is blockage of the uterine (falloplian) tubes caused by scarring from repeated pelvic inflammatory disease; in men, the primary cause is low sperm count. In vitro fertilization (IVF) techniques can circumvent these problems, although the success rate (approximately 20%) is low.

4. Pelvic inflammatory diseases, such as gonorrhea, are a major cause of occluded oviducts (uterine tubes). Although the patient may be cured, scarring closes the lumen of the tubes and prevents the passage of sperm to the oocyte and of the oocyte to the uterine cavity. IVF can overcome the difficulty by fertilizing the woman’s oocytes in culture and transferring them to her uterus for implantation.

---

**Chapter 4**

1. The second week is known as the week of 2s because the trophoblast differentiates into two layers, the syncytiotrophoblast and cytotrophoblast; the embryoblast differentiates into two layers, the epiblast and hypoblast; the extraembryonic mesoderm splits into two layers, the splanchnic (visceral) and somatic (parietal) layers; and two cavities, the amniotic and yolk sac cavities, form.

2. It is not clear why the conceptus is not rejected by the maternal system. Recent evidence suggests that secretion of immunosuppressive molecules, such as cytokines and proteins, and expression of unrecognizable antigens of the major histocompatibility complex protect the conceptus from rejection. In some cases, maternal immunological responses do adversely affect pregnancy, as in some cases of autoimmune disease. Thus, patients with systemic lupus erythematosus have poor reproductive outcomes and histories of multiple spontaneous abortions. It has not been conclusively shown that maternal antibodies can cause birth defects.

3. In some cases, trophoblastic tissue is the only tissue in the uterus, and embryo-derived cells are either absent or present in small numbers. This condition is termed a hydatidiform mole, which, because of its trophoblastic origin, secretes human chorionic gonadotropin and mimics the initial stages of pregnancy. Most moles are aborted early in pregnancy, but those containing remnants of an embryo may remain into the second trimester. If pieces of trophoblast are left behind following spontaneous abortion or surgical removal of a mole, cells may continue to proliferate and form tumors known as invasive moles, or choriocarcinoma. Because early trophoblast development is controlled by paternal genes, it is thought that the origin of moles may be from fertilization of an ovum without a nucleus.

4. The most likely diagnosis is an ectopic pregnancy in the uterine tube, which can be confirmed by ultrasound. Implantation in a uterine tube results from poor transport of the zygote and may be a result of scarring. As with Down syndrome, the frequency of ectopic pregnancy increases with maternal age over 35 years.

---

**Chapter 5**

1. Unfortunately, consuming large quantities of alcohol at any stage during pregnancy may adversely affect embryonic development. In this case, the woman has exposed the embryo during the third week of gestation (assuming that fertilization occurred at the midpoint of the menstrual cycle), at the time of gastrulation. This stage is particularly vulnerable to insult by alcohol and may result in fetal alcohol syndrome (intellectual disability,
2. Such a mass is probably a sacrococcygeal teratoma. These tumors arise as remnants of the primitive streak, usually in the sacral region. The term teratoma refers to the fact that the tumor contains different types of tissues. Because it is derived from the streak, which contains cells for all three germ layers, it may contain tissues of ectoderm, mesoderm, or endoderm origin. Such tumors are three times as common in female fetuses as in male fetuses.

3. The baby has a severe form of caudal dysgenesis called sirenomelia (mermaid-like). Sirenomelia, which occurs in varying degrees, is probably caused by abnormalities in gastrulation in caudal segments. It was initially termed caudal regression, but it is clear that structures do not regress; they simply do not form. Also known as caudal agenesis and sacral agenesis, sirenomelia is characterized by varying degrees of flexion, inversion, lateral rotation, and occasional fusion of the lower limbs; defects in lumbar and sacral vertebrae; renal agenesis; imperforate anus; and agenesis of internal genital structures except the testes and ovaries. Its cause is unknown. It occurs sporadically but is most frequently observed among infants of diabetic mothers.

4. This patient has left-sided laterality sequence and should be evaluated for additional defects. Sidedness is established at the time of primitive streak formation (gastrulation) and is regulated by genes, such as NODAL, and PITX2 which become restricted in their expression. Partial reversal of left–right asymmetry is more often associated with other defects than complete asymmetry (situs inversus).

5. As you listen to your patient’s request to take one of the SSRIs (selective serotonin reuptake inhibitors) medications, you remember the thalidomide tragedy and its lesson that women who are planning to get pregnant or who already are should beware of taking any substance that could be harmful to their unborn baby. Also, you are aware of scientific studies showing that serotonin is an important signaling molecule during embryonic development, especially for establishing the left–right (laterality) axis, and you have read the epidemiological literature that establishes an association between the SSRIs and birth defects. Therefore, you advise your patient not to take the drugs. Instead, you try to get her involved in an exercise program and other social activities that have a similar efficacy as the SSRIs for preventing most levels of depression. Only in severe cases of anxiety and depression might an alternative strategy, including medication be advisable.
the neural fold border by upregulating PAX3. PAX3 and other transcription factors then initiate a genetic cascade that specifies crest cells. Two important components of the cascade are the transcription factors FOXD3, which specifies crest cells, and SLUG that promotes crest cell migration. Crest cells form many structures, including the bones, connective tissues, and dermis of the face, cranial nerve ganglia, sympathetic and parasympathetic ganglia, melanocytes, and conotruncal septa in the heart (see Table 6.1, p. 77).

3. Somites form from the paraxial portion of the mesodermal germ layer. They first appear as segmental blocks of loosely organized mesoderm (somitomeres) along the axis of the embryo. The cells then undergo an epithelization process to form somites that consist of a ventral portion, the sclerotome, and a dorsal portion that has two types of cells: the dermatome (central part) and myotome (medial and lateral parts). Cells in the myotome regions proliferate and migrate beneath the dermomyotome. Eventually, all the cells in the somite lose their epithelial characteristics and become mesenchymal again. Sclerotome cells migrate to form the vertebrae and ribs, myotomes form skeletal muscle, and the dermatomes form the dermis of the back.

4. Blood vessels form by vasculogenesis, whereby cells in blood islands coalesce to form endothelial tubes, and by angiogenesis, whereby vessels form by sprouting from existing vessels. Vascular endothelial growth factor (VEGF) stimulates both types of vessel development. In some cases, overproliferation of capillaries causes tumors called hemangiomas, but it is not clear whether or not overexpression of VEGF is involved in their origin.

5. The gut tube has three divisions: the foregut, midgut, and hindgut. The midgut maintains a connection to the yolk sac called the vitelline (yolk sac) duct, and this structure does not close completely until later in development. The opening into the pharyngeal gut is closed by the oropharyngeal membrane that degenerates in the fourth week; the opening into the hindgut is closed by the cloacal membrane that degenerates in the seventh week.

6. Development during the third to eighth weeks is critical because this is when cell populations responsible for organ formation are established and when organ primordia are being formed. Early in the third week, gastrulation begins to provide cells that constitute the three germ layers responsible for organogenesis. Late in the third week, differentiation of the central nervous system is initiated, and over the next 5 weeks, all of the primordia for the major organ systems will be established. At these times, cells are rapidly proliferating, and critical cell–cell signals are occurring. These phenomena are particularly sensitive to disruption by outside factors, such as environmental hazards, pharmaceutical agents, and drugs of abuse. Thus, exposure to such factors may result in abnormalities known as birth defects or congenital malformations.

---

1. Failure of the left pleuroperitoneal membrane to close the pericardioperitoneal canal on that side is responsible for the defect. This canal is larger on the left than on the right, closes later, and therefore may be more susceptible to abnormalities. The degree of hypoplasia of the lungs resulting from compression by abdominal viscera determines the fate of the infant. Treatment requires surgical repair of the defect and attempts to correct the malformation in utero have been made.

2. The defect is gastroschisis. It occurs because of a weakness in the body wall caused by abnormal closure of the ventral body wall. Because the bowel is not covered by the amnion, it may become necrotic because of exposure to the amniotic fluid. It is also possible for the bowel loops to twist around themselves (volvulus), cutting off their blood supply and producing an infarction. Gastroschisis is not associated with genetic abnormalities and only 15% have other malformations. Therefore, if damage to the bowel is not too extensive, survival rates are good.

3. During the fourth week, the septum transversum, which forms the central tendon of the diaphragm, lies opposite cervical segments three to five (C3 to C5). As the embryo grows and the head fold curves ventrally, the position of the septum transversum (diaphragm) shifts caudally into the thoracic cavity. Musculature for the diaphragm is derived
from the original cervical segments located at its site of origin, however. Therefore, because muscle cells always carry the nerve from their site of origin to wherever they migrate, it is the phrenic nerve from C3, C4, and C5 that innervates the diaphragm (C3, C4, and C5 keep the diaphragm alive).

Chapter 8

1. An excess of amniotic fluid is called hydramnios or polyhydramnios, and many times (35%) the cause is unknown (idiopathic). A high incidence (25%) is also associated with maternal diabetes and with birth defects that interfere with fetal swallowing, such as esophageal atresia and anencephaly.

2. No. She is not correct. The placenta does not act as a complete barrier, and many compounds cross freely, especially lipophilic substances, such as toluene and alcohol. Furthermore, early in pregnancy, the placenta is not completely developed, and the embryo is particularly vulnerable. These early weeks are also very sensitive to insult by compounds such as toluene, which causes toluene embryopathy.

Chapter 9

1. Neural tube defects, such as spina bifida and anencephaly, produce elevated α-fetoprotein (AFP) levels, as do abdominal defects, such as gastroschisis and omphalocele. Maternal serum AFP levels are also elevated, so that they may be used as a screen to be confirmed by amniocentesis. Ultrasonography is used to confirm the diagnosis.

2. Because Down syndrome is a chromosomal abnormality resulting most commonly from trisomy 21 (see Chapter 2), cells for chromosomal analysis can be collected by amniocentesis or chorionic villus biopsy (CVS). CVS has the advantage that sufficient cells can be obtained immediately to do the analysis, whereas cells collected by amniocentesis, which is not usually done prior to 14 weeks' gestation, must be cultured for approximately 2 weeks to obtain sufficient numbers. The risk of fetal loss following CVS is 1%, which is about twice as high as that of amniocentesis.

3. Status of the fetus is critical for managing pregnancy, delivery, and postnatal care. Size, age, and position are important for determining the time and mode of delivery. Knowing whether birth defects are present is important for planning postnatal care. Tests for determining fetal status are dictated by maternal history and factors that increase risk, such as exposure to teratogens, chromosome abnormalities in either parent, advanced maternal age, or the birth of a previous infant with a birth defect.

4. Factors that influence the action of a teratogen are (1) genotype of the mother and conceptus, (2) dose and duration of exposure to the agent, and (3) stage of embryogenesis when exposure occurs. Most major malformations are produced during the embryonic period (teratogenic period), the third to eighth weeks of gestation. Stages prior to this time, however, including the preimplantation period, and after the eighth week (fetal period) remain susceptible. The brain, for example, remains sensitive to insult throughout the fetal period. No stage of pregnancy is free of risk from teratogenic insult.

5. The woman is correct that drugs may be teratogenic. Severe hyperthermia such as this, however, is known to cause neural tube defects (spina bifida and anencephaly) at this stage of gestation. Therefore, one must weigh the risk of teratogenicity of an antipyretic agent with a low teratogenic potential, such as low-dose aspirin, against the risk of hyperthermia. Interestingly, malformations have been associated with sauna-induced hyperthermia. No information about exercise-induced hyperthermia and birth defects is available, but strenuous physical activity (running marathons) raises body temperature significantly and probably should be avoided during pregnancy.

6. Because more than 50% of pregnancies are unplanned, all women of childbearing age should consume 400 μg of folic acid daily as a supplement to prevent neural tube defects. If a woman has not been taking folic acid and is planning a pregnancy, she should begin the supplement 3 months prior to conception and continue throughout gestation. Folic acid is nontoxic even at high doses, can prevent up to 70% of neural tube defects, and may prevent conotruncal heart defects and facial clefts.
7. The woman’s concerns are valid, as infants of insulin-dependent diabetic mothers have an increased incidence of birth defects, including a broad spectrum of minor and major anomalies. Placing the mother under strict metabolic control using multiple insulin injections prior to conception and throughout pregnancy, significantly reduces the incidence of abnormalities and affords the greatest opportunity for a normal pregnancy. A similar scenario occurs with women who have phenylketonuria. Strict management of these patients’ disease prior to conception and during pregnancy virtually eliminates the risk of congenital defects in the offspring. Both situations stress the need for planning pregnancies and for avoiding potential teratogenic exposures, especially during the first 8 weeks of gestation, when most defects are produced.

Chapter 10

1. Cranial sutures are fibrous regions between flat bones of the skull. Membranous regions where more than two bones meet are known as fontanelles, the largest of which is the anterior fontanelle (soft spot). These sutures and fontanelles permit (1) molding of the head as it passes through the birth canal and (2) growth of the brain. Growth of the skull, which continues after birth as the brain enlarges, is greatest during the first 2 years of life. Premature closure of one or more sutures (craniosynostosis) results in deformities in the shape of the head, depending on which sutures are involved. Craniosynostosis is often associated with other skeletal defects, and evidence suggests that genetic factors are important in the causation (see Table 10.1, p. 149). Defects of the long bones and digits are often associated with other malformations and should prompt a thorough examination of all systems. Clusters of defects that occur simultaneously with a common cause are called syndromes, and limb anomalies, especially of the radius and digits, are common components of such clusters. Diagnosis of syndromes is important in determining recurrence risks and thus in counseling parents about subsequent pregnancies.

2. Formation of the vertebrae is a complex process involving growth and fusion of the caudal portion of one sclerotome with the cranial portion of an adjacent one. Not surprisingly, mistakes occur, and they result in fusions and increases and decreases in the number of vertebrae (Klippel-Feil sequence). In some cases, only half a vertebra forms (hemivertebra), resulting in asymmetry and lateral curvature of the spine (scoliosis). HOX (homeobox) genes that pattern the vertebra may have mutations that cause part of one not to form properly. Scoliosis may also be caused by weakness of back muscles.

Chapter 11

1. Muscle cells are derived from the ventrolateral (VLL) and dorsomedial (DML) lips (edges) of the somites. Cells from both regions contribute to formation of the dermomyotome, and in addition, some cells from the VLL lips migrate across the lateral somitic frontier into the parietal layer of lateral plate mesoderm. Together, these cells and lateral plate mesoderm constitute the abaxial mesodermal domain, whereas paraxial mesoderm around the neural tube forms the primaxial mesodermal domain. Muscles derived from the primaxial domain include the back muscles, some neck muscles, some muscles of the shoulder girdle, and the intercostal muscles. The abaxial domain forms the remainder of the axial and limb muscles (see Table 11.1, p. 158).

2. There is absence of the pectoralis minor and partial or complete absence of the pectoralis major muscle. The defect known as Poland anomaly is the most likely diagnosis. Poland anomaly is often associated with shortness of the middle digits (brachydactyly) and digital fusion (syndactyly). Loss of the pectoralis major muscle produces little or no loss of function because other muscles compensate. The defect’s disfiguring characteristics can be quite concerning, however, especially in females.

3. Patterning for muscles depends on connective tissue that forms from fibroblasts. In the head, with its complicated pattern of muscles of facial expression, neural crest cells direct patterning; in cervical and occipital regions, connective tissue from somites directs it; and in the body wall and limbs, somatic mesoderm directs it.

4. Innervation for muscles is derived from the vertebral level from which the muscle cells
Defects of the long bones and digits are often associated with other malformations and should prompt a thorough examination of all systems. Clusters of defects that occur simultaneously with a common cause are called syndromes, and limb anomalies, especially of the radius and digits, are common components of such clusters. Diagnosis of syndromes is important in determining recurrence risks and thus in counseling parents about subsequent pregnancies.

Chapter 13

1. A four-chambered view is sought in ultrasound scans of the heart. The chambers are divided by the atrial septum superiorly, the ventricular septum inferiorly, and the endocardial cushions surrounding the atrioventricular canals laterally. Together, these structures form a cross with integrity readily visualized by ultrasound. In this case, however, the fetus probably has a ventricular septal defect, the most commonly occurring heart malformation, in the membranous portion of the septum. The integrity of the great vessels should also be checked carefully because the conotruncal septum dividing the aortic and pulmonary channels must come into contact with the membranous portion of the interventricular septum for this structure to develop normally.

2. Because neural crest cells contribute to much of the development of the face and to the conotruncal septum, these cells have probably been disrupted. Crest cells may have failed to migrate to these regions, failed to proliferate, or may have been killed. Retinoic acid (vitamin A) is a potent teratogen that targets neural crest cells among other cell populations. Because retinoids are effective in treating acne, which is common in young women of childbearing age, great care should be employed before prescribing the drug to this cohort.

3. Endocardial cushion tissue is essential for proper development of these structures. In the common atrioventricular canal, the superior, the inferior, and two lateral endocardial cushions divide the opening and contribute to the mitral and tricuspid valves in the left and right atrioventricular canals. In addition, the superior and inferior cushions are essential for complete septation of the atria by fusion with the septum primum and of the ventricles by forming the membranous part of the interventricular septum. Cushion tissue in the conus and truncus forms the conotruncal septum, which spirals down to separate the aorta and pulmonary channels and to fuse with the inferior endocardial cushion to complete the interventricular septum. Therefore, any abnormality of cushion tissue may result in a number of cardiac defects, including atrial and ventricular septal defects, transposition of the great vessels, and other abnormalities of the outflow tract.

4. In the development of the vascular system for the head and neck, a series of arterial arches forms around the pharynx. Most of these arches undergo alterations, including regression, as the original patterns are modified. Two such alterations that produce difficulty swallowing are (1) double aortic arch, in which a portion of the right dorsal aorta (that normally regresses) persists between the seventh intersegmental artery and its junction with the left dorsal aorta, creating a vascular ring around the esophagus; and (2) right aortic arch, in which the ascending aorta and the arch form on the right. If in such cases the ligamentum arteriosum remains on the left, it passes behind the esophagus and may constrict it.

Chapter 14

1. This infant most likely has some type of tracheoesophageal atresia with or without a tracheoesophageal fistula. The baby cannot swallow, and this condition results in polyhydramnios. The defect is caused by abnormal partitioning of the trachea and esophagus by the tracheoesophageal septum. These defects are often associated with other malformations, including a constellation of vertebral anomalies, anal atresia, cardiac defects, renal
anomalies, and limb defects known as the VACTERL association.

2. Babies born before 7 months of gestation do not produce sufficient amounts of surfactant to reduce surface tension in the alveoli to permit normal lung function. Consequently, alveoli collapse, resulting in respiratory distress syndrome. Administration of steroids during pregnancy and use of artificial surfactants have improved the prognosis for these infants.

Chapter 15

1. The baby most likely has some type of esophageal atresia and/or tracheoesophageal fistula. In 90% of these cases, the proximal part of the esophagus ends in a blind pouch, and a fistula connects the distal part with the trachea. Polyhydramnios results because the baby cannot swallow amniotic fluid. Aspiration of fluids at birth may cause pneumonia. The defect is caused by an abnormal partitioning of the respiratory diverticulum from the foregut by the tracheoesophageal septum.

2. The most likely diagnosis is an omphalocele resulting from a failure of herniated bowel to return to the abdominal cavity at 10 to 12 weeks of gestation. Because the bowel normally herniates into the umbilical cord, it is covered by amnion. This situation is in contrast to gastroschisis, in which loops of bowel herniate through an abdominal wall defect and are not covered by amnion. The prognosis is not good because 25% of infants with omphalocele die before birth, 40% to 88% have associated anomalies, and approximately 15% show chromosomal abnormalities. If no other complicating defects are present, surgical repair is possible, and in experienced hands, survival is 100%.

3. This infant has an imperforate anus with a rectovaginal fistula, part of an anorectal atresia complex. She appears to have a high anorectal atresia because the fistula connects the rectum to the vagina, accounting for meconium (intestinal contents) in this structure. The defect was probably caused by a cloaca that was too small, so that the cloacal membrane was shortened posteriorly. This condition causes the opening of the hindgut to shift anteriorly. The smaller the cloaca is posteriorly, the farther anteriorly the hindgut opening shifts, resulting in a higher defect.

Chapter 16

1. The three systems to form are the pronephros, mesonephros, and metanephros—all derivatives of the intermediate mesoderm. They form in succession in a cranial-to-caudal sequence. Thus, the pronephros forms in cervical segments at the end of the third week but is rudimentary and rapidly regresses. The mesonephros, which begins early in the fourth week, extends from thoracic to upper lumbar regions. It is segmented in only its upper portion and contains excretory tubules that connect to the mesonephric (Wolffian) duct. This kidney also regresses but may function for a short time. It is more important because the tubules and collecting ducts contribute to the genital ducts in the male. Collecting ducts near the testes form the efferent ductules, whereas the mesonephric duct forms the epididymis, ductus deferens, and ejaculatory duct. In the female, these tubules and ducts degenerate because maintaining them depends on testosterone production. The metanephros lies in the pelvic region as a mass of unsegmented mesoderm (metanephric blastema) that forms the definitive kidneys. Urteric buds grow from the mesonephric ducts and, on contact with the metanephric blastema, induce it to differentiate. The ureteric buds form collecting ducts and ureters, whereas the metanephric blastema forms nephrons (excretory units), each of which consists of a glomerulus (capillaries) and renal tubules.

2. Both the ovaries and testes develop in the abdominal cavity from intermediate mesoderm along the urogenital ridge. Both also descend by similar mechanisms from their original position, but the uterus prevents migration of the ovary out of the abdominal cavity. In the male, however, a mesenchymal condensation, the gubernaculum (which also forms in females but attaches to the uterus), attaches the caudal pole of the testis, first to the inguinal region and then to the scrotal swellings. Growth and retraction of the gubernaculum, together with increasing intra-abdominal pressure, cause the testis to descend. Failure of these processes causes undescended testes,
known as cryptorchidism. Approximately 2% to 3% of term male infants have an undescended testicle, and in 25% of these, the condition is bilateral. In many cases, the undescended testis descends by age 1. If it does not, testosterone administration (because this hormone is thought to play a role in descent) or surgery may be necessary. Fertility may be affected if the condition is bilateral.

3. Male and female external genitalia pass through an indifferent stage during which it is impossible to differentiate between the two sexes. Under the influence of testosterone, these structures assume a masculine appearance, but the derivatives are homologous between males and females. These homologies include (1) the clitoris and penis, derived from the genital tubercle; (2) the labia majora and scrotum, derived from the genital swellings that fuse in the male; and (3) the labia minora and penile urethra, derived from the urethral folds that fuse in the male. During early stages, the genital tubercle is larger in the female than in the male, and this has led to misidentification of sex by ultrasound.

4. The uterus is formed by fusion of the lower portions of the paramesonephric (Müllerian) ducts. Numerous abnormalities have been described; the most common consists of two uterine horns (bicornuate uterus). Complications of this defect include difficulties in becoming pregnant, high incidence of spontaneous abortion, and abnormal fetal presentations. In some cases, a part of the uterus has a blind end (rudimentary horn), causing problems with menstruation and abdominal pain.

**Chapter 17**

1. Neural crest cells are important for craniofacial development because they contribute to so many structures in this region. They form all of the bones of the face and the anterior part of the cranial vault and the connective tissue that provides patterning of the facial muscles. They also contribute to cranial nerve ganglia, meninges, dermis, odontoblasts, and stroma for glands derived from pharyngeal pouches. In addition, crest cells from the hindbrain region of the neural folds migrate ventrally to participate in septation of the conotruncal region of the heart into aortic and pulmonary vessels.

Unfortunately, crest cells appear to be vulnerable to a number of compounds, including alcohol and retinoids, perhaps because they lack catalase and superoxide dismutase enzymes that scavenge toxic free radicals. Many craniofacial defects result from insults on neural crest cells and may be associated with cardiac abnormalities because of the contribution of these cells to heart morphogenesis.

2. The child may have DiGeorge anomaly, which is characterized by these types of craniofacial defects and partial or complete absence of thymic tissue. Loss of thymic tissue compromises the immune system, resulting in numerous infections. Damage to neural crest cells is the most likely cause of the sequence because these cells contribute to development of all of these structures, including the stroma of the thymus. Teratogens, such as alcohol, have been shown to cause these defects experimentally.

3. Children with midline clefts of the lip often have intellectual disabilities. Median clefts are associated with loss of other midline structures, including those in the brain. In its extreme form, the entire cranial midline is lost, and the lateral ventricles of the cerebral hemispheres are fused into a single ventricle, a condition called holoprosencephaly. Midline clefts, induced as the cranial neural folds begin to form (approximately days 19 to 21), result from the loss of midline tissue in the prechordal plate region.

4. The child most likely has a thyroglossal cyst that results from incomplete regression of the thyroglossal duct. These cysts may form anywhere along the line of descent of the thyroid gland as it migrates from the region of the foramen cecum of the tongue to its position in the neck. A cyst must be differentiated from ectopic glandular tissue, which may also remain along this pathway.

**Chapter 18**

1. Cranial and spinal nerves are homologues, but they differ in that cranial nerves are much less consistent in their composition. Motor neurons for both lie in basal plates of the central nervous system; and sensory ganglia, derived from the neural crest, lie outside the central nervous system. Fibers from sensory
neurons synapse on neurons in the alar plates of the spinal cord and brain. Three cranial nerves (I, II, and VIII) are entirely sensory; four (IV, VI, XI, and XII) are entirely motor; three (VII, IX, and X) have motor, sensory, and parasympathetic fibers; and one (III) has only motor and parasympathetic components. In contrast, each spinal nerve has motor and sensory fibers.

2. The components that come together to form a spinal nerve are the dorsal and ventral roots, which contain sensory (afferent) and motor (efferent) fibers, respectively. Cell bodies for motor neurons are located in the ventral horns of the spinal cord, whereas those of sensory neurons reside outside of the spinal cord in dorsal root ganglia and are derivatives of neural crest cells. Therefore, spinal nerves contain both motor and sensory fibers. Each spinal nerve is very short and divides almost immediately at each intervertebral foramen into a dorsal primary ramus (to back muscles) and a ventral primary ramus (to limb and body wall muscles). Each of these rami is a mixed nerve containing both motor and sensory fibers.

3. A spinal tap is performed between vertebra L4 and vertebra L5 because the spinal cord ends at the L2 to L3 level. Thus, it is possible to obtain cerebrospinal fluid at this level without damaging the cord. The space is created because after the third month, the cord, which initially extended the entire length of the vertebral column, does not lengthen as rapidly as the dura and vertebral column do, so that in the adult, the spinal cord ends at the L2 to L3 level.

4. The embryological basis for most neural tube defects is inhibition of closure of the neural folds at the cranial and caudal neuropores. In turn, defects occur in surrounding structures, resulting in anencephaly, some types of encephalocele, and spina bifida cystica. Severe neurological deficits accompany abnormalities in these regions. Neural tube defects, which occur in approximately 1 in 1,500 births, may be diagnosed prenatally by ultrasound and findings of elevated levels of α-fetoprotein in maternal serum and amniotic fluid. Recent evidence has shown that daily supplements of 400 μg of folic acid started 3 months prior to conception prevent up to 70% of these defects.

5. This condition, hydrocephalus, results from a blockage in the flow of cerebrospinal fluid from the lateral ventricles through the foramina of Monro and the cerebral aqueduct into the fourth ventricle and out into the subarachnoid space, where it would be resorbed. In most cases, blockage occurs in the cerebral aqueduct in the midbrain. It may result from genetic causes (X-linked recessive) or viral infection (toxoplasmosis, cytomegalovirus).

6. The autonomic nervous system is composed of the sympathetic and parasympathetic systems. The sympathetic portion has its preganglionic neurons located in the intermediate horn of the spinal cord from T1 to L2. The parasympathetic portion has a craniosacral origin with its preganglionic neurons in the brain and spinal cord (S2 to S4). The cranial outflow is carried by cranial nerves III, VII, IX, and X. Postganglionic cell bodies for both systems are derived from neural crest cells.

Chapter 19

1. A placode is a region of cuboidal ectoderm that thickens by assuming a columnar shape. The otic placodes form on both sides of the hindbrain and then invaginate to form otic vesicles. Placodes give rise to sensory organs, and the otic placodes are no exception. Thus, from the otic vesicle, tubular outpocketings form and differentiate into the saccule, utricle, semicircular canals, and the endolymphatic and cochlear ducts. Together, these structures constitute the membranous labyrinth of the internal ear.

2. The tympanic (middle ear) cavity and auditory tube are derivatives of the first pharyngeal pouch and are lined by endoderm. The pouch expands laterally to incorporate the ear ossicles and create the middle ear cavity, whereas the medial portion lengthens to form the auditory tube that maintains an open connection to the pharynx. The tympanic membrane (eardrum) forms from tissue separating the first pharyngeal pouch from the first pharyngeal cleft. It is lined by endoderm internally and ectoderm externally with a thin layer of mesenchyme in the middle.

3. Microtia involves defects of the external ear that range from small but well-formed ears to absence of the ear (anotia). Other defects
1. The lens forms from a thickening of ectoderm (lens placode) adjacent to the optic cup. Lens induction may begin very early, but contact with the optic cup plays a role in this process as well as in maintenance and differentiation of the lens. Therefore, if the optic cup fails to contact the ectoderm or if the molecular and cellular signals essential for lens development are disrupted, a lens will not form.

2. Rubella is known to cause cataracts, microphthalmia, congenital deafness, and cardiac malformations. Exposure during the fourth to eighth week places the offspring at risk for one or more of these birth defects.

3. As the optic cup reaches the surface ectoderm, it invaginates, and along its ventral surface, it forms a fissure that extends along the optic stalk. It is through this fissure that the hyaloid artery reaches the inner chamber of the eye. Normally, the distal portion of the hyaloid artery degenerates, and the choroid fissure closes by fusion of its ridges. If this fusion does not occur, colobomas occur. These defects (clefts) may occur anywhere along the length of the fissure. If they occur distally, they form colobomas of the iris; if they occur more proximally, they form colobomas of the retina, choroid, and optic nerve, depending on their extent. Mutations in PAX2 can cause optic nerve colobomas and may be responsible for other types as well. Also, mutations in this gene have been linked to renal defects and renal coloboma syndrome.

1. Mammary gland formation begins as budding of epidermis into the underlying mesenchyme. These buds normally form in the pectoral region along a thickened ridge of ectoderm, the mammary or milk line. This line or ridge extends from the axilla into the thigh on both sides of the body. Occasionally, accessory sites of epidermal growth occur, so that extra nipples (polythelia) and extra breasts (polymastia) appear. These accessory structures always occur along the milk line and usually in the axillary region. Similar conditions also occur in males.

Glossary of Key Terms

A

**Abaxial domain** Mesodermal domain composed of the parietal layer of lateral plate mesoderm and somite cells from the myotome and sclerotome regions that migrate across the lateral somitic frontier.

**Acrosome reaction** Release of enzymes from the acrosome on the head of sperm that assists in sperm penetration of the zona pellucida. Zona proteins induce the reaction following sperm binding.

**Adenohypophysis** Anterior portion of the pituitary derived from Rathke pouch.

**Alar plates** Sensory area in the dorsal region of the spinal cord and brain.

**Allantois** Vestigial structure that serves as a respiratory and waste storage organ for avian embryos. It extends from the ventral region of the urogenital sinus to the umbilicus. Later, its distal portion, called the urachus, becomes a fibrous cord and forms the median umbilical ligament. If it remains patent, then it may form a urachal fistula or cyst in this region.

**Alternative splicing** Process of removing (“splicing out”) introns to create different proteins from the same gene.

**Alveolar cells** Cells lining the alveoli. Type I cells are involved in gas exchange. Type II cells produce surfactant.

**Amelia** Complete absence of a limb.

**Amniocentesis** Procedure used to withdraw amniotic fluid for analysis of factors, such as α-fetoprotein (AFP) and cells (chromosomes), which provide information about the status of the fetus.

**Amniochorionic membrane** Membrane formed when expansion of the amniotic cavity obliterates the chorionic cavity causing the amnion to contact the chorion and the two to fuse. The amniochorionic membrane serves as a hydrostatic wedge during the initiation of labor.

**Amnion** Membrane derived from the epiblast that surrounds the fluid-filled amniotic cavity around the embryo and fetus. The fluid cushions the fetus and forms a hydrostatic wedge to assist with dilation of the cervix during labor. The fluid itself can be used for analysis of fetal well-being.

**Amniotic bands** Pieces of amnion that tear loose and can wrap themselves around digits and limbs causing constrictions and amputations or can be swallowed by the fetus causing disruptions in facial development. The origin of bands is unknown.

**Anencephaly** Neural tube defect in which the cranial neural folds fail to close, leading to tissue degeneration and little or no formation of higher brain centers, cerebral cortex, etc. The abnormality is lethal, but 70% of these defects can be prevented by daily maternal use of 400 μg of folic acid beginning 2 to 3 months prior to conception and continuing throughout pregnancy.

**Angiogenesis** Formation of blood vessels by sprouting from existing vessels.

**Annulus fibrosis** Outer ring of fibrous tissue in an intervertebral disc.

**Anterior visceral endoderm (AVE)** Collection of endoderm cells at the cranial end of the bilaminar disc responsible for inducing the head region through secretion of transcription factors, including *OTX2*, *LIM1*, and *HESXI*.

**Anti-müllerian hormone** Another term for müllerian-inhibiting substance produced by Sertoli cells that causes regression of the müllerian (paramesonephric) ducts in males.

**Aortic arch** Branch from the aortic sac to the dorsal aorta traveling in the center of each pharyngeal arch. Initially, there are five pairs, but these undergo considerable remodeling to form definitive vascular patterns for the head and neck, aorta, and pulmonary circulation.

**Apical ectodermal ridge (AER)** Layer of thickened ectoderm at the distal tip of the limb that controls outgrowth of the limb by maintaining a rapidly proliferating population of adjacent mesoderm cells, called the progress zone.

**Apoptosis** Programmed cell death, for example, between the digits.

**Atresia** Congenital absence of an opening or lumen, for example, gut atresia.

**Autonomic nervous system** Composed of the sympathetic and parasympathetic nervous systems that control smooth muscle and glands.

B

**Basal plates** Motor area in the ventral portion of the spinal cord and brain.

**Bladder extrophy** Ventral body wall defect caused by lack of closure of the lateral body wall folds in the pelvic region resulting in protrusion of the bladder through the defect.

**Blastocyst** Stage of embryogenesis at the time of implantation where outer trophoblast cells form a fluid-filled sphere with a small group
of embryoblast cells, the inner cell mass, at one pole.

**Bone morphogenetic proteins (BMPs)** Members of the transforming growth factor β family that serve as signal molecules for a number of morphogenetic events, including dorsalizing the central nervous system, participating in bone formation, etc.

**Bowman’s capsule** Cup-shaped structure at the end of each proximal convoluted tubule that partially surrounds a glomerulus.

**Brachycephaly** Type of craniosynostosis in which the coronal sutures close prematurely resulting in a tall, short head shape.

**Brachydactyly** Short digits.

**Brain vesicles** Once the neural tube closes, expanded spaces in the brain fill with fluid to form three primary brain vesicles: the prosencephalon (forebrain); mesencephalon (midbrain); and rhombencephalon (hindbrain). These three primary vesicles form five definitive vesicles: The prosencephalon divides into the telencephalon and diencephalon; the mesencephalon does not divide; and the rhombencephalon forms the metencephalon and myelencephalon.

**Brainstem** “Lower” centers of the brain, including the myelencephalon, pons of the metencephalon, and the mesencephalon.

**Capacitation** A period of sperm conditioning in the female reproductive tract lasting about 7 hours that is required for sperm to be able to fertilize an egg.

**Cardiac looping** Bending of the heart tube positions the heart in the left thoracic region and creates the “typical” heart shape with the atria posterior to the ventricles.

**Cardinal veins** System of anterior, posterior, and common cardinal veins that drain the head and body of the embryo in the late third and early fourth weeks.

**Caudal dysgenesis** Also called sirenomelia or mermaid syndrome, it is caused by insufficient production of mesoderm by the primitive streak. Consequently, there are not enough cells to form the lower part of the body so that the legs are fused. Renal agenesis is usually the cause of death. The defects are most often observed in infants from insulin-dependent diabetics.

**Cerebral aqueduct (of Sylvius)** Lumen of the mesencephalon that connects the third and fourth ventricles. It is often the site for abnormalities that impede the flow of cerebrospinal fluid and cause hydrocephalus.

**Chondrocranium** Part of the neurocranium that forms the base of the skull and arises by first establishing cartilage models for the bones (endochondral ossification).

**Chorion** Multilayered structure consisting of the somatic layer of extraembryonic mesoderm, cytotrophoblast, and syncytiotrophoblast. It contributes the fetal portion of the placenta, including the villi and villus lakes.

**Chorion frondosum (leafy chorion)** Embryonic side of the chorion, where villi form.

**Chorion laeve (smooth chorion)** Abembryonic side of the chorion, where villi regress, leaving a smooth surface.

**Chorionic cavity** Space formed between the extraembryonic mesoderm lining the cytotrophoblast (somatic extraembryonic mesoderm) and that surrounding the yolk sac and embryo (splanchnic extraembryonic mesoderm). The chorionic cavity will eventually be obliterated by expansion of the amniotic cavity and fusion of the amnion with the chorion.

**Choroid plexuses** Vascularized structures formed in the lateral, third, and fourth ventricles that produce cerebrospinal fluid.

**Cloaca** Common chamber for the hindgut and urinary systems. Its anterior portion forms the urogenital sinus, and its posterior portion forms the anus.

**Cloacal membrane (plate)** Membrane formed at the caudal end of the embryo from adhesion between epiblast and hypoblast cells. Later, it covers the cloaca and eventually breaks down to form openings into the urogenital sinus and anus.

**Coloboma** Defect in the eye due to incomplete closure of the optic fissure. Usually, these defects are restricted to the iris.

**Compaction** Process whereby cells of the morula stage form tight junctions to seal themselves in preparation for forming and pumping fluid into the blastocyst cavity.

**Connecting stalk** Mesodermal connection that connects the embryo to the placenta. It contains the allantois and umbilical vessels and will be incorporated into the umbilical cord with the yolk sac (vitelline) stalk (duct).

**Congenital malformation** Synonymous with the term birth defect, it refers to any structural, behavioral, functional, or metabolic disorder present at birth.

**Cotyledons** Compartments (15 to 20) in the placenta formed when decidual septa grow into the intervillous spaces. These septa never reach the chorionic plate so that there is communication between cotyledons.

**Cranial nerves (CNs)** Twelve pairs of nerves associated with the brain, with all but two (the olfactory and optic) originating from the brainstem.

**Craniosynostosis** Premature closure of one or more cranial sutures, leading to an abnormally shaped
skull. A major cause is mutations in fibroblast growth factor receptors (FGFRs).

Crista terminalis Ridge of tissue in the right atrium between the original trabeculated part of the right atrium and the smooth-walled part derived from the sinus venosus.

Cryptorchidism Failure of one or both testes to descend to the scrotum.

Cytotrophoblast Proliferative inner layer of the trophoblast.

Deformations Altered development of structures caused by mechanical forces, for example, clubfeet resulting from too little room in the amniotic cavity.

Dermatome Dorsal portion of each somite that forms the dermis of the skin of the back. Dermatomes are segmented and supplied by spinal nerves from the segments at which they originated. This segmental pattern is maintained as they migrate over the body. Thus, each region that they occupy on the skin is also called a dermatome and is innervated by the same spinal nerve that originally supplied the dermatome region of the somite.

Diaphysis Shaft of the long bones.

Diencephalon Derived from the caudal portion of the prosencephalon (forebrain) and forms the thalamus, hypothalamus, posterior lobe of the pituitary, optic stalks (nerves), and other structures.

Dihydrotestosterone Converted from testosterone and responsible for the differentiation of the mesonephric duct and external genitalia.

Diploid The normal chromosome complement present in somatic cells. In these cells, chromosomes appear as 23 homologous pairs to form the diploid number of 46.

Disruptions Term used to describe birth defects resulting from destructive processes that alter a structure after it had formed normally, for example, vascular accidents that cause bowel atresias and amniotic bands that cause limb or digit amputations.

Dizygotic twins Twins formed from two eggs, the most common form of twinning (66%).

Dorsal mesentery Double layer of peritoneum suspending the gut tube from the dorsal body wall from the lower end of the esophagus to the rectum. Later, as the gut grows and rotates, some parts of the dorsal mesentery are lost as portions of the gut fuse to the posterior body wall, that is, parts of the duodenum and colon.

Dorsal primary ramus Branch of a spinal nerve that innervates intrinsic back muscles, derived from primaxial muscle cells, and skin over the back.

Dorsal root Sensory fibers passing from a dorsal root ganglion to the spinal cord.

Dysmorphology Study of the causes, prognoses, treatment, and prevention of birth defects. Usually, a dysmorphologist is a clinical geneticist in a genetics department.

Ectoderm One of the three basic germ layers that forms skin, the central nervous system, hair, and many other structures.

Ectopia cordis Ventral body wall defect resulting from lack of closure of the lateral body wall folds in the thoracic region causing the heart to lie outside the thoracic cavity.

Ectopic Something that is not in its normal position, for example, an embryo's implantation site.

Ectroductality Missing digits.

Efferent ductules Tubules that connect the rete testis to the mesonephric duct for the passage of sperm from the seminiferous tubules to the epididymis. The tubules are derived from nephric tubules of the mesonephric kidney.

Embryogenesis Another term for organogenesis, meaning the period of organ formation from approximately the third to eighth weeks after fertilization.

Endocardial cushions Structures consisting of loose connective tissue covered by endothelium that are responsible for most septation processes occurring in the heart.

Endochondral ossification Mechanism for forming bone by first establishing a cartilaginous model followed by ossification. This type of bone formation is characteristic of the bones of the limbs and base of the skull.

Endoderm One of the three basic germ layers that form the gut and its derivatives.

Enhancers Regulatory elements of DNA that activate utilization of promoters, control promoter efficiency, and regulate the rate of transcription.

Epiblast Dorsal (top) layer of cells comprising the bilaminar germ disc during the second week of development. The hypoblast forms the ventral layer. All tissues of the embryo are derived from the epiblast.

Epibranchial placodes Four thickened regions of ectoderm lying dorsal to the pharyngeal arches that form sensory ganglia for cranial nerves V, VII, IX, and X.

Epididymis Highly convoluted region derived from the mesonephric duct and used for sperm storage.

Epiphyseal plate Cartilaginous region between the diaphysis and epiphysis of the long bones that continues to produce bone growth by endochondral ossification until the bones have
acquired their full length. Then these plates disappear (close).

Epiphysis End of the long bones.

Epiploic foramen (of Winslow) Opening between the lesser and greater sacs in the abdominal cavity located at the free margin of the lesser omentum between the duodenum and the liver. In its ventral border lie the common bile duct, hepatic artery, and portal vein (the portal triad).

Epithelial-mesenchymal interactions Process whereby virtually every organ is formed. Examples include limb ectoderm and underlying mesenchyme, gut endoderm and surrounding mesenchyme, ureter epithelium and metanephric mesenchyme, etc. Signals pass back and forth between these cell types to regulate organ differentiation.

Exon Region of a gene that can be transcribed into a protein.

F

Falciform ligament Part of the ventral mesentery that attaches the liver to the ventral body wall.

Fibroblast growth factors (FGFs) Signal proteins in a large family having over 15 members. They are involved in a number of embryological events, including formation of the suture and bones of the skull. Mutations in their receptors (FGFRs) cause a variety of craniofacial abnormalities, including many forms of craniosynostosis.

Fistula An abnormal passageway.

Folic acid A "B" vitamin that can prevent approximately 70% of neural tube defects if taken as a 400-μg supplement by mothers beginning 2 to 3 months prior to conception and continuing throughout pregnancy.

Fontanelle Wide spaces in the skull created where more than two bones meet. The largest is the anterior fontanelle, sometimes called the "soft spot," located where the two parietal and two frontal bones meet.

Foramen cecum Pit at the junction of the anterior two-thirds and posterior one-third of the tongue representing the site of origin of the thyroid gland.

Foramen ovale Opening in the interatrial septum that permits shunting of blood from right to left during fetal development.

Foregut Part of the gut tube beginning caudal to the pharynx just proximal to the lung bud and extending to a point just distal to the liver bud. It forms the esophagus, stomach, and part of the duodenum, in addition to the lungs, liver, gallbladder, and pancreas, which all form from diverticula (buds) off the gut tube.

Fossa ovalis Depression on the right side of the interatrial septum formed when the septum primum and septum secundum are pressed against each other and the foramen ovale is closed at birth.

G

Gastroschisis Ventral body wall defect resulting from a lack of closure of the lateral body wall folds in the abdominal region resulting in protrusion of intestines and sometimes other organs through the defect.

Gastrulation Process of forming the three primary germ layers from the epiblast involving movement of cells through the primitive streak to form endoderm and mesoderm.

Germ layers Three basic cell layers of ectoderm, mesoderm, and endoderm derived from the process of gastrulation. These layers form all of the structures in the embryo.

Glomerulus Tuft of capillaries formed in the Bowman capsule at the end of each proximal convoluted tubule.

Gray rami communicantes Connections carrying postganglionic sympathetic fibers from ganglia in the sympathetic trunks to spinal nerves. Gray rami exist at all levels of the spinal cord.

Greater omentum Double layer of peritoneum formed from dorsal mesentery and extending down over the intestines from the greater curvature of the stomach. It serves as a storage site for fat and can wall off pockets of infection (the police officer of the abdomen).

Greater sac Most of the abdominal cavity with exception of the lesser sac lying dorsal to the lesser omentum. The two sacs are connected via the epiploic foramen (of Winslow).

Growth factors Proteins that act as signal molecules that are usually secreted and have their signals transduced by receptors on target cells.

Gubernaculum Condensation of mesenchyme extending from the testis to the floor of the scrotum that assists in descent of the testis from the posterior abdominal wall to the scrotum.

H

Haploid Term used to denote the number of chromosomes in the gametes (23), which is half the number present in somatic (diploid) cells.

Hindgut Part of the gut tube extending from the distal one-third of the transverse colon to the upper portion of the anal canal. It forms part of the transverse colon, the descending colon, the sigmoid colon, the rectum, and the upper part of the anal canal.

Holoprosencephaly Defect where so much midline tissue for the face and brain has been lost that the
two lateral ventricles fuse together and appear as one.

**Homeobox genes** Transcription factors that contain a homeobox, a specific DNA-binding motif (sequence) within a region called the homeodomain. These genes are important for patterning the embryonic axis, establishing different regions of the brain, determining the origin and type of gut derivatives, patterning the limbs, and other similar phenomena.

**Hydatidiform mole** Trophoblast forms placental tissue, but with no embryo. Moles express only paternal genes and probably arise from fertilization of an enucleated egg followed by duplication of the paternal chromosomes to restore a diploid number. Moles secrete high concentrations of human chorionic gonadotropin and may become invasive (malignant).

**Hydrocephalus** Increased amounts of cerebrospinal fluid in the brain leading to increased intracranial pressure; usually due to a block in the circulatory pattern of the fluid, which most often occurs in the cerebral aqueduct of Sylvius in the mesencephalon. If the cranial sutures have not fused, the child’s head enlarges, sometimes to great proportions if the pressure is not relieved.

**Hyperplasia** An increase in cell number.

**Hypertrophy** An increase in size of a part or organ.

**Hypoblast** Ventral layer of the bilaminar germ disc. Contributes to formation of the yolk sac and extraembryonic mesoderm but not to tissues of the embryo.

**Hypospadias** An opening of the urethra along the ventral aspect of the penis or scrotum.

**Induction** Process whereby one population of cells or a tissue causes another set of cells or tissues to change their fate. Thus, one cell type is the inducer, and one is the responder.

**Inguinal canal** Oblique passageway from the lower abdomen to the scrotum for the testes. Forms in female fetuses as well.

**Inner cell mass** Cluster of cells segregated to one pole of the blastocyst and from which the entire embryo develops.

**Intermediate segment** Formed from the medial nasal processes; it includes the philtrum region of the upper lip, the upper jaw component housing the four incisor teeth, and the primary palate.

**Intermediate column** Origin of the sympathetic cell bodies (lateral horn cells) in the spinal cord from T1 to L2.

**Intermediate mesoderm** Mesoderm-derived layer lying between the paraxial and lateral plate layers and responsible for forming much of the urogenital system.

**Intervertebral disc** Cushioning disc formed between each vertebra consisting of a central gelatinous portion, the nucleus pulposus, and an outer ring of fibrous tissue called the annulus fibrosus.

**Intramembranous (membranous) ossification** Formation of bone directly from mesenchyme cells, such as in the flat bones of the skull.

**Intraperitoneal** Organs suspended in the abdominal cavity by a mesentery.

**Intron** Region of a gene that cannot be transcribed into a protein.

**Juxtacrine signaling** Type of cell-to-cell signaling that does not use diffusible proteins. There are three types: (1) a protein (ligand) on one cell surface reacts with its receptor on another cell surface, (2) ligands in the extracellular matrix secreted by one cell interact with another, and (3) direct transmission of signals via gap junctions.

**Karyotype** Chromosomal makeup of an individual.

**L**

**Lateral horn** Origin of neurons (intermediate columns) for the sympathetic nervous system lying in the lateral region of the spinal cord from T1 to L1–L2.

**Lateral plate mesoderm** Mesoderm-derived tissue that splits into splanchnopleure (visceral) and somatopleure (parietal) layers surrounding the organs and body cavity.

**Lateral somitic frontier** Border between each somite and the parietal layer of lateral plate mesoderm. Some cells from the myotome and sclerotome regions of each somite migrate across the frontier to enter the lateral plate mesoderm and with it form the abaxial domain.

**Laterality sequences** Right and left sides are established during gastrulation in the third week of development. Patients with defects in sidedness, such that they are primarily bilaterally right or left sided, have laterality sequences.

**Lesser omentum** Double layer of peritoneum forming part of the ventral mesentery and extending from the liver to the proximal end of the duodenum and lesser curvature of the stomach.

**Lesser sac** Space behind the lesser omentum that communicates with the rest of the abdominal cavity (greater sac) via the epiploic foramen (of Winslow).

**Ligand** A signal molecule.
Mantle layer  Inner layer of the neural tube containing neurons (gray matter).

Marginal layer  Peripheral layer of the neural tube containing nerve fibers (white matter).

Meiosis  Cell divisions that take place in the germ cells to generate male and female gametes. Meiosis requires two cell divisions to reduce the number of chromosomes from 46 to the haploid number of 23.

Membranous ossification  Process of forming bone directly from mesenchyme. This process is characteristic of the flat bones of the cranial vault.

Meningocele  Herniation of meninges and brain tissue through a defect in the skull, usually in the occipital region.

Meromelia  Partial absence of a limb.

Mesencephalon  One of the three primary brain vesicles that does not subdivide.

Mesenchyme  Any loosely organized tissue composed of fibroblast-like cells and extracellular matrix regardless of the origin of the cells.

Mesentery  Double layer of peritoneum that connects portions of the gut or other viscera to the body wall or to each other. Mesenteries provide pathways for nerves, blood vessels, and lymphatics to and from the viscera and help to support the organs in the abdomen.

Mesoderm  One of three basic germ layers that form blood vessels, bone, connective tissue, and other structures.

Mesonephric ducts (Wolffian ducts)  Collecting ducts for the mesonephric kidney that regress in female fetuses but form the epididymis, ductus deferens, seminal vesicle, and ejaculatory ducts in male fetuses.

Mesonephros  Primitive kidney that forms tubules and ducts in the thoracic and lumbar regions. Most of these structures degenerate, but the main duct (mesonephric duct) and some of the tubules contribute to the male reproductive system.

Metanephros  Definitive kidney formed from metanephric mesoderm (metanephric blastema) in the pelvic region.

Metencephalon  Derived from the cranial portion of the rhombencephalon (hindbrain) and forms the cerebellum and pons.

Midgut  Part of the gut tube extending from immediately distal to the liver bud to the proximal two-thirds of the transverse colon. It forms part of the duodenum, jejunum, ileum, cecum, appendix, ascending colon, and part of the transverse colon.

Müllerian inhibiting substance  Another term for anti-müllerian hormone. Produced by Sertoli cells and causes regression of the Müllerian (paramesonephric) ducts in male fetuses.

Myelencephalon  Derived from the caudal portion of the rhombencephalon (hindbrain) and forms the medulla oblongata.

Myelomeningocele  Protrusion of meninges and spinal cord tissue through a defect in the vertebral arch called spina bifida.

Myotome  Muscle forming region of a somite formed by myocytes derived from the ventrolateral and dorsomedial regions that coalesce beneath the dermatome. These cells remain in the primaxial domain and form the intrinsic back muscles, intercostal and cervical muscles and some muscles of the upper limb girdle.

Nephron  Functional unit of the kidney consisting of the proximal and distal convoluted tubules, loop of Henle, Bowman capsule, and a glomerulus.

Neural crest cells  Cells of the neuroepithelium that form at the tips ("crest") of the neural folds and then migrate to other regions to form many structures, including spinal ganglia, bones and connective tissue of the face, septa for the outflow tract of the heart, some cranial nerve ganglia, ganglia for the gut tube (enteric ganglia), melanocytes, etc. These cells are vulnerable to teratogenic insult and provide a rationale for why many children with facial clefts also have cardiac defects.

Neurocranium  Part of the skull that forms a protective case around the brain (the other part of the skull is the viscerocranium or face). It consists of two parts, the membranous neurocranium, or flat bones of the skull, and the cartilaginous neurocranium or chondrocranium, forming the base of the skull.

Early in development, it forms the primary intestinal loop with the superior mesenteric artery as its axis. This loop is involved in gut rotation and physiological umbilical herniation and is connected to the yolk sac by the vitelline duct.

Mitosis  The process whereby one cell divides giving rise to two daughter cells each with 46 chromosomes.

Monogygotic twins  Twins formed from a single oocyte. Splitting may occur at the two-cell stage or after formation of the germ disc but usually takes place at the time of inner cell mass formation.

Morphogen  Molecule secreted at a distance that can induce cells to differentiate. The same morphogen can induce more than one cell type by establishing a concentration gradient.

Myelencephalon  Derived from the caudal portion of the rhombencephalon (hindbrain) and forms the medulla oblongata.

Myelomeningocele  Protrusion of meninges and spinal cord tissue through a defect in the vertebral arch called spina bifida.

Myotome  Muscle forming region of a somite formed by myocytes derived from the ventrolateral and dorsomedial regions that coalesce beneath the dermatome. These cells remain in the primaxial domain and form the intrinsic back muscles, intercostal and cervical muscles and some muscles of the upper limb girdle.

Nephron  Functional unit of the kidney consisting of the proximal and distal convoluted tubules, loop of Henle, Bowman capsule, and a glomerulus.

Neural crest cells  Cells of the neuroepithelium that form at the tips ("crest") of the neural folds and then migrate to other regions to form many structures, including spinal ganglia, bones and connective tissue of the face, septa for the outflow tract of the heart, some cranial nerve ganglia, ganglia for the gut tube (enteric ganglia), melanocytes, etc. These cells are vulnerable to teratogenic insult and provide a rationale for why many children with facial clefts also have cardiac defects.

Neurocranium  Part of the skull that forms a protective case around the brain (the other part of the skull is the viscerocranium or face). It consists of two parts, the membranous neurocranium, or flat bones of the skull, and the cartilaginous neurocranium or chondrocranium, forming the base of the skull.
Neuromeres  Brain segments associated with somitomeres. They are especially prominent in the hindbrain where they are called rhombomeres.

Neuropores  Cranial and caudal openings in the neural tube that exist from the time that closure of the neural folds is initiated until it is complete, that is, unclosed portions of the closing neural tube.

Neurulation  Process of transforming the neural plate into the neural tube. Neurulation begins in the third week and ends at 28 days. Failure of the neural folds to close the tube results in neural tube defects, including anencephaly and spina bifida.

Notochord  An extended column of midline cells lying immediately ventral to the floor plate of the central nervous system and extending from the hypophysis to the end of the spinal cord. It is important for inducing the neural plate, the ventral (motor) region of the brain and spinal cord, and the sclerotome portion of the somites to form vertebrae. The major signal molecule for these phenomena is sonic hedgehog (SHH).

Nucleosome  Basic unit of structure of chromatin, containing a complex of histone proteins and approximately 140 base pairs of DNA.

Nucleus pulposus  Central gelatinous portion of an intervertebral disc derived from proliferation of notochord cells.

Omental bursa (lesser peritoneal sac)  Space created posterior to the stomach by gut rotation. This space connects to the rest of the peritoneal cavity (greater peritoneal sac) through the epiploic foramen (of Winslow).

Omentum  Fold of peritoneum passing from the stomach to the liver (lesser omentum) or from the stomach to the transverse colon and beyond (greater omentum).

Omphalocele  Ventral body wall defect caused by failure of physiologically herniated loops of bowel to return to the body cavity in the 10th week.

Organogenesis  Period of development when the organ primordia are established, usually considered to be from the beginning of the third week to the end of the eighth week of gestation. This is the time when organs are most sensitive to insult, and induction of most birth defects occurs.

Oropharyngeal membrane  Membrane formed at the cranial end of the germ disc by adhesion between epiblast and hypoblast cells. Later, it covers the opening of the oral cavity and breaks down as the pharynx develops. (The old term was buccopharyngeal membrane.)

Outer cell mass  Cells that surround the blastocyst cavity and cover the inner cell mass and that will form the trophoblast.

Paracrine signaling  Type of signaling from one cell to another where proteins synthesized by one cell diffuse short distances to interact with other cells.

Paramesonephric ducts (Müllerian ducts)  Ducts that parallel the mesonephric duct and extend from the abdominal cavity to the posterior wall of the urogenital sinus. These ducts regress in the male fetus but form the uterus, uterine (fallopian) tubes, and upper part of the vagina in female fetuses.

Paraxial mesoderm  Mesoderm-derived tissue along the axis of the embryo responsible for forming somites and somitomeres.

Parenchyma  The specific cells of a gland or organ held together by connective tissue called the stroma.

Parietal  Pertaining to the wall of any cavity.

Parturition  Birth.

Pericardioperitoneal canal  Openings from the abdomen to the thorax posterior to the septum transversum that are closed by the pleuroperitoneal membranes during formation of the diaphragm.

Peritoneal ligaments  Thickenings of peritoneum that join organs together. For example, the spleen and kidney by the lienorenal ligament and the liver to the duodenum by the hepatoduodenal ligament.

Pharyngeal arches  Bars of mesenchyme derived from mesoderm and neural crest cells that form in five pairs around the pharynx, somewhat like the gills (branchia) of a fish. They are covered by ectoderm externally and endoderm internally. Clefts are present externally between pairs of arches, whereas pouches are present between arches internally. However, there is no communication between clefts and pouches.

Pharyngeal cleft  Ectoderm-lined indentation between pharyngeal arches on their external surfaces.

Pharyngeal pouch  Endoderm-lined indentation between pharyngeal arches on their internal surfaces.

Phenotype  Physical characteristics of an individual.

Phocomelia  Partial absence of a limb (a type of meromelia) in which the long bones are missing or very short resulting in the hand or foot attached to the side of the body.

Placode  A thickened region of ectoderm that forms sensory organs and ganglia. Examples include the nasal, otic, lens, and epibranchial placodes.

Pleuropericardial folds  Extensions of mesoderm from the lateral body wall that meet in the midline.
to separate the pleural and pericardial cavities. The folds carry the phrenic nerve with them, contribute to the parietal pericardium, and form the fibrous pericardium.

**Pleuroperitoneal folds** Extensions of mesoderm that extend from the body wall to meet the septum transversum and mesentery of the esophagus, thereby closing the pericardioperitoneal canals during formation of the diaphragm.

**Polydactyly** Extra digits.

**Prechordal plate** Collection of mesoderm cells lying between the oropharyngeal membrane and the cranial end of the notochord. These cells represent some of the first to pass through the primitive streak and are important for forebrain induction using sonic hedgehog as a signal molecule.

**Primary heart field (PHF)** Cardiac progenitor cells that have migrated through the primitive streak and positioned themselves in the splanchnic (visceral) layer of lateral plate mesoderm in a horseshoe shape cranial to the cranial region of the neural plate. These cells will coalesce to form the heart tube and will contribute to the formation of the atria, left ventricle, and right ventricle.

**Primary intestinal loop** Loop formed around the superior mesenteric artery by the midgut. It rotates and lengthens as it herniates into the umbilicus in the sixth week. It then continues its growth and rotation as it reenters the abdominal cavity beginning in the 10th week.

**Primary palate** Formed by the medial nasal prominences as part of the intermaxillary segment. It fuses with the secondary palate.

**Primaxial domain** Region of mesoderm around the neural tube that contains only somite-derived (paraxial mesoderm) cells.

**Primitive body cavity** Created by ventral body wall closure, this space extends from the cervical region to the pelvis. It will be divided by the diaphragm into thoracic and peritoneal cavities and by the pleuropericardial folds into the pleural and pericardial cavities.

**Primitive node** Elevated region around the cranial end of the primitive streak that is known as the “organizer” because it regulates important processes such as laterality and formation of the notochord.

**Primitive pit** Depression in the primitive node.

**Primitive streak** Groove formed in the epiblast at the caudal end of the bilaminar germ disc stage embryo through which epiblast cells migrate to form endoderm and mesoderm during gastrulation.

**Primordial germ cells** Cells responsible for differentiating into eggs and sperm. They migrate from the wall of the yolk sac to the genital ridges.

**Processus vaginalis** Outpocketing of peritoneum that precedes the testis through the inguinal canal. Once it reaches the scrotum, it pinches off from the abdominal cavity and forms the tunica vaginalis of the testis. If it fails to pinch off, then it can serve as a path for herniation of bowel through the canal into the scrotum, forming an inguinal (indirect) hernia.

**Proctodeum** Ectodermally lined pit that invaginates to form the lower third of the anal canal. Initially, this region is separated from the remainder of the anal canal by the anal membrane (once the posterior portion of the cloacal membrane), which breaks down to permit continuity between the two parts of the canal.

**Progress zone** Proliferating population of mesenchyme cells immediately beneath the apical ectodermal ridge (AER). By signaling through FGFs, the AER maintains the progress zone and promotes proximodistal growth of the limb.

**Promoter region** Site in a typical gene that binds RNA polymerase for the initiation of transcription.

**Pronephros** Primitive kidney that forms a few nonfunctional vestigial tubules in the cervical region.

**Prosencephalon** One of three primary brain vesicles that form the telencephalon and diencephalon.

**Pseudohermaphrodite** Individual in whom the genotypic sex is masked by a phenotype that resembles the opposite sex. Female pseudohermaphrodisms is most often caused by abnormalities in the adrenal glands (congenital adrenal hyperplasia [CAH]); male pseudohermaphrodites usually occur because of androgen insensitivity syndrome (AIS,) which causes their external genitalia to be incapable of responding to dihydrotestosterone.

### Glossary of Key Terms

**Round ligament of the liver** Formed by the obliterated umbilical vein that runs in the free margin of the falciform ligament.
Scaphocephaly  Type of craniosynostosis in which the sagittal suture closes prematurely resulting in a long, narrow head shape.

Sclerotome  Ventromedial part of each somite that forms the vertebrae.

Secondary heart field (SHF)  Group of cells in the visceral (splanchnic) layer of lateral plate mesoderm lying beneath the floor of the posterior part of the pharynx. Regulated by neural crest cells migrating in the region, SHF cells contribute to formation of the right ventricle, and outflow tract (conus cordis and truncus arteriosus) of the heart.

Secondary palate  Derived from the maxillary processes of the first arch and includes the soft and hard palates. Fuses with the primary palate anteriorly.

Septum primum  First septum to grow down from the roof of the common atrium and contributes to the interatrial septum. Prior to contact with the atrioventricular endocardial cushions, programmed cell death creates a new opening in this septum to maintain communication between the atrial chambers. This septum will form the valve of the foramen ovale.

Septum secundum  Second septum to grow down from the roof of the common atrium toward the atrioventricular endocardial cushions. It never makes contact with the cushions, such that an oblique opening, the foramen ovale, is created between the septum secundum and septum primum that allows shunting of blood from the right atrium to the left during fetal development. At birth, this opening is closed when the septum primum is pressed against the septum secundum and the adult pattern of blood flow is established.

Septum transversum  Mesoderm tissue originally lying cranial to the heart but repositioned between the heart and connecting stalk by cranial folding of the embryo. It gives rise to the central tendon of the diaphragm, connective tissue for the liver, and ventral mesentery.

Situs inversus  Complete reversal of left- and right-sidedness of the organs in the thorax and abdomen.

Somatic (parietal) mesoderm  That layer of lateral plate mesoderm associated with ectoderm. It forms the parietal pleura, parietal peritoneum, etc.

Somatopleure  Combination of the parietal (somatic) layer of the lateral plate mesoderm and the adjacent layer of ectoderm.

Somites  Epithelial balls of cells formed in segmental pairs along the neural tube from paraxial mesoderm. Somites differentiate into vertebrae, muscles of the back and body wall, and dermis of the skin.

Somitomeres  Loosely organized segmented collections of paraxial mesoderm in the cranial region. Somitomeres form muscles and bones of the face and skull.

Sonic hedgehog  Secreted protein that acts as a morphogen in several embryonic sites, including the limbs, somites, gut formation, and establishment of the midline in the central nervous system.

Spina bifida  Neural tube defect that involves incomplete development of the vertebral arches with or without defects of the underlying neural tube. If only the vertebrae are involved, the defect is called spina bifida occulta because it is usually skin-covered and not visible from the surface. If the underlying neural tube is affected, then the defect is called spina bifida cystica. Seventy percent of these defects can be prevented by daily maternal use of 400 µg of folic acid beginning 2 to 3 months prior to conception and continuing throughout pregnancy.

Spinal ganglion (dorsal root ganglion)  Ganglion derived from neural crest cells that lie outside the spinal cord and houses the sensory cell bodies for a spinal nerve.

Spinal nerve  Nerve formed by the junction of dorsal and ventral roots at each intervertebral foramen.

Splanchnic (visceral) mesoderm  That part of the lateral plate mesoderm that is associated with endoderm and forms the visceral pleura, visceral peritoneum, etc.

Splanchnic nerves  Preganglionic sympathetic and parasympathetic fibers in the thorax (greater [T5-T9], lesser [T10 and T11], and least [T12] splanchnic nerves; sympathetic), lumbar region (lumbar splanchnic nerves [L1 and L2]; sympathetic), and pelvic region (pelvic splanchnic nerves S2-S4; parasympathetic).

Splanchnopleure  Combination of the visceral (splanchnic) layer of lateral plate mesoderm with the adjacent layer of endoderm.

Stenosis  A narrowing of a canal or orifice.

Stomodeum  The ectodermally lined primitive oral cavity, separated from the pharynx by the oropharyngeal membrane, that later breaks down.

Stroma  Connective tissue of glands.

Surfactant  Phospholipid made by alveolar type II cells that reduce surface tension in alveoli, which is essential for respiration. Production does not begin until the end of the sixth month, making it difficult for premature infants born before this time to survive.

Suture  Narrow seams of connective tissue that separate the flat bones of the skull allowing molding of the skull through the birth canal and growth and expansion as the brain grows.

Sympathetic trunks  Paired collections of sympathetic ganglia lying on the posterior body wall lateral to the vertebral bodies. Sometimes called sympathetic chain ganglia.
Syncytiotrophoblast: Outer multinucleated layer of the trophoblast that serves to invade the endometrium of the uterus.

Syndactyly: Fusion of one or more digits.

Syndrome: A group of abnormalities occurring together that have a known cause, for example, Down syndrome and fetal alcohol syndrome (FAS).

**T**

Telencephalon: Derived from the most cranial portion of the prosencephalon (forebrain) and forms the cerebral hemispheres.

Teratogen: A factor that causes a birth defect, such as a drug or environmental toxicant.

Teratology: Science that studies the origin, causes, and prevention of birth defects.

Teratoma: Tumor-containing derivatives from all three germ layers. They may arise from remnants of the primitive streak or from germ cells that do not migrate successfully to the gonadal ridges. The most common ones are caudal teratomas arising in the buttocks region.

Thyroglossal duct: Duct formed along the path of thyroid migration extending in the midline from the foramen cecum in the tongue to the neck.

Tracheoesophageal septum: Septum that separates the trachea from the gut tube.

Transcription factors: Proteins that have DNA-binding sites that regulate the expression of downstream genes.

Trophoblast: Outer cell layer surrounding the blastocyst from which placental tissues are derived.

**U**

Urachus: Vestigial remnant of the allantois from the ventral surface of the urogenital sinus to the umbilicus that normally regresses to a fibrous cord, forming the median umbilical ligament. Sometimes it may remain patent to form a urachal fistula or cyst.

Urogenital ridge: Bilateral epithelial-covered elevation of intermediate mesoderm that lies in the lower thoracic and lumbar regions and that forms the mesonephric kidneys and the gonads.

Urorectal septum: Wedge of mesoderm that grows down between the hindgut and primitive urogenital sinus, partially separating these two structures. The caudal end of the septum forms the perineal body.

Uterovesical pouch: Depression between the vagina and the bladder.

**V**

Vasculogenesis: Formation of blood vessels from blood islands in situ.

Ventral mesentery: Double layer of peritoneum derived from the septum transversum and extending from the liver to the ventral body wall (the falciform ligament) and from the liver to the stomach and duodenum (lesser omentum).

Ventral primary ramus: Ventral branch of a spinal nerve that innervates limb and trunk muscles except the intrinsic (“true”) back muscles, which are innervated by dorsal primary rami.

Ventral root: Motor fibers passing from ventral horn cells in the spinal cord to a spinal nerve.

Visceral: Relating to the organs of the body.

Viscerocranium: Part of the skull that comprises the bones of the face (the other part of the skull is the neurocranium).

Vitelline duct: Connection between the yolk sac and the primary intestinal loop of the midgut through the connecting stalk. Failure of this duct to degenerate results in fistulas and diverticula (Meckel diverticulum) from the small intestine to the umbilicus.

**W**

White rami communicantes: Connections carrying preganglionic sympathetic fibers from spinal nerves to the sympathetic trunks. White rami exist only at levels T1–L2.

**Y**

Yolk sac: Structure located ventral to the bilaminar germ disc derived from the hypoblast. It is the site of origin of the first blood cells and remains attached to the midgut via the vitelline (yolk sac) duct until late in development.

**Z**

Zone of polarizing activity (ZPA): Population of mesoderm cells at the posterior border of the limb next to the apical ectodermal ridge that regulates anterior-posterior patterning of the limb.

Hormonal contraceptive methods,
41b
Hormones, 116–117
Indifferent gonad, 262, 262f, 263f
Inferior vena cava
absence of, 211b, 212f
double, 211f, 212f
Alveolar bone, 238
intestinal, 363b
Hypoplastic left heart syndrome
(HLHS), 191b, 192f
Hypoplastic right heart syndrome
(CHRHS), 191b, 192f
Hypospadias, 271b, 271f
Hypothalamus, 323, 341
Hypoxia, 135

I
IAA. See Interrupted aortic arch
Ichthyosis, 363b
ICSI. See Intracytoplasmic sperm
injection
Identical twins, 120
IGF-1. See Insulin-like growth factor-1
IL-1β. See Interleukin-1β
Ileal diverticulum, 245b
Ileum, 133
Impervious anus, 247b
Implantation, 57
abnormal, 54b–56b
uterus and, 45–48, 46f, 47f
Imprinting, 5, 12, 23b, 32, 56b
Inborn errors of metabolism, 24b
Incisional foramen, 297, 298b
Incus, 147, 280, 346, 347f
Indifferent gonad, 262, 262f, 263f
Infectious agents, 129
Pyogenic, 131
Inferior vena cava
absence of, 211b, 212f
double, 211b, 212f
hepaticoduodenal portion of, 208
renal segment of, 211
valve of, 184
Infertility, 41b–42b, 48
Infundibulum, 324
Inguinal hernia, 275b, 276f
Inheritance, chromosomal theory of,
15–17
Inner cell mass, 48, 56
Insulin, 134
secretion, 238
Insulin-like growth factor-1 (IGF-1),
109b
Integrins, 7
Integumentary system
fingernails and toenails, 365
hair, 364
mammary glands, 365–366
skin, 362–364
sweat glands, 365
Intellectual disability, 333b
alcohol and, 133
Interleukin-1β (IL-1β), 223
Intermediate mesoderm, 64, 79, 82–83,
92, 96
Internal ear, 343–346, 343f, 351
Internal pudendal arteries, 247
Interrupted aortic arch (IAA), 207b, 208f
Interstitial cells of Leydig, 262
Interventricular foramen, 197
Interventricular septum, 197, 216
Intervillosus space, 110, 125
Interzone, 164, 165
Intestinal loop, primary, 239, 240f
Intestinal loops, 105, 243f
duplications of, 245b
mesenteries of, 242
reversed rotation of, 245
Intracytoplasmic sperm injection (ICSI), 42b, 48, 134
Intramembranous ossification, 143, 144f, 145, 155
Intrauterine device (IUD), 41b
Intrauterine growth restriction (IUGR), 109b
Introns, 3, 5, 10
Invasion, 58, 68
In vitro fertilization (IVF), 42b, 45b
birth defects and, 134
Iodine deficiency, 135
Ionomizing radiation, 131
Iridopupillary membrane, 355, 356, 357b
Iris, 353–355, 356f
Isoimmunization, 115b
Isotretinoin (Accutane), 131, 350b
Isthmus, 329
IUD. See Intrauterine device
IUGR. See Intrauterine growth restriction
IVF. See In vitro fertilization
K
Kartagener syndrome, 66b
Keratinization of skin, 363b
Kidney
abnormal location, 257b, 258f
ascent of, 257
development, molecular regulation of, 253–255, 254f
function, 257
position, 257
systems, 250–251
Kinase, 6, 12
Kleeblattschädel, 148b
Klinefelter syndrome, 21b, 273b–274b
Klipper–Feil sequence, 153b
Kupffer cells, 236
L
Labia majora, 270, 272, 277
Labia minora, 272, 277
Labor, 120
Lacrimal sac, 295
Lamina terminales, 324, 326, 341
Laminin, 7, 255
Lanugo hair, 105, 364, 367
Laron dwarfism, 109b
Laryngeal nerves, 204–205, 220, 291
Laryngeal orifice, 218, 291
Larynx, 220, 220f, 283
Last normal menstrual period (LNMP), 105, 125
Lateral cervical cyst, 288b, 289f
Laterality, 62
birth defects associated with, 659–66b
defects, 63, 177b
sequences, 181b
Lateral plate mesoderm, 64, 79, 92, 96, 103
axial skeleton and, 143
head formation and, 278
mesodermal germ layer and, 83, 83f
parietal layer of, 159
LBW. See Low birth weight
Lead, 135
Left–right (L–R) axis, 59–64, 62, 63f
Lens, 355
placodes, 76–77
vesicle, 352–354, 352f
Lentiform nucleus, 325
Lesser omentum, 227, 232–233, 234f, 236
Lexapro. See Selective serotonin reuptake inhibitors
LH. See Luteinizing hormone
Ligamentum arteriosum, 206b, 215
Ligamentum teres hepatis, 210, 215, 217
Ligamentum venosum, 210, 215, 217
LIM1, 69, 328
Limbs
defects, 170b–173b
growth and development, 163–165, 169f
molecular regulation of, 168–170, 169f
innervation, 167, 167f
musculature, 156, 159–161, 166–170, 166f
transverse, defects, 173
Linked genes, 15
Lithium, 132
Liver, 93
abnormalities, 238b
formation, 233, 233f, 234f
induction, molecular regulation of, 236–237
LNMP. See Last normal menstrual period
Loop of Henle, 253
Low birth weight (LBW), 109b, 125
L–R axis. See Left–right axis
t. transposition of the great arteries, 191b
Lumbar curvature, 153
Lungs, 220–221, 221f
bud formation, 218, 218f, 219f, 223
congenital cysts of, 224b
maturation, 222–223, 222f, 223f
Luteinizing hormone (LH), 28, 34
Lymphatic system, 215, 217
Lymph sacs, 215
M
Maculae acusticae, 346
MAIS. See Mild androgen insensitivity syndrome
Male “pill,” 41b
Malformations, 127, 140, 316b
congenital, 126
teratogens associated with, 130f
Malleus, 147, 280, 346–348, 347f
Mammary glands, 365–367, 366f
abnormalities, 366b
Mandible, 146, 280
Mandibular process, 146, 280
Mandibular prominences, 280, 281f, 292, 294f, 304
Mandibulofacial dysostosis, 289b
Mantle layer, 307–308
Marfan syndrome, 172b
Maternal antibodies, transmission of, 116
Maternal disease
birth defects and, 134–135
heart defects, 191b
Maternal serum screening, 136, 137–138, 140
Mature vesicular follicles, 27–28, 28f, 33
Maxilla, 146, 280, 295
Maxillary artery, 202
process, 146, 280
prominences, 280, 281f, 292, 294f, 304
Meckel cartilage, 146, 280
Meckel diverticulum, 245b
Meckel–Gruber syndrome, 256b
Medial umbilical ligaments, 205, 214, 217
Medulla, 75, 263, 338, 342
Medulla oblongata, 317, 341
Medullary cords. See Testis
Megacolon, congenital, 247b, 340b
Meeosis, 18b
crossover, 16–17, 16f
polar bodies, 17, 17f
Melanocytes, 75, 367
Meningocele, 147b, 147f, 331b, 331f
Meningoencephaloceles, 331b, 331f, 332b, 332f
Meningohydroencephaloceles, 331b, 331f
Menstrual phase, 45, 47
Mercury, 135
Meromelia, 131, 170b, 171f
Mesencephalon (midbrain), 306, 320f, 321–322, 341
Mesenchyme, 75, 143
Mesenteries, 227–228, 272.
See also Dorsal mesentery; Ventrail mesentery
abnormalities of, 243b
of intestinal loops, 242
Mesoderm, 69–70, 75.
