### Contents

12. **Water, electrolytes and acid–base balance**
   - MM Yaqoob
   - 649

13. **Cardiovascular disease**
   - AJ Camm and N Bunce
   - 681

14. **Respiratory disease**
   - AJ Frew and ST Holgate
   - 811

15. **Intensive care medicine**
   - CJ Hinds and D Watson
   - 889

16. **Drug therapy and poisoning**
   - M Rawlins and JA Vale
   - 923

17. **Environmental medicine**
   - ML Clark, CRA Clarke and A Geddes
   - 953

18. **Endocrine disease**
   - TA Howlett and MJ Levy
   - 963

19. **Diabetes mellitus and other disorders of metabolism**
   - EAM Gale and JV Anderson
   - 1029

20. **The special senses**
   - M Harries, F Vaz and S Verma
   - 1077

21. **Neurological disease**
   - CRA Clarke
   - 1095

22. **Psychological medicine**
   - PD White and AW Clare
   - 1185

23. **Skin disease**
   - DG Paige
   - 1225

Index
- 1273
The seventh edition of *Kumar & Clark’s Clinical Medicine* has an online version that can be accessed via www.studentconsult.com. The online version consists of the full text and illustrations for the seventh edition as well as other additional features, some of which are unique to Kumar & Clark. To access the online version, readers should follow the instructions on the book’s inside front cover. The list below provides a guide to some of the online features, and you can also find them listed online in the ‘extras’ folder.

**ONLINE APPENDIX**
edited by Professor Janaka de Silva

This appendix, which will be updated regularly, provides supplementary information on diseases and problems that are more prevalent in certain parts of the world, up to date for the seventh edition. The need for this material – which enlarges on what can be found in the print version – became plain to the Editors from their travels to various parts of the world. We are grateful to members of the Kumar & Clark International Advisory Panel and other colleagues for their contributions to this unique resource.

- Brucellosis *Professor S S Fedail*
- Dengue fever *Dr R Sood*
- Diarrhoeas including amoebiasis *Professor S A Azer*
- Human avian influenza infection *Professor M Ellis*
- HIV in resource-limited settings *Dr M Mendelson and Professor G Maartens*
- Infections caused by Rickettsiae, Orientiae and Coxiella *Dr R Premaratna*
- Leprosy *Dr S A Kamath*
- Malaria *Dr S A Kamath*
- Rabies *Professor K N Viswanathan*
- Rheumatic fever *Professor K N Viswanathan*
- Rift Valley fever *Professor O. Khalafallah, Dr A A K Jebriel, Dr M El Sadig, Dr M Mirghani, Professor S S Fedail*
- Severe acute respiratory syndrome (SARS) *Professor K N Lai*
- Soil-transmitted helminths *Professor N de Silva*
- Vaccination for adults *Dr R Dewan*
- Fluorosis *Professor F S Hough*
- Tropical sprue *Professor S A Azer*
- Liver transplantation *Dr J T Wells, Professor M R Lucey*
- Thrombotic thrombocytopenic purpura (TTP) associated with HIV *Professor V J Louw*

**INTERACTIVE SURFACE ANATOMY**
from Drake et al: Gray’s Anatomy for Students

This programme relates anatomy to the skills of clinical examination. Over 40 interactive animations take the student through the seven body regions, demonstrating major anatomical features, surface landmarks and other palpable structures. By working through each module students see their role when performing a general physical examination, listening for heart sounds, examining movements of the eye, and many others. We are grateful to the authors of *Gray’s Anatomy for Students* for the opportunity to provide Kumar & Clark readers with the benefits of this unique interactive learning tool and to introduce them to this outstanding anatomy textbook.

**Back**

- How to identify specific vertebral spinous processes
- Visualizing the inferior ends of the spinal cord and subarachnoid space

**Thorax**

- How to count ribs
- Surface anatomy of the breast in women
- Visualizing structures at the T4/5 vertebral level
- Visualizing structures in the superior mediastinum
- Visualizing the margins of the heart
- Where to listen for heart sounds
- How to visualize the pleural cavities and lungs
- Where to listen to right lung sounds
- Where to listen to left lung sounds

**Pelvis and perineum**

- Identification of structures in the urogenital triangle of women
- Identification of structures in the urogenital triangle of men
Abdomen
- How to find the superficial inguinal ring
- How to determine lumbar vertebral levels
- Visualizing structures at the L1 vertebral level
- Visualizing the position of major blood vessels
- Using abdominal quadrants to locate major viscera
- Defining surface regions to which pain from the gut is referred
- Where to find the kidneys and spleen

Lower limb
- Avoiding the sciatic nerve
- Finding the femoral artery in the femoral triangle
- Identifying structures around the knee
- Visualizing the contents of the popliteal fossa
- Finding the tarsal tunnel
- Identifying tendons around the ankle and in the foot
- Finding the dorsalis pedis artery
- Identifying major superficial veins
- Where to take peripheral arterial pulses in the lower limb

Upper limb
- Visualizing the axilla, its contents and related structures
- Locating the brachial artery in the arm
- Locating the triceps brachii tendon and the position of the radial nerve
- Identifying the cubital fossa and its contents
- Identifying tendons and locating major vessels and nerves in the distal forearm
- Identifying the position of the flexor retinaculum and the recurrent branch of the median nerve
- Visualizing the positions of the superficial and deep palmar arches
- Where to take peripheral arterial pulses in the upper limb

Head and neck
- Visualizing structures at the CIII/CIV and CVI vertebral levels
- How to outline the anterior and posterior triangles of the neck
- How to locate the cricothyroid ligament (membrane)
- How to find the thyroid gland
- Where to take peripheral arterial pulses in the head and neck
- Testing eye movements – demonstration illustrating the muscle involved in each activity.

ANIMATIONS OF PRACTICAL PROCEDURES
This feature brings to life a selection of key practical procedures in a way not usually possible outside the clinic or skills laboratory. Once again, the existence of the online version has made it possible to provide this unique feature, where the animations build on the descriptions given in the ‘practical boxes’ in Kumar & Clark.
- Arterial cannulation
- Arterial puncture
- Bladder catheterization: female
- Bladder catheterization: male
- Central venous catheterization (CVC): jugular vein
- Central venous catheterization (CVC): subclavian vein
- Joint aspiration
- Lumbar puncture
- Venepuncture

HEART AND LUNG SOUNDS
by Dr Salvatore Mangione
This feature provides readers with the opportunity to improve their clinical skills by listening to 10 pulmonary and 12 cardiac sounds. The sounds can be heard on their own or accompanied by an instructive narrative. This workshop has been prepared by Dr Salvatore Mangione, and we are grateful for the opportunity to make it available to readers of Kumar & Clark.

CARDIAC AUSCULTATION:
- Opening snap
- Aortic regurgitation and systolic flow murmur
- Pericardial friction rub
- S3 gallop
- Mid-systolic click
- Patent ductus arteriosus
- Early-systolic ejection sound
- Aortic stenosis
- S4 gallop
- Mitral regurgitation
- Aortic regurgitation
- Mitral stenosis and opening snap

PULMONARY AUSCULTATION:
- Bronchial breath sounds
- Crackles
- Wheezes
- Vesicular breath sounds
- Rhonchi
- Pleural friction rub
- Bronchial breath sounds and late-inspiratory crackles
- Late-inspiratory squeak
- Amphoric breath sounds
- Whispered pectoriloquy

ASK THE AUTHORS
This popular feature continues on into the seventh edition of Kumar & Clark. It gives readers the opportunity to submit questions to the editors and to read the answers online. Readers can view the most recent questions, or can access the complete list of questions and answers that have been logged on the site.
Contributors

Jane Anderson BSc PhD MB BS FRCP
Consultant Physician, The Centre for the Study of Sexual Health and HIV, Homerton University Hospital NHS Foundation Trust; Professor, The Institute of Cell and Molecular Science, Barts and The London School of Medicine and Dentistry, Queen Mary University of London, London, UK
Infectious diseases, tropical medicine and sexually transmitted infection

John V Anderson MD MA MBBS FRCP
Consultant Physician, Homerton University Hospital NHS Foundation Trust and Barts and The London NHS Trust; Honorary Senior Lecturer at Barts and The London School of Medicine and Dentistry, Queen Mary University of London, London, UK
Diabetes mellitus and other disorders of metabolism

Nicholas Harry Bunce BSc MBBS MD
Consultant Cardiologist, St George’s Healthcare NHS Trust, London, UK
Cardiovascular disease

Andrew Kenneth Burroughs MBChB (Hons) FRCP
Consultant Physician and Hepatologist, Professor of Hepatology, The Royal Free Sheila Sherlock Liver Centre, and Department of Surgery, Royal Free Hospital, London, UK
Liver, biliary tract and pancreatic disease

A John Camm MD FRCP
Professor of Clinical Cardiology, St George’s, University of London, London, UK
Cardiovascular disease

Anthony W Clare MD FRCP FRCPsych MPhil (deceased)
Formerly Associate Professor of Psychiatry, Dublin University; Consultant Psychiatrist, St Patrick’s Hospital, Dublin, Ireland
Psychological medicine

Michael L Clark MD FRCP
Honorary Senior Lecturer, Barts and The London School of Medicine and Dentistry, Queen Mary University of London, London, UK
Environmental medicine

Charles Richard Astley Clarke MA MB FRCP
Honorary Consultant Neurologist, National Hospital for Neurology and Neurosurgery, London, UK
Environmental medicine

Juliet Compston MD FRCP FMedSci
Professor of Bone Medicine, Department of Medicine, University of Cambridge, School of Clinical Medicine, Cambridge; Honorary Consultant Physician, Addenbrookes’ NHS Trust, Cambridge, UK
Bone disease

Annie Cushing PhD FDSRCS (Eng) BDS (Hons)
Reader in Clinical Communication Skills, Institute of Health Sciences Education, Barts and The London School of Medicine and Dentistry, Queen Mary University of London, London, UK
Communication

Andrew Davies MRCP PhD
Senior Lecturer in Medical Oncology and Honorary Consultant, Cancer Services Division, Southampton General Hospital, Southampton, UK
Malignant disease

Len Doyal BA MSc Emeritus Professor of Medical Ethics, University of Nottingham, Nottingham, UK
Health, healthcare ethics and the law

Marinos Elia BSc (Hons) MD FRCP
Professor of Clinical Nutrition and Metabolism, University of Southampton, Southampton, UK
Nutrition

Peter D Fairclough MD FRCP
Honorary Consultant Gastroenterologist, Barts and The London NHS Trust, London, UK
Gastrointestinal disease

Roger Finch FRCP FRCPath FMedSci (Edin)
Professor of Infectious Diseases, Division of Infectious Diseases, School of Molecular Medical Sciences, Faculty of Medicine and Health Sciences, The University of Nottingham, Nottingham, UK
Infectious diseases, tropical medicine and sexually transmitted infection

Anthony J Frew MA MD FRCP
Professor of Allergy and Respiratory Medicine, Brighton and Sussex Medical School, Brighton, UK
Respiratory disease

Edwin AM Gale MB FRCP
Professor of Diabetic Medicine, University of Bristol, Bristol, UK
Diabetes mellitus and other disorders of metabolism

Christopher J Gallagher MBChB PhD FRCP
Consultant Medical Oncologist, St Bartholomew’s Hospital, Barts and The London NHS Trust, London, UK
Malignant disease

Alasdair MacIntosh Geddes CBE MBChB FRCPath (Lond & Edin) FFPH FMedSci Emeritus Professor of Infectious Diseases, School of Medicine, University of Birmingham, Birmingham, UK
Environmental medicine

Meredydd Harries FRCS MSc
Consultant ENT Surgeon, Royal Sussex County Hospital, Brighton, UK
The special senses

Charles Hinds FRCP FRCA
Professor of Intensive Care Medicine, William Harvey Research Institute, Barts and The London School of Medicine and Dentistry, Queen Mary University of London, and Barts and The London NHS Trust, London, UK
Intensive care medicine

Stephen T Holgate BSc MB BS MD DSc FRCP FRCPath FiBiol FMedSci
Professor of Immunopharmacology, School of Medicine, University of Southampton, Southampton, UK
Respiratory disease

Trevor A Howlett MD FRCP
Consultant Physician and Endocrinologist, Leicester Royal Infirmary, University Hospitals of Leicester NHS Trust, Leicester, UK
Endocrine disease

Raymond Kruse Iles BSc MSc PhD CBiol MIBiol FRSC
Associate Dean, Research, and Professor of Biomedical Sciences, School of Health and Social Sciences, Middlesex University, Hendon, UK
Molecular cell biology and genetic disorders
William L Irving MA PhD MB BChir MRCP FRCP
Professor of Virology, The University of Nottingham; Honorary Consultant Virologist, Nottingham University Hospitals NHS Trust, Nottingham, UK
Infectious disease; tropical medicine and sexually transmitted infection

Miriam J Johnson MD FRCP MRCPG MB ChB (Hons)
Senior Lecturer in Palliative Medicine, Hull York Medical School; Honorary Consultant to St Catherine’s Hospice and the Acute Scarborough and North East Yorkshire Health Care Trust, North Yorkshire, UK
Palliative care

Miles J Levy MD FRCP
Consultant Physician and Endocrinologist, Leicester Royal Infirmary, University Hospitals of Leicester NHS Trust, Leicester, UK
Endocrine disease

T Andrew Lister MD FRCP FRCPath FRCR FMedscc
Professor of Medical Oncology, St Bartholomew’s Hospital, Barts and The London School of Medicine and Dentistry, Queen Mary University of London, London, UK
Haematological disease

Christopher Niels Mallinson BA MB BCh FRCP
Emeritus Consultant Physician, University Hospital Lewisham, The Lewisham Hospital NHS Trust, London; Founder Board Member of European Association for Communication in Health Care (EACH); Former President of Communication in Healthcare Forum of the Royal Society of Medicine, London, UK
Communication

Peter J Moss MB ChB MD FRCP DTMH
Consultant in Infectious Diseases, Department of Infection and Tropical Medicine, Hull and East Yorkshire Hospitals NHS Trust; Honorary Senior Lecturer, Hull York Medical School, UK
Infectious diseases, tropical medicine and sexually transmitted infection

Michael F Murphy MD FRCP FRCPath
Professor of Blood Transfusion Medicine, University of Oxford; Consultant Haematologist, NHS Blood & Transplant and Department of Haematology, Oxford Radcliffe Hospitals NHS Trust, Oxford, UK
Haematological disease

Donncha O’Gradaigh MB PhD FFSEM MRCP
Consultant Rheumatologist, Department of Rheumatology, Waterford Regional Hospital, Ireland
Rheumatology and bone disease

David Paige MA MBBS FRCP
Consultant Dermatologist, Barts the London NHS Trust; Honorary Senior Lecturer, Queen Mary University of London; Barts and the London School of Medicine and Dentistry, London, UK
Skin disease

K John Pasi PhD MBChB FRCP FRCPath FRCPCH
Professor of Haemostasis and Thrombosis, Centre for Haemostatology, Institute of Cell and Molecular Science, Barts and The London School of Medicine and Dentistry, Queen Mary University of London, London, UK
Haemostology and disease

Mark Peakman MB BS BSc MSc PhD FRCP FRCPath
Professor of Clinical Immunology, King’s College London School of Medicine; Honorary Consultant in Immunology, King’s College Hospital, London, UK
The immune system and diseases

Anisur Rahman MA PhD BM BCh FRCP
Professor of Rheumatology, University College London; Honorary Consultant Rheumatologist, University College London Hospital, London, UK
Rheumatology and bone disease

Sir Michael Rawlins MD FRCP FMedSci
Chairman, National Institute for Health and Clinical Excellence; Honorary Professor, London School of Hygiene and Tropical Medicine, London, UK
Drug therapy and poisoning

Michael Shipley MA MD FRCP
Consultant Rheumatologist, University College Hospital and King Edward VII’s Hospital, London, UK
Rheumatology

DBA Silk MD AGAF FRCP
Professor of Clinical Nutrition, Department of Biosurgery and Surgical Technology, Division of SORA, Imperial College London, London, UK
Gastrointestinal disease

Allister Vale MD FRCP FRCPE FRCPG FFOM FAACT FBTS Hon FRCPsG
Director, National Poisons Information Service (Birmingham Unit) and West Midlands Poisons Unit, City Hospital, Birmingham; Honorary Professor of Toxicology, School of Biosciences and College of Medical and Dental Sciences, University of Birmingham, Birmingham, UK
Drug therapy and poisoning

Francis Vaz MBBS BSc (Hons) FRCS (ORL-HNS)
Consultant ENT/Head and Neck Surgeon, Department of ENT/Head and Neck Surgery, University College London Hospital, London, UK
The special senses

Seema Verma MBBS MD FRCP FRCOphth
Consultant Ophthalmic Surgeon and Director of A&E, Moorfields Eye Hospital, London, UK
The special senses

James Stephen Wainscoat FRCP FRCPath
Consultant Haematologist, Department of Haematology, Oxford Radcliffe Hospital, Oxford Radcliffe Hospitals NHS Trust, Oxford, UK
Haematological disease

David Watson BSc (Hons) FRCA
Consultant and Senior Lecturer in Intensive Care Medicine, William Harvey Research Institute, Barts and The London School of Medicine and Dentistry, Queen Mary University of London, and Homerton University Hospital NHS Trust, London, UK
Intensive care medicine

David Westaby MA Cantab FRCP
Consultant Physician and Gastroenterologist, Director of Endoscopic Service, Lead for Hepatobiliary Medicine at the Imperial College Healthcare NHS Trust, Hammersmith Hospital, London, UK
Liver, biliary tract and pancreatic disease

Peter D White MD FRCP FRCPsyCh
Professor of Psychological Medicine, Centre for Psychiatry, Wolfson Institute of Preventive Medicine, Barts and The London School of Medicine and Dentistry, Queen Mary University of London, UK
Psychological medicine

Muhammad Magdi Yaqoob MD FRCP
Professor, William Harvey Research Institute, Barts and the London School of Medicine and Dentistry, Queen Mary University of London; Consultant, Department of Renal Medicine and Transplantation, Barts and the London NHS Trust, London, UK
Renal disease

Richard Zajicek MD FRCP
Professor of Neurology, University of Oxford; Consultant in Neurology, Oxford University Hospitals NHS Foundation Trust, Oxford, UK
Neurorology
International Advisory Panel

AUSTRALIA
Associate Professor Peter Katelaris
Senior Consultant, Gastroenterology Department, Concord Hospital, University of Sydney, Sydney
Professor N Thomson
Professor and Head, Department of Medicine and Central and Eastern Clinical School, Monash University Medical School, The Alfred Hospital, Melbourne, Victoria

BANGLADESH
Professor Salimur Rahman
Professor of Hepatology, Department of Hepatology, Faculty of Medicine, Bangabandhu Sheikh Mujib Medical University, Bangladesh

CHINA
Professor Kar Neng Lai
Yu Chiu Kwong Chair of Internal Medicine and Chief of Medicine, Department of Medicine, University of Hong Kong, Queen Mary Hospital, Hong Kong
Professor Debabrata Bandyopadhyay

Professor of Medicine, Department of Medicine, Faculty of Medicine, University of Kelaniya, Ragama

Professor Nilanthi de Silva
Professor, Department of Parasitology, Faculty of Medicine, University of Kelaniya, Ragama

Professor Rezvi Sheriff
Senior Professor of Medicine and Director Postgraduate Medicine, Department of Clinical Medicine, Faculty of Medicine, University of Colombo, Colombo

SUDAN

Professor Suliman S Fedail
Professor of Medicine and Gastroenterologist, Chairman of Fedail Medical Centre, Department of Gastroenterology, University of Khartoum, Khartoum

UNITED ARAB EMIRATES

Professor S George Carruthers
Professor of Internal Medicine and Dean, Faculty of Medicine & Health Sciences, United Arab Emirates University, Al Ain

Professor Michael Ellis
Professor and Chair, Department of Medicine, Faculty of Medicine and Health Sciences, United Arab Emirates University, Al Ain

Dr J M Muscat-Baron
Professor of Medicine, Clinical Dean, Department of Medicine, Dubai Medical College, Dubai

United States of America

Dr Michael R Lucey
Professor of Medicine and Chief, Section of Gastroenterology and Hepatology, University of Wisconsin School of Medicine and Public Health, Madison, Wisconsin
It is almost 25 years since we first had the idea of writing and editing this book. Now in its 7th edition, *Kumar & Clark’s Clinical Medicine* continues to play a primary role in the education of medical students and doctors worldwide, enabling us all to provide better medical care to our patients. We are committed to ensuring that the book continues to change and be updated constantly in line with evolving methods of learning and, particularly, the increasing uses of the internet and advent of new technologies.

When we sat down to think about the 7th edition we were determined the book would not get bigger in size. Thanks to an innovative new design, we have managed to reduce the number of pages whilst accommodating a huge amount of new material. This includes increased coverage and emphasis on new technologies, and more material on areas such as rehabilitation medicine. We have brought in new authors to many chapters, and this edition has once again been thoroughly revised and updated, clearly and colourfully illustrated, and attractively presented. We hope its clarity will help students learn more effectively.

*Kumar & Clark’s Clinical Medicine* was one of the first textbooks to go online and is the progenitor of Student Consult. In this new edition our International Advisory Panel has expanded the online appendix of topics. There are 14 new chapters written by experts working in areas where the diseases covered are common. They provide more detailed advice and local emphasis than is possible in the printed text. *Kumar & Clark’s Clinical Medicine* has always aimed to be a clinical book (with a very strong basis in science) and the view of doctors worldwide who see these clinical problems every day is most valuable.

In addition, the online book comes with one year’s free access to *Cecil’s Medicine* online; a selection of animated procedures (such as lumbar puncture, catheterisation, cannulation, aspiration and other procedures); heart and lung sounds, and an interactive surface anatomy resource.

*Kumar & Clark’s Clinical Medicine* continues to be a book read and used in many parts of the world. The 6th edition has been translated into Turkish, Greek, Italian and most recently Chinese. In this new edition we remain totally committed to providing an accessible account of the current state of evidence on the prevention and treatment of diseases worldwide.

*Kumar & Clark’s Clinical Medicine* is now the hub of a large body of related publications. The family of books includes *Pocket Essentials of Clinical Medicine* by Ballinger and Patchett, *Pass Finals* by Smith, Carty and Langmead, and our own *Acute Clinical Medicine* (based on clinical cases). There is also a series of pocket books on other medical specialities (paediatrics, psychiatry, clinical surgery, obstetrics and gynaecology, and general practice). Our readers worldwide include not only medical students and doctors but also members of the nursing, pharmacy and other allied healthcare professions. Since the book has been online, readers frequently email questions to the editors who do their best to provide sensible answers to often very difficult questions. These questions have now been collected into a new book in the Kumar and Clark family, *1000 Questions and Answers from Clinical Medicine*.

This book would not continue to be so successful without the constant input, help and guidance we get from colleagues, be they students, young doctors or senior medical experts. Everyone likes to engage with the content of the book, which means that it is constantly being reviewed so that it is always useful for the understanding and solving of clinical problems. This indeed is what *Kumar & Clark’s Clinical Medicine* has always striven for; to be a book that allows professionals to understand how the problems occurred, how they can be diagnosed and finally how they can be treated.

As always we would like to thank our families, our own and those of our authors, for their patience and support when ‘book work’ interferes with family life.

The editors are supporting the charity Water Aid with a percentage of their royalties from the 7th edition.

PJK

MLC
A book of this size could never be completed without the help and advice of many. We would like to thank many of our colleagues who have helped in the preparation of this edition. Many have given us useful advice, helped us to collect photographs and indeed read the manuscripts to make sure that the contents are totally up-to-date. In particular we would like to acknowledge: Mr Peter Hamilton (for his help with the eye section of the diabetes chapter); Professor Graham Foster and Professor Mark Thursz (for their help with the hepatitis section); Dr Paul Jarmon, Professor Adrian Dixon and the X-Ray department of Addenbrooke’s Hospital in Cambridge (for pictures in the neurology chapter); Mr Trevor Beedham (prenatal diagnosis); Mr Fausto Palazzo (surgical aspects of endocrinology); Mr Paul Hamilton (rheumatology); Professor David van Heels (genetics); and Dr Susannah Leaver for general help with the book from a junior doctor’s perspective.

We are delighted to welcome several new contributors to this edition. They replace some of our authors who have stepped down from the book after many years of commitment and loyalty. We would like to thank Dr Jacqueline Parkin and Professor Anthony Pinching (immunology); Professor Don Jeffries (virology); Dr Teresa Tait (palliative care); Professor Carol Black and Dr Christopher Denton (rheumatology); and Professor Brian Colvin (haematology).

We were extremely saddened by the death of Professor Anthony Clare who had been an author from the very beginning of the book and who is much missed.

Our ward rounds and outpatient reviews are a continuing source of evidence-based education and we are grateful to our specialist registrars, and junior trainees, including Foundation officers, as well as our own medical students who continue to stimulate us by asking penetrating questions.

Our travels around the world give us much insight into the practice of medicine and we would like to thank the many who have escorted us through their hospitals and medical schools. We are grateful to those who write to us, and we are extremely grateful to our International Advisory Panel. Members provide very helpful advice about their regions and contribute to the online appendix articles. In particular we would like to thank Professor Janaka de Silva for his advice and expertise and careful editing of these online contributions.

We are extremely grateful for the skilled and support of our publisher, Elsevier, whose staff have maintained a commitment and loyalty to the book. We would like to acknowledge: Pauline Graham, our commissioning editor, who has taken us through this new edition; the production team of Frances Affleck (project manager), Sarah Russell, Gillian Murray and Stewart Larking (design and illustration), and Janice Urquhart (development editor), who have all contributed to the production of this extremely high quality edition. We are also grateful for the meticulous work of the copy editors, Ruth Swan and Pat Croucher, and to Caroline Cockrell. Caroline has played a major part in the day to day activities of the book in arranging endless couriers and parcels, but most particularly we are grateful for her careful management of the International Advisory Panel and the ‘Ask the Authors’ questions and answers included in the book’s website. We would also like to express our sincere thanks to the many other people behind the scenes who have contributed in so many ways; we thank them for their loyalty and commitment.

Finally, we would like to thank Ms Jillian Linton for her meticulous preparation and co-ordination of all the chapters, and also Ms Sophie Rambaud and the Princess Grace Hospital for general assistance.

ETHICS

WHY STUDY ETHICS AND LAW APPLIED TO MEDICINE?

Professional concern about ethics and law

Many clinical choices created by advances in medical technology are essentially ethical rather than scientific. Doctors may be expert in understanding and applying clinical science, yet this expertise does not in itself answer many ethical questions about the circumstances in which such science should or should not be applied. For example, they may know a great deal technically about advanced life-support systems or the termination of pregnancy. Their knowledge, however, will not tell them whether or not it is ethical to withdraw ventilatory support from a severely brain-damaged patient who will not otherwise die or to perform a termination on a 13-year-old girl who does not want her parents to know that she is pregnant. Answers to these questions derive from moral beliefs and arguments.

Patients are increasingly aware of what they believe to be their human rights and expect doctors to respect them. These may differ in different countries but the basic principles are the same.

- Rights are claims for specific types of goods or services that individuals are believed to be entitled to make on others (e.g. free speech, access to primary and secondary education, access to an acceptable standard of medical care).
- In the UK, if patients believe their rights have been ignored by doctors, they may formally complain to the General Medical Council (GMC) or seek legal redress.
- As it pertains to medicine, the law establishes boundaries for what government and the courts – through statute and common law – have deemed to be acceptable professional practice. The GMC – the UK regulatory body – sets boundaries for acceptable standards of conduct and care through guidance documents formulated by its Committee on Standards of Professional Conduct and on Medical Ethics and decisions in cases heard under the jurisdiction of its Fitness to Practice Committee.
- Whether or not legal actions or formal complaints against doctors are successful, they contribute toward bringing the medical profession into disrepute.

The three duties of clinical care

The rights of patients may be summarized by three corresponding duties of care, which apply to all patients for whom doctors have clinical responsibility.

1. Protect life and health. Clinicians should practise medicine to a high standard, taking care not to cause unnecessary harm or suffering. Patients should only be given treatments which they need. Treatments should not be prescribed, for example, just because patients request them.

2. Respect autonomy. Competent humans have autonomy – the ability to reason, plan and make choices about the future. Respect for these attributes goes hand in hand with respect for human dignity. Doctors should respect the autonomy, and thus the dignity, of their patients. This duty to respect the autonomy of patients leads to two further rights – informed consent and confidentiality. Competent patients should be able to choose to accept proposed treatments and to control personal information which they divulge concerning such treatments. Denying patients such choice and control robs them of their human dignity.
2 Ethics and communication

**Box 1.1 General Medical Council (UK), Good Medical Practice**

**The importance of protecting life and health:**
- ‘Adequately assessing the patient’s conditions, taking account of the history . . . the patient’s views, and where necessary examining the patient’
- ‘Prescribe drugs or treatment, including repeat prescriptions, only when you have adequate knowledge of the patient’s health, and are satisfied that the drugs or treatment serve the patient’s needs’
- ‘Provide effective treatments based on the best available evidence’

**The importance of respect for autonomy:**
- ‘Listen to patients, ask for and respect their views about their health and respond to their concerns and preferences’
- ‘Share with patients, in a way they can understand, the information they want or need to know about their condition, its likely progression, and the treatment options available to them, including associated risks and uncertainties’
- ‘Respect patients’ privacy and right to confidentiality’

**The importance of fairness and justice:**
- ‘You must treat your patients with respect whatever their choices and beliefs . . . (and must not) . . . discriminate against them by allowing your personal views to affect adversely your professional relationship with them or the treatment you provide or arrange’
- ‘You must not refuse or delay treatment because you believe that a patient’s actions have contributed to their condition’

Similar statements are made by a variety of professional bodies in many countries.

3. **Protect life and health and respect autonomy with fairness and justice.** In the conduct of public and professional life, it is generally thought that people have the right to expect to be treated equally. Medicine is no exception and doctors have a duty to practise accordingly. The access to, and quality of, clinical care should be based only on the dictates of need rather than arbitrary prejudice or favouritism.

**Why should doctors take the duties of care seriously?**

**Professional regulation**

Within the UK, the General Medical Council (GMC) plays a crucial role in regulating the practice of medicine. It is responsible for the registration of doctors, setting and monitoring the quality of their undergraduate education and disciplining them for unprofessional conduct. Doctors have no professional choice but to conform to the standards laid down by the GMC, which are based on the three duties of care (Box 1.1). These same duties are confirmed by other professional bodies like the Royal College of Physicians, the Royal College of Surgeons, the British Medical Association and the Medical Research Council.

National practices differ but all countries have similar regulatory bodies.

**The law**

The three duties of care are also enshrined in statute and common law, which also regulate medical practice. Doctors can be sued in civil law for financial compensation for any harm that they cause while failing in their professional duties. If it can be shown that this failure is intentional, or reckless causing extreme harm or death, doctors may face prosecution in the criminal courts and, if found guilty, imprisonment.

UK law includes the Human Rights Act 1998. This law incorporates the European Convention on Human Rights, making it legally binding in the UK (Box 1.2). The provisions of the Act impose duties on doctors to ensure that their clinical practice is not in violation of these rights – the same duties that all other doctors in Europe must observe. The Act also thus helps to ensure that what constitutes legal practice in the UK is judged by broader, trans-national moral standards.

**Rational self-interest**

The most rational way for doctors to ensure that their own medical treatment (as well as the treatment of those for whom they have deep personal feelings) meets high standards of care is to support, through the usual professional and legal channels, the right of all patients to the same high standards of care.

**The clinical importance of trust**

Patients will not trust doctors whom they suspect may ignore their human rights. Without trust, patients will not cooperate in their diagnosis and treatment, undermining the prospect for clinical success. Lack of trust also engenders a defensive and impersonal approach to medicine by both clinicians and patients, potentially spoiling the quality of patient care and professional life.

**The doctor–patient relationship**

Doctors are expected to treat patients, and their carers where appropriate, as active partners in the healing process. Patients and doctors should make decisions together about the patients’ care and management.

**Box 1.2 European Convention on Human Rights**

**Substantive rights which apply to evaluating good medical practice**

- Right to life (Article 2)
- Prohibition of torture, inhuman or degrading treatment or punishment (Article 3)
- Prohibition of slavery and forced labour (Article 4)
- Right to liberty and security (Article 5)
- Right to a fair trial (Article 6)
- No punishment without law (Article 7)
- Right to respect for private and family life (Article 8)
- Freedom of thought, conscience and religion (Article 9)
- Freedom of expression (Article 10)
- Right to marry (Article 12)
- Prohibition of discrimination (Article 14)

**THE NATURE OF MEDICAL MISTAKES**

Doctors have a duty to protect the life and health of patients to an acceptable professional standard. What does this mean in practice and what are the penalties for not doing so?
Clinical negligence

If clinicians are suspected not to have provided an acceptable standard of clinical care, they may be sued for negligence – a breach of their professional duty. To win a legal action and financial damages for negligence, patients/claimants must provide convincing evidence to a judge that:

- they were harmed
- the harm was caused by the accused doctor
- the action which caused the harm was a breach of professional duty.

However, in practice, demonstrating that these three things have occurred poses problems. For example, the alleged harm may have occurred against the background of a complex medical condition or course of treatment, making it difficult to establish the actual cause.

When has a breach of professional duty occurred?

In the UK, whether or not a doctor has acted inconsistently with the duty to protect life and health to an acceptable standard is ordinarily decided in civil cases by a judge on the basis of testimony from expert witnesses.

- Such experts are selected to represent a responsible body of professional opinion. The testimony of these experienced clinicians will be used to help the court determine a professional standard which doctors working in their specializations should meet in clinical practice of the kind under dispute. Both the patient/claimant and doctor/defendant will try to produce experts to support their case.
- There will be clinical conduct so unreasonable that its negligence speaks for itself (e.g. a dramatic and harmful mistake about drug dosage).
- If acceptable expert witnesses are found for the doctor/defendant, who will state that under similar circumstances, they would have clinically responded in the same way as the doctor then the patient/claimant will probably lose the case. Provided that the doctor’s testimony is logically consistent and compatible with other widely accepted professional beliefs about good clinical practice, it is likely that the doctor’s actions will be found to be reasonable. This will not necessarily depend on how representative the clinical opinions given in court are of other doctors practising in the same field. Experts can differ about what is and is not clinically acceptable. In the face of such conflict, what a judge deems reasonable will partly depend on how probable the evidence presented against the doctor is judged to be (e.g. about any harm alleged by the patient). Such a civil standard of proof differs from the criminal standard which is more stringent and where juries must be convinced of guilt ‘beyond reasonable doubt’. Equally, the more serious the allegation of clinical negligence, the higher will be the quality of evidence that will be demanded by judges before deciding the outcome of the case.

Inexperience is irrelevant

Lack of experience is not taken into account in legal determinations of negligence or the GMC’s formal hearings. All doctors are expected to work to a professional standard of expertise based on similar clinical work of experienced clinicians. This does not mean that doctors have to be experts in everything. In the face of doubts about their ability or training to provide treatment to a reasonable standard, doctors should seek appropriate supervision and refuse to proceed otherwise.

Mistakes are not necessarily to be feared

Poor professional practice – for example, clinical care which is overly defensive – can result from unfounded fears of patients’ readiness to make formal complaints or take legal action.

- All doctors make clinical mistakes in their professional careers. Yet it should be clear that a clinical error is not necessarily a negligent error. Responsible and experienced clinicians may testify that the erroneous action was and is unavoidable in that type of clinical practice. Under similar circumstances, they too sometimes make – or might make – the same error.
- Just because doctors can make professionally defensible mistakes does not mean that they should in any way relax their professional standards.
- Professional bodies within medicine, and the defence associations which insure doctors against negligence, recommend that doctors should be honest and apologetic about their mistakes, remembering that to do so is not necessarily an admission of negligence. As a result of such honesty and humility, there is mounting evidence that patients will feel that they have been respected and are less likely to take legal action or to make formal complaints.

For all of these reasons, there is less to fear legally from patients than doctors sometimes believe. The law offers wide protection for clinicians provided that they do their best to act reasonably and responsibly in protecting the lives and health of their patients.

RESPECT FOR AUTONOMY

Legally valid consent

Obtaining the consent of patients to treatment is just as fundamentally a part of good medical care, as is proper clinical diagnosis and good therapeutic management. Doctors seeking consent for a particular procedure must be competent in the knowledge of how the procedure is performed and its problems.

For agreement to treatment to be legally acceptable it must meet three conditions:

- Consent must be informed to an adequate standard.
- Patients must be competent to consent to treatment.
- Patients must not be coerced into accepting treatment against their wishes.

Patients need to weigh up the pros and cons of proposed treatments with other objective interests in their personal lives. They cannot do so without the basic ability to reason about information concerning what is wrong with them, what their doctors propose to do about it, and with what potential benefits and risks. If patients are coerced into making choices
about treatment, the ethical and legal right to exercise control over their personal life is ignored. In these circumstances, such choices become more those of clinicians who unduly pressure patients rather than of patients themselves.

**Battery**

It is an unlawful battery to intentionally touch a competent person without their consent.

- For competent adult patients to be touched lawfully, they must be given information in broad terms about the proposed treatment — what it is and why it is being suggested. Thus a clinician will commit a battery if such a patient is given an injection without permission, irrespective of the need for it.
- Treatment can be given legally to adult patients without consent if they are temporarily or permanently incompetent to provide it and they have not previously refused such future treatment in a legally acceptable way or such treatment is not refused on their behalf by a representative with the legal authority to do so. Further, given the condition of such patients, treatment must be necessary to save their life, or to prevent them from incurring serious and permanent injury. Otherwise, consent must be obtained from patients expected to regain competence when they do so, however inconvenient this may be for the patient or clinician.

**Negligence: information about risks**

Clinicians may also be in breach of their professional duty to obtain adequate consent through not providing a reasonable amount of information about the risks of proposed treatment. Here the legal claim of a patient/claimant would be for negligence.

**The reasonable doctor standard of disclosure**

- Success will depend on the court being convinced that the patient/claimant had been harmed by the treatment and would not have agreed to it if they had been given more information about its risks.
- The patient/claimant must also show the amount of information provided about risks was unreasonable. If the clinician/defendant can find expert witnesses deemed to constitute a reasonable body of medical opinion who will say that they too (at that point in time) would have provided no more information about risks, the patient/claimant can face serious difficulties in convincing a judge of the unreasonableness of the amount of information, just as we saw in the case of litigation for clinical negligence.
- This ‘professional standard’ of disclosure of information about risks has been increasingly disputed in the courts.

**The reasonable patient standard of disclosure**

Patients may disagree with clinicians about how much information they require to protect their personal interests. Indeed, in deciding what information to disclose to patients about risks, clinicians may know little about how they perceive their interests. Since it is the health and lives of patients that are potentially at risk, the moral focus of such disclosure should be on what is acceptable to them rather than to the medical profession.

- It is increasingly recognized that clinicians obtaining consent to treatment should ask what sort of information about risks a ‘reasonable person’ in the position of the patient would want before agreeing to treatment. To do otherwise constitutes an unacceptable threat to the moral rights and dignity of patients and entails a potential loss of trust in the medical profession.
- Practically, clinicians should interpret this standard of disclosure of the reasonable person as meaning that they should ask what sort of information someone in the position of the patient needs, in order to make an informed choice. When in doubt, clinicians should also ask what sort of information they would want for themselves, their families and friends. They should also remember that the graver the risk, the more necessary it is to disclose information about it, even when the chance of it occurring is small.

**Consent to treatment**

This may be obtained in the following ways:

- **Express consent** may be verbal or written, usually through the patient signing a consent form. Here consent is given explicitly in relation to specific information about the proposed treatment. Consent to surgical treatment is usually ‘express’ and ‘written’. Consent to lesser forms of physical intervention (e.g. venepuncture) is ordinarily ‘express’ and ‘verbal’. Clinicians should always remember that a signed consent form is not legal or professional proof that proper express consent has been obtained. Informed consent should be viewed as an educational process. Signed consent forms are symbols of the completion rather than the success of this process.
- Consent may also be implied by the fact that the patient accepts treatment without question, protest or any other physical sign that might be associated with rejection. Implied consent is ordinarily given against the background of an express consent to a specific treatment, which has already been obtained. For example, once patients have given their express consent for being connected to a drip, there is no need for them to give further consent whenever its contents are replenished.
- Patients have not given their implied consent to a specific treatment simply because they have presented themselves for care in a hospital. They must be given appropriate information about the proposed care and provide express consent to it.
- Patients and doctors should make decisions in a spirit of partnership.
- Medical students or their supervisors should always obtain the explicit consent of patients to provide case histories or to be examined for purely educational purposes. Students should always make it clear to patients that they are not qualified doctors.

**Confidentiality**

If clinicians violate the privacy of their patients, they risk causing harm rather than protecting patients from it. Through violating the right of patients to control information which
they divulge as part of their medical care, such clinicians disrespect autonomy, undermine trust and call the medical profession into disrepute. These rights are protected by common and statute law. Doctors who breach the confidentiality of patients may face severe professional and legal sanctions.

Respecting confidentiality in practice

Patients should be informed of the ways in which information about them will need to be shared with other clinicians and healthcare workers involved in their treatment. On the basis of this information, unless patients state the contrary, they give their implied consent for this information to be shared. Where patients object to particular information being shared, their wish should be respected unless this interferes with the successful execution of their treatment. Information should be sought from patients as early as possible about whom they would wish to be given information about their condition and treatment. A note should be made of their wishes in the clinical record. Clinicians or healthcare workers not involved in the care of a patient have no right of access to related information without the patient’s consent, simply because such information is considered useful for other purposes. In almost all clinical circumstances, therefore, the confidentiality of patients must be respected.

When confidentiality must or may be breached

The principle of privacy in medicine is not absolute. Sometimes, the law dictates that clinicians must reveal private information about patients to others in contexts that they may or do object to. At other times, they have the discretion to do so, in accordance with good professional practice. Both circumstances highlight the difficult ethical tension, which can be posed between the rights of individual patients and the interests of the public. The right to privacy does not entail the right to harm others in exercising it.

Therefore, clinicians must breach confidentiality when (among others):

- patients have infectious diseases which must be notified, through informing the relevant local authority officer
- they are presented with a court order by a judge or asked to do so by a judge in judicial proceedings
- police request information about patients who have been involved in a traffic accident
- patients are suspected of engaging in terrorist activity in the UK.

Clinicians have the discretion to breach confidentiality when they become aware of, for example:

- past or potential criminal and violent behaviour that has resulted, or is likely to result, in serious harm to the patient or others, such as child abuse – note that in these circumstances, the ordinary expectation would be in favour of discretion
- refusal of patients to comply with their own legal obligations to provide information about their medical condition to the relevant authority (e.g. to the Driver and Vehicle Licensing Agency); again, it would usually be expected for this discretion to be exercised
- infectious patients who pose a threat to specific individuals through undisclosed risks.

In all these circumstances, patients should be informed of any intent to breach their confidentiality, unless doing so may place the clinician or others at risk of serious harm. Clinicians should always remember that they are professionally accountable for discretionary breaches and may be asked to justify in court, or by the GMC in the UK, their decision either to disclose or not to disclose.

Respect for autonomy in the treatment of vulnerable patients

We have seen that for consent to treatment to be valid, patients must be competent to give it. In England, the legal criteria for the determination of competence are stated in the Mental Capacity Act 2005.

What is competence?

Competence should be understood as task-oriented. People may be competent to do some things but incompetent to do others. This means that they should not be judged to be either competent or incompetent in absolute terms. Legally, if patients are competent they must be able to:

- understand information about their condition and treatment
- remember this information
- deliberate about the therapeutic choices posed by the information
- communicate their choices to others.

Competence to consent to treatment may be compromised by many things, e.g. age, mental illness, congenital disease, accident and injury.

Children

In the UK, the legal age of presumed competence to consent to treatment is 16. Below this age, those with parental responsibility are the legal proxies of their children and usually consent to treatment on their behalf. Yet:

- The age of 16 is somewhat arbitrary and many children below this age clearly possess the abilities associated with competence. For example, they may be mature enough to understand and reason about information given to them about their condition and treatment.
- Clinicians should ordinarily respect the dignity of such children through asking them if they agree to the proposed treatment, even when the consent of parents is also obtained.
- If such children wish to have clinical consultations and clinically indicated care without the knowledge of their parents then this – along with their confidentiality – should be respected.
- Young children may be incompetent to make decisions about their medical care, although they may have developed some degree of autonomy in this regard. They should be consulted about their care and due consideration given to their wishes.
- In England, unlike Scotland, young people do not acquire the right to refuse medical treatment thought to be in their best interest until the age of 18. In practice,
the legal ability to force treatment on mature children against their wishes should only be contemplated in circumstances where life is at risk or there is a risk of serious and permanent injury. Doing otherwise is not in the best interests of young people because of the potentially dangerous alienation that it may create toward doctors and medicine.

Those with parental responsibility should always be consulted about their child’s care. However, they have question-able legal authority to direct clinicians to administer or withdraw treatments deemed necessary to protect children from death or serious harm. The court should be consulted about such disagreements, unless an emergency dictates otherwise.

**Psychiatric illness**

The vast majority of patients being treated for psychiatric illness are competent to consent and to refuse treatment. There is no difference between their rights and those of other competent patients. Because of the danger of stigma associated with mental illness, great care should be taken to protect their confidentiality. If patients with severe psychiatric illness are incompetent to understand the nature and consequences of their illness, they will be unable to provide valid consent to treatment. Here, the ethical duty of care shifts from respect for autonomy of such patients to protecting them.

**The Mental Health Act 2007**

Mental illness may so compromise the autonomy of patients that they become a danger to themselves and/or to others. Patients with ‘any disorder or disability of the mind’ may be detained under the Mental Health Act 2007 for further examination and treatment in England and Wales. This aboliishes the ‘treatability’ provision in the previous Act. Because of the terrible risks and ethical significance of denying someone their ordinary civil liberties, the conditions of detain-ment under the Act are highly specific: the longer the period of detention, the more safeguards there are to ensure the clinical need for it (see Table 22.29). Relevant legislation in other legal jurisdictions have similar provisions.

**Psychiatric treatment without consent**

Under certain circumstances, detained patients may be given psychiatric treatment without their consent. However, attempts should be made to obtain consent, if possible. Unless their mental illness has made them incompetent to do so, such patients must still give their consent to proposed treatments for physical disorders. Again, incompetence in one respect does not entail incompetence in all respects. However, if patients are unable competently to consent because of the severity of their psychiatric condition – and treatment is required to save their life or to prevent serious and permanent disability – they can be given necessary care without it. If treatment can wait, without seriously compromising their interests, then patients should be asked to consent to it when they become competent to do so.

**Other forms of incompetence to provide consent to treatment**

Patients may also be incompetent because of congenital, developmental or accidental brain damage. Here, good legal and professional practice is again determined by the Mental Capacity Act 2005, along with its Code of Practice. The Act makes provision for adults to act as the legal representatives for adult patients who are permanently incompetent. Other legal jurisdictions (e.g. Scotland) also endorse forms of re-presentative authority, some stronger than others. In England, if no appropriate representative is nominated by the patient or by the appropriate court, relatives do not have the final say about treatment decisions. In the absence of such delegated authority, not allowing relatives the authority to make such decisions can be morally justified by the fact that some people might not be motivated by protecting the best interests of their family members. Even so, relatives should be asked their views about the wishes or concerns of the patient and consulted about medically relevant information, which might be used to optimize the success of the patient’s care. However, unless this is legally appropriate, they should not be given the impression as a result of such consultation that it is they who are determining treatment decisions. Therefore, often, doctors and no one else will continue to decide what is and is not in the best clinical interests of patients who are permanently incompetent. Without the intervening authority of legally designated representatives and/or legally accept-able advance decisions of refusal, all forms of treatment can be administered to such adults on this basis. Of course, the moral coherence of these arguments depends on the assumption that clinicians are best placed to protect the interest of vulnerable patients and this, in turn, rests on consistent high standards of clinical care and reflection about ethics and law.

---

**ETHICAL AND LEGAL BOUNDARIES OF THE DUTY TO PROTECT LIFE AND HEALTH**

Generally speaking, clinicians are professionally obligated to intervene to save the lives of patients for whom they have clinical responsibility. However, there are a range of circum-stances where the duty of care to provide life-sustaining treatment is superseded by other ethical and legal responsibilities.

**Competent refusal**

The right of competent refusal supersedes the ordinary duty clinicians have to try to save the lives of such patients, along with any preferences others might have that they should be forced to accept treatment (Box 1.3). Patients may refuse life-sustaining treatment explicitly when it is offered or, as already suggested, they may formulate an advance decision refusing treatment. This should stipulate the circumstances under which they refuse it, should they become incompetent to do so in the future. Competent refusals of life-sustaining treatment (e.g. refusal of blood transfusion by Jehovah’s Witnesses) must be made on the basis of clear information about the types of treatment refused. Equally, decisions not to attempt to sustain life medically should also only be made with the consent of competent patients (e.g. a decision not to provide cardiopulmonary resuscitation). Such patients may have arrangements, which they need to make that their...
clinicians will know nothing about and it would be ethically wrong to pre-empt this.

The best interests of the incompetent

There will be some situations where the provision of life-sustaining treatment will not be regarded as being in the best interests of permanently incompetent patients, even though not providing it will lead to their death occurring before it otherwise would. This is when prolongation of patients’ lives will be of no benefit to them, against the background of their dire clinical circumstances. For example, it is acceptable not to use medical means to prolong the lives of such patients when:

- it is believed on good evidence that further treatment will not save life
- patients are already imminently and irreversibly close to death
- patients are so permanently or irreversibly brain damaged that they will always be incapable of any future self-directed activity or intentional social interaction.

One ethical justification for the latter two provisions is that such patients have no further need for medical treatment because they have no further objective interest in continuing to live. Because of their clinical condition, they can no longer do or achieve anything in life. However, because of potential differences in moral and religious belief, decisions not to provide or continue life-sustaining treatment should always be made with as much consensus as possible among the clinical team responsible for the patient’s care and people close to the patient who are consulted about their care. In the absence of an advance decision refusing treatment, efforts should still be made to determine what the patients would have wished under these circumstances. Where there is unsolvable conflict between those involved in decision-making, especially in relation to children and their parents, the relevant court should be consulted. In some circumstances, the court may appoint a deputy to represent the best interest of the patient. Healthcare staff should appoint an independent healthcare advocate in the absence of other forms of appropriate representation. In emergencies, judges are always available in the relevant court. As already mentioned, other legal jurisdictions have similar arrangements. Key legal differences usually focus on the extent of decision-making authority automatically given to relatives of the patient.

Clinicians may decide not to prolong the lives of imminently dying and/or extremely brain-damaged patients for the legally acceptable reason that they are acting in the best interests of their patients to attempt to minimize their suffering rather than intending to kill them. To do the latter would be murder. Clearly, when contemplating not providing or withdrawing life-sustaining treatments, doctors should do their best to act within the law. However, it should also not be forgotten that much debate continues about whether or not there is a much closer ethical link between clinical decisions not to save life and decisions actively to end it. The law concerning such matters may change at some point in the future.

The duty as a doctor to be fair and just

The principle of equality of persons should dominate the way in which the duties of care are discharged in clinical practice. Clinicians may show technical mastery of treatment options and great ability and sensitivity in obtaining informed consent to treatment and maintaining confidentiality. However, if in the process of doing so, they actively discriminate against individual or groups of patients, they are still acting unprofessionally and should be penalized accordingly. For example, discrimination on the basis of race, age, social worth, class, intelligence or occupation should not be tolerated (Box 1.4).

Scarce resources

As a matter of right in the UK, the National Health Service (NHS) provides equal access to appropriate medical care on the basis of need alone. This right is mitigated by scarce resources and the courts have made it clear that they will not force health authorities or trusts to provide treatments which are beyond their means. However, the courts also demand that decisions about such means must be made on reasonable grounds and that patients have a clear right to expect this. Thus on both ethical and legal grounds, prejudice or favouritism is not acceptable in the allocation of scarce resources. If rationing healthcare is inevitable in the NHS, as many believe to be the case, then ways must be found to do so which are fair and just. In practice this means that scarce resources should be allocated to patients on the basis of the similarity and extremity of their need (e.g. kidney transplantation) and the time at which they presented themselves for treatment (e.g. the randomness imposed by the ‘lottery of nature’). To the degree that this procedure of allocation is followed, all

---

**Box 1.3 Competent refusal**

‘Prima facie every adult has the right and capacity to decide whether or not he will accept medical treatment, even if a refusal may risk permanent injury to his health or even lead to premature death. Furthermore, it matters not whether the reasons for the refusal were rational or irrational, unknown or even non-existent. This is so notwithstanding the very strong public interest in preserving the life and health of all citizens.’

Re T (adult: refusal of medical treatment) [1992]

**Box 1.4 The duty as a doctor to be fair and just**

According to the General Medical Council, injustice can occur in medicine through treating patients unequally according to, e.g.:

- Age
- Colour
- Ethnic or national origin
- Gender
- Lifestyle
- Marital or parental status
- Race
- Religion or beliefs
- Sexual orientation
- Social and economic status
patients will be said to have had an equal opportunity to be treated on the basis of equal need. It is respect by clinicians and healthcare teams for these principles of equality – equal need and equal chance – that guarantees fairness and justice in the delivery of healthcare. In the UK, the National Institute for Health and Clinical Excellence (NICE) is a body set up to evaluate treatments on a clinical and cost-effective basis, and to ensure equal access to care across the country. In circumstances of scarcity, waste and inefficiency are clearly matters of great ethical concern.

More specifically, any well-run A&E department within the UK and many other countries will follow precisely these moral principles in the way in which decisions are made about who to treat first and with what. The treatments on offer will be those that have been shown to deliver optimal results for minimal expense. Patients who are in the most need – as determined by the triage nurse – will be seen first. Everyone else will receive treatment in relation to the assessment of the urgency of their need and when they initially register for treatment. In this way a waiting list will be constructed for each clinical session. So long as no one attempts to jump the queue, patients traditionally respect these rules – sometimes to a point of waiting for long periods to be seen without complaint. Waiting lists in other clinical settings should be similarly constructed, although here other variables will come into play (e.g. the accuracy with which general practitioners communicate the urgency of need to hospital consultants). What is unacceptable in any aspect of the allocation of scarce healthcare resources is for prejudice or favouritism – treating equals unequally – to influence their construction.

**Lifestyle**

Patients should not be denied potentially beneficial treatments on the grounds that their lifestyles have been more unhealthy than others with whom they compete for the same treatments. Decisions to do so are almost always prejudicial. For example, why single out smokers or the obese for blame as opposed to those who engage in dangerous sports? Patients are not equal in their abilities to lead healthy lives and to make correct healthcare choices for themselves. Some are better educated and informed, more emotionally confident and more supported by their social environment. To ignore this, to regard all patients as equal competitors and to reward the already better off is unjust and unfair. In this situation it is incorrect to treat unequals equally.

**COMMUNICATION**

**COMMUNICATION IN HEALTHCARE**

The aim of every healthcare professional is to provide care that is evidence based, unconditionally patient centred and shared in a collaborative partnership with the patient. Good communication between a patient and the professional forms the basis of such care. Effective communication has been shown to develop the trust between patient and clinician and produces better outcomes. Fortunately the effective skills in healthcare communication are learnable.

**What is patient-centred communication?**

Patient-centred communication involves reaching a common ground about the illness, its treatment, and the roles that the clinician and the patient will assume (Fig. 1.1). This means discovering and connecting both the biomedical facts in detail and the patient’s ideas and feelings. This information is essential for diagnosis and appropriate management and also to gain the confidence, the trust and the involvement of the patient.

---

**GENERAL READING**

The traditional approach of ‘doctor knows best’ with patients’ views not being considered is now very outdated. This change is not just societal but driven by evidence about improved health outcome and is spreading world-wide.

There are two main reasons for this:

- Patients increasingly expect information about their condition and treatment options and want their views taken into account in deciding treatment. They also like to be equally involved if they wish to reduce risks from their habits and lifestyles. This does not mean clinicians totally abdicate power. Patients want their doctors’ opinions and expertise and may still prefer to leave matters to the clinician.

- Clinicians can usually offer practical help with patients’ feelings, ideas and concerns but, if not, they can always listen supportively. Patients may also hold misconceptions, which can profoundly affect their symptoms and ability to recover; these can be corrected with information. A distinguishing feature of the healthcare professions is that patients expect humanity and empathy from their doctors as well as competence.

Patient-centred communication tries to achieve a good balance between:
Clinicians asking all the questions needed to include or exclude diagnoses
Patients being asked to express their ideas, concerns, expectations and feelings
Clinicians explaining and advising in ways patients can understand and be involved in decisions.

What are the effects of communication

There are enormous benefits to be gained from good communication (Box 1.5). When clinicians communicate effectively with patients they identify patients’ problems more accurately and efficiently. When they do not they can miss problems and concerns. The failures in identifying problems are shown in Box 1.6.

(i) Health outcomes

Several widely different conditions have been found to be improved by good communication (Box 1.7). The converse also applies. For example, the main predictive factor for patients developing full-blown psychiatric disorders on learning of the diagnosis of cancer depends upon the way their bad news is broken. Hospital visits, admissions and length of stay were dramatically reduced where clinicians used a biopsychosocial approach to managing patients with medically unexplained symptoms. The mortality rate was also significantly reduced.

(ii) Adherence to treatment

Some 45% of patients are not following treatment advice. Costs of medicines prescribed and not used runs into millions of pounds wasted in the UK. Patients may not understand or remember what they were told, whilst others actively decide not to follow advice and commonly do not tell their doctors.

Errors in use of medications are also a common problem, which risk patient safety. Research on consultations shows clinicians rarely check patients’ understanding or their views and doubts. Communication is a major contributing factor to adherence (Practical Box 1.1)

(iii) Patient satisfaction

Satisfaction, as reported to the Patients’ Association in the UK, is largely a result of patients knowing they are:

- getting the best appropriate biomedical healthcare
- being treated humanely as individuals and not as items on a conveyor belt.

---

Box 1.5 Benefits of good communication

- Improved health outcomes
- Increased patient adherence to therapies
- Increased patient and clinician satisfaction
- Reduced litigation
- Improved time management and costs
- Patient safety

Box 1.6 Failures in identifying problems

Patients report the following problems in interviews:

- 54% of complaints and 45% of concerns were not elicited
- 50% of psychological problems not elicited
- 80% of breast cancer patients’ concerns remain undisclosed
- In 50% of visits, patients and doctors disagreed on the main presenting problem
- In 50% of cases, patient’s history was blocked by interruption within 24 seconds

---

Fig. 1.1 The patient-centred clinical interview. Adapted from Levenstein JH. In: Stewart M, Roter D (eds) Communicating with Medical Patients. Thousand Oaks, California: Sage Publications, 1989, with permission.
Satisfaction affects psychological well-being and adherence to treatment both of which have a knock on effect on clinical outcomes. It also reduces patient complaints and litigation.

(iv) Clinician satisfaction

Healthcare professionals have a very high rate of occupational stress and burnout, which is costly to both them and health services. Notwithstanding pressure from staffing shortages and inadequate resources, it is the quality of their relationships with their patients and colleagues which are the most reliable global indicator of clinician satisfaction and happiness.

(v) Dissatisfaction between patients and clinicians

Failures in communication of information about illness and treatment are the most frequent source of patient dissatisfaction. Some 70% of lawsuits are a result of poor communication rather than failures of biomedical practice. Patients felt deserted and devalued by their clinician and thought the information to aid their understanding was delivered poorly. Authoritarian and paternalistic styles revealed in questioning style and tone of voice increase the chances of being sued. By contrast, the behaviours of primary care physicians who have never been sued are shown in Practical Box 1.2. Complaints and lawsuits represent only the tip of the iceberg of discontent as revealed by surveys of patients in hospital and general practice.

(vi) Time and costs

Clinicians commonly interrupt patients, after an average 24 seconds, whether or not a patient has finished explaining their problem. Uninterrupted patients will talk for 90 seconds on average (maximum 2.5 minutes). If clinicians wait they avoid the situation of the late-arising problems, which then take longer. Those who integrate patient-centred communication into all interviews actually save time and also reduce non-essential investigations and referrals, which waste resources. Time skimped deprives the patient and actually involves more time later either for themselves or colleagues.

Patients given the latest evidence on treatment options commonly choose more conservative management with no adverse effects on health outcomes. This has potential for considerable savings in health budgets.

Barriers and difficulties in communication

Only recently has healthcare education included training to help clinicians communicate well. Hence many remain

---

**Practical Box 1.1** Communication factors which improve adherence to clinical advice

- Clinician
  - Listens to and understands the patient
  - Tone of voice
  - Elicits all the patient’s health concerns

- Patient
  - Is comfortable asking questions
  - Feels sufficient time is spent with the clinician

**Practical Box 1.2** Behaviours leading to good relationships

- Primary care physicians who have never been sued:
  - Orientated patients, e.g. ‘We are going to do this first and then go on to that’
  - Used facilitative comments, e.g. ‘uh huh, I see’
  - Used active listening
  - Checked understanding
  - Asked patients their opinions
  - Used humour and laughter appropriately
  - Conducted slightly longer visits (18 versus 15 minutes)

**Box 1.8** Strategies that doctors use to distance themselves from patients’ worries

- Selective attention to cues
  - ‘I have this headache and I’m worried . . .’
  - ‘What is the pain like?’

- Normalizing
  - ‘It’s normal to worry. Where is the pain?’

- Premature reassurance
  - ‘Don’t worry. I’m sure you’ll be fine’

- False reassurance
  - ‘Everything is OK’

- Switching topic
  - ‘Forget that. Tell me about . . .’

- Passing the buck
  - ‘Nurse will tell you about that’

- Jollying along
  - ‘Come on now, look on the bright side’

- Physical avoidance
  - Passing the bedside without stopping

**Box 1.9** Common barriers and difficulties in communication

- Clinician factors:
  - Lack of knowledge of: influence and prevalence of psychosocial matters in illness and its recovery skills that can help communication
  - Attitude: authoritarian manner and negative attitude to shared care unwillingness to examine own communication skills
  - Skills: using distancing tactics to avoid difficult topics using jargon lack of empathy

- Patient factors:
  - Anxiety
  - Feeling powerless
  - Reticence to disclose concerns
  - Misconceptions
  - Conflicting information
  - Forgetfulness
  - Hearing/visual and speech impairment

- Shared factors:
  - Different first language
  - Lack of privacy
  - Lack of time
  - Different cultural backgrounds
unaware of the influence of psychosocial issues on illness (25–50% of primary care visits are for medically inexplicable complaints), or their costly impact on healthcare. They will avoid such discussions if they fear it will unleash emotions too difficult to handle, upset the patient or take too much time (Box 1.8).

Patients for their part won’t disclose concerns if they sense clinicians aren’t interested. Anxiety or embarrassment may also cause them to withhold information. Other common barriers are listed in Box 1.9.

Clinicians are human and can be rushed, unhappy, and have ignorant patches. They all work against the clock and in fallible systems. But as professionals it is they, together with healthcare managers, who bear the responsibility for dealing with these difficulties and problems; not the patient.

### 3. Gathering information

The components of a complete history are shown in Table 1.1.

### Listening skills

Attentive listening is a necessary communication skill. Patients will recognize clinicians are listening if they look at them and not the notes or computer. Clinicians should nod occasionally, smile appropriately and avoid interrupting before the patient has finished talking. Ask the patient to tell the story of the problem in their own words from when it first started up to the present.

### Questioning styles

The way a clinician asks questions determines whether the patient speaks freely or just gives one word or brief answers (Practical Box 1.3). Start with open questions (‘What problems have you brought you in today?’) and move to screening, focused and closed questions. Open methods allow clinicians more time to generate their problem-solving approach and provide more information on which to base their theories and hypotheses. Closed questions are necessary to check specific symptoms but if used too early on may narrow down and lead to inaccuracies by missing patients’ problems.

Leading questions which imply the expected answer (‘You’ve given up drinking haven’t you?’) risk inaccurate responses as patients may want to go along with the clinician rather than disagree.

### 4. Understanding the patient

Finding out the patient’s perspective is an essential step towards achieving common ground.

#### Ideas, concerns and expectations (ICE)

Patients seek help because of their own ideas or concerns about their condition. If these aren’t heard they may think the clinician has not got things right and then not follow advice. Moreover any misconceptions will continue to prevail. A patient’s view can emerge if the clinician listens carefully and picks up on cues. But if they do not, it is still a very necessary task to ask specific questions, e.g.:

- ‘What do you think is wrong?’
- ‘Are there any particular concerns you have about …?’
- ‘Was there anything you were hoping we might do about this?’

---

**THE MEDICAL INTERVIEW**

**Structure and skills for effective interviewing**

Clinicians conduct some 200 000 medical interviews during their careers. There is no single prescription for a medical interview, and flexibility is a skill in itself because each patient is different. However a framework helps clinicians use their time and that of patients’ most productively.

The example below is in the context of a first medical interview in a consulting room and will obviously be different in a follow-up interview, or an emergency.

There are seven essential steps in the medical interview:

1. **Building a relationship**

   Because patients are frequently anxious and may feel unwell, building a relationship is the first stage in the interview. Introductions and first impressions are critical to create rapport and trust. Well-organized arrangements for appointments, reception and punctuality put patients at ease. Non-verbal communication is a powerful element, e.g. making eye contact, facial expression and tone of voice should all convey friendliness, interest and respect. Sitting at a slight angle, not behind a desk or computer, helps communication.

   Clinicians’ own non-verbal messages, body language and unspoken attitudes have a huge impact on the emotional tone of the interview.

2. **Opening the discussion**

   The aim is to obtain all the patients’ concerns, remembering that they usually have at least three (range 1–12). Ask ‘What would you like to discuss today?’ or ‘What problems have brought you to see me today?’

   Listen attentively without interrupting. Ask ‘And is there something else?’ to screen for any other problems before exploring the history in detail. Clinicians are failing if a serious point is raised only as the patient has a hand on the doorknob, preparing to leave.

   Only when all concerns are identified can the agenda be prioritized, balancing the patients’ concerns with the clinician’s main points of interest.

---

**FURTHER READING**

Hearing patients’ ideas, acknowledging their concerns and empathizing, are essential steps in engaging a patient’s trust, and beginning to ‘treat the whole patient’. The example in Practical Box 1.3 also shows how information that may be biomedically relevant emerges while listening to patients.

**Non-verbal communication**

In adult conversation some 5% of meaning derives from words, 35% from tone of voice and 65% from body language and non-verbal communication. When there is mismatch between words and tone the non-verbal communication elements hold the truer meaning. Patients who are anxious, uneasy, puzzled or confused are more likely to communicate this through expression and/or restlessness, for example of the feet and hands, than to tell the clinician outright. The observant clinician can pick up on this ‘You seem uneasy about what I have said . . .’ thus inviting the patient to share their concerns.

**Empathizing**

Empathy has been described as ‘imagination for others’. It is different from sympathy (feeling sorry for the patient), which rarely helps. Empathy is a key skill in building the patient–clinician relationship and is highly therapeutic. The starting point is attentive listening and observing patients to try and understand their predicament. This understanding then needs to be conveyed back in a supportive way. For example, by saying: ‘It sounds like . . .’ (patient heard), ‘I can see you are upset’ (patient seen), ‘I realize that this is a shock’ (acknowledgement), ‘I can tell you that most people in your circumstances get angry’ (accepting the patient).

Like other communication skills, empathy can be taught and learnt but it has to be genuine and cannot be counterfeited by a repertoire of routine mannerisms.

Whilst empathy is about trying to understand, the phrase ‘I understand’ may be met with ‘how could you!’ It is more helpful to reflect back using some of the patient’s own words and ideas.

5. **Sharing information**

The key is to tailor the information to both what the patient wants to know and the detail they prefer as this helps them understand.

Patients generally want to know: ‘is this problem serious and how will it affect me; what can be done about it; and what is causing it?’ Research has shown it is difficult for patients to take in explanations about cause if they are still worrying about the first two concerns.

There is a large amount of research to show that:

- Information must be related not only to the biomedical facts, but to patients’ ideas about their condition and tailored to what they want to know.
- Most patients want to be fully informed irrespective of socioeconomic group.
- Most patients of all ages will understand and recall 70–80% of even the most unfamiliar, complex or alarming information if it is provided along the guidelines given below:

Find out what patient already knows or thinks is wrong. Then confirm, correct or add new information.

**Chunk and Check** – give information in assimilable chunks, one thing at a time. Check after each chunk that the patient is understanding.

**Signpost**. ‘I’ll explain first of all . . .’ ‘Can I move on now to explain treatment options . . .’ Explain the cause and effect of the condition in the context of the patient’s symptoms, e.g. ‘The reason you are experiencing . . . is because . . .’

Use simple language; translate any unavoidable medical terms and write them down.

Make your information and instructions direct, detailed and concrete.

Tell patients you will write down the key words in case they worry they will forget. Use simple diagrams, and offer them other aids to memory. Provide information to take away, or a source of it (Practical Box 1.4).

Write out the risks of operations for patients, which tend to be rapidly forgotten after operations, however well understood before.

**Check understanding.** Ask patients what they have understood – explain that this is not to test them but to make sure you have explained it clearly enough. Always remember that information about the patient belongs to the patient, not the clinician and not, without permission, the relatives or anyone else.

---

### 6. Reaching agreement on management

Once the patient has understood the information, the clinician and patient need to agree on the best course as regards possible investigations and treatments.

**Negotiating the next steps – enlisting the patient’s collaboration**

The clinician’s opinion should be given and the patient’s views sought. Check if they want to be involved or leave decisions up to the clinician.

Patients will adhere best to suggestions about investigation and treatment when they are thus enlisted as partners as a result of:

- a frank exchange of information
- a negotiation of options
- involving the patient in decisions.

**Summarizing**

This allows a patient to correct or add information and correct any misunderstandings. It is a feature of shared decision making and good practice.

### 7. Providing closure

**Summary**

A final summary of agreed course of action and next steps indicates the closing stage of the interview. Plans for follow-up and informing other healthcare professionals involved in the patient care are confirmed.

**Closing**

Some clinicians close the interview by asking whether the consultation has been useful before saying goodbye.

---

### Possible aids to giving information

- cultural differences
- patients with impaired faculties for communication.

#### Breaking bad news

Bad news is any information which is likely to alter drastically a patient’s view of the future. The way news is broken has an immediate and long-term effect. When skilfully performed the patient and family are enabled to understand, cope and make the best of even very bad circumstances. These interviews are difficult because biomedical measures may be of little or no help, patients are upset and can react unpredictably, and the clinician may be upset as well – the more so if there is an element of medical mishap. The most difficult things clinicians report are how to be honest with the patient whilst not destroying hope and how to deal with the patient’s emotions.

Withholding information from patients or telling just the family is becoming a thing of the past even in those parts of the world where traditionally disclosure did not occur. Although truth can hurt, deceit hurts more. It erodes trust and deprives patients of information to make choices. Most people now express the wish to be told the truth and the evidence is that patients:

- usually know more than anyone realizes and may imagine things are worse than they are
- appreciate clear information even about the worst news and want the opportunity to talk openly and ask questions rather than join in a charade of deception
- differ in how much they can take in at a time.

#### A framework

Having a plan helps clinicians to present bad news in a factual, unhurried, balanced and empathic fashion that responds to each patient. The S-P-I-K-E-S strategy is:

**S – Setting**

- See the patient as soon as possible once the current information has been gathered.
- Ask not to be disturbed and hand over bleeps to colleagues.
- If possible, the patient should have someone with them.
- Choose a quiet place with everyone seated, introduce everyone.
- Indicate your status and the extent of your responsibility toward the patient and the time available.

**P – Perception**

Before telling, ask what has happened to the patient since the last appointment, what have they been told or construed so far and how have they reacted. This stage helps gauge the patient’s perception, but should not be too drawn out.

**I – Invitation**

- Indicate you have the results and ask if the patient wants you to explain.
- Assess how much the patient would like to know.
- If patients do not want details, offer to answer any questions they may have later or to talk to a relative or friend.

---

**INTERVIEWS IN WHICH DIFFICULTIES IN COMMUNICATION CAN BE EXPECTED**

The skills above form the basis of any patient interview but some interviews are particularly difficult:

- breaking bad news
- complaints and lawsuits
K – Knowledge
If the patient wishes to know:
- Give a warning to help the patient prepare: ‘I’m afraid it looks more serious than we hoped.’ Then give the details.
- At this point WAIT: allow the patient to think, and only continue when the patient gives some lead to follow. This pause may be a long one, commonly a matter of minutes, while thoughts go round in the patient’s head, and is often accompanied by shutdown which makes patients unable to hear anything further until these thoughts settle down.
- Give the information without fudging, in small chunks. Avoid technical terms. Check understanding frequently: ‘Is this making sense so far?’ before moving on. Watch for signs the patient can take no more.
- Emphasize that some things, for example pain and other symptoms, are fixable and others are not. A broad time frame can be given for the fixable aspects of care.
- Be prepared for the question: ‘How long have I got?’ Avoid the trap of providing a figure which is bound to be inaccurate. There are no easy answers and this is where training can help rehearse responses that work for each clinician. Common faults are to be overly optimistic. Stress the importance of ensuring that the quality of life is made as good as possible from day to day.
- Provide some positive information and hope tempered with realism.

E – Empathy
Responding to the patient’s emotions is about the human side of medical care and also helps patients to take in and adjust to difficult information. A range of emotions are experienced in seriously and terminally ill patients (Box 1.10).
- Be prepared for the patient to have disorderly emotional responses of some kind. Acknowledge them early on as being what you expect and understand and wait for them to settle before continuing.
- Crying can be a release for some patients. Allow time if the patient needs it rather than rushing in to stop the crying.
- Learn to judge which patients wish to be touched and which do not. You can always reach out and touch their chair.
- Always watch out for shutdown.
- Keep pausing to allow patients to think and frame their questions.
- Stop the interview if necessary and arrange to resume later.

S – Strategy and summary
Patients who have a clear plan for the next and future steps are less likely to feel anxious and uncertain. The clinician must ensure that:
- the patient has understood what has been discussed because thought processes are disorganized at times of emotion and misconceptions can take root
- the patient writes down crucial information to take away
- the patient knows how to contact the appropriate team member and thus has a safety net in place, the next interview date – preferably soon – has been agreed, for what purpose and with whom
- family members are invited to meet the clinicians as the patient wishes and written material or further sources of information are readily available
- everyone is bid goodbye, starting with the patient.

Follow-up
Bad news is a process and not a one-off. Patients may well not remember everything from the last visit and recapping is necessary. Always start by asking patients what they have understood so far. It is extremely distressing for patients to hear different things from different clinicians. Keep colleagues informed and document accurately what was said.

The move from active treatment to palliative care is a difficult stage in bad news. Patients want to know what happens next. They want to know ‘Will I be in pain?’, ‘Can I stay at home?’ and ‘How long do I have?’ Give clear answers with acknowledgement of any uncertainty. The priorities in patient care now are relief of symptoms, quality of life and enabling the patient to settle family matters or unfinished business.

The clinician’s role is to mediate between the patient, other medical staff and the patient’s relatives whilst continuing to be an empathic and caring doctor.

COMPLAINTS: WHAT TO DO IF THE RELATIONSHIP BREAKS DOWN?

Much of the enormous increase in complaints and medical lawsuits is related to failures in communication.

Clinicians tend not to deal effectively with grumbles and complaints at the appropriate time, which is as soon as they are made. They use avoiding strategies as for other forms of difficulty and tend to become defensive. The consultation that occurs after an adverse experience is crucial in influencing any decision to sue.

A national commission in the UK on patients’ complaints recommended that all healthcare professionals should have training in communication and be aware of their responsibility for dealing promptly and personally with complaints made by patients in their care. They should not automatically dump complaints on managers.

Complaints
The majority of complaints come from the exasperation of patients who:

Box 1.10 Emotional responses to the fact or threat of loss: some or all of these can be expected but in no particular pattern
- Despair
- Denial
- Anger
- Bargaining
- Depression
- Acceptance

have not been able to get clear information
feel that they are owed an apology
are concerned that other patients will go through what they have.

Many complaints are resolved satisfactorily once these points are dealt with, and the sooner the better. An apology, as an expression of regret, as medical defence organizations emphasize, is not an expression of guilt; it is a courtesy. Nor should it be wrapped up so cautiously as to become a worthless token. Clinicians should work in a professional culture, which regards complaints as a valuable source of feedback which deserve to be noted, collected systematically and acted upon if need be.

When clinicians learn of a complaint they should:

- remember the complainant is still a patient
- listen to the complainant and acknowledge distress
- be objective, not resentful or defensive – remember that there is a duty of care to the patient in this as every other way
- allow all the facts to speak through a clear account, verbal or written
- express regret
- explain the reasons and circumstances behind the facts
- explain how things will improve
- leave the medical records strictly unaltered.

Honest disclosure in the case of medical injury increases trust and reduces the likelihood of legal action.

Lawsuits

Lawsuits, the extreme form of complaint, are commonly rooted in poor communication or miscommunication, aggrieved by a sense of grievance. Some 17% of patients affected by medical injury in the UK want financial compensation or disciplinary action. Any clinician faced with a lawsuit must seek specialist advice.

CULTURE AND COMMUNICATION

Whilst doctors strive to treat all patients equally, those from minority cultures get poorer healthcare than others of the same socioeconomic status even when they speak the same language. They experience fewer expressions of empathy, shorter consultations and fewer attempts to include them in shared decision-making. They also tend to say less in consultations.

Clinicians commonly express anxiety and uncertainty about how to respond to cultural diversity, how to use interpreters, and how to avoid causing offence.

Beliefs

We all take our culture for granted but it can profoundly affect notions about symptoms, sickness and appropriate behaviour and treatment.

It influences practices about when to seek medical assistance and what patients and doctors expect of the consultation. In some cultures for example it is very difficult for a woman to see a male doctor. Sometimes family members may think it is their duty to talk for the patient whilst the doctor might expect to talk directly with the patient. Sensitive topics may be difficult to address but failure to do so could jeopardize care. It helps to apologize if offence is inadvertently caused and to explain why such questions are required. Clinicians vary too and those from more traditional cultures may have a more paternalistic style than some patients want.

Language

Patients sometimes bring a family member, friend or even child to interpret. This can be problematic because they may not have sufficient vocabulary, they could be censoring sensitive matters or saying things that suit their agenda. Confidentiality cannot be guaranteed and patients may feel restricted in what they can say. Children should not be used to interpret although often still are.

When communicating through an interpreter/advocate, ask for the correct pronunciation of a patient’s name and if there are any cultural differences in body language. Arrange the seating to see both the patient and advocate but look and speak directly to the patient. Speak in short phrases, avoid jargon and find out the patient’s ideas, concerns and expectations. Watch for non-verbal communication and check the patient’s understanding. Whilst examining the patient, ask the advocate to stand outside the curtain and always thank the advocate at the end of the interview. If professional interpreters are not available use telephone language lines or ask colleagues who speak the patient’s language. Advocates are people from the patient’s culture who can do more than translate. They can explain beliefs and concerns that could be relevant in the patient’s culture and help patients to understand the workings of the healthcare systems.

Clinicians sometimes worry that interpreters are editing when long exchanges are followed by only a short summary back to them. It helps to ask interpreters to translate exactly what has been said, e.g.:

Patient: Long explanation.
Interpreter: She says she is sick.
Doctor: Could you please translate exactly what she said so that I can understand everything.
Interpreter: I have been feeling dizzy, my head hurts all the time and this morning I was sick.

Non-verbal communication

Awareness of cultural taboos, for example handshaking, eye contact, personal space and subjects that would be offensive to talk about, can help in maintaining dignity and respect.

Paraverbal communication also varies across cultures. We infer things from tone of voice, stress on words and phrases, silence, pace, and politeness conventions used. Some cultures are more open, direct and assertive than others. Some languages do not differentiate gender in common nouns and pronouns, so ‘he’ and ‘she’ may be used interchangeably. It is hardly surprising that misunderstandings occur and it can be much harder to create rapport. It is worth remembering that smiling is a universal expression of kindness and warmth.

Patients may be more or less traditional so check out assumptions.

Training materials are available to help health professionals to respond to the needs of ethnically diverse patients (http://info.cancerresearchuk.org/proceed/).
patients with impaired faculties for communication

All healthcare professionals need patience, ingenuity and willingness to learn to be able to communicate effectively with patients who have impaired communication faculties.

Impaired hearing

Patients with severely impaired hearing may be accompanied by a signer in one of the two sign languages but less than 1% of hearing-impaired people sign. Many hard of hearing people lip-read and some commonsense tips not always followed are listed in Practical Box 1.5.

Conversation aids are available which involve a microphone and amplifier. Specially adapted textphones, Minicom, allow people to type messages which the operator relays to the person on the phone. Mobile textphones are also now available.

Impaired vision

Patients with visual impairment can miss non-verbal cues in communication. Whilst it may sound obvious, it helps to make more conscious efforts to use the patient’s name so they know they are being spoken to. Clinicians should avoid sudden touch, explain what they are about to do and say what they are doing as they go along. Large print information sheets should be available for those with limited vision; audiotapes and Braille versions for the blind (www.mib.org.uk).

Patients with limited understanding or speech

Aphasia is a communication disorder (see p. 1099). Even though hearing and thought processes are unaffected, patients find it hard to understand or they know what they want to say but cannot find the words; they are literally ‘lost for words’. This also affects their ability to write, gesture, draw or mime their thoughts.

Patients will have a strength in one area, for example understanding, with a weakness in the other area, i.e. expression, or vice versa.

It helps to find a quiet place without distractions, to make eye contact and get the person’s attention. Speak slowly and clearly, using simple phrases and leave plenty of time between sentences to allow for the extra processing time it takes with aphasia. Make it obvious when changing the subject.

Closed questions requiring yes or no answers are easier. Write down key words or headings that both the patient and clinician can refer to. This helps because the auditory memory needed to ‘hold on to’ the spoken word taxes patients language system. Use pictures and have pen and paper at hand if the patient can use them. Much can be learnt from carers or watching speech and language therapists – http://www.ukconnect.org/index.aspx.

NEW INFLUENCES ON COMMUNICATION

The internet

The internet has revolutionized ready access to information and is a fast growing source of health information and support for patients. A recent UK survey found 30% of 45 year olds and over had searched for health information on the web. Research on its impact on the doctor–patient relationship is emerging.

Some clinicians welcome it whilst others fear longer consultations, demands which can’t be met, commercially biased information and patients knowing more than them.

Public trust in information is essential and far from undermining the doctor–patient relationship it can enhance communication. Quality control organizations exist such as Health on the Net Foundation (www.HON.ch), Royal College of Physicians (http://www.rcplondon.ac.uk/patientcarer.asp) and the National Patient Safety Association (http://www.npsa.nhs.uk/pleaseask/).

The web also has sites where patients share experiences of illness and treatment. These provide support and again enable patients to bring informed questions to the consultation (www.dipex.org.uk, www.patientsvoices.org.uk).

Decision aids

Decision aids written in non-technical language, and which are evidence based, are available to help patients weigh up risks and benefits on healthcare choices. They are reliable and from independent sources. There are currently over 400 listed on the Cochrane register (www.ohri.ca/decisionaid). The numbers are growing and many are available on the internet.

Studies show they do not increase patients’ anxiety and their use results in 21–44% reductions in choice of invasive surgical options over more conservative treatments without adverse effects on health.

Communication and patient safety

Clear handovers and accurate signed and dated, legible records are the responsibility of everyone in the healthcare team. They are vital in providing best care, reducing error and ensuring patient safety.

Clinical records

The content of records is listed in Table 1.2 and essential criteria listed in Table 1.3. In addition to documenting an
Team communication

Effective team communication is essential if patients are to get the best care. This is never more important than when a patient is critically ill and patient safety is vitally dependant on teamwork. Lessons from industries such as aviation and energy have been useful in understanding how to reduce error from communication. Frameworks such as the SBAR (Situation-Background-Assessment-Recommendation) technique provide an easy and focussed way to set expectations for what will be communicated and how between members of the team (www.ihi.org/IHI/Topics/PatientSafety/SafetyGeneral/Tools/).

Training in communication skills

There is now evidence that communication ability is not necessarily innate and that it can be improved and subsequently used in everyday practice. However it cannot be learned from books. As with learning any skill the opportunity to practise and receive constructive feedback on performance is essential together with feedback.

individual patient’s care they are valuable as part of audit aimed at improving standards of healthcare.

Patients are also entitled to see their records in the UK and they provide essential information when a complaint or claim for negligence is made.

Computer records are increasingly replacing written records and research suggests they are more understandable. They include more information and overcome problems of legibility. A recent study found prescription errors are reduced by a striking 66% when electronic systems replace handwritten prescriptions.

E-mails and texts need to be lodged in medical records as part of the record and care needs to be taken with confidentiality.

With adequate data protection the internet holds immense potential for unifying patient record systems and allowing access electronically by members of the healthcare team in primary, secondary and tertiary care sectors.

### Table 1.2 Records should include

| Relevant clinical and psychosocial information – history and examination |
| Relevant findings, both positive and negative |
| Diagnosis including uncertainties |
| Investigations arranged |
| Test results |
| Decisions made |
| Information given to patients |
| Consent |
| Drugs or other treatments prescribed |
| Follow-up and referrals |

### Table 1.3 Criteria for good records

| Clear, accurate, legible and contemporaneous |
| Dated and signed with printed name |
| Written in pen |
| First hand |
| Original – never altered – but an additional note, signed and dated, should be made alongside any mistake |
| Kept secure |

Molecular cell biology and genetic disorders

THE CELL

The cell (Fig. 2.1) is a highly organized structure and consists of various common organelles held by an adaptive internal scaffolding (the cytoskeleton), which radiates from the nuclear membrane to the cell plasma membrane. The number and finer detail of these common organelles varies according to the specialized function a cell might perform. For example, the mitochondria of muscle cells contain many infolded cristae, producing large amounts of ATP (from the electron transport chain that sits on the inner membrane), whereas the mitochondria of liver cells are smaller and rounded as they produce low levels of ATP. However, many products from the inner matrix feed other metabolic pathways. Each cell is a component unit but ‘talks’ to adjacent cells via specific channels and receptors. Within a cell there is a constant flow of traffic between the organelles.

THE CELL MEMBRANE

- The plasma cell membrane is a bilayer of amphiphatic phospholipids that consist of a polar hydrophilic head (e.g. phosphatidyl choline) and an insoluble non-polar lipid hydrophobic tail (commonly two long-chain fatty acids). The phospholipids spontaneously form bilayers (as complete circular structures) that form an effective barrier that is impermeable to most water-soluble molecules. This barrier defines the interior environment of the cell. The exchanges across the plasma membrane

Fig. 2.1 Diagrammatic representation of the cell, showing the major organelles and the sites of receptor activation (see Fig. 2.3), intracellular messengers, protein formation and secretion, endocytosis of large molecules and production of ATP (see also Fig. 2.4). For basolateral channels and pores, see Figure 2.2.
are regulated by various proteins that are embedded in the lipid bilayer (Fig. 2.2). The lipids’ hydrophobic structure means that relatively weak bonds hold the plasma membrane together. However, this strongly opposes the transverse movement of hydrophilic molecules but allows considerable freedom for lateral ‘fluid’ movement by membrane proteins that are embedded in it. The plasma membrane is thus a very dynamic structure. Cell-to-cell communication is the key to many diseases and chemotherapeutic interventions.

- The membrane proteins embedded in the lipid bilayer either traverse the whole membrane or are associated only with the outer or inner leaflet of the bilayer (Fig. 2.2). These proteins are responsible for the cell’s interaction with its external environment. The molecules involved are either channels, receptors or cell adhesion molecules (see below).

### Cell dynamics

Cell components are continually being formed and degraded, and most of the degradation steps involve ATP-dependent multienzyme complexes. Old cellular proteins are mopped up by a small cofactor molecule called ‘ubiquitin’, which interacts with these worn proteins via their exposed hydrophobic residues. Ubiquitin is a small 8.5 kDa regulating protein present universally in all living cells. Cells mark the destruction of a protein by attaching molecules to the protein. This ‘ubiquitination’ signals the protein to move to lysosomes or proteosomes for destruction. A complex containing more than five ubiquitin molecules is rapidly degraded by a large proteolytic multienzyme array termed ‘26S proteosome’. Ubiquitin also plays a role in regulation of the receptor tyrosine kinase in the cell cycle and in repair of DNA damage. The failure to remove worn proteins can result in the development of chronic debilitating disorders. For example, Alzheimer and frontotemporal dementias are associated with the accumulation of ubiquinated proteins (prion-like proteins), which are resistant to ubiquitin-mediated proteolysis. Similar proteolytic-resistant ubiquinated proteins give rise to inclusion bodies found in myositis and myopathies. This resistance can be due to point mutation in the target protein itself (e.g. mutant p53 in cancer; see p. 49) or as a result of an external factor altering the conformation of the normal protein to create a proteolytic-resistant shape, as in the prion protein of variant Creutzfeldt–Jakob disease (vCJD). Other conditions include von Hippel–Lindau syndrome (p. 666) and Liddle’s syndrome (p. 666).

#### Free radicals

A free radical is any atom or molecule which contains one or more unpaired electrons, making it more reactive than the native species. The major free radical species produced in the human body are the hydroxyl radical (OH), the superoxide radical ($\cdot$O$_2^-$) and nitric oxide (NO).

Free radicals have been implicated in a large number of human diseases. The hydroxyl radical is by far the most reactive species but the others can generate more reactive species as breakdown products. When a free radical reacts with a non-radical a chain reaction ensues which results in direct tissue damage by membrane lipid peroxidation. Furthermore hydroxyl radicals can cause genetic mutations by attacking purines and pyrimidines. Superoxide dismutases (SOD) convert superoxide to hydrogen peroxide and are thus part of an inherent protective antioxidant mechanism. Patients with dominant familial forms of amyotrophic lateral sclerosis (motor neurone disease) have mutations in the gene for Cu-Zn SOD-1 catalases. Glutathione peroxidases are enzymes that remove hydrogen peroxide generated by SOD in the cell cytosol and mitochondria.

Free radical scavengers bind reactive oxygen species. Alpha-tocopherol, urate, ascorbate and glutathione remove free radicals by reacting directly and non-catalytically. Severe deficiency of $\alpha$-tocopherol (vitamin E deficiency) causes neurodegeneration. There is evidence that cardiovascular disease and cancer can be prevented by a diet rich in substances that diminish oxidative damage (p. 224). The principal dietary antioxidants are vitamin E, vitamin C, $\beta$-carotene and flavonoids.

#### Heat shock proteins

The heat shock response is a highly conserved and ancient response to tissue stress (chemical and physical) that is mediated by activation of specific genes leading to the production of specific heat shock proteins (HSPs). The diverse functions of HSPs include the transport of proteins in and out of specific cell organelles, acting as molecular chaper-

**Fig. 2.2** Cell membrane showing lipid structures and main types of integral proteins such as receptors, G-proteins, channels, secondary messenger enzyme complexes and cell adhesion molecules.
ones (the catalysis of protein folding and unfolding) and the degradation of proteins (often by ubiquitination pathways). As well as heat, cytotoxic chemicals and free radicals can trigger HSP expression. The unifying feature, which leads to the activation of HSPs, is the accumulation of damaged intracellular protein. Tumours have an abnormal thermotolerance, which is the basis for the observation of the enhanced cytotoxic effect of chemotherapeutic agents in hyperthermic subjects. The HSPs are expressed in a wide range of human cancers and have been implicated in tumour cell proliferation, differentiation, invasion, metastasis, cell death and immune response.

**Phagocytosis, pinocytosis and exocytosis**

- **Phagocytosis.** Specialized cells such as macrophages and neutrophils can engulf about 20% of their surface area in the pursuit of large particles such as bacteria. Lysosomes rapidly fuse with phagosomes, giving equally rapid digestion of the contents, and recycling as much of the internalized membrane as possible. Phagocytosis is only triggered when specific cell surface receptors – such as the macrophage Fc receptor – are occupied by their ligand.

- **Pinocytosis** is a much smaller-scale model of phagocytosis and is continually occurring in all cells. In contrast to phagocytosis, receptors for smaller molecular complexes, such as low-density lipoprotein (LDL) (Fig. 2.3) result in surface clumping and the internal accumulation of a protein called clathrin. Clathrin-coated pits pinch inwards as clathrin-coated vesicles. Clathrin prevents fusion of lysosomes, and thus its removal will result in lysosomal fusion and degradation of the contents.

- **Exocytosis.** Maintenance of a clathrin coat can result in transcellular transit of the contents and their exocytosis at another side of the plasma membrane, i.e. apical to basal surface transcytosis. Similarly, cell organelles bud off vesicles coated in clathrin to prevent lysosomal fusion and degradation. Some of these vesicles rapidly fuse with the plasma membrane and exocytose their contents. Other vesicles do not immediately fuse with the plasma membrane (or indeed any other organelle). The clathrin-coated vesicles have additional lipid bilayer-embedded proteins called v-SNAREs (signal and response elements), which interact with target organelle membrane proteins called t-SNAREs. Vesicle fusion is therefore specific, comprising fusion in the correct place (at a particular organelle or part of the plasma membrane) and at the correct time (e.g. the fusion of neuronal transmitter vesicles and release of the transmitter at the synaptic membrane when stimulated).

Defects in every molecular process associated with phagocytosis can lead to disease. For example, hypercholesterolaemia can arise not only because mutations render the LDL receptor unable to bind LDL but also due to failures of secondary proteins to trigger clathrin coating of the vesicle.

**Membrane transport and ion channels**

The plasma membrane is freely permeable to gases such as O₂, CO₂ and N₂, and to small uncharged molecules such as H₂O (not H⁺ and OH⁻) and urea. Whilst larger hydrophobic

![Fig. 2.3 Intracellular transport.](image-url)
lipid-soluble molecules – like steroids – also pass freely through the membrane, large uncharged molecules (glucose, amino acids and nucleotides) and small charged ions (K⁺, Na⁺, Ca²⁺, Cl⁻, Mg²⁺ and HCO₃⁻) cannot pass unless via a specific transport protein embedded in the plasma membrane. Two structural types of transport molecules/complexes exist (Fig. 19.2):

- **Channel proteins** literally open a channel in the lipid membrane to allow a specific solute to pass through.
- **Carrier proteins** are slower in action, shuttling the solute across and either facilitating diffusion down a gradient across the membrane, or actively pumping solutes against the gradient using ATP as an energy source.

Active carrier pumps and gated ion channels work together in neural transmission (see Fig. 21.1). These carrier proteins pump Na⁺ and K⁺ across the neuronal cell membrane to create a differential gradient, but ion channels open in response to stimuli to cause a rapid depolarization, allowing the ions to flow back. At synaptic junctions these ion channels open in response to chemical signals such as the release of glutamate, epinephrine (adrenaline) or acetylcholine.

ATP-dependent transport molecules (ATPases) belong to a superfamily called the ‘ABC transporter superfamily’. These include the multidrug-resistance protein (MRP), which pumps out hydrophobic drugs and is overexpressed by tumour cells, and the chloride ion pump coded by the cystic fibrosis gene (see Fig. 2.19). All share a common structure of repeating six transmembrane domains interrupted by a cytoplasmic ATPase domain. The cystic fibrosis chloride ion channel is unusual in that it requires the binding and hydrolysis of both ATP and cAMP for activation.

**Receptors**

Membrane surface receptors pass their extracellular signal across the plasma membrane to cytoplasmic secondary signalling molecules. Examples of these receptors include the non-lipid-soluble ligands such as growth hormone (GH), insulin, insulin-like growth factor (IGF) and luteinizing hormone (LH). These membrane-bound receptors can be subclassified according to the mechanism by which they activate signalling molecules:

- ion channel linked (see above)
- G-protein linked
- enzyme linked.

Structurally these plasma membrane receptors can be:

- **serpentine** (seven transmembrane domains, e.g. the LH receptor)
- **transmembrane with large extra- and intracellular domains** (e.g. the epidermal growth factor (EGF) receptor)
- **transmembrane with a large extracellular domain only** (the macrophage scavenging receptors)
- **entirely linked onto the outer membrane** leaflet by a lipid moiety known as a GPI (glycan phosphatidylinositol) anchor (e.g. T cell receptor).

The function of these membrane receptors is to initiate a secondary message that ultimately results in activation of a specific enzyme or a DNA-binding protein. This may involve translocation to the nucleus and initiation of transcription of a specific set of genes.

**G-protein-linked receptors**

The G-protein-linked receptor, once activated by a ligand, binds a trimeric complex (α, β, γ) which is anchored to the inner surface of the plasma membrane. This complex is a GTP-binding protein, or G-protein. The G-protein binds GTP rather than GDP, and then interacts with enzyme complexes anchored into the inner leaflet of the membrane. These complexes in turn activate one or all three of the secondary messengers:

- cyclic AMP (cAMP)
- Ca²⁺ ions
- inositol 1,4,5-trisphosphate/diacylglycerol (IP₃/DAG).

**Enzyme-linked surface receptors**

These receptors usually have a single transmembrane-spanning region, and a cytoplasmic domain that has intrinsic enzyme activity or will bind and activate other membrane-bound or cytoplasmic enzyme complexes. Four classes of enzymes have been designated:

- **Guanylyl cyclase-linked receptors** (e.g. the atrial natriuretic peptide receptor), which produce cyclic GMP. This in turn activates a cGMP-dependent kinase (G-kinase), which binds to and phosphorylates serine and threonine residues of specific secondary messengers.
- **Tyrosine kinase receptors** (e.g. the platelet-derived growth factor (PDGF) receptor), which either specifically phosphorylate kinases on a small set of intracellular signalling proteins, or associate with proteins that have tyrosine kinase activity.
- **Tyrosine phosphatase receptors** (e.g. CD45), which remove phosphates from tyrosine residues of specific intracellular signalling proteins.
- **Serine/threonine kinase receptors** (e.g. the transforming growth factor-beta (TGF-β) receptor), which phosphorylate specific serine and threonine residues of intracellular signalling proteins.

There are many intracellular receptors that bind lipid-soluble ligands such as steroid hormones (e.g. progesterone, cortisol) and T₃ and T₄. These cytoplasmic receptors often change shape in response to binding their ligands, form dimers, enter the nucleus and interact directly with specific DNA sequences (see DNA-binding proteins, p. 30).

**CYTOPLASM**

This is the fluid component inside the cell membrane and contains many specialized organelles (see Fig. 2.1). It contains a scaffolding or cytoskeleton that regulates the passage and direction in which the interior solutes and storage granules flow. The cytoplasm contains:

- **Endoplasmic reticulum (ER).** This consists of interconnecting tubules or flattened sacs (cisternae) of lipid bilayer membrane. It may contain ribosomes on the surface (termed rough endoplasmic reticulum (RER) when present, or smooth endoplasmic reticulum (SER) when absent). The ER is involved in the processing of proteins: the ribosomes translate mRNA into a primary sequence of amino acids of a protein peptide chain (see Fig. 2.4). This chain is synthesized into the ER where it
is first folded and modified into mature peptides. The ER is the major site of drug metabolism.

- **Golgi apparatus.** This consists of flattened cisternae similar to the ER. It is characterized as a stack of cisternae from which vesicles bud off from the thickened ends. The primary processed peptides of the ER are exported to the Golgi apparatus for maturation into functional proteins (e.g. glycosylation of proteins which are to be excreted occurs here) before packaging into secretory granules and cellular vesicles that bud off the ends (see Fig. 2.3).

- **Lysosomes.** These are dense cellular vesicles containing acidic digestive enzymes. They fuse with phagocytotic vesicles from the outer cell membrane, digesting the contents into small biomolecules that can cross the lysosomal lipid bilayer into the cell cytoplasm. Lysosomal enzymes can also be released outside the cell by fusion of the lysosome with the plasma membrane. Lysosomal action is crucial to the function of macrophages and polymorphs in killing and digesting infectious agents, tissue remodelling during development and osteoclast remodelling of bone. Not surprisingly, many metabolic disorders result from impaired lysosomal function (p. 1071).

- **Peroxisomes.** These are dense cellular vesicles so named because they contain enzymes that catalyse the breakdown of hydrogen peroxide. They are involved in the metabolism of bile and fatty acids, and are primarily concerned with detoxification, e.g. o-amino acid oxidase and H2O2 catalase. The inability of the peroxisomes to function correctly can lead to rare metabolic disorders such as Zellweger’s syndrome and rhizomelic dwarfism.

- **Mitochondria.** These organelles are the powerhouse of the cell. Each mitochon- drion comprises two lipid bilayer membranes and a central matrix. It also possesses several copies of its own DNA in a circular genome. The outer membrane contains many gated receptors responsible for the import of raw materials like pyruvate and ADP, and the export of products such as oxaloacetate (precursor of amino acids and sugars) and ATP. An interesting caveat to our symbiotic relationship is that proteins of the Bcl-2/Bax family are incorporated in this outer membrane and can release mitochon- drial enzymes that trigger apoptosis. The inner membrane is often highly infolded to form cristae to increase its effective surface area. It contains transmembrane enzyme complexes of the electron transport chain, which generate an H+ ion gradient. This gradient then drives the adjacent transmembrane ATPase complex to form ATP from ADP and P. The inner matrix contains the enzymes of the Krebs cycle that generate the substrates of both the electron transport chain (FADH2,

---

**Fig. 2.4** Receptor and secondary messengers. (i) **G-protein receptor** binds ligand (e.g. hormone) and activates G-protein complex. The G-protein complex can activate three different secondary messengers: (a) cAMP generation; (b) inositol 1,4,5-trisphosphate (IP3) and release of Ca2+; (c) diacylglycerol (DAG) activation of C-kinase and subsequent protein phosphorylation. (ii) **Dimeric hormone** binds receptor subunits bringing them into close association. Intracellular domains cross-phosphorylate and link to the phosphorylation cascades via molecules such as RAS (superfamily of GTPases). (iii) **Lipid-soluble molecules,** e.g. steroids, pass through the cell membrane and bind to cytoplasmic receptors, which enter the nucleus and bind directly to DNA. ER, endoplasmic reticulum; iKB, inhibitory factor kappa B; NFkB, nuclear factor kappa B.
and NADH) and central metabolism (e.g. succinyl CoA, α-oxoglutarate, oxaloacetate).

**SECONDARY MESSENGERS**

Secondary messengers are molecules that transduce a signal from a bound receptor to its site of action (e.g. the nucleus). There are essentially four mechanisms by which secondary messengers act but they cross talk and are rarely activated independently of each other (Fig. 2.4). These mechanisms are cyclic AMP, IP$_3$/DAG, Ca$^{2+}$ ions and protein phosphorylation.

**Cyclic AMP, IP$_3$/DAG and Ca$^{2+}$ ions**

- The generation of cAMP by G-protein-linked receptors results in an increase in cellular cAMP (Fig. 2.4(iia)), which binds and activates specific cAMP-binding proteins. These dimerize and enter the cell nucleus to interact with set DNA sequences (the cAMP response elements). In addition, cofactors in the cAMP response element binding proteins (CREB) are co-activated and interact with the phosphorylation pathway.

- Other G-protein complexes activate inner membrane-bound phospholipase complexes. These in turn cleave membrane phospholipid-polyphosphoinositide (PIP$_2$) into two components (Fig. 2.4(ib)). The first is the water-soluble molecule inositol trisphosphate, IP$_3$. This floats off into the cytoplasm and interacts with gated ion channels in the endoplasmic reticulum (or sarcoplasmic reticulum in muscle cells), causing a rapid release of Ca$^{2+}$. The lipid-soluble component diacylglycerol (DAG) (Fig. 2.4(ic)) remains at the membrane, but activates a serine/threonine kinase, protein kinase C (see phosphorylation section below).

- The cellular calcium-binding proteins and ion pumps rapidly remove Ca$^{2+}$ from the cytoplasm back into a storage compartment (such as the endoplasmic reticulum). Free Ca$^{2+}$ interacts with target proteins in the cytoplasm, inducing a phosphorylation/dephosphorylation cascade, resulting in activated DNA-binding proteins entering the nucleus.

**Protein phosphorylation**

Although phosphorylation of the cytoplasmic secondary messengers is often a consequence of secondary activation of cAMP, Ca$^{2+}$ and DAG, the principal route for the protein phosphorylation cascades is from the dimerization of surface protein kinase receptors, which have bound their ligands. The tyrosine kinase receptors phosphorylate each other when ligand binding brings the intracellular receptor components into close proximity (see Fig. 2.4(iii)). The inner membrane and cytoplasmic targets of these activated receptor complexes are ras, protein kinase C and ultimately the MAP (mitogen activated protein) kinase, Janus-Stat pathways or phosphorylation of IxB causing it to release its DNA-binding protein, nuclear factor kappa B (NFxB). These intracellular signalling proteins usually contain conserved non-catalytic regions called SH2 and SH3 (SRC homology regions 2 and 3). The SH2 region binds to phosphorylated tyrosine. The SH3 domain has been implicated in the recruitment of intermediates that activate ras proteins. Like G-proteins, ras (and its homologous family members rho and raf) switch between an inactive GDP-binding state and an active GTP-binding state. NFxB undergoes a conformational change, enters the nucleus and initiates transcription of specific genes.

Lipid-soluble ligands (e.g. steroids; Fig. 2.4(iii)) do not need secondary messengers; their cytoplasmic receptors, once activated, enter the nucleus as DNA-binding proteins and alter gene expression directly.

**THE CYTOSKELETON**

This is a complex network of structural proteins which regulates not only the shape of the cell, but also its ability to traffic internal cell organelles and even move in response to external stimuli (see Fig. 2.2). The major components are microtubules, intermediate filaments and microfilaments.

- **Microtubules** (Fig. 2.5). These are made up of two protein subunits, α and β tubulin (50 kDa), and are continuously changing length. They form a ‘highway’, transporting organelles through the cytoplasm. There are two motor microtubule-associated proteins – dynein and kinesin – allowing antegrade and retrograde movement. Dynein is also responsible for the beating of cilia. During interphase the microtubules are rearranged by the microtubule-organizing centre (MTOC), which consists of centrosomes containing tubulin and provides a structure on which the daughter chromosomes can separate. Another protein involved in the binding of organelles to microtubules is the cytoplasmic linker protein (CLIP). Drugs that disrupt the microtubule assembly (e.g. colchicine and vinblastine) affect the positioning and morphology of the organelles. The anticancer drug paclitaxel causes cell death by binding...
to microtubules and stabilizing them so that organelles cannot move, and thus mitotic spindles cannot form.

**Intermediate filaments.** These form a network around the nucleus and extend to the periphery of the cell. They make cell-to-cell contacts with the adjacent cells via desmosomes, and with basement matrix via hemidesmosomes (Fig. 2.6). Their function appears to be in structural integrity; they are prominent in cellular tissues under stress. The intermediate filament fibre proteins are specific to the embryonic lineage of the cell concerned, for example keratin intermediate fibres are only found in epithelial cells whilst vimentin is only found in mesothelial (fibroblastic) cells.

**Microfilaments.** Muscle cells contain a highly ordered structure of actin (a globular protein, 42–44 kDa) and myosin filaments, which form the contractile system.

These filaments are also present throughout the non-muscle cells as truncated myosins (e.g. myosin 1), in the cytosol (forming a contractile actomysin gel), and beneath the plasma membrane. Cell movement is mediated by the anchorage of actin filaments to the plasma membrane at adherent junctions between cells (Fig. 2.6). This allows a non-stressed coordination of contraction between adjacent cells of a tissue. Similarly, vertical contraction of tissues is anchored across the cell membrane to the basement matrix at focal adhesion junctions where actin fibres converge (Fig. 2.6). Actin-binding proteins (e.g. fimbrin) modulate the behaviour of microfilaments, and their effects are often calcium-dependent. The actin-associated proteins can be tissue type specific, for example actin-binding troponin is a complex of three subunits and two of these have

---

**Fig. 2.6 Cell adhesion molecules and cellular junctions.**

(a) **Five main groups of adhesion molecules.** The **cadherins** have a Ca\(^{2+}\)-dependent homodimer homophilic interaction and their intracellular domains link to the cytoskeleton. **Immunoglobulin superfamily** cell adhesion molecules (CAMs) have both homophilic and heterophilic (integrin) interactions. Binding is Ca\(^{2+}\) independent and the intracellular domains are cell signalling. **Integrins** have heterophilic interactions mostly with basement matrix components. They have an \(\alpha-\beta\) chain structure and their intracellular domains are predominantly cell signalling but can directly interact with cytoskeletal complexes. **Selectins** have a weak binding affinity for specific sugar molecules found on mucins. **Mucins** are long tandem-repeat peptides which protrude from the cell membrane and are covered in glycosylation moieties.

(b) **Adjacent cells form focal adhesion junctions.** **Desmosomes** are where the membrane forms a proteinaceous plaque containing molecules like desmoglein, from which cadherins protrude and bind cadherins of the adjacent cell. Intracellularly the plaque binds loops of cytoskeleton intermediate filaments, e.g. keratin in epithelial cells and vimentin in fibroblasts. **Tight junctions** are mediated by integral membrane proteins, claudins and occludins, which associate to form subunits bridging the intercellular gap. **Gap junctions** consist of connexin subunits that form a regulated hollow tube. **Adherent junctions** are similar to desmosomes in that cell-to-cell adhesion is mediated by cadherins but the membrane proteinaceous plaque components are different and bind contractile cytoskeletal fibres like actin at the terminus.

(c) **Basement membrane adhesion.** This is similar to desmosomes and adherent junctions in that membrane plaques link intercellular intermediate filaments (e.g. keratin or vimentin) in **hemidesmosomes** and contractile cytoskeleton actin in **focal adherent junctions** to the basement matrix. However, integrins replace cadherins as the surface adhesion molecules. RGD, Arg-Gly-Asp adhesion sequence.
isomers which are only found in cardiac muscle. Cardiac troponin I and T are released into the blood circulation after the onset of a myocardial infarction (p. 752).

Alterations in the cell’s actin architecture are also controlled by the activation of small ras-like GTP-binding proteins rho and rac. These are involved in rearrangement of the cell during division, and thus dysfunctions of these proteins are associated with malignancy.

**INTERCELLULAR CONNECTIONS**

The cytoskeleton and plasma membrane interconnect, and extracellular domains form junctions between cells to form tissues. There are three types of junction between cells: tight junctions, adherent junctions and gap junctions (Fig. 2.6).

**Tight junctions**

Tight junctions (zonula occludens) hold cells together. They are situated at the ends of margins adjacent to epithelial cells (e.g. intestinal and renal cells) and form a barrier to the movement of ions and solutes across the epithelium, although they can be variably ‘leaky’ to certain solutes. The proteins responsible for the intercellular tight junction closure are called claudins. They show selective expression within tissue and regulate what small ions may pass through the gaps between cells. For example, the kidney displays a differential expression of these claudin proteins. Mutations of claudin-16 (which is expressed in the thick ascending limb in the loop of Henle in the kidney, where magnesium is reabsorbed) are responsible for some abnormalities of magnesium reabsorption of Gitelman’s syndrome (p. 665). Since magnesium reabsorption is paracellular, tight junctions (which contain claudin-16) prevent these divalent ions rapidly diffusing back between the cells into renal tubules.

**Adherent junctions**

Adherent junctions (zonula adherens) are continuous on the basal side of cells. They contain cadherins and are the major site of attachment of intracellular microfilaments. Intermediate filaments attach to desmosomes, which are apposed areas of thickened membranes of two adjacent cells. Hemidesmosomes attach cells to the basal lamina and are also connected to intermediate filaments. Transmembrane integrins link the extracellular matrix to microfilaments at focal areas where cells also attach to their basal laminae. In blistering dermatological disorders autoantibodies cause damage by attacking tight junction desmosomal proteins such as desmoglein-3 in *pemphigus vulgaris* and desmoglein-1 in *pemphigus foliaceus* (p. 1255).

**Gap junctions**

Gap junctions allow substances to pass directly between cells without entering the extracellular fluids. Protein channels (connexins) are lined up between two adjacent cells and allow the passage of solutes up to molecular weight 1000 kDa (e.g. amino acids and sugars), as well as ions, chemical messengers and other factors. The diameter of these channels is regulated by intracellular Ca²⁺, pH and voltage. Connexins are made up of six subunits surrounding a channel and their isoforms in tissues are encoded by different genes. Mutant connexins can cause disorders, such as the X-linked form of Charcot-Marie-Tooth disease (p. 1175).

**CELL ADHESION MOLECULES**

Adhesion molecules and adhesion receptors are essential for tissue structural organization. Differential expression of such molecules is implicit in the processes of cell growth and differentiation, such as wound repair and embryogenesis. There are four major families of cell adhesion molecules.

**Cadherins**

The cadherins establish molecular links between adjacent cells. They form zipper-like structures at ‘adherens junctions’, areas of the plasma membrane where cells make contact with other cells. Through these junctions, bundles of actin filaments run from cell to cell. Related molecules such as desmogleins form the main constituents of desmosomes, the intercellular contacts found abundantly between epithelial cells. Desmosomes serve as anchoring sites for intermediate filaments of the cytoskeleton. When dissociated embryonic cells are grown in a dish, they tend to cluster according to their tissue of origin. The homophilic (like with like) interaction of cadherins is the basis of this separation, and has a key role in segregating embryonic tissues. The expression of specific adhesion molecules in the embryo is crucial for the migration of cells and the differentiation of tissues. For example, when neural crest cells stop producing N-CAM (see below) and N-cadherin and start to display integrin receptors they can separate, and begin to migrate on the extracellular matrix. Changes in cadherin expression are often associated with tumour metastatic potential.

**Integrins**

These are membrane glycoproteins with α and β subunits which exist in active and inactive forms. The integrins principally bind to extracellular matrix components such as fibrinogen, elastase and laminin. The amino acid sequence arginine–glycine–aspartic acid (RGD) is a potent recognition sequence for integrin binding, and integrins replace cadherins in the focal membrane anchorage of hemidesmosomes and focal adhesion junctions (Fig. 2.6). A feature of integrins is that the active form can come about as a result of a cytoplasmic signal that causes a conformational change in the extracellular domain, increasing affinity for its ligand. This ‘inside-out’ signalling occurs when leucocytes are stimulated by bacterial peptides, rapidly increasing leucocyte integrin affinity for immunoglobulin superfamilies such as the Fc portion of immunoglobulin. The ‘outside-in’ signalling follows the binding of the ligand to the integrin and stimulates secondary signals resulting in diverse events such as endocytosis, proliferation and apoptosis. Defective integrins are associated with many immunological and clotting disorders such as *Bernard–Soulier syndrome* and *Glanzmann’s thrombasthenia* (p. 437).

**Immunoglobulin superfamily cell adhesion molecules (CAMs)**

These molecules contain domain sequences which are immunoglobulin-like structures. The neural cell adhesion molecule (N-CAM) is found predominantly in the nervous system. It mediates a homophilic (like with like) adhesion. When bound to an identical molecule on another cell, N-CAM can also associate laterally with a fibroblast growth factor receptor and stimulate the tyrosine kinase activity of that receptor to induce the growth of neurites. Thus adhesion molecules can trigger cellular responses by indirect activa-
tion of other types of receptors. The placenta and gastrointestinal tract also express immunoglobulin superfamily members, but their function is not completely understood.

**Selectins**

Unlike most adhesion molecules (which bind to other proteins), the selectins interact with carbohydrate ligands or mucin complexes on leucocytes and endothelial cells (vascular and haematological systems). Selectins were named after the tissues in which they were first identified. *L-selectin* (CD62L) is found on leucocytes and mediates the homing of lymphocytes to lymph nodes. *E-selectin* (CD62E) appears on endothelial cells after they have been activated by inflammatory cytokines; the small basal amount of E-selectin in many vascular beds appears to be necessary for the migration of leucocytes. *P-selectin* (CD26H) is stored in the alpha granules of platelets and the Weibel–Palade bodies of endothelial cells, but it moves rapidly to the plasma membrane upon stimulation of these cells. All three selectins play a part in leucocyte rolling (p. 68).

---

**THE NUCLEUS AND ITS RESPONSES**

A nucleus is present in all eukaryotic cells that divide. It contains the human genome and is bound by two bilayer lipid membranes. The outer of the two is continuous with the endoplasmic reticulum. Nuclear pores are present in the membranes, allowing the passage of nucleotides and DNA interacting proteins in, and mRNA out (see Fig. 2.4). The genome consists of DNA and all the apparatus for replication and transcription into RNA (see p. 29). There are two types of cell division – meiosis and mitosis. In *meiosis*, which occurs only in germ cells, the chromosome complement is halved (haploid) and, at fertilization, the union of two cells restores the full complement of 46 chromosomes. *Mitosis* occurs in dividing cells after fertilization, and results in two identical daughter cells. It is only during cell division that chromosomes (see p. 36) become visible.

A nucleolus is a dense area within the nucleus. It is rich in proteins and RNA and is chiefly concerned with the synthesis of ribosomal RNA (rRNA) and ribosomes.

**The cell cycle** (Fig. 2.7)

Cells in the quiescent G0 phase (G, gap) of the cycle are stimulated by the receptor-mediated actions of growth factors (e.g. EGF, epithelial growth factor; PDGF, platelet-derived growth factor; IGF, insulin-like growth factor) via intracellular second messengers. Stimuli are transmitted to the nucleus (see below) where they activate transcription factors and lead to the initiation of DNA synthesis, followed by mitosis and cell division. Cell cycling is modified by the cyclin family of proteins (see below). Thus from G0 the cell moves on to G1 (gap 1) when the chromosomes are prepared for replication. This is followed by the synthetic (S) phase, when the 46 chromosomes are duplicated into chromatids, followed by another gap phase (G2), which eventually leads to mitosis (M).

**Cyclin and cyclin-dependent kinases**

As the cell progresses through the cell cycle a series of small serine/threonine kinases are produced. Indeed it is the coordinated cyclic expression of these cyclin-dependent kinases that drives the cell replication cycle. The progression of the cell cycle is catalysed by cyclin-dependent kinases (Cdks) which are activated by a class of proteins called cyclins (Cyc). After stimulation from a pro-mitotic extracellular signal (e.g. a growth factor), *G1* cyclin–Cdk complexes (CycB/Cdk4/6; CycE/Cdk2) become active to prepare the cell for *S phase*, promoting the expression of transcription factors that in turn promote the expression of S cyclins (CycB/Cdk2) and of enzymes required for DNA replication. The G1 cyclin–Cdk complexes also promote the degradation of molecules that function as S phase inhibitors by targeting them for ubiquitination. Active S cyclin–Cdk complexes phosphorylate proteins that make up the pre-replication complexes assembled during *G1 phase* on DNA replication origins. The phosphorylation serves two purposes: to activate each already assembled pre-replication complex, and to prevent new complexes from forming. This ensures that every portion of the cell’s genome will be replicated once only. Mitotic cyclin–Cdk complexes (e.g. CycB/Cdk2), which are synthesized but inactivated during *G2 phase*, promote the initiation of mitosis by stimulating downstream proteins involved in chromosome condensation and mitotic spindle assembly.

**Apoptosis (programmed cell death)**

*Apoptosis* or physiological cell death occurs through the deliberate activation of constituent genes whose function is to cause their own demise.

*Necrotic cell death*, in contrast, is where some external factor (e.g. hypoxia, chemical toxins) damages the cell’s physiology and results in the disintegration of the cell. Char-
Fig. 2.8 Extrinsic and intrinsic apoptotic signalling network. The Fas protein and Fas ligand (FasL) are two proteins that interact to activate an apoptotic pathway. Fas and FasL are both members of the TNF (tumour necrosis factor) family – Fas is part of the transmembrane receptor family and FasL is part of the membrane-associated cytokine family. When the homotrimer of FasL binds to Fas, it causes Fas to trimerize and brings together the death domains (DD) on the cytoplasmic tails of the protein. The adaptor protein, FADD (Fas-associating protein with death domain), binds to these activated death domains and they bind to pro-caspase 8 through a set of death effector domains (DED).

When pro-caspase 8s are brought together, they transactivate and cleave themselves to release caspase 8, a protease that cleaves protein chains after aspartic acid residues. Caspase 8 then cleaves and activates other caspases which eventually leads to activation of caspase 3.

Caspase 3 cleaves ICAD, the inhibitor of CAD (caspase activated DNase), which frees CAD to enter the nucleus and cleave DNA. Although caspase 3 is the pivotal execution caspase for apoptosis, the processes can be initiated by intrinsic signalling which always involves mitochondrial release of cytochrome C and activation of caspase 9.

The release of cytochrome C and mitochondrial inhibitor of IAPs is mediated via Bcl-2 family proteins (including Bax, Bak) forming pores in the mitochondrial membrane. Interestingly, the extrinsic apoptotic signal is aided and amplified by activation of tBid which recruits Bcl-2 family members and hence also activates the intrinsic pathway.

Apa1, apoptotic protease activating factor 1; Bid, family member of Bcl-2 protein; IAPs, inhibitor of apoptosis proteins.

Characteristically there is an influx of water and ions, after which cellular organelles swell and rupture. Cell lysis induces acute inflammatory responses in vivo owing to the release of lysosomal enzymes into the extracellular environment.

Apoptotic cell death has characteristic morphological features:

- chromatin aggregation, with nuclear and cytoplasmic condensation into distinct membrane-bound vesicles which are termed apoptotic bodies
- organelles remain intact
- cell ‘blebs’ (which are intact membrane vesicles)
- no inflammatory response
- cellular ‘blebs’ and remains are phagocytosed by adjacent cells and macrophages.

This process requires energy (ATP), and several Ca$^{2+}$- and Mg$^{2+}$-dependent nuclease systems are activated which specifically cleave nuclear DNA at the inter-histone residues.

An endonuclease destroys DNA following apoptosis. This involves the enzyme caspase (cysteine-containing aspartate-specific protease) which activates the CAD (caspase-activated DNase)/ICAD (inhibitor of CAD) system which can destroy DNA. Regulated apoptosis is essential for many life processes, from tissue structure formation in embryogenesis and wound healing to normal metabolic processes such as autodestruction of the thickened endometrium to cause menstruation in a non-conception cycle. In oncology, chemotherapy and radiotherapy regimens only work if they can trigger the tumour cells’ own apoptotic pathways. Failure to do so in resistant tumours can result in the accumulation of further genetic damage to the surviving cells.

Several factors initiate apoptosis but in general there are two signalling pathways: the extrinsic apoptotic pathway triggered by death receptors on the cell surface and the intrinsic pathway initiated at the mitochondrial level. Death receptors are all members of the TNF receptor superfamily and include CD95 (APO-1/Fas), TRAIL (TNF-related apoptosis ligand)-R1, TRAIL-R2, TNF-R1, DR3 and DR6.

The extrinsic pathway is involved in processes such as tissue remodelling and induction of immune self-tolerance. Activated receptors with internal death domain complexes multiply pro-caspase 8 molecules whose autocatalytic activity results in release of the initiator caspase 8 (Fig. 2.8). In turn caspase 8 cleaves pro-caspase 3 and caspase 3, in combination with the other effector caspases, activating DNA cleavage, cell condensation and fragmentation.

The intrinsic pathway centres on the release of cytochrome C from the mitochondria. Cellular stress, such as growth factor withdrawal and p53 cell cycle arrest induces the expression of the pro-apoptotic Bcl-2 family of proteins, Bax and Bak. These form tetrameric complexes, which imbide into the outer mitochondrial membrane forming permissive pores. Cytochrome C, released from the mitochondria, binds Apa1, forming a complex known as the apoptosome, which then activates an initiator caspase, in this case caspase 9. Caspase 9 then activates the effector caspase, caspase 3. Other proteins released from damaged mitochondria, Smac/DIABLO and Omi/HtrA2, counteract the effect of IAPs (inhibitor of apoptosis proteins), which normally bind and prevent activation of pro-caspase 3. Anti-apoptotic Bcl-2 protein, when incorporated as a member of the Bak/Bax pore complex, renders the mitochondrial pore non-permissive to release of cytochrome C and the anti-IAPs.

There is an amplification link between the extrinsic and intrinsic apoptotic pathways in that caspase 8 cleaves a Bcl-2 family member, tBid, which then aids formation of the Bcl-2/Bax/Bak pore complexes. If this complex is predominantly formed from pro-apoptotic members of the Bcl-2 family of...
proteins then apotopsome/caspase 9, along with mitochondrial anti-IAPs, amplifies the apoptotic activation of effector caspases 3 (Fig. 2.8). Conversely, overexpression of anti-apoptotic Bcl-2 will not only inhibit intrinsic, but also dampen down extrinsic apoptotic signalling.

Stem cells
The majority of our cells are terminally differentiated in that although they contain the blueprint to produce all the proteins ever expressed by the body, each tissue has permanently deactivated all but those required for the function of the specialized cells. Such differentiated cells can not replicate indefinitely and eventually shut down. Therefore we must have nests of cells within all our different tissues that have not shut down their genetic blueprint. These stem cells give rise to not only a daughter cell that is differentiated and of a limited ability to replicate but a daughter cell which will not differentiate and has the infinite ability to replicate. In mammals there are three broad source categories of stem cells:

- embryonic stem cells, derived from blastocysts
- adult stem cells, found in adult tissues
- cord blood stem cells, found in the umbilical cord.

The source of stem cells can also be subcategorized by ‘potency’. This specifies the differentiation potential (the potential to differentiate into different cell types) of the stem cell.

- Totipotent stem cells are produced from the fusion of an egg and sperm cell. Cells produced by the first few divisions of the fertilized egg are also totipotent. These cells can differentiate into embryonic and extraembryonic cell types.
- Pluripotent stem cells are the descendants of totipotent cells and can differentiate into cells derived from any of the three germ layers.
- Multipotent stem cells can produce only cells of a closely related family of cells (e.g. haematopoietic stem cells differentiate into red blood cells, white blood cells, platelets, etc.).
- Unipotent cells can produce only one cell type, but have the property of self-renewal which distinguishes them from non-stem cells.

In 2003 the Human Genome Project was completed. All $3.2 \times 10^9$ base pairs of DNA were sequenced. Over 99% of the DNA sequence is identical between individuals, but still millions of different base pair variations (polymorphisms) occur.

DNA STRUCTURE AND FUNCTION

Genetic information is stored in the form of double-stranded deoxyribonucleic acid (DNA). Each strand of DNA is made up of a deoxyribose–phosphate backbone and a series of purine (adenine (A) and guanine (G)) and pyrimidine (thymine (T) and cytosine (C)) bases of the nucleic acid. For practical purposes the length of DNA is generally measured in numbers of base-pairs (bp).

The monomeric unit in DNA (and in RNA) is the nucleotide, which is a base joined to a sugar–phosphate unit (Fig. 2.9a). The two strands of DNA are held together by hydrogen bonds between the bases. There are only four possible pairs of nucleotides – TA, AT, GC and CG (Fig. 2.9b). The two strands twist to form a double helix with major and minor grooves, and the large stretches of helical DNA are coiled around histone proteins to form nucleosomes and further condensed into the chromosomes that are seen at metaphase (Fig. 2.9c,d).

GENES

A gene is a portion of DNA that contains the codes for a polypeptide sequence. Three adjacent nucleotides (a codon) code for a particular amino acid, such as AGA for arginine, and TTC for phenylalanine. There are only 20 common amino acids, but 64 possible codon combinations that make up the genetic code. This means that most amino acids are encoded for by more than one triplet; other codons are used as signals for ‘initiating’ or ‘terminating’ polypeptide-chain synthesis.

**Fig. 2.9** DNA and its structural relationship to human chromosomes.

(a) A polynucleotide strand with the position of the nucleic bases indicated. Individual nucleotides form a polymer linked via the deoxyribose sugars. The 5’ carbon of the heterocyclic sugar structure links to the 3’ carbon of the next via a phosphate molecule forming the sugar–phosphate backbone of the nucleic acid. The 5’–3’ linkage gives an orientation to a sequence of DNA.

(b) Double-stranded DNA. The two strands of DNA are held together by hydrogen bonds between the bases. As T always pairs with A, and G with C, there are only four possible pairs of nucleotides – TA, AT, GC and CG. The orientation of the complementary single strands of DNA (ssDNA) is always opposite; i.e. one will be 5’–3’ whilst the partner will be 3’–5’. The helical 3D structure will have major and minor grooves and a complete turn of the helix will contain 12 base-pairs. These grooves are structurally important, as DNA-binding proteins predominantly interact with the major grooves.

(c) Supercoiling of DNA. In humans, and other higher organisms, the large stretches of helical DNA are coiled to form nucleosomes and further condensed into the chromosomes that can be seen at metaphase. DNA is first packaged by winding around nuclear proteins – histones – every 180 bp. This can then be coiled and supercoiled to compact nucleosomes and eventually visible chromosomes.

(d) At the end of the metaphase DNA replication will result in a twin chromosome joined at the centromere. This picture shows the chromosome, its relationship to supercoiling, and the positions of structural regions: centromeres, telomeres and sites where the double chromosome can split.

**Nomenclature of chromosomes.** This is the assigned number or X or Y, plus short arm (p) or long arm (q). The region or subregion is defined by the transverse light and dark bands observed when staining with Giemsa (hence G-band) or quinacrine and numbered from the centromere outwards. **Chromosome constitution** = chromosome number + sex chromosomes + abnormality; e.g. 46XX = normal female 47XX+21 = Down’s syndrome (trisomy 21) 46XY (2:19) (p21:p12) = male with a normal number of chromosomes but a translocation between chromosome 2 and 19 with breakages at short-arm bands 21 and 12 of the respective chromosomes.

RNA polymerase and so indicate where transcription is to commence.

Two **AT-rich promoter sites** are present in eukaryotic genes. The first, the **TATA box**, is located about 25 bp upstream of (or before) the transcription start site, while the second, the **CAAT box**, is 75 bp upstream of the start site.

The initial or primary mRNA is a complete copy of one strand of DNA and therefore contains both introns and exons. While still in the nucleus, the mRNA undergoes post-transcriptional modification whereby the 5’ and 3’ ends are protected by the addition of an inverted guanidine nucleotide (CAP) and a chain of adenine nucleotides (Poly A) (see Fig. 2.10). In higher organisms, the primary transcript mRNA is further processed inside the nucleus whereby the introns are spliced out. Splicing is achieved by small nuclear RNA in association with specific proteins. Furthermore, alternative splicing is possible whereby an entire exon can be omitted. Thus more than one protein can be coded from the same gene. The processed mRNA then migrates out of the nucleus into the cytoplasm. Polysomes (groups of ribosomes) become attached to the mRNA; the ribosomes consist of subunits composed of small RNA molecules (rRNA) and proteins. The rRNA components are key to the binding and translation of the genetic code. Held by the ribosomes, triplets of adjacent bases on the mRNA called codons are exposed and recognized by complementary sequences, or anti-codons, in transfer RNA (tRNA) molecules. Each tRNA molecule carries an amino acid that is specific to the anti-codon. As the ribosome passes along the mRNA in the 5’–3’ direction, amino acids are transferred from tRNA molecules and sequentially linked by the ribosome in the order dictated by the order of codons. The ribosome, in effect, moves along the mRNA like a ‘zipper’, linking the assembled amino acids to form a polypeptide chain. The first 20 or more nucleotides are recognition and regulatory sequences and are untranslated but necessary for translation and possibly earlier transcription.

Translation begins when the triplet AUG (methionine) is encountered. All proteins start with methionine but this is often lost as the leading sequence of amino acids of the native peptides is removed during protein folding and post-translational modification into a mature protein. Similarly the Poly A tail is not translated (3’ untranslated region) and is preceded by a stop codon, UAA, UAG or UGA.

**THE CONTROL OF GENE EXPRESSION**

Gene expression can be controlled at many points in the steps between the translation of DNA to proteins. Proteins
Transcriptional control

Gene transcription (DNA to mRNA) is not a spontaneous event and is possible only as a result of the interaction of a number of DNA-binding proteins with genomic DNA. Regulation of a gene’s expression must first start with the opening up of the double helix of DNA in the correct region of the chromosome. In order to do this, a class of protein molecules that recognize the outside of the DNA helix has evolved. These DNA-binding proteins preferentially interact with the major groove of the DNA double helix (see Fig. 2.9). The base-pair composition of the DNA sequence can change the geometry of a DNA helix to facilitate the fit of a DNA-binding protein with its target region: CG-rich areas form the Z-structure DNA helix; sequences such as AAAAAANN cause a slight bend, and if this is repeated every 10 nucleotides it produces pronounced curves. DNA-binding proteins that recognize these distorted helices result either in the opening up of the helix so that the gene may be transcribed, or in the prevention of the helix being opened.

Structural classes of DNA-binding proteins

There are four basic classes of DNA-binding protein, classified according to their structural motifs (see Fig. 2.11 and Table 2.1).

Control regions and proteins

DNA-binding proteins act as regulators of gene expression in three different ways. They are the promoters, the operators and the enhancers. The primary gene expression regulators are the promoters. The RNA polymerases bind to a promoter region, normally adjacent to the transcribed sequence of DNA. In eukaryotes active transcription is possible only when a number of DNA-binding and associated proteins come together and interact. Known as ‘general transcription factors’, these proteins are thought to assemble at promoter sites used by RNA polymerases (e.g. Pol II) that are characterized by specific motifs such as the TATA sequence.

Other DNA regulator proteins operate in close proximity to the site of promoter binding. These are called operator proteins/regions and act either as repressors by binding to DNA sequences within the promoter site or as positive regulators facilitating RNA polymerase binding. The third class of regulator proteins operate as enhancer sequences which are at least 200 bp away from the site of transcription initiation. Binding of regulator proteins to enhancer regions, several hundred bases from the promoter site, upregulates the expression. This turns out to be a distance favourable for DNA to loop back on itself without straining the backbone bonds of the DNA double helix.

The GAL4 enhancer of yeast physically aids the binding of transcription factors to the TATA region of the promoter, and thus acts like a catalyst for general transcription factor assembly, and consequently also the rate of RNA polymerase activity. In mammals, it is frequently a region termed the ‘cyclic AMP response element’ (CRE) that acts in this manner. Increasing intracellular cAMP levels cause activation and release of CRE-binding protein (CREB). This binds to the CRE sequence and enhances the transcription rate.

These relatively remote regulatory regions need not just enhance gene expression but may also repress transcription.
The four classes of DNA-binding proteins.

(a) Helix-turn-helix (HTH) motifs. The simplest and most common, it consists of a helix connected by a fixed angle to a second helix. (i) This represents the ‘core’ motif of HTH DNA-binding proteins but considerable modifications occur. (ii) Like all DNA-binding proteins they interact as dimers, binding at exactly one turn of the double helix (3.4 nm or 12 bp) apart. The homeodomain HLH DNA-binding proteins are a special class of HTH proteins. Discovered in the 1980s during investigation of the gene controlling Drosophila development, they contain an almost identical stretch of 60 amino acids. They have a third helix which holds the DNA-binding region in a fixed orientation. Indeed, all homeodomain proteins appear to have specific conserved amino acid positions and residues which interact with DNA. (iii) Furthermore, random orientation extension chains at the N-terminal can interact with the minor groove.

(b) Zinc finger motifs, characterized by the incorporation of zinc, in some form, into the protein’s quaternary structure. (i) The term originated from the structural model of a Xenopus laevis protein which uses a zinc ion to hold a loop in a ‘finger’-shape by cross-linking two histidine residues with two cysteine residues. The Cys–Cys–His–His family of zinc finger DNA regulator proteins typically consists of an anti-parallel sheet forming a tight tertiary association with its own helix by zinc interaction with Cys and His residues within each of the two secondary structures. (ii) Several clusters of zinc fingers are found together and form a repeating structure which can interact with repetitive sequences in DNA.

(c) Leucine zipper motif. (i) This consists of a long α-helix which has many hydrophobic leucine residues at one end, responsible for dimer formation, whilst the opposite hydrophilic ends interact with DNA across the major groove of the double helix. (ii) The quaternary structure of the leucine zippers need not be homodimeric, and indeed heterodimers are extremely common. Thus multiple sequences may be recognized by two or three DNA leucine zipper proteins depending on the type of dimer formed.

(d) Helix-loop-helix (HLH) motifs. (i) These consist of a DNA-binding α-helix joined to a protein dimerization secondary α-helix via a loop. (ii) These combine leucine zipper properties with those of helix motif DNA-binding proteins. A helix interacting with DNA is linked via a loop to a large second helix which non-covalently binds to a similar HLH protein. Homo- and heterodimers can form, but the loop gives flexibility in the orientation of the given DNA-binding α-helix domain.
Indeed, loops can be formed from regulatory regions down-stream as well as upstream of the gene’s coding sequence. Repressors can inhibit the transcription of a given gene by binding to the regulatory sequence and blocking positive regulators, binding and thus inactivating the positive regulator, or by interfering with the promoter protein assembly. Multiple regulatory regions and DNA-binding proteins can surround a given gene and precisely control its expression at a basal level and in response to a cellular stimulus (Table 2.1).

### CHROMOSOMES, INTRONS AND THE SIZE OF THE HUMAN GENOME

Human genetics differs from that of bacteria in structural components of the genetic code and in the way DNA is packaged. The fact that humans have chromosomes and introns affects how much DNA we require to code for all our proteins in an unusual way. We have far more DNA (3.2 × 10⁸ bp) than protein-coding genes (32,000), whereas simple bacteria appear to have a much more economical DNA to gene ratio. Simple organisms like bacteria that have circular genomes that are not contained within a membrane-bound organelle (the nucleus) are termed ‘prokaryotes’. Higher eukaryotic organisms have their linear genomic packages – chromosomes – separated from the general cytoplasm by the nuclear envelope. In eukaryotes, genomic DNA is associated with nuclear proteins called histones.

Coiling around histones and structural regions such as the centromeres and telomeres requires regions of DNA devoted specifically to the purpose of packaging (see Fig. 2.9c). Ten per cent of human DNA is highly repetitive (or ‘satellite’ DNA), consisting of long arrays of tandem repeats. These regions tend to be supercoiled around histones in condensed regions termed heterochromatin, even when the cell is not undergoing division. In contrast, most other DNA regions are relatively uncondensed and constitute the euchromatin. This remaining DNA is either moderately repetitive, accounting for about 30% of the genome, or codes for unique genes and gene families, occupying some 2% of the genome.

Although supercoiling of DNA around histones, intronic spacing (all giving tighter control of specific gene expression) and packaging into functional chromosomes accounts for some 40% of our total DNA, at least 60% is random and has no apparent function. However, life outside of the sea is exposed to increased DNA damage by radiation and chemicals. This additional genomic mass of terrestrial animals, compared to deep-sea creatures, may be there to absorb the increased risk of DNA damage.

### FURTHER READING

### TOOLS FOR MOLECULAR BIOLOGY

#### Preparation of genomic DNA

The first step in studying the DNA of an individual involves preparation of genomic DNA. This is a simple procedure in which any cellular tissue including blood (the nucleated cells are isolated from the erythrocytes) can be used. The cells are lysed in order to open their cell and nuclear membranes, releasing chromosomal DNA. Following digestion of all cellular protein by the addition of proteolytic enzymes, the genomic DNA is isolated by chemical extraction with phenol. DNA is stable and can be stored for years.

#### Restriction enzymes and gel electrophoresis

Restriction enzymes recognize specific DNA sequences and cut double-stranded DNA at these sites. For example, the enzyme EcoRI will cut DNA wherever it reads the sequence GAATTC, and so human genomic DNA is cut into hundreds of thousands of fragments. Whenever the genomic DNA from an individual is cut with EcoRI, the same ‘restriction fragments’ (restriction fragment length polymorphisms, RFLPs) are produced. As DNA is a negatively charged molecule, genomic DNA fragments digested with a restriction enzyme can be separated according to their size and charge, by electrophoresing the DNA through a gel matrix. The DNA sample is loaded at one end of the gel, a voltage is applied across the gel, and the DNA migrates towards the positive anode. The small fragments move more quickly than the large fragments, and so the DNA fragments separate out. Fragment size can be determined by running fragments of known size on the same gel.

Pulsed-field gel electrophoresis (PFGE) can be used to separate very long pieces of DNA (hundreds of kilobases) which have been cut by restriction enzymes that cut at rare sites in the genome.

#### Hybridization techniques

A fundamental property of DNA is that when two strands are separated, for example by heating, they will always reassoci-
ate and stick together again because of their complementary base sequences. Therefore the presence or position of a particular gene can be identified using a gene ‘probe’ consisting of DNA or RNA with a base sequence that is complementary to that of the sequence of interest. A DNA probe is thus a piece of single-stranded DNA that can be labelled with a radioactive isotope (usually $^{32}$P) or a fluorescent signal. The probe will locate and bind to its complementary sequence.

Hybridization is exploited in a number of techniques including:

- **Southern blotting** (DNA fragments separated by gel electrophoresis and transferred onto a membrane sheet)
- **Northern blotting** (RNA separated by gel electrophoresis and transferred onto a membrane sheet)
- **in situ hybridization** (localization of native nucleic acid sequences within the cell and its component organelles, including chromosomes).

The polymerase chain reaction (PCR)

Minute amounts of DNA can be amplified over a million times within a few hours using this in vitro technique (Fig. 2.12). The exact DNA sequence to be amplified needs to be known because the DNA is amplified between two short (generally 17–25 bp) single-stranded DNA fragments (‘oligonucleotide primers’) which are complementary to the sequences at each end of the DNA of interest.

The technique has three steps.

- The double-stranded genomic DNA is denatured by heat into single-stranded DNA.
- The reaction is then cooled to favour DNA annealing, and the primers bind to their target DNA.
- The DNA is extended using a polymerase.

Finally, a DNA polymerase is used to extend the primers in opposite directions using the target DNA as a template.

After one cycle there are two copies of double-stranded DNA, after two cycles there are four copies, and this number rises exponentially with the number of cycles. Typically a polymerase chain reaction is set for 25–30 cycles, allowing millions of amplifications, i.e. $2^n$ where $n$ = number of cycles.

This technique has revolutionized genetic research because minute amounts of DNA not previously amenable to analysis can be amplified, such as from buccal cell scrapings, blood spots, or single embryonic cells.

Real-time PCR

Real-time polymerase chain reaction, also called quantitative real-time polymerase chain reaction (QRT-PCR), is the simultaneous quantification and amplification of a given DNA sequence. It can be used to determine whether or not a specific sequence is present in the sample (e.g. a viral genome) and if it is present, the number of copies in the sample. Frequently, real-time polymerase chain reaction is combined with reverse transcription polymerase chain reaction to quantify low abundance messenger RNA (mRNA), enabling a researcher to quantify relative gene expression at a particular time in a particular cell/tissue.

The procedure follows the general pattern of the polymerase chain reaction, but the DNA is quantified after each round of amplification; this is the ‘real-time’ aspect of it. Two common methods of quantification are the use of fluorescent dyes that intercalate with double-stranded DNA, and modified DNA oligonucleotide probes that fluoresce when hybridized with a complementary DNA.

Expression microarrays/gene chips

This is a methodology developed to examine the relative abundance of mRNA for thousands of genes present in cells/tissue of different types or conditions, for example, to examine the changes in gene expression from normal colonic tissue to that of malignant colonic polyps. The basic technology is the ability to immobilize sequences of DNA complementary to specific genes or different regions of known genes, onto a solid surface in precise microdot arrays (Fig. 2.13). Total mRNA is extracted from one tissue and labelled with fluorescent tag Cy3-green, and the mRNA from the second tissue with fluorescent tag Cy5-red. The two fluorescent-tagged total mRNA samples are mixed in a 1:1 ratio and washed over the DNA gene chips. The mRNA for specific genes will bind to their complementary microdot and can be detected by laser-induced excitation of the fluorescent tag and the position and light wavelength and intensity recorded by a scanning confocal microscope. The relative intensity of Cy5-red:Cy3-green is a reliable measure of the relative abundance of specific mRNAs in each sample. Yellow results from equal binding of both fluorescent-tagged mRNAs. If no hybridization occurs on a dot then the area is black. The power of the system is that many thousands of genes can be screened not only for their expression but relative expression in normal and diseased tissue. Microarray analysis is now widely used for gene expression profiling and mutation detection; it is rapid and many samples can be analysed.
The DNA fragment of interest is inserted into the vector DNA sequence using an enzyme called a ligase. This takes place in vitro. The next step, cloning, creates many copies of the ‘recombinant DNA molecule’ and takes place in vivo when the plasmid or other vector is placed back into the bacterial (or yeast) host. Bacteria that have successfully taken up the recombinant plasmid can be selected if the plasmid also carries an antibiotic resistance gene (so bacteria without the plasmid die in the presence of antibiotic).

The DNA fragment of interest to be cloned may be a restriction fragment. Alternatively it could be cDNA which has been copied from an mRNA sequence. mRNA provides the template from which a viral enzyme called reverse transcriptase (RT) can synthesize a complementary single-stranded DNA copy (cDNA). A DNA polymerase may then be used to produce a double-stranded copy by PCR. A cDNA molecule contains all the sequences necessary for a functional gene, but unlike genomic DNA it lacks introns.

**DNA cloning**

A particular DNA fragment of interest can be isolated and inserted into the genome of simple self-replicating organisms or organelles such as viruses and plasmids. When used for this purpose they are referred to as vectors. Replication by the million of the vector results in multiple copies or clones of the inserted sequence. Thus, after removal from the host vector, cloned gene sequences can be prepared in large quantities independently of other sequences. Vectors include: bacteriophage viruses; plasmids, which are self-replicating episomal circular DNA molecules found in bacteria that carry antibody resistance genes; and ‘yeast artificial chromosomes’ (YACs), which are derived from centromeric and telomeric DNA sequences found in yeast. Each vector takes an optimum size of cloned DNA insert. Typically, viruses can accommodate only small sequences up to a maximum of a kilobase, larger fragments of 2–10 kilobases can be inserted into a plasmid, and sequences of several hundred kilobases can be inserted into a YAC. Each has its relative merits, viruses being very efficient, but the vectors which take large clones being considerably less so. A hybrid between a plasmid and a bacteriophage (called a cosmid) has been constructed artificially. This has the ability to clone reasonably large sequences as plasmids within host bacteria. However, cosmids trick infections into packaging them into a viral body, and this viral body is then able to infect the target bacteria, giving efficient transfection rates.

**DNA sequencing**

A chemical process known as dideoxy-sequencing allows the identification of the exact nucleotide sequence of a piece of DNA. As in PCR, an oligonucleotide primer is annealed adjacent to the region of interest. This primer acts as the starting point for a DNA polymerase to build a new DNA chain that is complementary to the sequence under investigation. Chain extension can be prematurely interrupted when a dideoxynucleotide becomes incorporated (because they lack the necessary 3’-hydroxyl group). As dideoxynucleotides are present at a low concentration, not all the chains in a reaction tube will incorporate a dideoxynucleotide in the same place; so the tubes contain sequences of different lengths but which all terminate with a particular dideoxynucleotide. Each base dideoxynucleotide (G, C, T, A) has a different fluorochrome attached, and thus each termination base can be identified by its fluorescent colour. As each strand can be separated efficiently by capillary electrophoresis according to its size/length, simply monitoring the fluorescence as the reaction products elute from the capillary will give the gene sequence (see Fig. 2.14).

**Genetic polymorphisms**

Techniques have been developed to identify and quantitate genetic polymorphisms such as single nucleotide morphisms (SNPs). SNPs (pronounced ‘snips’) consist usually of two nucleotides at a particular site and vary between populations...
Molecular cell biology and genetic disorders

and ethnic groups. They must occur in at least 1% of the population to be a SNP. SNPs can be in coding or non-coding regions of the genes or be between genes and thus may not change the amino acid sequence of the protein. SNP databases can be developed by microarray techniques. Thus polymorphisms can be mapped by using SNPs or different patterns of DNA fragments with a restriction enzyme technique. An inherited disease can be attributed to a specific gene by comparing a ‘map’ of an affected with an unaffected person and identifying ‘locus’ where the abnormal gene is placed.

**Linkage disequilibrium.** SNPs that are closer together (50 kb or less) are more likely to have alleles that move together in a block than those further apart. This phenomenon is called ‘linkage disequilibrium’ and enables us to use one SNP variant in this block to act as a marker for the presence of other SNP variants.

The ‘lod score’. The likelihood of recombination between the marker under study and the disease allele must be taken into account. This measure of likelihood is known as the ‘lod score’ (the logarithm of the odds) and is a measure of the statistical significance of the observed co-segregation of the marker and the disease gene, compared with what would be expected by chance alone. Positive lod scores make linkage more likely; negative lod scores make it less likely. By convention a lod score of +3 is taken to be definite evidence of linkage because this indicates 1000 to 1 odds that the co-segregation of the DNA marker and the disease did not occur by chance alone.

Linkage analysis has provided many breakthroughs in mapping the positions of genes that cause genetic diseases, such as the gene for cystic fibrosis which was found to be tightly linked to a marker on chromosome 7, or the gene for Friedreich’s ataxia which is tightly linked to a marker on chromosome 9.

**International Hapmap Project.** A haplotype map (‘hapmap’) is being developed by collaborating international scientists. SNPs close together are inherited in blocks (haplotypes). Each haplotype has a few SNPs that can be identified (tag SNPs), which reduces the number of SNPs in the genome that have to be identified and typed and correlated with a phenotype. A comprehensive hapmap will enable studies on the role of genetic factors in different diseases and is being used to decide which therapy is likely to have a beneficial effect (p. 467).

The **Wellcome Trust Case Control Consortium** was set up to analyse thousands of DNA samples from patients with different diseases in which there is thought to be a genetic component. Genetic markers have been found in many diseases including diabetes, hypertension and Crohn’s disease. Many polymorphic markers are also being studied in breast cancer, multiple sclerosis and autoimmune thyroid disease.

**In silico cloning.** Information arising from the human genome and similar animal programmes is now being used for bioinformatic (semi-automated) identification of genes. In silico cloning is largely based on the abundance of databases of expressed sequence tags (ESTs). ESTs represent portions of expressed genes and are produced by one-shot sequencing of cDNA clones taken from a cDNA library. These are rapidly generated and result in sequences whose length is limited by the prevailing technology – usually only 500–800 nucleotides in length. The significance is that these ESTs represent markers of active genes present in the specific tissue from which the cDNA library was generated. Bioinformatics allows the searching and matching of ESTs to complementary sequences (spliced or not) in the huge databases of the genome project. The position of the gene can be defined and other ESTs in libraries throughout the world can be matched to the same location, mapping out the expressed gene. The genomic limits of the expressed gene, predicting its protein product, shape and function and tissue specific expression can all be achieved by searching and manipulating computer-based databases.

**THE BIOLOGY OF CHROMOSOMES**

**HUMAN CHROMOSOMES**

The nucleus of each diploid cell contains $6 \times 10^9$ bp of DNA in long molecules called chromosomes. Chromosomes are massive structures containing one linear molecule of DNA that is wound around histone proteins into small units called nucleosomes, and these are further wound to make up the structure of the chromosome itself. Diploid human cells have 46 chromosomes, 23 inherited from each parent; thus there are 23 ‘homologous’ pairs of chromosomes (22 pairs of ‘autosomes’ and two ‘sex chromosomes’). The sex chromosomes, called X and Y, are not homologous but are different in size and shape. Males have an X and a Y chromosome; females have two X chromosomes. (Primary male sexual characteristics are determined by the SRG gene – sex determining region, Y chromosome.)

The chromosomes can be classified according to their size and shape, the largest being chromosome 1. The constriction in the chromosome is the centromere, which can be in the middle of the chromosome (metacentric) or at one extreme end (acrocentric). The centromere divides the chromosome into a short arm and a long arm, referred to as the p arm and the q arm respectively (see Fig. 2.9d). In addition, chromosomes can be stained when they are in the metaphase stage of the cell cycle and are very condensed. The stain gives a different pattern of light and dark bands that is diagnostic for each chromosome. Each band is given a number, and gene mapping techniques allow genes to be positioned within a band within an arm of a chromosome. For example, the CFTR gene (in which a defect gives rise to cystic fibrosis) maps to 7q21; that is, on chromosome 7 in the long arm in band 21.

During cell division (mitosis), each chromosome divides into two so that each daughter nucleus has the same number of chromosomes as its parent cell. During gametogenesis, however, the number of chromosomes is halved by meiosis, so that after conception the number of chromosomes remains the same and is not doubled. In the female, each ovum contains one or other X chromosome but, in the male, the sperm bears either an X or a Y chromosome.

Chromosomes can only be seen easily in actively dividing cells. Typically, lymphocytes from the peripheral blood are stimulated to divide and are processed to allow the chromosomes to be examined. Cells from other tissues can also be used – for example amniotic fluid, placental cells from chorionic villus sampling, bone marrow and skin (see Box 2.1).
Box 2.1 Indications for chromosomal analysis

Chromosome studies may be indicated in the following circumstances.

**Antenatal**
- Pregnancies in women over 35 years
- Positive maternal serum screening test for aneuploid pregnancy
- Ultrasound features consistent with aneuploid fetus
- Severe fetal growth retardation
- Sexing of fetus in X-linked disorders

**In the neonate**
- Congenital malformations
- Suspicion of trisomy or monosomy
- Ambiguous genitalia

**In the adolescent**
- Primary amenorrhoea or failure of pubertal development
- Growth retardation

**In the adult**
- Screening parents of a child with a chromosomal abnormality for further genetic counselling
- Infertility or recurrent miscarriages
- Learning difficulties
- Certain malignant disorders (e.g. leukaemias and Wilms’ tumour)

**THE X CHROMOSOME AND INACTIVATION**

Although female chromosomes are XX, females do not have two doses of X-linked genes (compared with just one dose for a male XY) because of the phenomenon of X inactivation or Lyonization (after its discoverer, Dr Mary Lyon). In this process, one of the two X chromosomes in the cells of females becomes transcriptionally inactive, so the cell has only one dose of the X-linked genes. Inactivation is random and can affect either X chromosome.

**TELOMERES AND IMMORTALITY**

The ends of chromosomes, telomeres (see Fig. 2.9d), do not contain genes but many repeats of a hexameric sequence TTAGGG. Replication of linear chromosomes starts at coding sites (origins of replication) within the main body of chromosomes and not at the two extreme ends. The extreme ends are therefore susceptible to single-stranded DNA degradation back to double-stranded DNA. Thus cellular ageing can be measured as a genetic consequence of multiple rounds of replication with consequential telomere shortening. This leads to chromosome instability and cell death.

Stem cells have longer telomeres than their terminally differentiated daughters. However, germ cells replicate without shortening of their telomeres. This is because they express an enzyme called telomerase, which protects against telomere shortening by acting as a template primer at the extreme ends of the chromosomes. Most somatic cells (unlike germ and embryonic cells) switch off the activity of telomerase after birth and die as a result of apoptosis. Many cancer cells, however, reactivate telomerase, contributing to their immortality. Conversely, cells from patients with progeria (premature ageing syndrome) have extremely short telomeres. Transient expression of telomerase in various stem and daughter cells is part of their normal biology. The inability to activate telomerase (in addition to overexpression) in cells such as those of the immune system can produce disease pathologies.

**THE MITOCHONDRIAL CHROMOSOME**

In addition to the 23 pairs of chromosomes in the nucleus of every diploid cell, the mitochondria in the cytoplasm of the cell also have their own genome. The mitochondrial chromosome is a circular DNA (mtDNA) molecule of approximately 16,500 bp, and every base-pair makes up part of the coding sequence. These genes principally encode proteins or RNA molecules involved in mitochondrial function. These proteins are components of the mitochondrial respiratory chain involved in oxidative phosphorylation (OXPHOS) producing ATP. They also have a critical role in apoptotic cell death. Every cell contains several hundred mitochondria, and therefore several hundred mitochondrial chromosomes. Virtually all mitochondria are inherited from the mother as the sperm head contains no (or very few) mitochondria. Disorders are shown in Figure 2.15.

**Fig. 2.15 Mitochondrial chromosome abnormalities.** Disorders that are frequently or prominently associated with mutations in a particular gene are shown in bold. Diseases due to mutations that impair mitochondrial protein synthesis are shown in blue. Diseases due to mutations in protein-coding genes are shown in red.

ECM, encephalomyopathy; FBSN familial bilateral striatal necrosis; LHON, Leber’s hereditary optic neuropathy; LS, Leigh’s syndrome; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes; MERRF, myoclonic epilepsy with ragged-red fibres; MILS, maternally inherited Leigh’s syndrome; NARP, neuropathy, ataxia and retinitis pigmentosa; PEO progressive external ophthalmoplegia; PPK, palmoplantar keratoderma; SIDS, sudden infant death syndrome.
GENETIC DISORDERS

The spectrum of inherited or congenital genetic disorders can be classified as the chromosomal disorders, including mitochondrial chromosome disorders, the Mendelian and sex-linked single-gene disorders, a variety of non-Mendelian disorders, and the multifactorial and polygenic disorders (Table 2.2 and Box 2.2). All are a result of a mutation in the genetic code. This may be a change of a single base-pair of a gene, resulting in functional change in the product protein (e.g. thalassaemia) or gross rearrangement of the gene within a genome (e.g. chronic myeloid leukaemia). These mutations can be congenital (inherited at birth) or somatic (arising during a person’s life). The latter are responsible for the collective disease known as cancer, and the principles underlying Mendelian inheritance act in a similar manner to produce dominant and recessive traits. Both gross chromosomal and point mutations occur in somatic genetic disease.

CHROMOSOMAL DISORDERS

Chromosomal abnormalities are much more common than is generally appreciated. Over half of spontaneous abortions have chromosomal abnormalities, compared with only 4–6 abnormalities per 1000 live births. Specific chromosomal abnormalities can lead to well-recognized and severe clinical syndromes, although autosomal aneuploidy (a differing from the normal diploid number) is usually more severe than the sex-chromosome aneuploidies. Abnormalities may occur in either the number or the structure of the chromosomes.

Abnormal chromosome numbers

If a chromosome or chromatids fail to separate (‘non-disjunction’ either in meiosis or mitosis, one daughter cell will receive two copies of that chromosome and one daughter cell will receive no copies of the chromosome. If this non-disjunction occurs during meiosis it can lead to an ovum or sperm having either (i) an extra chromosome, so resulting in a fetus that is ‘trisomic’ and has three instead of two copies of the chromosome; or (ii) no chromosome, so the fetus is ‘monosomic’ and has one instead of two copies of the chromosome. Non-disjunction can occur with autosomes or sex chromosomes. However, only individuals with trisomy 13, 18 and 21 survive to birth, and most children with trisomy 13 and trisomy 18 die in early childhood. Trisomy 21 (Down’s syndrome) is observed with a frequency of 1 in 650 live births regardless of geography or ethnic background. This should be reduced with widespread screening (p. 45). Full autosomal monosomies are extremely rare and very deleterious. Sex-

Although individual genetic diseases are rare, regional variation is enormous – the incidence of Down’s syndrome varies from 1/1000 to 1/100 world-wide. Single gene diseases collectively comprise over 15000 recognized genetic disorders. The global prevalence of all single gene disorders at birth is approximately 10/1000.
chromosome trisomies (e.g. Klinefelter’s syndrome, XXX) are relatively common. The sex-chromosome monosomy in which the individual has an X chromosome only and no second X or Y chromosome is known as Turner’s syndrome and is estimated to occur in 1 in 2500 live-born girls.

Occasionally, non-disjunction can occur during mitosis shortly after two gametes have fused. It will then result in the formation of two cell lines, each with a different chromosome complement. This occurs more often with the sex chromosome, and results in a ‘mosaic’ individual.

Very rarely the entire chromosome set will be present in more than two copies, so the individual may be triploid rather than diploid and have a chromosome number of 69. Triploidy and tetraploidy (four sets) result in spontaneous abortion.

### Abnormal chromosome structures

As well as abnormal numbers of chromosomes, chromosomes can have abnormal structures, and the disruption to the DNA and gene sequences may give rise to a genetic disease.

- **Deletions.** Deletions of a portion of a chromosome may give rise to a disease syndrome if two copies of the genes in the deleted region are necessary, and the individual will not be normal with just the one copy remaining on the non-deleted homologous chromosome. Many deletion syndromes have been well described. For example, Prader–Willi syndrome (p. 228) is the result of cytogenetic events resulting in deletion of part of the long arm of chromosome 15, Wilms’ tumour is characterized by deletion of part of the short arm of chromosome 11, and microdeletions in the long arm of chromosome 22 give rise to the DiGeorge syndrome.

- **Duplication.** Duplications occur when a portion of the chromosome is present on the chromosome in two copies, so the genes in that chromosome portion are present in an extra dose. A form of neuropathy, Charcot–Marie–Tooth disease (p. 1175), is due to a small duplication of a region of chromosome 17.

- **Inversion.** Inversions involve an end-to-end reversal of a segment within a chromosome; e.g. abcdefgh becomes abcdedfg, for example, haemophilia (p. 438).

- **Translocations.** Translocations occur when two chromosome regions join together, when they would not normally. Chromosome translocations in somatic cells may be associated with tumorigenesis (see p. 451).

Translocations can be very complex, involving more than two chromosomes, but most are simple and fall into one of two categories:

- **Reciprocal translocations** occur when any two non-homologous chromosomes break simultaneously and rejoin, swapping ends. In this case the cell still has 46 chromosomes but two of them are rearranged.

  Someone with a balanced translocation is likely to be normal (unless a translocation breakpoint interrupts a gene); but at meiosis, when the chromosomes separate into different daughter cells, the translocated chromosomes will enter the gametes and any resulting fetus may inherit one abnormal chromosome and have an unbalanced translocation, with physical manifestations.

- **Robertsonian translocations** occur when two acrocentric chromosomes join and the short arm is lost, leaving only 45 chromosomes. This translocation is balanced as no genetic material is lost and the individual is healthy. However, any offspring have a risk of inheriting an unbalanced arrangement. This risk depends on which acrocentric chromosome is involved. Clinically relevant is the 14/21 Robertsonian translocation. A woman with this karyotype has a 1 in 8 risk of having a baby with Down’s syndrome (a male carrier has a 1 in 50 risk).

  However, they have a 50% risk of producing a carrier like themselves, hence the necessity for genetic family studies. Relatives should be alerted to the increased risk of Down’s syndrome in their offspring, and should have their chromosomes checked.

Table 2.3 shows some of the syndromes resulting from chromosomal abnormalities.

### Mitochondrial chromosome disorders (see Fig. 2.15)

The mitochondrial chromosome (p. 37) carries its genetic information in a very compact form; for example there are no introns in the genes. Therefore any mutation has a high chance of having an effect. However, as every cell contains hundreds of mitochondria, a single altered mitochondrial genome will not be noticed. As mitochondria divide there is a statistical likelihood that there will be more mutated mitochondria, and at some point this will give rise to a mitochondrial disease.

Most mitochondrial diseases are myopathies and neuropathies with a maternal pattern of inheritance. Other abnormalities include retinal degeneration, diabetes mellitus and hearing loss. Many syndromes have been described.

- **Myopathies** include chronic progressive external ophthalmoplegia (CPEO); encephalomyopathies include myoclonic epilepsy with ragged red fibres (MERRF) and mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes (MELAS) (see p. 1182).

- **Keams–Sayre syndrome** includes ophthalmoplegia, heart block, cerebellar ataxia, deafness and mental deficiency due to long deletions and rearrangements. Leber’s hereditary optic neuropathy (LHON) is the commonest cause of blindness in young men, with bilateral loss of central vision and cardiac arrhythmias, and is an example of a mitochondrial disease caused by a point mutation in one gene.

- **Multisystem disorders** include Pearson’s syndrome (sideroblastic anaemia, pancytopenia, exocrine pancreatic failure, subtotal villous atrophy, diabetes mellitus and renal tubular dysfunction). In some families, hearing loss is the only symptom, and one of the mitochondrial genes implicated may predispose patients to aminoglycoside ototoxicity.

### Analysis of chromosome disorders

The cell cycle can be arrested at mitosis with colchicines and, following staining, the chromosomes with their characteristic banding can be seen and any abnormalities identified (Fig. 2.16).

YAC-cloned probes are also available and cover large genetic regions of individual chromosomes. These probes can be labelled with fluorescantly tagged nucleotides and used in in situ hybridization of the nucleus of isolated tissue

from patients. These tagged probes allow rapid and relatively unskilled identification of metaphase chromosomes, and allow the identification of chromosomes dispersed within the nucleus. Furthermore, tagging two chromosome regions with different fluorescent tags allows easy identification of chromosomal translocations (Fig. 2.17).

**GENE DEFECTS**
Mendelian and sex-linked single-gene disorders are the result of mutations in coding sequences and their control elements. These mutations can have various effects on the expression of the gene, as explained below, but all cause a dysfunction of the protein product.

**Mutations**
Although DNA replication is a very accurate process, occasionally mistakes occur to produce changes or mutations. These changes can also occur owing to other factors such as radiation, ultraviolet light or chemicals. Mutations in gene sequences or in the sequences which regulate gene expression (transcription and translation) may alter the amino acid sequence in the protein encoded by that gene. In some cases protein function will be maintained; in other cases it will change or cease, perhaps producing a clinical disorder. Many different types of mutation occur.

**Point mutation**
This is the simplest type of change and involves the substitution of one nucleotide for another, so changing the codon in
a coding sequence. For example, the triplet AAA, which codes for lysine, may be mutated to AGA, which codes for arginine. Whether a substitution produces a clinical disorder depends on whether it changes a critical part of the protein molecule produced. Fortunately, many substitutions have no effect on the function or stability of the proteins produced as several codons code for the same amino acid. However, some mutations may have a severe effect; for example, in sickle cell disease a mutation within the globin gene changes one codon from GAG to GTG, so that instead of glutamic acid, valine is incorporated into the polypeptide chain, which radically alters its properties.

**Insertion or deletion**

Insertion or deletion of one or more bases is a more serious change, as it results in the alteration of the rest of the following sequence to give a frame-shift mutation. For example, if the original code was:

\[
\text{TAA GGA GAG TTT}
\]

and an extra nucleotide (A) is inserted, the sequence becomes:

\[
\text{TAA AGG AGA GTT T}
\]

Alternatively, if the third nucleotide (A) is deleted, the sequence becomes:

\[
\text{TAG GAG AGT TT}
\]

In both cases, different amino acids are incorporated into the polypeptide chain. This type of change is responsible for some forms of thalassaemia (p. 407). Insertions and deletions can involve many hundreds of base-pairs of DNA. For example, some large deletions in the dystrophin gene remove coding sequences and this results in Duchenne muscular dystrophy. Insertion/deletion (ID) polymorphism in the angiotensin-converting enzyme (ACE) gene has been shown to result in the genotypes II, ID and DD. The deletion is of a 287 bp repeat sequence, and DD is associated with higher concentrations of circulating ACE and possibly cardiac disease (see p. 747).

**Splicing mutations**

If the DNA sequences which direct the splicing of introns from mRNA are mutated, then abnormal splicing may occur. In this case the processed mRNA which is translated into protein by the ribosomes may carry intron sequences, so altering which amino acids are incorporated into the polypeptide chain.
**Termination mutations**

Normal polypeptide chain termination occurs when the ribosomes processing the mRNA reach one of the chain termination or ‘stop’ codons (see above). Mutations involving these codons will result in either late or premature termination. For example, Haemoglobin Constant Spring is a haemoglobin variant where instead of the ‘stop’ sequence, a single base change allows the insertion of an extra amino acid (see p. 409).

The Copy Number Variation Project has been set up to investigate large pieces of DNA between 10 thousand and 5 million letters (copy number variation) in the hope of identifying diseases that may be associated with this type of mutation.

**Single-gene disease**

Monogenetic disorders involving single genes can be inherited as dominant, recessive or sex-linked characteristics. Although classically divided into autosomal dominant, recessive or X-linked disorders, many syndromes show multiple forms of inheritance pattern. This is predominantly because multiple defects can occur within a given disease-associated gene or in separate genes which all contribute to a particular molecular/cellular pathway and thus give rise to the same phenotype. For example in Ehlers–Danlos syndrome we find autosomal dominant, recessive and X-linked inheritance. In addition there is a spectrum between autosomal recessive and autosomal dominance in that having just one defective allele gives a mild form of the disease whereas having both alleles with the mutation results in a more severe form of the syndrome. In some cases, such as factor V Leiden disease, the boundary between dominant and recessive forms is very blurred.

A list of some autosomal dominant and autosomal recessive genetic diseases with their chromosomal localization can be found on the internet (http://www.genetests.org). Some diseases show a racial or geographical prevalence. Thalassaemia (see p. 407) is seen mainly in Greeks, South East Asians and Italians, porphyria variegata occurs more frequently in the South African white population, and Tay–Sachs (p. 1072) disease particularly occurs in Ashkenazi Jewish people. The most common recessive disease in the UK is cystic fibrosis (see pp. 46 and 844). Thus the prevalence of a disease may be low world-wide but much higher in specific populations. Some disorders are rare to the extent that the prevalence is counted in the total number of cases ever reported. Molecular biology has enabled the subclassification of some syndromes according to which gene is giving rise to the disease (e.g. polycystic kidney disease) and the proportion of cases arising from defects in that particular gene can be estimated from linkage analysis. However, this may not be reflected in the detection rate of a given clinical genetic test, since a single test cannot detect all the possible mutations arising at a particular locus.

**Autosomal dominant disorders** (Fig. 2.18a)

Each diploid cell contains two copies of all the autosomes. An autosomal dominant disorder occurs when one of the two copies has a mutation and the protein produced by the normal form of the gene cannot compensate. In this case a heterozygous individual who has two different forms (or alleles) of the same gene will manifest the disease. The offspring of heterozygotes have a 50% chance of inheriting the chromosome carrying the disease allele, and therefore also of having the disease. However, estimation of risk to offspring for counselling families can be difficult because of three factors:

- These disorders have a great variability in their manifestation. ‘Incomplete penetrance’ may occur if patients have a dominant disorder but it does not manifest itself clinically in them. This gives the appearance of the gene having ‘skipped’ a generation.
- Dominant traits are extremely variable in severity (variable expression) and a mildly affected parent may have a severely affected child.
- New cases in a previously unaffected family may be the result of a new mutation. In this case, the risk of a further affected child is negligible. Most cases of achondroplasia are due to new mutations.

The overall incidence of autosomal dominant disorders is 7 per 1000 live births.

---

**Fig. 2.18 Modes of inheritance of simple gene disorders**, with a key to the standard pedigree symbols.
Autosomal recessive disorders (Fig. 2.18b)
These disorders manifest themselves only when an individual is homozygous for the disease allele, i.e. both chromosomes carry the mutated gene. In this case the parents are generally unaffected, healthy carriers (heterozygous for the disease allele). There is usually no family history, although the defective gene is passed from generation to generation. The offspring of an affected person will be healthy heterozygotes unless the other parent is also a carrier. If carriers marry, the offspring have a 1 in 4 chance of being homozygous and affected, a 1 in 2 chance of being a carrier, and a 1 in 4 chance of being genetically normal. Consanguinity increases the risk. The clinical features of autosomal recessive disorders are usually severe; patients often present in the first few years of life and have a high mortality. The overall incidence of autosomal recessive disorders is about 2.5 per 1000 live births.

Sex-linked disorders (Fig. 2.18c,d)
Genes carried on the X chromosome are said to be ‘X-linked’, and can be dominant or recessive in the same way as autosomal genes. As females have two X chromosomes they will be unaffected carriers of X-linked recessive diseases. However, since males have just one X chromosome, any deleterious mutation in an X-linked gene will manifest itself because no second copy of the gene is present.

X-linked dominant disorders
These are rare. Females who are heterozygous for the mutant gene and males who have one copy of the mutant gene on their single X chromosome will manifest the disease. Half the male or female offspring of an affected mother and all the female offspring of an affected man will have the disease. Affected males tend to have the disease more severely than the heterozygous female.

X-linked recessive disorders
These disorders present in males and present only in homozygous females (usually rare). X-linked recessive diseases are transmitted by healthy female carriers or affected males if they survive to reproduce. An example of an X-linked recessive disorder is haemophilia A (see p. 438), which is caused by a mutation in the X-linked gene for factor VIII. It has been shown that in 50% of cases there is an intrachromosomal rearrangement (inversion) of the tip of the long arm of the X chromosome (one break point being within intron 22 of the factor VIII gene).

Of the offspring from a carrier female and a normal male:
- 50% of the girls will be carriers as they inherit a mutant allele from their mother and the normal allele from their father; the other 50% of the girls inherit two normal alleles and are themselves normal
- 50% of the boys will have haemophilia as they inherit the mutant allele from their mother (and the Y chromosome from their father); the other 50% of the boys will be normal as they inherit the normal allele from their mother (and the Y chromosome from their father).

The male offspring of a male with haemophilia and a normal female will not have the disease as they do not inherit his X chromosome. However, all the female offspring will be carriers as they all inherit his X chromosome.

Y-linked genes
Genes carried on the Y chromosome are said to be Y-linked and only males can be affected. However, there are no known examples of Y-linked single-gene disorders which are transmitted.

Sex-limited inheritance
Occasionally a gene can be carried on an autosome but manifests itself only in one sex. For example, frontal baldness is an autosomal dominant disorder in males but behaves as a recessive disorder in females.

Other single-gene disorders
These are disorders which may be due to mutations in single genes but which do not manifest as simple monogenic disorders. They can arise from a variety of mechanisms, including the following.

Triplet repeat mutations (Table 2.4)
In the gene responsible for dystrophia myotonica (p. 1181), the mutated allele was found to have an expanded 3’UTR region in which three nucleotides, CTG, were repeated up to about 200 times. In families with dystrophia myotonica, people with the late-onset form of the disease had 20–40 copies of the repeat, but their children and grandchildren who presented with the disease from birth had vast increases

in the number of repeats, up to 2000 copies. It is thought that some mechanism during meiosis causes this ‘triplet repeat expansion’ so that the offspring inherit an increased number of triplets. The number of triplets affects mRNA and protein function. See also page 45 for the phenomenon of ‘anticipation’.

**Mitochondrial disease** (see Fig. 2.15)

As discussed on pages 39 and 40, various mitochondrial gene mutations can give rise to complex disease syndromes with incomplete penetrance maternal inheritance.

**Imprinting**

It is known that normal humans need a diploid number of chromosomes of 46. However, the maternal and paternal contributions are different and, in some way which is not yet clear, the fetus can distinguish between the chromosomes inherited from the mother and the chromosomes inherited from the father, although both give 23 chromosomes. In some way the chromosomes are ‘imprinted’ so that the maternal and paternal contributions are different. Imprinting is relevant to human genetic disease because different phenotypes may result depending on whether the mutant chromosome is maternally or paternally inherited. A deletion of part of the long arm of chromosome 15 (15q11–q13) will give rise to the Prader–Willi syndrome (PWS) if it is paternally inherited. A deletion of a similar region of the chromosome gives rise to Angelman’s syndrome (AS) if it is maternally inherited. The affected gene has been identified as ubiquitin (UBE3A). Significantly, maternal chromosome 15 UBE3A is expressed in the brain and hypothalamus. Defective maternal ubiquitin in Angelman’s syndrome is thus responsible for accumulation of undegraded protein, and hence neuronal damage.

**Complex traits: multifactorial and polygenic inheritance**

Characteristics resulting from a combination of genetic and environmental factors are said to be multifactorial; those involving multiple genes can also be said to be polygenic.

Measurements of most biological traits (e.g. height) show a variation between individuals in a population, and a unimodal, symmetrical (Gaussian) frequency distribution curve can be drawn. This variability is due to variation in genetic factors and environmental factors. Environmental factors may play a part in determining some characteristics, such as weight, whilst other characteristics such as height may be largely genetically determined. This genetic component is thought to be due to the additive effects of a number of alleles at a number of loci, many of which can be individually identified using molecular biological techniques, for example studying identical twins in different environments.

A common genetic variation in the 3’ untranslated region of the prothrombin gene is associated with elevated prothrombin (up to fourfold) and an increased risk of venous thrombosis (thrombophilia, see p. 442). Presumably the 3’ mutation induces overexpression of the prothrombin gene by increasing mRNA stability. In some pedigree studies, those homozygous for this mutation and heterozygous for factor V Leiden mutation have an even greater risk of thrombotic events (p. 442). Conversely, downregulation of the αp-antithrombin gene (due to similar mutation in the 3’ and 5’ untranslated regions) is associated with emphysema and cirrhosis (p. 358).

*Percentage of the total variation of a trait which can be attributed to genetic factors.

There are sex differences. Congenital pyloric stenosis is most common in boys, but if it occurs in girls the latter have a larger number of affected relatives. This difference suggests that a larger number of the relevant genes are required to produce the disease in girls than in boys. Most human diseases, such as heart disease, diabetes and common mental disorders, are multifactorial traits (Table 2.5).

### POPULATION GENETICS

The genetic constitution of a population depends on many factors. The Hardy–Weinberg equilibrium is a concept, based on a mathematical equation, that describes the outcome of random mating within populations. It states that ‘in the absence of mutation, non-random mating, selection and genetic drift, the genetic constitution of the population remains the same from one generation to the next’.

This genetic principle has clinical significance in terms of the number of abnormal genes in the total gene pool of a population. The Hardy–Weinberg equation states that:

\[
p^2 + 2pq + q^2 = 1
\]

where \( p \) is the frequency of the normal gene in the population, \( p \) is the frequency of the abnormal gene, \( p^2 \) is the frequency of the normal homozygote, \( q^2 \) is the frequency of the affected abnormal homozygote, \( 2pq \) is the carrier frequency, and \( p + q = 1 \).

**Example.** The equation can be used, for example, to find the frequency of heterozygous carriers in cystic fibrosis. The incidence of cystic fibrosis is 1 in 2000 live births. Thus \( q^2 = 1/2000 \), and therefore \( q = 1/44 \). Since \( p = 1 - q \), then \( p = 43/44 \). The carrier frequency is represented by \( 2pq \), which in this case is 1/22. Thus 1 in 22 individuals in the whole population is a heterozygous carrier for cystic fibrosis.

### CLINICAL GENETICS AND GENETIC COUNSELLING

Genetic disorders pose considerable health and economic problems because often there is no effective therapy. In any pregnancy the risk of a serious developmental abnormality is approximately 1 in 30 pregnancies; approximately 15% of paediatric inpatients have a multifactorial disorder with a predominantly genetic element.
People with a history of a congenital abnormality in a member of their family often seek advice as to why it happened and about the risks of producing further abnormal offspring. Interviews must be conducted with great sensitivity and psychological insight, as parents may feel a sense of guilt and blame themselves for the abnormality in their child.

Genetic counselling should have the following aims:

- **Obtaining a full history.** The pregnancy history, drug and alcohol ingestion during pregnancy and maternal illnesses (e.g. diabetes) should be detailed.
- **Establishing an accurate diagnosis.** Examination of the child may help in diagnosing a genetically abnormal child with characteristic features (e.g. trisomy 21) or whether a genetically normal fetus was damaged in utero.
- **Drawing a family tree is essential.** Questions should be asked about abortions, stillbirths, deaths, marriages, consanguinity and medical history of family members. Diagnoses may need verification from other hospital reports.
- **Estimating the risk of a future pregnancy being affected or carrying a disorder.** Estimation of risk should be based on the pattern of inheritance. Mendelian disorders (see earlier) carry a high risk; chromosomal abnormalities carry a low risk. Empirical risks may be obtained from population or family studies.
- **Information giving on prognosis and management with adequate time given so that all information is discussed openly, freely and repeated as necessary.**
- **Continued support and follow-up.** Explanation of the implications for other siblings and family members.
- **Genetic screening.** This includes prenatal diagnosis if requested, carrier detection and data storage in genetic registers. A growing number of molecular genetic tests are now available [http://www.geneclinics.org](http://www.geneclinics.org).

Genetic counselling should be non-directive, with the couple making their own decisions on the basis of an accurate presentation of the facts and risks in a way they can understand.

**GENETIC ANTICIPATION**

It has been noted that successive generations of patients with, for example, dystrophy myotonica and Huntington’s chorea, present earlier and with progressively worse symptoms. This ‘anticipation’ is due to unstable mutations occurring within the disease gene. Trinucleotide repeats such as CTG (dystrophy myotonica) and CAG (Huntington’s chorea) expand within the disease gene with each generation, and somatic expansion with cellular replication is also observed. This novel type of genetic mutation can occur within the translated region or untranslated (and presumably regulatory) regions of the target genes. This genetic distinction has been used to subclassify a number of genetic diseases which have now been shown to be caused by trinucleotide repeat expansion and display phenotypic ‘anticipation’ (Table 2.4).

**PRENATAL DIAGNOSIS**

This should be offered to all pregnant women in the UK [NICE Clinical Guideline 62, 2008]. Practice and uptake varies in different maternity units, with some offering screening only to high-risk mothers. The risks of Down’s syndrome increase disproportionately and rapidly for children born to mothers older than 35 years. Infants born to mothers with a history or family history of other conditions due to chromosomal abnormalities may be at increased risk.

**Personal choice**

There should be a detailed discussion with all mothers as to the possible consequences of each screening test before they are offered it.

In particular they should have an understanding of the failure rates, the detection rates, the false positive and most importantly the false negative rates of each test so that they can properly exercise choice.

**Investigations depend on gestation**

**7–11 Weeks (vaginal ultrasound)**

Confirm viability, fetal number and gestation by crown–rump measurement.

**11–13 Weeks and 6 days (combined test)**

Ultrasound for nuchal translucency measurement (normal fold less than 6 mm) to attempt to detect major chromosomal abnormalities (e.g. trisomies and Turner’s syndrome).

Maternal serum is tested for pregnancy-associated plasma protein-A (PAPP-A from the syncytial trophoblast) and β-human chorionic gonadotrophin for trisomy 21. The combined test is more accurate than the triple test alone at 16 weeks.

NB. All serum marker measurements are corrected for gestational ages, a multiple of the mean (MOM) value for the appropriate week of gestation. If abnormalities are detected, it is necessary to continue to discuss whether further investigation is desired or not. Chorionic villus sampling (CVS) at 11–13 weeks under ultrasound control to sample the placental site, or amniocentesis at 15 weeks to sample amniotic fluid and obtain the fetal cells necessary for cytogenetic testing are the next options.

**14–20 Weeks (serum triple or quadruple test if too late for earlier test or previous option not offered)**

The triple test for chromosomal abnormalities consists of testing maternal serum for:

- α-fetoprotein (low)
- unconjugated oestriadiol (low)
- human chorionic gonadotrophin (high) for Down’s syndrome and for neural tube defects.

The α-fetoprotein is high for neural tube defects.

The quadruple test also measures inhibin A – high in Down’s syndrome.

**14–22 Weeks**

Ultrasound for structural abnormalities (e.g. neural tube defects; the gestation period for detection depends on severity). The best time to detect congenital heart defects is 18–22 weeks.

Reported detection rates for all congenital defects vary, e.g. from 14 to 61% for hypoplastic ventricle to 97 to 100% for anencephaly.

In time some of these tests are likely to be superseded by the salvage of fetal cells from the maternal blood, from cervical secretions or by retrieving maternal plasma cell free fetal DNA. Other conditions such as myotonic dystrophy and Huntington’s chorea may be detected from fetal circulating nucleic acids.
APPLICATIONS OF MOLECULAR GENETICS

The use of molecular biological techniques in genetics is having a massive impact on the investigation, diagnosis, treatment and control of genetic disorders.

The avoidance and control of genetic disease

Some genetic disorders, such as phenylketonuria or haemophilia, can be managed by diet or replacement therapy, but most have no effective treatment. By understanding what causes genetic damage, potential mutagens such as radiation, environmental chemicals, viruses or drugs (e.g. thalidomide) can be avoided.

GENE THERAPY

There are many technical problems to overcome in gene therapy, particularly in finding delivery systems to introduce DNA into a mammalian cell. Very careful control and supervision of gene manipulation will be necessary because of its potential hazards and the ethical issues.

Gene therapy entails placing a normal copy of a gene into the cells of a patient who has a defective copy of the gene.

Experiments have concentrated on recessive disorders, such as cystic fibrosis where the disease is due to the absence of a normal gene product. In dominant disorders the pathogenic potential of the mutant allele is normally expressed in the presence of a normal allele. This requires gene correction, whereby the mutant sequence is replaced by an equivalent sequence from a normal allele, or the mutant allele is inactivated. Such procedures are more difficult.

Two major factors are involved in gene therapy:

- the introduction of the functional gene sequence into target cells
- the expression and permanent integration of the transfected gene into the host cell genome.

Suitable diseases for current gene therapy experiments include cystic fibrosis, adenosine deaminase deficiency, and familial hypercholesterolaemia.

Cystic fibrosis (see also p. 361 and p. 844)

The gene responsible for cystic fibrosis (the cystic fibrosis transmembrane regulator gene (CFTR)) was first localized to chromosome 7 by linkage analysis. The CFTR gene spans about 250 kbp and contains 27 exons. The DNA sequence analysis predicts a polypeptide sequence of 1480 amino acids. The CFTR gene also encodes a simple chloride ion channel within the cystic fibrosis transmembrane regulator (Fig. 2.19). The commonest is a single mutation with a 3 bp deletion in exon 10 resulting in the removal of a codon specifying phenylalanine (F508del). There are also over 1000 different minor mutations of the CFTR gene with most mapping to the ATP-binding domains.

Gene therapy experiments are still under way in trying to restore CFTR function by transfection of cells with wild type receptor. Two different routes have been tried, either placing the CFTR gene in an adenovirus vector (Fig. 14.30) or into a liposome. The latter can be conveyed to the lung using an aerosol spray, and the fatty surface of the liposome fuses with the cell membrane to deliver the CFTR DNA into the cell, where the gene should function normally. However, neither is yet a treatment option. An alternative method is to suppress premature translation of codons and thus permit translation to continue; topical nasal gentamicin (an aminoglycoside antibiotic) has been shown to result in the expression of functional CFTR channels.

Adenosine deaminase (ADA) deficiency

Gene therapy for this rare immunodeficiency disease entails introducing a normal human ADA gene into the patient’s lymphocytes to reconstitute the function of the cellular and humoral immune system in severe combined immunodeficiency (SCID). Lymphocytes have been tried for short-term therapy, but for longer-term treatment bone marrow transplantation would be the definitive approach (see p. 462).

Familial hypercholesterolaemia

This disorder is a result of a defective low-density lipoprotein (LDL) receptor gene. In therapy, a receptor gene is inserted into hepatocytes, removed by liver biopsy from the patient. Gene-corrected hepatocytes are then reimplanted into the portal circulation of the patient. These cells migrate back to the liver where they are reincorporated and should start to produce LDL receptor protein, which would dramatically lower the patient’s cholesterol level.

Muscle-cell-mediated gene therapy

Much of the problem associated with gene therapy of chronic genetic disease is how long the transfected cells will survive. Isolated myoblasts transfected with a retrovirus have been shown to function and live for the lifetime of mouse models (2 years). The myoblasts fuse with the animal’s muscle fibres and express the transfected protein. The long life of the muscle fibres and their rich blood supply make them an ideal site for treatment of diseases in which functional serum-born factors are missing (e.g. human growth hormone, coagulation factors and erythropoietin).

Obviously, myoblast transfection would appear to be the best option for the treatment of Duchenne muscular dystrophy. However, the Duchenne gene is far too large to fit into
any current viral vector, and reimplanted myoblasts do not colonize muscles fibres distant from the site of injection.

Treatment of somatic disease

Gene therapy which requires only a transient expression of the transfected genetic material circumvents the problems currently plaguing gene therapy of inherited disorders. This may also prove to be the front-line of gene therapy.

Vascular disease

The ideal therapy in heart disease would be neovascularization to increase blood flow and the repair of cardiac tissue after a myocardial infarction. In fact, any vascular disease might require regeneration or new blood vessel growth. Temporary expression of angiogenic factors at the site of a blockage would induce new blood vessels. Alternatively, local transient expression of clot-disintegrating enzymes such as streptokinase and lipases may repair damaged and diseased arteries. It is quite possible to deliver liposomes loaded with DNA or, in fact, directly inject DNA plasmids into the tissue, and the protein will be expressed by the cells which take it up. Only 1–3% will do so, but this is sufficient for the local effect required and it is a transient expression. This gives a controllable gene therapy.

Neuronal disease

Neurotrophic factors can be transiently expressed as described above for vascular diseases. The local expression of neurotrophins is essential for nerve cell regeneration and maintenance. It is possible to extend the expression period of the neurotrophin by injecting transfected myocytes into the damaged area. They will fuse with any adjacent muscle tissue to give a prolonged expression of the factor gene.

Cancer

Cancer is a genetic disease and many genes are deregulated. p53 is a tumour suppressor gene; the reintroduction and overexpression of a functional p53 in tumours is being investigated with some success. Since p53 will induce apoptosis in cells with damaged genetic material, the transient expression of high levels in a tumour cell with p53 pathway defects should induce its own (apoptotic) demise. Since this is only likely to occur in rapidly dividing cells, this is a perfect target for cancer gene therapy. Transient expression induced by repeated exposure to vectors such as retroviruses, liposomes and naked DNA plasmids is all relatively straightforward. Trials using aerosols of these vectors in patients with lung cancer are being performed.

Tumour growth depends on the development of new blood vessels (angiogenesis), and inhibitors of this process are also being used in trials.

Stem cell therapy

It is claimed that stem cell therapy has the potential to radically change the treatment of human disease. A number of adult stem cell therapies already exist, particularly bone marrow transplants. It is currently anticipated that technologies derived from stem cell research can be used to treat a wider variety of diseases in which replacement of destroyed specialist tissues is required, such as in Parkinson’s disease, spinal cord injuries and muscle damage.

The potency of the stem cells used in therapy is therefore of great importance. In a developing embryo, embryonic stem cells can differentiate into all of the specialized embryonic tissues. In adult organisms, adult stem cells (and progenitor cells) act as a repair system for the body, replenishing specialized cells. In 2001 several studies reported on the plasticity of human embryonic stem cells (HESCs). With respect to repair of nerves, HESCs can be induced to differentiate into the three neural lineages (astrocytes, oligodendrocytes and mature neurons) in vitro. Furthermore, when transplanted into new born (mouse) brains they migrated along established neuronal tracts and differentiated to the appropriate cell type in a region-specific manner (i.e. responded to local paracrine signals and cues – totipotentiality).

The blood within the umbilical cord is a readily available and rich source of haemopoietic stem cells (i.e. CD34-positive and CD38-negative). These cord blood stem cells readily colonize the bone marrow, rapidly populating the marrow with all the various cells (erythrocytes and leukocytes) required of a fully functional blood system – pluripotentiality.

Umbilical cord blood is proving an invaluable source of stem cells for bone marrow transplants. Cord blood banks have been set up where collected cord blood or indeed the clamped and early cut umbilical cord itself, is cryogenically preserved for long-term (and costly) storage should the child or a tissue-type-matched individual ever require the stem cells. In 2005 researchers claimed to have discovered a category of cord stem cell, dubbed cord-blood-derived embryonic like stem cells (CBEs), which were able to differentiate into more types of tissue than simply haemopoietic cells (super pluripotentiality). Similarly, although peripheral blood monocytes are believed to be the unipotent precursors of phagocytes, in 2007 it was claimed that a primitive monocyte-derived multipotential cell (MOMC) could be isolated from adult peripheral circulating monocytes. Furthermore, these MOMCs can be induced (given the correct paracrine, environmental and adhesion signals) into endothelia, neurones, cardiomyocytes and mesenchymal lineages. Similar reports have appeared concerning adult stem cells isolated from skin.

There is a great deal of social, as well as scientific controversy surrounding stem cell research. Human embryonic stem cell research is particularly controversial as the establishment of a stem cell line requires the destruction of a human embryo and/or therapeutic cloning. However, recently, it has been shown that embryonic stem cell lines can be generated without destroying embryos using single-cell biopsy, similar to the approach used in pre-implantation genetic diagnosis. This, in combination with recent results discussed above concerning the isolation of cord blood and adult totipotent (or super pluripotent) stem cells, may circumvent the ethical blockade on using HESCs in stem cell therapy.

Creating and using animal models

There is a need for model systems in which to test gene therapies prior to use in patients. To some extent gene ‘knock-out’ experiments in mice are providing new animal models of disease. In these experiments the normal gene of interest in a mouse is targeted using recombinant DNA techniques so that gene function is impaired, in analogy to the situation in the particular gene of a human patient. However, mice and humans are different and it will not be possible to
mimic some human genetic diseases in mice. Transgenic mice are created when exogenous DNA carrying a gene of interest is injected into a mouse egg. If this egg is fertilized then all the cells of the resulting animal will carry the extra gene sequences. Transgenic mice have also been used as animal models of human diseases in which new therapies may be tested.

Other animal models have paved the way for gene therapy techniques. For example, some of the first experiments in the transfer of globin genes (which will be useful for gene therapy for sickle cell disease and thalassaemia) have taken place in mice. These include transplanting normal donor cells with normal genes into lethally irradiated mice, which results in engraftment of the donor cells.

The human proteome project

A more direct route to understanding genetic and somatic disease is by studying the protein expression characteristics of normal and diseased cells – the proteome. This relies on the separation of proteins expressed by a given tissue by molecular size and charge on a simple two-dimensional display and is achieved by using two-dimensional gel electrophoresis. The pattern of dots corresponds to the different proteins expressed. With the improvement in technology, the patterns are reproducible and can be stored as electronic images. Non-, over- and underexpression of a given protein can be detected by a corresponding change on the proteome two-dimensional electrophoresis image. As can be seen in Figure 2.20, the protein profile of synovial fluid from a diseased joint shows a new protein arising with disease. Such proteins have been identified as inflammatory cytokines. Furthermore, post-translational modifications of the protein show up as a change in either size or charge on the proteome picture. In order to positively identify the altered protein and the post-translational modification it may contain, these protein spots are eluted and subjected to modern mass spectrometry techniques such as matrix-assisted laser desorption ionization (MALDI) and electrospray ionization (ESI) time of flight (TOF), which not only give the precise mass of the protein, up to ~500 000 Da, but can also sequence its amino acid, phosphorylation and glycosylation structure. This cannot be detected by genome analysis. Looking for such changes has already led to the discovery of new protein markers for the diagnosis of Creutzfeldt–Jakob disease, multiple sclerosis, schizophrenia, Parkinson’s disease (spinal fluid protein) and Alzheimer’s disease (blood and brain proteins). In 2000, the Swiss Institute of Bioinformatics (SIB) and the European Bioinformatics Institute (EBI) announced a major effort to annotate, describe and provide highly accurate information concerning human protein sequences, effectively launching the Human Proteomics Initiative (HPI).

Metabolomics

In the post-genomic era, computing power, statistical software, separation science and modern mass spectrometry have allowed the analysis of a complex mixture as a complete entity, and not merely the fluctuation in concentration of one analyte within it. Metabolomics is the study of the repertoire of non-proteinaceous, endogenously synthesized small molecules present in an organism. Such small molecules include well-known compounds like glucose, cholesterol, ATP and lipid signalling molecules. These molecules are the ultimate product of cellular metabolism, and the metabolome refers to the catalogue of those molecules in a specific organism, e.g. the human metabolome. In terms of clinical biochemistry, the analysis of the pattern of change of such molecules in urine samples of individuals with and without a particular disease and those treated with specific drugs represents a change in the metabolome. It is very likely that, in the future, medicine-regulating authorities will require metabolomic studies on all new drugs.

Ethical considerations

Ethical considerations must be taken into account in any discussion of clinical genetics. For example, prenatal diagnosis with the option of termination may be unacceptable on moral or religious grounds. With diseases for which there is no cure and currently no treatment (e.g. Huntington’s), genetic tests can predict accurately which family members will be affected; however, many people would rather not know this information. One very serious outcome of the new genetic information is that disease susceptibility may be predictable, for example in Alzheimer’s disease, so the medical insurance companies can decline to give policies for individuals at high risk.

Society has not yet decided who should have access to an individual’s genetic information and to what extent privacy should be preserved.

Fig. 2.20 Two-dimensional gel electrophoresis comparing paired serum and synovial fluid in a patient with rheumatoid arthritis. Biofluids were first separated according to isoelectric point on a linear immobilized pH gradient followed by SDS-PAGE in a 10% gel. The circled proteins indicate major proteins which differ between the two biofluids. Although serum contained many proteins not found in synovial fluid, one major protein was found to be present in the synovial fluid electropherogram but not in the serum electropherogram. This indicates that synovial fluid is not a simple transudate of serum. Courtesy of Prof. D Perrett and Dr R Bevan, Department of Medicine, Barts and The London School of Medicine.

FURTHER READING

THE GENETIC BASIS OF CANCER

Cancers are genetic diseases and involve changes to the normal function of cellular genes. However, multiple genes interact during oncogenesis and an almost stepwise progression of defects leads from an overproliferation of a particular cell to the breakdown of control mechanisms such as apoptosis (programmed cell death). This would be triggered if a cell were to attempt to survive in an organ other than its tissue of origin. For the vast majority of cancer cases (especially those in older people) the multiple genetic changes which occur are somatic. However, it is clear that susceptibility to the development of a particular form of cancer can be inherited. Indeed for some rare cancers a dominant single-gene defect can give rise to an almost Mendelian trend. In some other cancers (e.g. forms of breast cancer) the mode of inheritance is much more complex. In these cases close relatives may have an increased susceptibility to cancer (Table 9.3), and the genetics are clearly those of a multifactorial trait.

- Cancer tissues are clonal, and tumours arise from changes in only one cell, which then proliferates in the body.
- The genes that are primarily damaged by the genetic changes which lead to cancer fall into two categories: oncogenes and tumour suppressor genes.
- Oncogenesis is a multistep process in that a number of mutations or alterations to key genes are required before a malignant phenotype is expressed.
- Once mutations have begun to cause unchecked clonal expansion of the primary tumour cells, further mutations occur within the subsequent generations of daughter cells that give rise to clones which are invasive and/or form metastases.

**ONCOGENES (see p. 451)**

The genes coding for growth factors, growth factor receptors, secondary messengers or even DNA-binding proteins would act as promoters of abnormal cell growth if mutated. This concept was verified when viruses were found to carry genes which, when integrated into the host cell, promoted oncogenesis. These were originally termed viral or ‘v-oncogenes’, and later their normal cellular counterparts, c-oncogenes, were found. Thus, oncogenes encode proteins that are known to participate in the regulation of normal cellular proliferation e.g. erb-B on chromosome 17q11–q12 encodes for the thyroid hormone receptor. See also Table 9.4.

**Activation of oncogenes**

Non-activated oncogenes which are functioning normally have been referred to as ‘proto-oncogenes’. Their transformation to oncogenes can occur by three routes.

**Mutation**

Carcinogens such as those found in cigarette smoke, ionizing radiation and ultraviolet light can cause point mutations in genomic DNA. By chance some of these point mutations will occur in regions of the oncogene which lead to activation of that gene. Not all bases in an oncogene cause cancer if mutated, but some (e.g. those in the coding region) do.

**Chromosomal translocation**

If during cell division an error occurs and two chromosomes translocate, so that a portion swaps over, the translocation breakpoint may occur in the middle of two genes. If this happens then the end of one gene is translocated on to the beginning of another gene, giving rise to a ‘fusion gene’. Therefore sequences of one part of the fusion gene are inappropriately expressed because they are under the control of the other part of the gene.

An example of such a fusion gene (the Philadelphia chromosome) occurs in chronic myeloid leukaemia (CML, see p. 472). Similarly in Burkitt’s lymphoma a translocation causes the regulatory segment of the myc oncogene to be replaced by a regulatory segment of an unrelated immunoglobulin.

**Viral stimulation**

When viral RNA is transcribed by reverse transcriptase into viral cDNA and in tumour cells is inserted into the cellular DNA, the viral DNA may integrate within an oncogene and activate it. Alternatively the virus may pick up cellular oncogene DNA and incorporate it into its own viral genome. Subsequent infection of another host cell might result in expression of this viral oncogene. For example, the Rous sarcoma virus of chickens was found to induce cancer because it carried the ras oncogene.

After the initial activation event other changes occur within the DNA. A striking example of this is amplification of gene sequences, which can affect the myc gene for example. Instead of the normal two copies of a gene, multiple copies of the gene appear either within the chromosomes (these can be seen on stained chromosomes as homogeneously staining regions) or as extrachromosomal particles (double minutes). N-myc sequences are amplified in neuroblastomas, as are N-myc or L-myc in some lung small-cell carcinomas.

**TUMOUR SUPPRESSOR GENES**

These genes restrict undue cell proliferation (in contrast to oncogenes), and induce the repair or self-destruction (apoptosis) of cells containing damaged DNA. Therefore mutations in these genes which disable their function lead to uncontrolled cell growth in cells with active oncogenes. An example is the germline mutations in genes found in non-polyposis colorectal cancer which are responsible for repairing DNA mismatches (p. 302).

The first tumour suppressor gene to be described was the RB gene. Mutations in RB lead to retinoblastoma which occurs in 1 in 20000 young children and can be sporadic or familial. In the familial variety, the first mutation is inherited.
and by chance a second somatic mutation occurs with the formation of a tumour. In the sporadic variety, by chance both mutations occur in both the RB genes in a single cell. Since the finding of RB, other tumour suppressor genes have been described, including the gene p53. Mutations in p53 have been found in almost all human tumours, including sporadic colorectal carcinomas, carcinomas of breast and lung, brain tumours, osteosarcomas and leukaemias. The protein encoded by p53 is a cellular 53 kDa nuclear phosphoprotein that plays a role in DNA repair and synthesis, in the control of the cell cycle and cell differentiation and programmed cell death – apoptosis. p53 is a DNA-binding protein which activates many gene expression pathways but it is normally only short-lived. In many tumours, mutations that disable p53 function also prevent its cellular catabolism. Although in some cancers there is a loss of p53 from both chromosomes, in most cancers (particularly colorectal carcinomas; see Fig. 6.45) such long-lived mutant p53 alleles can disrupt the normal alleles’ protein. As a DNA-binding protein, p53 is likely to act as a tetramer. Thus, a mutation in a single copy of the gene can promote tumour formation because a hetero-tetramer of mutated and normal p53 subunits would still be dysfunctional.

How tumour suppressor genes work
Tumour suppressor gene products are intimately involved in control of the cell cycle (see Fig. 2.7). Progression through the cell cycle is controlled by many molecular gateways, which are opened or blocked by the cyclin group of proteins that are specifically expressed at various stages of the cycle. The RB and p53 proteins control the cell cycle and interact specifically within many cyclin proteins. The latter are affected by INK 4α acting on p16 proteins. The general principle is that being held at one of these gateways will ultimately lead to programmed cell death. p53 is a DNA-binding protein which induces the expression of other genes and is a major player in the induction of cell death. Its own expression is induced by broken DNA. The induction of p53 by damage initially causes the expression of DNA repair enzymes. If DNA repair is too slow or cannot be effected, then other proteins that are induced by p53 will effect programmed cell death.

One gateway event that has been largely elucidated is that between the G1 and the S phase of the cell cycle. The transcription factor dimer E2F-DP1 causes progression from the G1 to the S phase. However, the RB protein binds to the E2F transcription factor, preventing its induction of DNA synthesis. Other, cyclin D-related molecules inactivate the RB protein, thus allowing DNA synthesis to proceed. This period of rapid DNA synthesis is susceptible to mutation events and will propagate a pre-existing DNA damage. Damaged DNA-induced p53 expression rapidly results in the expression of a variety of closely related (and possibly tissue-specific) proteins WAF-1/p21, p16, p27. These inhibit the inactivation of RB by cyclin D-related molecules. As a result, the normal gate which stops the cell cycle, binds to the E2F-DP1 transcription factor complex, halting S phase DNA synthesis. If the DNA damage is not repaired apoptosis ensues.

Viral inactivation of tumour suppressors
The suppression of normal tumour suppressor gene function can be achieved by disabling the normal protein once it has been transcribed, rather than by mutating the gene. Viruses have developed their own genes which produce proteins to do precisely this. The main targets of these proteins are RB and p53 to which they bind and thus disable. The best understood are the adenovirus E1A and human papillomavirus (HPV) E7 gene products which bind RB, whilst the adenovirus E1B and HPV E6 gene products bind p53. The SV40 virus large T antigen binds both RB and p53.

Microsatellite instability
Microsatellites are short (50–300 bp) sequences composed of tandemly repeated segments of DNA two to five nucleotides in length (dinucleotide/trinucleotide/tetranucleotide repeats). Scattered throughout the genome in the non-coding regions between genes or within genes (introns), many of these microsatellites are highly polymorphic. Often used as markers for linkage analysis because of high variability in repeat number between individuals, these regions are inherently unstable and susceptible to mutations. Somatic microsatellite instability (MSI) has been detected in a number of tumours. Detecting MSI involves comparing the length of microsatellite alleles amplified from tumour DNA with the corresponding allele in normal tissue from the same individual. Recent studies indicate that MSI can be detected in approximately 90% of tumours from individuals with hereditary non-polyposis colorectal cancer (HNPCC). The presence of these additional microsatellite alleles (repeated segments) in tumour cells results from the inherent susceptibility of these areas to such alterations and from mutations in the DNA mismatch repair mechanism that would normally correct these errors.

Tumour angiogenesis
Once a nest of cancer cells reaches 1–2 mm in diameter, it must develop a blood supply in order to survive and grow larger, as diffusion is no longer adequate to supply the cells with oxygen and nutrients. As with all tissues, solid tumour cancer cells secrete substances that promote the formation of new blood vessels – a process called angiogenesis. Over a dozen substances have been identified that promote angiogenesis (e.g. angiopoietin-1, basic fibroblast growth factor (bFGF) and vascular endothelial growth factor (VEGF)). This has led to the discovery of a number of inhibitors of angiogenesis and some have already advanced to clinical trials as part of a cancer treatment strategy such as:

- angioatin – a polypeptide of approximately 200 amino acids, produced by the cleavage of plasminogen; it binds to subunits of ATP synthase exposed at the surface of the cell embedded in the plasma membrane
- endostatin – a polypeptide of 184 amino acids which is derived from the globular domain found at the C-terminal of type XVIII collagen (a specific collagen of blood vessels) cleaved from the parent molecule.

Several therapeutic vaccine preparations are under development to produce a range of host immunity responses (humoral, cellular) against pro-angiogenic factors and their receptors in tumours. One approach has been directed at cell adhesion molecules found in tumour blood vessels. It turns out that the new blood vessels in tumours express a vascular integrin – designated alpha-v/beta-3 – that is not found on the old blood vessels of normal tissues. Vitaxin, a monoclonal antibody directed against the alpha-v/beta-3 vascular integrin, shrinks tumours in mice without harming them. In phase II clinical trials in humans, vitaxin has shown some promise in shrinking solid tumours without harmful side-effects.
It is clear that a mutation causing the dysfunction of a single oncogene or tumour suppressor gene is not sufficient to induce unregulated clonal expansion. The Knudson multi-hit hypothesis elegantly unites the genetics of familial and sporadic tumour development: an inherited mutation in one gene allele may be insufficient to cause a tumour but will cause a significant susceptibility to the development of a particular cancer. Subsequent lifetime exposure to environmental carcinogens (viral, chemical, radiation), along with simple mistakes during cell division, may deregulate the normal allele. Other mutations which accumulate in a similar manner then lead to tumour development. Research has clearly shown that germine mutations in particular genes, such as p53 and RB, have a much stronger influence on the chance of subsequent tumour development than others.

Epigenetics and cancer

The term ‘epigenetics’ is used to explain changes in gene expression that do not involve changes in the underlying DNA sequence. Despite not altering the decoding sequence, the effects of epigenetic changes are stable over rounds of cell division, and sometimes between generations. There are two principal molecular epigenetic mechanisms implicated in cancer:

- Modifications to DNA’s surface structure, but not its base pair sequence – DNA methylation resulting in non-recognition of gene transcription DNA-binding domains.
- Modification of chromatin proteins (in particular histones), which will not only support DNA but bind it so tight as to regulate gene expression – at the extreme, such binding can permanently prevent the DNA sequences being exposed to, let alone acted on by, gene transcription (DNA-binding) proteins.

Hypermethylation of gene regulatory regions (denoted by CpG islands, cytosine, guanine nucleotides joined by a phosphodiester bond (p. 31)) whereby cytosine is converted to 5-methyl cytosine has been identified at a number of gene loci at the 5’ regulatory region and is associated with oncogenesis. The Hic-1 gene is noticeably silenced by hypermethylation in numerous tumours. The enzymes responsible for methylation, DNA methyltransferases (e.g. DNMT1), are attracted to replication foci and preferentially modify hemimethylated DNA CpG regions. The net result is not only maintenance of the methylated status in daughter strands but also its expansion within the loci.

Methylation is not limited to CpG-rich regions of DNA – the associated histones are also modified. The lysine-rich tail of histone protein 3 (H3) interacts with DNA by attracting and compensating for the strong polar negative charge–negative charge repulsion of the phosphate backbone of DNA. Effectively it buffers this repulsion, allowing DNA to twist and coil tighter. Acetylation of the H3 tail lysines removes their buffering positive charge, causing the DNA to spring away from the histone packaging. In this histone-influenced free form, the DNA helix is able to assume conformational shapes driven by its own internal bond length strains. Thus, where the double helix is under stress from distortion by CpG-rich regions, this springing away from the nucleosomal histones allows access to DNA-binding proteins that initiate transcription. Deacetylation of the H3 tail lysines results in DNA being pulled onto the histone body and effectively burying the CpG-rich transcription recognition regions. However, methylation of the H3 tail lysines results in even tighter coiling and like-with-like attraction of similar modified histones of other nucleosomes. The net result is the tight packing of large regions of DNA in what is termed heterochromatin. Thus DNA methylation can recruit DNMTs to methylate daughter strand loci during replication and their associated histones to effectively shut a gene region. If the region includes tumour repressor gene loci, oncogenic progression can proceed without direct mutation of the gene in question.

More epigenetic mechanisms are being discovered that further help explain the phenomenon of ‘book marking’ which has been observed in several biological species. The name refers to the observation that some genes appear to remain active long after the initiating signals for transcription have been removed – much like a book falling open at a much-read page once dropped. Recent studies have focused on small RNA species that are the product (or spliced byproduct) of transcriptional activated genes. These RNAs tend to form double-stranded species that keep the gene loci open for continued transcription. This is not an unusual phenomenon in that the protein product of genes such as Hnf4 and MyoD is known to feedback and maintain autotranscription. However, small RNA species can freely diffuse through nuclear pores and into other cells via gap junctions. This unhindered passage makes such RNA species pervasive, upregulating and locking the on switch of oncogenic genes in transformed and neighbouring cells without DNA mutation. In several species the so-called ‘maternal effect phenotype’ is believed to be due to such small RNA species being laid down in the oocyte by nurse cells and then acting on genes of the resulting offspring as it develops.

DNA methylation is low in tumour cells compared to normal tissue.

ANATOMY AND PRINCIPLES OF THE IMMUNE SYSTEM

Immunity can be defined as protection from infection, whether it be due to bacteria, viruses, fungi or multicellular parasites. Like other organs involved in human physiology, the immune system is composed of cells and molecules organized into specialized tissues (Fig. 3.1).

The primary lymphoid organs are where the cells originate and develop into immature forms. Cells and molecules of the immune system circulate in the blood, but immune responses do not take place there. Rather, an immune response is initiated at the site of infection (typically the mucosa or skin) and then propagated and refined in the secondary lymphoid organs (e.g. lymph nodes). After resolution of the infection, immunological memory specific for the pathogen resides in cells (lymphocytes) in the spleen and lymph nodes as well as being widely secreted in a molecular form (antibodies).

Development of cells involved in immune responses

Cells destined to be myeloid cells or lymphocytes are derived from a common pluripotent stem cell in the bone marrow.

Myeloid cells. Neutrophils, eosinophils, basophils and dendritic cells are derived from precursor cells generated in the bone marrow (see Fig. 8.1).

T lymphocytes. Immature cells leave the bone marrow to enter the thymus as thymocytes. Gene rearrangement takes place to form the antigen-specific T cell receptor. Positive and negative selection occur to ensure that functional cells that are non-auto-reactive survive and differentiate to CD4+ or CD8+ cells. These antigen naïve T cells leave the thymus to populate peripheral lymphoid tissue. On encountering their specific antigen they proliferate and activation occurs to give them either helper (CD4+) or cytotoxic (CD8+) cell function (see p. 65).

B lymphocytes undergo development to maturity within the bone marrow, including gene rearrangement for production of antigen-specific antibody molecules. The mature cells are released and populate the follicles of lymph nodes and lymphoid tissue. Lymphoid tissue is frequently found in mucosal surfaces in non-encapsulated patches. This is termed mucosa associated lymphoid tissue (MALT), consisting of genitourinary and gut-associated lymphoid tissue (GALT, mainly Peyer’s patches), bronchus-associated lymphoid tissue (BALT, found in the lobes of the lungs along the main bronchi) and skin-associated lymphoid tissue (SALT).

On meeting their specific antigen, B cells proliferate and differentiate to antibody-secreting plasma cells.

The immune system

Cells and molecules involved in immune responses are classified into innate and adaptive systems. There are also non-immunological barriers that are involved in host protection, and very often it is the lowering of these that allows a pathogen to take a foothold (Table 3.1).

The immune system is immensely powerful, in terms of its ability to inflame, damage and kill, and it has a capacity to recognize a myriad of molecular patterns in the microbial world. However immune responses are not always beneficial. They can give rise to a range of autoimmune and inflammatory diseases, known as immunopathologies. In addition, the immune system may fail, giving rise to immune deficiency states. These conditions are grouped under the umbrella of clinical immunology.

A major feature of the immune system is the complexity of the surface-bound, intracellular and soluble structures that mediate its functions. In particular it is necessary to be aware of the CD (clusters of differentiation)
The immune system and disease

Cytokines

These are small polypeptides released by a cell in order to change the function of the same or another cell. These chemical messengers are found in many organ systems, but especially the immune system. Cytokines have become markers in the investigation of disease pathogenesis; therapeutic agents in their own right; and the targets of therapeutic agents (see p. 75). The key features of a cytokine are pleiotropy (different effects on different cells); autocrine function (modulates the cell secreting it); paracrine function (modulates adjacent cells); endocrine effects (modulates cells and organs at remote sites); and synergy (acting in concert to achieve effects greater than the summation of their individual actions). The main immune cytokines are the interferons (IFNs) and the interleukins (IL). The IFNs are limited to a few major types (α, β and γ) whilst IL-35 is the latest cytokine to be defined (for listings and functions see http://www.copewithcytokines.de/).
Box 3.1 The CD classification

This is the ultimate way of defining a cell.

- Immune cells are distinguished by the surface receptors and molecules that they express in order to mediate their particular range of immunological functions, e.g. cell–cell signalling, cell activation
- The surfaces are covered with such proteins and indicate the cell lineage or differentiation pathway. The discovery of monoclonal antibodies (proteins tailored to bind to a specific target) made this feasible
- Surface molecules defining the origin and function of selected groups of cells are known as clusters of differentiation (CD). Over 300 CD numbers exist
- In clinical practice, e.g. the number of peripheral blood lymphocytes expressing CD4 (‘the CD4 count’) are used to monitor HIV infection (see p. 196)
- An updated listing is available at http://www.hcdm.org/

Chemokines

The defining feature of chemokines is their function as chemo tactic molecules – that is, they attract cells along a gradient of low to high chemical concentration. Chemokines are involved in the trafficking of cells of the immune system – particularly from the blood into the tissues and tissues into lymphatics – and also have the ability to activate immune cells. Like cytokines, chemokines are pleiotropic. All chemokines have a similar structure relating to the configuration of cysteine residues that gives rise to four families:

- Two cysteines separated by any other amino acid residue (X) is CXC.
- Two cysteines next to each other is CC.
- One cysteine is C.
- Two cysteines separated by any three amino acids are CX3C.

Receptors on the surface are denoted by ‘R’, and are all distinct G-coupled protein receptors with seven transmembrane spanning domains. Some chemokines are released by many nucleated cells in response to inflammation and have a role in chemotaxis, attracting immune cells to inflam matory foci (e.g. CXCL8 (interleukin 8)); others are released in a programmed fashion by specialized cells in the immune system and have specific functions. CXCL12, for example, is necessary for the development of secondary lymphoid organs.

Anti-inflammatory drugs that block chemokine functions, or drugs that promote cell activation and migration, for example into tumours, are being developed (for listings and functions see http://www.copewithcytokines.de/).

*Antigen is a molecular structure (protein, peptide, lipid, carbohydrate) that generates an immune response

Complement

The complement cascade is activated through three distinct pathways, alternative, classical and mannan-binding lectin. These pathways are composed of three distinct enzyme cascades that culminate in the cleavage of C3 and C5. Cleavage of C3 produces a number of biological consequences, while breakdown of C5 achieves the same and, in addition, provides the triggering stimulus to the final common (‘membrane attack’) pathway, which provides most of the biological activity (Fig. 3.2).

The main functions of complement activation are to:

- promote inflammation (e.g. through the actions of the anaphylatoxins)
- recruit cells (e.g. through chemoattractants)
- kill targeted cells, such as bacteria
- to solubilize and remove from the circulation antigen–antibody (‘immune’) complexes.

During an immune response, removal of immune complexes protects unaffected tissues from the deposition of these large, insoluble composites which could result in unwanted inflammation. Failure of this protective mechanism can result in immunopathology, for example in the joints, kidney and eye.

Neutrophils (p. 430)

Neutrophils phagocytose and kill microorganisms. They have a distinctive multilobed nucleus (hence the alternative name ‘polymorph’) and neutral staining granules. Neutrophils come from the bone marrow, which can produce between

* Opsonize = coat bacteria to enhance phagocytosis by granulocytes and monocytes/macrophages.
† C-reactive protein (CRP) is an acute phase protein. Blood levels rise 10–100 fold within hours of the start of an infective or inflammatory process, making it extremely useful in monitoring infective or inflammatory diseases, and their response to treatment.

10¹¹ (healthy state) and 10¹² (during infection) new cells per day. In health, neutrophils are rarely seen in the tissues. There are approximately 100 different molecules in neutrophil granules (azurophilic and specific), the key ones and their functions being shown in Table 3.4.

Neutrophils are phagocytic cells activated by interaction with bacteria, either directly or when these are coated to make them more ingestible (termed opsonization (Fig. 3.3)). Granule contents are released both intracellularly (predominantly azurophilic granules) and extracellularly (specific granules) following fusion with the plasma membrane. Granule contents kill and digest microorganisms.

- **Myeloperoxidase** and cytochrome b₅₅₈ are each key components of major oxygen-dependent bactericidal systems (called the hydrogen peroxide–myeloperoxidase–halide system and the respiratory burst, respectively).
- **Cathepsins, proteinase-3 and elastase** are deadly to Gram-positive and Gram-negative organisms, as well as some *Candida* species.
- **Defensins** are naturally occurring cysteine-rich antibacterial and antifungal polypeptides (29–35 amino acids).
- **Collagenase and elastase** break down fibrous structures in the extracellular matrix, facilitating progress of the neutrophil through the tissues.

**Granule release** is initiated by the products of bacterial cell walls, complement proteins (e.g. inactive complement 3b, iC3b), leukotrienes (LTB₄) and chemokines (e.g. CXCL8, also known as interleukin 8 (IL-8)) and cytokines such as tumour necrosis factor α (TNF-α).

**Eosinophils**

In contrast to neutrophils, several hundred times more eosinophils are present in the tissues than in the blood. They collect preferentially at epithelial surfaces and survive for...
The main role of eosinophils is protection against multicellular parasites such as worms (helminths). This is achieved by the release of toxic, cationic proteins. In populations and societies in which such parasites are rare, eosinophils contribute mainly to allergic disease, particularly asthma (see p. 850). Eosinophils have specific (95%) and primary (5%) granules.

The specific granules contain the cationic proteins, of which there are four main types. *Major basic protein (MBP), eosinophil cationic protein (ECP) and eosinophil neurotoxin* are all potently and exquisitely toxic to helminths, while ECP also has some bactericidal properties. *Eosinophil peroxidase* has similar activity to neutrophil myeloperoxidase.

*Primary granules* synthesize and release *leukotrienes C4 and D4 and platelet activating factor (PAF)* which alter airway smooth muscle and vasculature (see p. 850).

Eosinophils are activated and recruited by a variety of mediators via specific surface receptors, including complement factors and leukotriene (LT) B4. In addition, the CC chemokines eotaxin-1 (CCL11) and eotaxin-2 (CCL24) are highly selective in eosinophil recruitment. Receptors are also present for the cytokines IL-3 and IL-5, which promote the development and differentiation of eosinophils.

**Mast cells and basophils**

Mast cells and basophils share features in common, especially the presence of histamine-containing granules and the possession of high-affinity receptors for immunoglobulin E (IgE; an antibody type that is involved in allergic disease, see p. 72). Mast cells are tissue fixed and found at regular intervals in the skin and mucosae. Mast cell and basophil mediators are categorized as pre-formed and those synthesized de novo (Table 3.5).

*Histamine* is a low-molecular-weight amine (111 Da) with a blood half-life of less than 5 minutes; it constitutes 10% of the mast cell’s weight. When injected into the skin, histamine induces the typical ‘weal and flare’ or ‘triple’ response. Initially there is reddening (erythema) of the skin at the site as arterioles dilate and post-capillary venules contract. This is followed by increased vascular permeability, with leakage of plasma fluid into the tissues causing swelling (weal). Finally, histamine acts directly on local axons to induce more widespread vascular changes distant from the injection site (flare).

The *complement-derived anaphylatoxins C3a, C4a and C5a* activate basophils and mast cells in response to a range of stimuli, whilst activation through binding of antigen to surface-bound antibody molecules of the IgE class is a feature of allergic disease. New evidence emphasizes that the mast cell also has a role in the early response to bacteria through release of TNF-α, which recruits and activates neutrophils as well as promoting readiness in nearby lymph nodes. In animal models mast cells can also be involved in recruitment to inflammatory sites such as arthritic joints, in promotion of tumour growth by enhancing neo-vascularization and in allograft tolerance.
Monocytes and macrophages

Cells of the monocyte/macrophage lineage (also called mononuclear phagocytes) are highly sophisticated phagocytes. Monocytes are the blood form of a cell that spends a few days in the circulation before entering into the tissues to differentiate into macrophages, and possibly some types of dendritic cells. This is especially likely to happen during episodes of inflammation.

Blood monocytes can be divided into two subsets: those expressing CD14 (a receptor for lipopolysaccharide, a bacterial cell wall component) and those expressing CD14 and CD16 (a receptor for IgG antibodies). In vitro, both subsets have the potential to differentiate into myeloid dendritic cells (after culture with IL-4 and granulocyte-monocyte colony stimulating factor, GM-CSF) and into macrophages.

A key role of tissue macrophages is the maintenance of tissue homeostasis, through clearance of cellular debris, especially following infection or inflammation:

- **Alveolar macrophages** in the lung clear microorganisms and debris encountered in the air.
- **Gut macrophages** are specialized towards bactericidal activity.
- **Osteoclasts**, another form of tissue macrophage, are multinucleate giant cells that resorb bone.

In general, the mononuclear phagocytes are responsive to a range of proinflammatory stimuli, using a pattern recognition receptor (PRR) to recognize pattern associated molecular patterns (PAMPs); once activated they engulf and kill microorganisms, especially bacteria and fungi; in doing so they release a range of proinflammatory cytokines and have the capacity to present fragments of the microorganisms to T lymphocytes (see below) in a process called antigen presentation.

Macrophages have proinflammatory and microbicidal capabilities similar to those of neutrophils. Under activation conditions, antigen presentation (see p. 62) is enhanced and a range of cytokines secreted, notably TNF-α, IL-1 and IFN-γ.

Dendritic cells

The major function of dendritic cells (DCs) is that they alone are capable of activating naïve T lymphocytes to initiate adaptive immune responses. The definition of a dendritic cell is one that has:

- **dendritic morphology** (Fig. 3.4)
- **machinery for sensing pathogens**
- **the ability to process and present antigens to CD4 and CD8 T lymphocytes, coupled with the ability to activate these T cells from a naive state**
- **the ability to dictate the T cell’s future function and differentiation**.

This is a powerful cell type, that functions as a critical bridge between the innate and adaptive immune systems. In a sequence of events that spans 1–2 days, immature DCs are activated by PAMPs in the tissues and migrate to the local lymph node with the engulfed pathogen. During migration the DC matures, upregulating machinery required to activate T lymphocytes. Once in the lymph node, the DC interacts with naïve T lymphocytes (antigen presentation), resulting in two key outcomes. First is the activation of T cells with the ability to recognize peptide fragments (termed epitopes) of the pathogen; second is the polarization of the T cell towards a functional phenotype (see below) that is tailored to the particular pathogen.

The major types are the myeloid DC (mDC), the plasmacytoid DC (pDC) and a variety of specialized DCs found in tissues that resemble mDCs (e.g. the Langerhans cell in the skin, see Fig. 23.1). DCs have several distinctive cell surface molecules, some of which have pathogen-sensing activity (e.g. DEC205 on mDCs) whilst others are involved in interaction with T cells (Table 3.6). Immature mDCs and pDCs are present in the blood, but at very low levels (<0.5% of lymphocyte/monocyte cells).

Pathogen sensing is a key component of the function of immature DCs, as well as monocytes/macrophages, and is achieved through expression of a limited array of specialized PRR molecules capable of binding to structures common...

**Table 3.7** Toll-like receptors (TLR)

mDC: myeloid dendritic cell; pDC: plasmacytoid dendritic cell.

It is upregulated by bacterial lipopolysaccharides but not in non-infective disorders.

The key principle at play here is that the immune system has devised a means of identifying most types of invading microorganisms by using a limited number of PRRs recognizing common molecular patterns, or PAMPs. This recognition event has been termed a ‘danger signal’: it alerts the immune system to the presence of a pathogen. Sensing danger is a key role of the DC and a key first step towards activation of the adaptive immune system.

**DCs and T cell activation**

The binding of a PAMP to a PRR activates the DC, resulting in one of the most amazing phenomena in cell biology as an immature DC changes its shape, gene and molecular profile and function within a matter of hours to take on a mature form, with altered functions (Table 3.8 and Fig. 3.5). Immature pDCs are small rounded cells that develop dendrites upon activation and function within a matter of hours to take on a mature form, with altered functions (Table 3.8 and Fig. 3.5). Immature pDCs are small rounded cells that develop dendrites upon activation and secrete enormous quantities of IFN-α, a potent antiviral and proinflammatory cytokine.

The net result of these changes is that the mature DC is ready to activate naïve T cells in the lymph node. The mature DC provides three major signals to naïve T cells:

- Signal 1 = presentation of peptide fragments from the pathogen bound to surface HLA molecules.
- Signal 2 = co-stimulation through CD80 and CD86 interacting with CD28 on T cells.
- Signal 3 = secretion of cytokines, notably IL-12.

**HLA MOLECULES AND ANTIGEN PRESENTATION**

On the short arm of chromosome 6 is a collection of genes representing 0.1% of the whole genome and termed the major histocompatibility complex (MHC), which plays a critical role in immune function. In particular, the MHC contains a group of genes that code for proteins expressed on the surface of a variety of cell types that are involved in antigen recognition by T lymphocytes. In humans, these are known as the human leukocyte antigens, or HLA system. The T lymphocyte receptor for antigen recognizes its ligand pre-
The immune system and disease

HLA genes are particularly interesting for clinicians and biologists. First, differences in HLA molecules between individuals are responsible for tissue and organ graft rejection (hence the name histocompatibility). Second, the differences are many, as this is the most polymorphic region of the human genome. Third, possession of certain HLA genes is linked to susceptibility to particular diseases (Table 3.9).

**The human major histocompatibility complex**

The human MHC comprises three major classes (I, II and III) of genes involved in the immune response (Fig. 3.6 and see Table 3.9).

In addition, several genes lie in the HLA region but do not fall into any of the three major categories.

- **Classical class I HLA genes** (also termed Ia) are designated HLA-A, HLA-B and HLA-C. Each encodes a class I α chain, which combines with a β chain to form the class I HLA molecule (the same β chain, called β2-microglobulin, is used for all α chains). The HLA class I molecule has the role of presenting short (8–10 amino acids) antigenic peptides to the T cell receptor on the subset of T lymphocytes that bear the co-receptor CD8. As an example of HLA polymorphism, there are nearly 200 allelic forms at the A gene locus. Class I HLA molecules are expressed on all nucleated cells.

- **Non-classical HLA class I genes** are less polymorphic, have a more restricted expression on specialized cell types, and present a restricted type of peptide or none at all. These are the HLA-E, F, and G (Ib genes) and MHC class I-related (MIC, or class Ic) genes, A and B. The products of these genes are predominantly found on epithelial cells, signal cellular stress and interact with lymphoid cells, especially natural killer cells (see p. 66).

- **The class II genes** have three major subregions, DP, DQ and DR. In these subregions are genes encoding A and B genes that combine to form dimeric αβ molecules that present short (12–15 amino acid) peptides to T lymphocytes that bear the CD4 co-receptor. Class II HLA genes (apart from DRA) are highly polymorphic. Other genes in this region encode proteins with key roles in antigen presentation (e.g. TAP, HLA-DM, HLA-DO, proteasome subunits; see below). Class II HLA genes are expressed on a restricted cohort of cells, that go by the general term of antigen presenting cells (APCs; DCs, monocyte/macrophages, B lymphocytes).

- **HLA class III genes** encode proteins that can regulate/modify immune responses, e.g. tumour necrosis factor (TNF), heat shock protein (HSPs) and complement protein (C2, C4).

HLA genotype is a risk factor for certain inflammatory diseases (Table 3.9) and also determines donor–recipient compatibility in transplantation and is denoted first by the letters that designate the locus (e.g. HLA-A, DR, DQ). For class I alleles, this is followed by an asterisk and then a two- four digit number defining the allelic variant at that locus, often called the HLA type (e.g. HLA-A*02 is the 02 variant of the HLA-A gene). The class II nomenclature is the same, except that both A and B genes are named (HLA-DR molecules only require the name of the B gene, as the A gene is the same in all of us).

Some general principles apply to the HLA genes and their protein products.

First, the presence of multiple genes on each chromosome, and the fact that both maternal and paternal genes are co-dominantly expressed, allows considerable breadth in the number of HLA molecules that an individual expresses.
The immune system and disease

The presence of polymorphisms at each locus provides great breadth in the number of HLA molecules expressed at a population level. The polymorphic forms of HLA molecules differ predominantly in the peptide-binding groove (Fig. 3.7).

Second, the presence of polymorphisms at each locus provides great breadth in the number of HLA molecules expressed at a population level. The polymorphic forms of HLA molecules differ predominantly in the peptide-binding groove (Fig. 3.7).

Overall, then, each human can bind a range of peptide epitopes from pathogens to enhance individual protection, and the population an even greater range of protection, to ensure population survival.

Antigen presentation

HLA molecules bind short peptide fragments which are processed (‘chopped up’) from larger proteins (antigens) derived from pathogens. The peptide–HLA complex is presented on antigen presenting cells (APCs) for recognition by T cell receptors (TCRs) on T lymphocytes. There are three major routes to antigen processing and presentation:

- **The endogenous route** is a property of all nucleated cells and samples the internal milieu to generate peptide–HLA class I complexes for display on the cell surface. In a healthy cell, the peptides will be derived from self-proteins from the cytoplasm (Fig. 3.8), and will be ignored by the immune system. In a virus-infected cell, viral proteins are processed and presented. The resulting viral peptide–HLA class I complex is presented to CD8 T lymphocytes with cytotoxic (killer) function. In an immune response against a virus infection, CD8 T lymphocytes recognizing viral peptide–HLA complexes on the surface of an infected cell will kill, as a means to limit and eradicate infection.

- **The exogenous route** is a property of APCs and samples the external milieu (Fig. 3.9). Antigens are internalized, either in the process of phagocytosis of a pathogen, through pinocytosis, or through specialized surface receptors (e.g. for antigen/antibody/complement complexes). Within specialized intracellular compartments, the antigen is broken down by a combination of low pH and proteolytic enzymes for loading into HLA class II molecules. The pathogen peptide–HLA class II complex at the APC surface is able to interact with CD4 T lymphocytes. Presentation by DCs can initiate an adaptive immune response by activating a naïve, pathogen-specific CD4 T lymphocyte. Presentation by monocyte/macrophages and B lymphocytes can maintain and enhance this response by activating effector and memory pathogen-specific CD4 T lymphocytes.

- **Cross-presentation** refers to the ability of some APCs (mainly DCs) to internalize exogenous antigens and process them through the endogenous route (Fig. 3.8). This is an essential component in the activation of CD8 cytotoxic T lymphocyte responses against a virus.

# Cells and Molecules of the Adaptive Immune System

The information gained by DCs that interact with a pathogen is passed on, in the form of signals 1–3 (see Fig. 3.5b), to generate the adaptive arm of the immune response, a process through which specific recognition and removal of pathogens is organized by T lymphocytes. T lymphocytes may be involved in pathogen removal directly (e.g. by killing) or indirectly (e.g. by recruiting B lymphocytes to make specific antibody).
Antigen receptors on T and B lymphocytes

One of the key features of the adaptive immune system is specificity for antigen. For example, if you are immunized against measles virus, you do not have immunity to hepatitis B, and vice versa. Specificity is conferred by two types of receptor – the TCR on T lymphocytes and an equivalent on B lymphocytes, the BCR. BCRs are also termed surface immunoglobulin (sIg) and differ from TCRs in also being secreted in large quantities by end-stage B lymphocytes (plasma cells) as soluble immunoglobulins, commonly known as antibodies. To maintain protection against the multiplicity of pathogens in our environment, each of us generates great diversity amongst TCRs and antibodies. This is achieved through a mechanism shared by both TCR and antibody, in which distinct families of genes are encoded in the germline, each family (called constant, variable, diversity and joining) contributing a sequence to part of the receptor. Recombination between randomly selected members of each family ensures diversity in the end product. Recombination frequently involves base deletions and additions, adding to the diversity. In the case of antibodies, the result is a potential capacity of $>10^{13}$ different antibody molecules; for TCRs it may be as high as $10^{16}$.

Immunoglobulins

These are produced from plasma cells which are end stage B cells. In structural terms, antibodies have four chains; two identical heavy and two identical light chains (Fig. 3.10). Each chain contains both highly variable and essentially constant regions. The variable parts of the heavy and light chains pair to form the potentially diverse part of the antibody molecule that binds antigen. The constant region of the heavy chain dictates the function of the antibody, and belongs to one of the classes M, G1-4, A1-2, D and E, giving rise to antibodies called IgM, IgG1-4, IgA1-2, IgD and IgE. The characteristics of these different isotypes are shown in Table 3.10.

Essential points about antibody production are:

- IgM is the first isotype to be made in a primary immune response and thus measurement of pathogen specific IgM is a useful diagnostic test for recent infection.
- IgG dominates in the second exposure to antigen.
- IgG and IgM are the most efficient complement activators when bound to antigen in an immune complex.
- IgG antibodies cross the placenta, and can carry both immunity and disease to the unborn fetus.

![Fig. 3.10 Immunoglobulin structure.](image)

(a) Basic subunit consisting of two heavy and two light chains.
(b) Schematic diagram of the same molecule. C and V, constant and variable domains; H and L, heavy and light chains; Fab, fragment antigen binding; Fc fragment crystalline.
(c) Genes on the Fab and Fc regions of an immunoglobulin. The chain is made up of a V (variable) gene which is translocated to the J (joining) chain. The VJ segment is then spliced to the C (constant) gene. Heavy chains have an additional D (diversity) segment which forms the VDJ segment that bears the antigen-binding site determinants.

Cells and molecules of the adaptive immune system
IgA antibodies are present in secretions (tears, saliva, GI tract) to give protection to the mucosae.

As it matures, and under the instruction of T lymphocytes, a B lymphocyte may change the class (class switching), but never the specificity, of the antibody it makes.

As B lymphocytes mature and are stimulated to undergo further division, minor changes in antibody gene sequence can arise (somatic mutation) potentially allowing antibodies with higher affinity to arise and be selected for the effector response (affinity maturation).

Essential points about antibody function are:

- In host defence, antibodies target, neutralize and remove from the circulation and tissues infectious organisms and toxins, often through recruitment of innate host effector mechanisms such as complement, phagocytes and mast cells (by binding to specific surface receptors).
- In clinical medicine, specific antipathogen antibody levels are used in diagnosing/monitoring infectious disease, and may also be administered as serum pools to passively provide host protection.
- Antibodies can be raised in animals to generate monoclonal antibodies, which are commonly used in diagnostic immunology tests and increasingly used as therapeutics (e.g. to target cancer cells), often after ‘humanization’ (see below).

The genomic organization of TCR genes and principles of generation of receptor diversity are similar to those of immunoglobulin genes. The TCR exists as a heterodimer, with a similar overall structure as the antibody molecule. There are two TCR types:

- α and β chain (αβ TCR; expressed on all CD4 T lymphocytes and ~90% of CD8 T lymphocytes play a role in adaptive immune responses)
- γ and δ chains (γδ TCR fewer in number, mainly on intraepithelial lymphocytes; involved in epithelial defence).

The chains of each type of TCR are divided into variable and constant domains, each domain being encoded by separate gene pools. Like the B lymphocyte producing a single clone of immunoglobulin molecules, the T cell expresses only one form of TCR once the genes have been rearranged. Unlike antibodies, TCRs do not undergo somatic hypermutation and are not secreted.

**T lymphocyte development and activation**

T cells are generated from precursors in the bone marrow, which migrate to the thymus (Fig. 3.11). Only 1% of the cells that enter will leave the thymus as naïve T lymphocytes to populate the lymph nodes. This process (termed thymic selection) leads to a cohort of cells (Table 3.11) with:

- functionally rearranged genes allowing surface expression of a receptor for antigen (the T cell receptor, TCR) alongside the CD3 accessory molecule involved in transducing the antigen-specific signal
- selection of a co-receptor, either CD4 or CD8, to stabilize the interaction between TCR and peptide–HLA:
  - CD4 T cell responses require presentation of peptide antigens by self HLA class II molecules
  - CD8 T cell responses require presentation of peptide antigens by self HLA class I molecules
- a reduced or absent tendency of the selected TCR to recognize self antigens (and thus avoid autoimmunity).

Thus, during thymic education most TCRs are rejected for further use (negative selection), either because they are unable to bind self HLA molecules, or because they bind with too strong an affinity, which would run the risk of self-reactivity and autoimmune disease. The chosen TCRs (positive selection) have low/intermediate affinity for self HLA molecules. During post-thymic activation in the lymph node, the interaction with HLA will need to be bolstered by addi-
Cells and molecules of the adaptive immune system

Regulatory T cells

The generation of B and T lymphocytes provides a potentially vast array of rearranged antigen receptors. Although there are selection processes to remove lymphocytes with ‘dangerous’ avidity for ‘self’ these are not foolproof and the potential for autoreactivity remains. The fact that there is no self-destruction in the vast majority of people implies a state of immunological self-tolerance; the controlled inability to respond to self. Several mechanisms operate to maintain this state, including CD4 T lymphocytes that respond to antigenic stimulation by suppressing ongoing immune responses. These regulatory T cells (Tregs) have different origins, phenotypes and modes of action:

</tbody>
</table>

Major functions of CD4 T lymphocytes are:

- licensing of DCs during antigen presentation to activate CD8 T lymphocytes and generate cytotoxic cells
- licensing of B lymphocytes to initiate and mature antibody responses, leading to class switching, affinity maturation of antibodies and generation of plasma cells or memory cells
- secretion of cytokines responsible for growth and differentiation of a range of cell types, especially other T cells, macrophages and eosinophils
- regulation of immune reactions.
CD4+ CD25hi Tregs; express high levels of CD25, the receptor for IL-2; regulate other T cells by cell-cell contact and also secrete the immune suppressive cytokines IL-10 and TGF-β; can be generated in the thymus or post-thymically in the periphery; have high expression of the transcription factor Foxp3.

- Tr1 Tregs; generated naturally or induced (e.g. by repeated antigen injection); regulate through production of IL-10.

Evidence that Tregs are clinically relevant is given by the example of immune deficiency states in which they are defective. For example, genetic defects in the Foxp3 gene give rise to IPEX (Immune dysregulation, Polyendocrinopathy, Enteropathy, X-linked syndrome). Patients with this rare syndrome have defective Tregs and develop a range of conditions soon after birth, including organ-specific autoimmune disease such as type 1 diabetes. Much research effort is directed at harnessing this natural regulatory potential, for example to control organ graft rejection and autoimmune disease.

**CD8 T lymphocyte functions**

Cytotoxic CD8 T lymphocytes (CTLs) are involved in defence against viruses. CTLs kill virus-infected cells following recognition of viral peptide–HLA class I complexes. CTL must be activated first in the lymph node by a DC cross-presenting the same viral peptide and licensed by a CD4 T lymphocyte recognizing viral peptide–HLA class II complexes. The same defence mechanism may also apply in tumour surveillance. This is a checkpoint that ensures that CTL responses, which have great destructive power, are only activated against a target for which there is also a CD4 T cell response.

CTLs kill via three mechanisms:

- cytotoxic granule proteins (cytolysins such as perforin, granzyme B)
- toxic cytokines (e.g. IFN-γ, TNF-α)
- death-inducing surface molecules (e.g. Fas ligand binds Fas on target cells mediating apoptosis via caspase activation) (see p. 28).

**Natural killer (NK) cells**

These are bone marrow-derived, present in the blood and lymph nodes and represent 5–10% of lymphoid cells. The name is derived from two features. Unlike B and T lymphocytes, NK cells are able to mediate their effector function (i.e. killing of target cells) spontaneously in the absence of previous known sensitization to that target. Also, unlike B and T lymphocytes, NK cells achieve this with a very limited repertoire of germ line-encoded receptors that do not undergo somatic recombination. The lack of requirement for sensitization and the absence of gene rearrangement to derive receptors for target cells mean that NK cells are part of the innate immune system. For identification purposes, the main surface molecules associated with NK cells are CD16 (see below) and CD56 (note, NK cells are CD3- and TCR-negative).

The role of NK cells is to kill ‘abnormal’ host cells, typically cells that are virus-infected, or tumour cells. Killing is achieved in similar ways to CTLs. NK cells also secrete copious amounts of IFN-γ and TNF-α, through which they can mediate cytotoxic effects and activate other components of the innate and adaptive immune system. To become activated, NK cells integrate the signal from a potential target cell through a series of receptor-ligand pairings (Table 3.13).

</tbody>
</table>

KIR, killer cell immunoglobulin-like receptors.

These pairings provide activating and inhibitory signals, and it is the overall balance of these that determines the outcome for the NK cell. The balance might be abnormal on a virus-infected or tumour cell, which might have altered expression of HLA molecules, for example, that mark them out for NK cytotoxicity. In addition, CD16 is the low affinity receptor for IgG (FcyRIIA) and through this NK cells can kill IgG-coated target cells in a process termed antibody-dependent cellular cytoxicity (ADCC).

As for T cells, NK cell activation requires initial contact, adhesion and polarization. It is not known which of the inhibitory or activating receptors (Table 3.13), if any, is the first to initiate target cell contact. Once contact is made, adhesion occurs and is predominantly mediated by LFA-1:ICAM-1 interactions (see below). These events polarize the NK cell on to its target and direct the release of granules and cytokines. One of the targets of NK cell activating receptors, MICA, is induced under conditions of cellular ‘stress’, such as might arise during infection or neoplastic transformation.

In practice, in vivo, how does the process of NK killing occur? Many viruses have developed immunoevasion strategies that avoid presentation of viral proteins to CTLs by interfering with the MHC class I presentation pathway. This renders infected cells susceptible to killing by NK cells, which detect the reduced levels of MHC class I molecules. Likewise, tumours that escape immune surveillance by CTLs through the outgrowth of daughter cells that have low MHC expression, then become NK cell targets. The relatively recent development of NK cell receptor diversity implies a strong evolutionary driving force, probably related to viral immunoevasion strategies. KIR–HLA interactions (KIR = killer cell immunoglobulin-like receptors) are thus vital to antiviral immunity, and this is confirmed by the numerous associations between KIR and HLA genotype combinations and susceptibility to chronic infection with viruses, notably the human immunodeficiency virus (see p. 184).

**CELL MIGRATION**

Immune cells are mobile. They can migrate into the lymph node to participate in an evolving immune response (e.g. a pathogen-loaded dendritic cell (DC) from the skin, or a recirc-
Fig. 3.12 Movement of an immune cell through a lymph node.

(a) T cells migrate through endothelial venules which express the chemokine CCL21 (secondary lymphoid tissue chemokine or SLC). (b) Dendritic cells (expressing CCR7), macrophages (expressing CCR2) enter lymph nodes via afferent lymphatics and localize in the paracortex. (c) Antigen presentation (see also Figs 3.8 and 3.9) results in activation of T cells. (d) Effector T cells leave lymph node via efferent lymphatic. Adapted from Charo IF, Ransohoff RM. New England Journal of Medicine 2006; 354: 610–621, figure 1. Copyright © 2006 Massachusetts Medical Society. All rights reserved.

Circulating naïve T cell), or can migrate from the lymph node, via the blood, to the site of a specific infection in the tissues. Such migration takes place along blood and lymphatic vessels, and is a highly regulated process.

Taking the example of a DC migrating into the lymph node from the tissues via the lymphatics (Fig. 3.12), this is highly dependent upon expression of the chemokine receptor CCR7 by the migrating cell and of its ligand (secondary lymphoid tissue chemokine, SLC or CCL21) by the target tissue. Likewise, circulating naïve lymphocytes are CCR7⁺ and migrate with ease into the lymph nodes from the blood or via tissue recirculation. In addition, naïve lymphocytes express L-selectin which binds a glycoprotein cell adhesion molecule (GlyCAM-1) found on the high endothelial venules of lymph nodes. This system can be upregulated in an inflamed lymph node, leading to an influx of naïve lymphocytes and the typical symptom of a swollen node.

Migration into inflamed tissue requires that:

(i) an affected organ or tissue signals that there is a focus of injury/infection and
(ii) that responding immune cells bind and adhere specifically to that tissue.

This process is highly organized and has a similar basis for all immune cells, involving three basic steps: rolling, adhesion and trans-migration. Each of these is dependent on specialized adhesion molecules, as shown in Figure 3.13.

- **Rolling** is mediated by selectins. P-selectin, E-selectin and L-selectin (for Platelet, Endothelium and Leucocyte, respectively) are named after the predominant cell type that expresses them and bind to carbohydrate moieties such as sialyl-LewisX (CD15s) on immune cells inducing them to slow and roll along the vessel lumen.

- **Adhesion** is mediated by integrins on immune cells binding to intercellular adhesion molecules (ICAMs) on the endothelium. The best known integrin is the heterodimer of CD11a/CD18 (called leucocyte function associated antigen-1; LFA-1) which binds ICAM-1.

- **Trans-migration** (diapedesis) is a complex process that includes structures known as platelet-endothelial cell adhesion molecule-1 (PECAM-1) and junctional adhesion molecules (JAMs).

The controlled regulation of these molecules (e.g. LFA-1 expression) is upregulated on T cells after activation in the lymph node. ICAM-1 expression on tissue endothelium is sensitive to numerous proinflammatory molecules and allows immune cells to be guided from the blood into the tissues. Once there, cells move along a gradient of increasing...
**Fig. 3.13 Neutrophil migration.** Neutrophils arrive at the site of the inflammation, attracted by various chemoattractants. They roll along the blood vessel wall through interaction between L-selectin, on their surface, binding to a carbohydrate structure (e.g. sialyl-Lewis”) on the endothelium. E-selectin on the endothelium mediates a similar effect.

Firm adhesion is then mediated via interaction between integrins on the neutrophil and ICAM-I/VCAM-1 on the endothelium. Following diapedesis, mediators such as interleukin-8, macrophage-chemotactic factor and TNF-α attract and activate the neutrophil to the infected tissue where it phagocytoses and destroys the C3b-coated bacteria.

LFA, leucocyte function antigen; PAF, platelet activating factor; LTB₄, leukotriene B₄; ICAM, intercellular adhesion molecule; VCAM, vascular cell adhesion molecule.

concentration of mediators such as chemokines in the process of chemotaxis.

### THE IMMUNE SYSTEM IN CONCERT

#### Acute inflammation: events and symptoms

This is the early and rapid host response to tissue injury. Taking a bacterial infection as the classic example, local expansion of pathogen numbers leads to direct activation of complement in the tissues, with ensuing degranulation of mast cells. Inflammatory mediators (from mast cells and complement) change the blood flow and attract and activate granulocytes. Concomitantly there are the local symptoms of heat, pain, swelling and redness, and perhaps more systemic symptoms such as fever due to the effect of circulating cytokines (IL-1, IL-6, TNF-α) on the hypothalamus. Systemically active mediators (especially IL-6) also initiate the production of C reactive protein (CRP) in the liver. Bacterial lysis follows through the actions of complement and neutrophils, leading to formation of fluid in the tissue space containing dead and dying bacteria and host granulocytes (‘pus’). The inflammation may become organized and walled off through local fibrin deposition to protect the host. Antigens from the pathogen travel via the lymphatics (which may become visible as red tracks in the superficial tissues – lymphangitis) in soluble form or are carried by dendritic cells to establish an adaptive immune response which, at the first host-pathogen encounter, takes approximately 7–14 days. This will lead to activation of pathogen-specific T cells, B cells and production of pathogen-specific antibody, initially of the IgM class and of low-moderate affinity and subsequently of the IgG class (or IgA if the infection is mucosal) and high affinity. Resolution of the infection is aided by the scavenging activity of tissue macrophages.

#### Chronic inflammation: events and symptoms

Inflammation arising in response to immunological insults that cannot be resolved in days/weeks gives rise to chronic inflammation. Examples include infectious agents (chronic viral infections such as hepatitis B and C or intracellular bacteria such as mycobacteria) and environmental toxins such as asbestos and silicon.

Chronic inflammation is also a hallmark of some forms of allergic disease, autoimmune disease and organ graft rejection. The common feature of these pathological processes is that the inciting stimulus is not easy to remove. For example, some viruses and mycobacteria remain hidden intracellularly; antigens that incite allergy (allergens) may be constantly present in the host’s environment; self or donated organs are a resident source of antigens. In many ways, the pathology that results is thus inadvertent; the immune system is caught between the repercussions of not dealing with the infection/insult, and the tissue damage that is caused by chronic activation of lymphoid and mononuclear cells.

Chronic inflammation may lead to permanent organ damage or impaired vascular function and can be fatal. If the inciting stimulus is removed, inflammation resolves. However, inflammation returns rapidly (24–48 hours) on re-exposure. This rapid recall response is the basis for patch testing to identify the cause of contact dermatitis, another form of chronic inflammation, and also for the Mantoux test of tuberculosis immunity. Together, these forms of immunopathology used to go under the umbrella term ‘Type IV hypersensitivity’.

The main immunological event is the presence of a pro-inflammatory focus comprising T and B lymphocytes and APCs, especially macrophages. If antigen persists, inflammation becomes chronic and the macrophages in the lesion fuse to form giant cells and epithelioid cells. Both Th1 and Th2 reactivity is recognized, but specific syndromes may be polarized towards one or the other (e.g. chronic mycobacterial or viral infection engenders Th1 responses, chronic allergic inflammation Th2).

When the inflammation is sufficiently chronic it may take on the appearance of organized lymphoid tissue resembling a lymph node germinal centre (e.g. in the joints in rheumatoid arthritis). There is massive cytokine production by T cells and APCs, which contributes to local tissue damage. Granuloma, which ‘wall off’ the inciting stimulus, may also arise and result in fibrosis and calcification. Symptoms typically relate to the site of the inflammation and the type of pathology, but there may also be systemic effects such as fever and weight loss.
In the clinical immunology laboratory, proteins and cells can be measured to ascertain the status of the immune system. The results may indicate an undiagnosed inflammatory or infectious disease (e.g. through high C-reactive protein level); a state of immune deficiency (e.g. low concentration of IgG); or a state of immune pathology (e.g. the presence of auto-antibodies or allergen-specific IgE).

Examples of the commoner tests and their interpretation are shown in Table 3.14.

### CLINICAL IMMUNODEFICIENCY

**Secondary (acquired) versus primary immunodeficiency** (Table 3.15)

Most forms of immunodeficiency are secondary – to infection (mainly HIV) or therapy (e.g. corticosteroids, anti-TNF-α monoclonal antibody therapy, cytotoxic anticancer drugs, bone marrow ablation pre-transplant). *Acquired neutropenias* are common (e.g. due to myelosuppression by disease or drugs or the increased rate of destruction in hypersplenism or autoimmune neutropenia) and carry a high risk of infection once the neutrophil count falls below 0.5 \(\times 10^9\)/L.

Acquired reductions in levels of immunoglobulins (hypogammaglobulinaemia) are seen in patients with myeloma and chronic lymphocytic leukaemia or lymphoma. Splenectomy causes impairment of defence against capsulated bacteria, especially pneumococcus, and such patients should receive pneumococcal, meningococcal and Hib vaccinations as a matter of course (see p. 423).

Primary immunodeficiency is rare and arises at birth as the congenital effect of a developmental defect or as a result of genetic abnormalities. Gene defects may not become manifest until later in infancy or childhood, and some forms of immunodeficiency typically present in adolescence or adulthood.

**Clinical features of immunodeficiency**

The infections associated with immunodeficiency have several typical features:
These patients have defective is a milder mixed deficiency such as transfusions or transplantation. This is an X-linked defect of immunocompetent T lymphocytes from an HLA non-identical donor (see below). GVHD usually arises from therapeutic interventions; and deficiency of IL-2, the T cell growth factor. These disorders are similar in presentation and management to the combined (T and B lymphocyte) immune deficiencies.

**Primary immunodeficiency**

### T lymphocyte deficiency

**DiGeorge syndrome** is due to T cell deficiency. The third and fourth pharyngeal arches, which normally give rise to the parathyroid glands, aortic arch and the thymus, fail to develop. DiGeorge arises in 1–5 per 100 000 of the population and presents at birth with dysmorphic facies, hypoparathyroidism and cardiac defects, followed by infections (fungi, protozoal) in later months. The lack of a location for T cell development, i.e. the thymus, means that affected children have reduced/absent T lymphocyte number and proliferation responses. Apart from calcium supplementation, correction of cardiac abnormalities and prophylactic antibiotics, cure has been reported with thymic transplantation using fetal tissue or stem cell transplant (SCT) from HLA identical siblings.

**Other T cell deficiencies** caused by single gene defects have been characterized and typically present from the age of 3 months with candidal infections of the mouth and skin, protracted diarrhoea, fever and failure to thrive. Examples include deficiency of CD3 itself; defects in signal transduction pathways; and deficiency of IL-2, the T cell growth factor. These disorders are similar in presentation and management to the combined (T and B lymphocyte) immune deficiencies.

### Other T cell deficiencies

**Severe combined immunodeficiencies (SCID)** are a heterogeneous group of rare (1–2 live births per 100 000), genetically determined disorders resulting from impaired T, NK and B cell immunity. The most common form of SCID is an X-linked defect in the IL-2 receptor γ chain, interfering with the function of not just IL-2 but also IL-4, IL-7, IL-9 and IL-15 which share this component in their receptors. Clinical features are similar to pure T cell deficiency and in the blood T and NK cells are lacking whilst B cell numbers may be normal. The most successful treatment for all forms of SCID is SCT, preferably from HLA-identical donors such as siblings.

**Hyper IgM syndrome (HIGM)** is a milder mixed deficiency, which may not be diagnosed until later in life. It results from an X-linked defect in the CD40 ligand (CD40L (ligand); CD154) gene. Signalling between CD40 on B cells and CD40L on T cells is necessary for the generation of class switched B cells bearing high affinity immunoglobulin, as well as for the maturation of the T cell response. In CD40L deficiency, B cells are trapped at the immature level producing only IgM. Levels of other types of immunoglobulin IgG and IgA are absent/low and there are mild defects in T cell function.

Opportunistic infections occur, for example pneumocystis, cryptosporidium, herpes viral infections, candida and cryptococcus.

**Wiskott-Aldrich syndrome.** This is an X-linked defect (at Xp11–23) in a gene involved in signal transduction and cytoskeletal function with associated eczema and thrombocytopenia; a mainly cell-mediated defect with falling immunoglobulins is seen, and autoimmune manifestations and lymphoreticular malignancy may develop.

**Ataxia telangiectasia.** These patients have defective DNA repair mechanisms and have cell-mediated defects with low IgA and IgG2; lymphoid malignancy is again common.

**EBV associated immunodeficiency (Duncan’s syndrome).** Apparently normal, but genetically predisposed (usually X-linked) individuals develop overwhelming EBV infection, polyclonal EBV-driven lymphoproliferation, combined immunodeficiency, aplastic anaemia and lymphoid malignancy. EBV appears to act as a trigger for the expression of a hitherto silent immunodeficiency.
B lymphocyte deficiency

X-linked agammaglobulinaemia (XLA) presents soon after maternal IgG protection fails, with recurrent infections of the upper and lower respiratory tract with pyogenic organisms, enteritis and malabsorption. Morbidity and mortality are high, mainly due to chronic lung disease and CNS infections with enteroviruses. IgG levels are usually much less than 2.0 g/L (a 1–2-year-old child will usually have an IgG level of 3.5–14 g/L) and all five classes of immunoglobulins are affected, with total levels of less than 2.5 g/L (typically >4 g/L at age 1–2 years). B cell development is arrested at the pre-B stage and B cells are absent in the blood. The cause is a loss of function mutation on chromosome Xq22 affecting the gene for a tyrosine kinase involved in cell activation and maturation.

Treatment is by i.v. immunoglobulins (IVIg) to a level that controls infections. Trough IgG concentrations should remain within normal limits (i.e. >5–6 g/L). Prognosis has improved in recent years as more patients survive into adulthood, but chronic lung disease and lymphomas are life-threatening complications.

Selective IgA deficiency (IgAD; serum IgA <0.05 g/L), with normal levels of IgG and IgM, is found in approximately 1/600 northern Europeans, making it the most common primary immunodeficiency, although the underlying defect is unknown. Patients typically present at any age with recurrent infections caused by pyogenic organisms and affecting mucosal sites. Treatment mainly comprises antibiotics. Some IgAD patients produce anti-IgA antibodies of the IgG and IgE class. Infusion of exogenous IgA (e.g. during a blood transfusion) could therefore result in anaphylaxis. IgAD patients should therefore be screened for anti-IgA antibodies, and transfused if necessary with washed red cells, blood from an IgAD donor or with stored aliquots of their own blood.

Common variable immunodeficiency (CVID) is a heterogeneous disease affecting 1/50 000 and arising during late childhood and early adulthood, with IgG levels <0.5 g/L. Presenting with recurrent upper and lower respiratory tract infections is typical and may progress to chronic bronchiectatic lung disease, malabsorption and diarrhoea. There may be additional features of T cell deficiency. Genetic defects underlying the condition have revealed a mutation in the gene encoding ICOS-L (ligand for inducible co-stimulator on activated T cells). IVIg and antibiotics are the treatments of choice.

Defects in antigen presenting cell function

A series of rare genetic defects have been uncovered in which APCs demonstrate an inability to mount protective responses to intracellular bacteria, particularly low virulence mycobacteria and salmonella. The axis affected is the interplay between CD4 T cells and APCs which drives Th1 responses, and therefore in turn activates mononuclear cells such as macrophages to kill and eradicate intracellular pathogens. Defective genes so far identified include those encoding a component chain of IL-12; a component chain of the IL-12 receptor; and IFN-γ receptor chains 1 or 2.

Neutrophil defects

Chronic granulomatous disease (CGD) is a rare (1/250 000) immunodeficiency due to a defect in neutrophil killing and characterized by deep-seated infections. The functional defect is an inability to generate antibacterial metabolites through the respiratory burst (see Table 3.4). Typical onset is at toddler age. Neutrophil numbers are normal or increased. A simple respiratory burst test of neutrophil function is diagnostic. Treatment of infections and prophylactic antibiotic and antifungal therapy are required. Immunotherapy with interferons may have a role in patients with intractable infections, and in some cases SCT is required.

Leucocyte adherence deficiency (LAD) results from defects in integrins (see p. 26). Numerous underlying defects in the gene encoding one of the component chains, CD18, have been described in LAD-I. LAD-I has an autosomal recessive inheritance presenting almost immediately after birth, with delayed umbilical cord separation. Recurrent infections similar to those in chronic granulomatous disease appear during the first decade of life. Blood neutrophil levels are high but cells are absent from the sites of infection, which require aggressive antimicrobial and antifungal treatment, and SCT for cure.

Hyper IgE syndrome (or Job’s syndrome) is an autosomal dominant (occasionally sporadic) immune disorder with high serum IgE levels, dermatitis, boils, pneumonias with cyst formation and bone and dental abnormalities. Mutations in STAT3 have been found.

Shwachman’s syndrome can resemble cystic fibrosis clinically with exocrine pancreatic insufficiency and pyogenic infections. A mild neutropenia is associated with a defect of neutrophil migration.

Chédiak–Higashi syndrome is a rare, recessive disorder due to a mutation in the lysosomal trafficking regulator gene (LYST) on chromosome 1q42–45. There are defects in neutrophil function with defective phagolysosome fusion and large lysosome vesicles are seen in phagocytes. Patients have recurrent infections, neutropenia, anaemia and hepatomegaly. Similar abnormalities in melanocytes cause partial oculocutaneous albinism.

Complement deficiency

The consequences of deficiency of complement proteins can be predicted from their functions (see Fig. 3.2).

■ Failures in innate response components (e.g. the alternative pathway) lead to impaired non-specific immunity with an increase in bacterial infections.

■ Genetically determined low levels of mannose binding lectin (MBL) are associated with a number of inflammatory and infectious diseases.

■ Failure of the classical pathway results in a tendency towards infection but also towards diseases in which immune complex deposition causes inflammation, such as systemic lupus erythematosus (e.g. C1 and C4 deficiency), vasculitis and glomerulonephritis.

An unexpected finding is that neisserial infections (e.g. meningitis due to N meningitidis) are often encountered in patients with complement defects of the membrane attack complex.

Complement regulatory proteins. Deficiency of C1 inhibitor (C1 esterase) deficiency (see also p. 1244) is relatively rare. Since this enzyme is involved in regulation of several plasma enzyme systems (e.g. the kinin system) and is continuously consumed, a single parental chromosome defect resulting in 50% of normal production barely copes with the demand and fails under stress (hence an autosomal dominant effect). As a result, uncontrolled activation of com-

Mediators involved in the allergic response

Preformed mediators

Histamine and serotonin:
- Bronchoconstriction
- Increased vascular permeability

Neutrophil and eosinophil chemotactic factors (NCF and ECF):
- Induce inflammatory cell infiltration

Newly formed mediators (membrane-derived)

Leukotriene (LT) B₄:
- Chemoattractant

LTC₄, -D₄, -E₄ (slow reacting substance of anaphylaxis, SRS-A):
- Sustained bronchoconstriction and oedema

Prostaglandins and thromboxanes:
- Platelet-activating factor (PAF)
- Prolonged airway hyperactivity

Type I Hypersensitivity and Allergic Disease

Normally host defence can cope with potentially harmful cells and molecules. Under some circumstances, a harmless molecule can initiate an immune response that can lead to tissue damage and death. Such exaggerated, inappropriate responses are termed hypersensitivity reactions or allergic disease.

In Type I (immediate) hypersensitivity the binding of an antigen to specific IgE bound to its high-affinity receptor on a mast cell surface results in massive and rapid cell degranulation and the inflammatory response outlined on page 57. The antigens involved are typically inert molecules present in the environment (termed allergens; see p. 831 and http://www.allergen.org/allergen.aspx). The immediate effects of allergen exposure are often very florid (early phase response), allergic disorders also have a second phase, occurring a few hours after exposure and lasting up to several days. These ‘late phase responses’ (LPR) are mediated by Th2 cells recognizing peptide epitopes of the allergen. Recruitment of eosinophils is often a prominent feature. From a pathological perspective, the late phase responses are termed hypersensitivity reactions or allergic disease.

In asthma the LPR gives rise to chronic inflammation which is difficult to control. In asthma the LPR gives rise to the prolonged wheezing that can be fatal. Immediate hypersensitivity is usually responsive to antihistamines but the LPR is not, requiring powerful immune modulators such as corticosteroids.

In immunopathological terms neutrophils and eosinophils are prominent in the first 6–18 hours of the LPR and may persist for 2–3 days. Th2 cells accumulate around small blood vessels and persist for 1–2 days. Mediators responsible for the cellular infiltrate include platelet activating factor and leukotrienes (Table 3.17), whilst the Th2 cytokines IL-4 and IL-5 and chemokines such as eotaxin act as growth and activation stimuli for eosinophils, which are capable of extensive tissue damage. Th2 cytokines are also responsible for the class switch of Ig production towards IgE, maintaining the cycle of immediate and late responses.

What makes an allergen so powerful? Several allergens are proteolytic enzymes allowing them to cross skin and mucosal barriers. They are often contained within small, aerodynamic particles (e.g. pollen grains) that gain access to nasal and bronchial mucosa.

Why do some people react and others not? The tendency to develop allergic responses (known as atopy) shows strong heritability. Between 20% and 30% of the UK population is atopic and two, one or no atopic parents pass on the atopic trait to their children with a risk of 75%, 50% and 15%, respectively. Amongst the predisposing genes are those encoding the β chain of the high affinity receptor for IgE and IL-4, both strongly associated with Th2 pathways. The presence of Th2 cells recognizing allergens is the pathological hallmark of allergy.

What environmental factors are involved? Early exposure to allergens (even in utero) may be a factor in developing atopy. Over-zealous attention to cleanliness (the hygiene hypothesis) in developed societies (use of antibiotics, reduced exposure to pathogens which might favour a Th1-like environment) may favour a Th2 response. This environmental factor is shown by the rapid increase of allergy in the Eastern part of Germany following reunification.

In clinical terms, approximately two-thirds of atopic individuals (who can be identified as those with circulating allergen-specific IgE) have clinical allergic disease (equating to 15–20% of the UK population). Allergy accounts for up to one-third of school absences because of chronic illness. Other allergic disorders include allergic rhinitis (hay fever), allergic eczema, bee and wasp venom allergy and some forms of food allergy, urticaria and angioedema.

Diagnosis of allergic disease is usually made on the history and backed up by skin prick testing (insertion of a tiny quantity of allergen under the skin and measurement of the size of the weal) and/or measurement of allergen-specific IgE. Mast cell tryptase serum levels peak 1–2 hours after an event remaining high for 24 hours.

Treatment

Avoidance is the first line of therapy.

- **Antihistamines** are effective for many immediate hypersensitivity reactions (but have no role in the treatment of asthma). A monoclonal antibody that mops up serum IgE (omalizumab) is also used (see p. 856).

- **Corticosteroids** have several well-identified modifying actions in the allergic process: production of prostaglandin and leukotriene mediators is suppressed, inflammatory cell recruitment and migration is inhibited and vasoconstriction leads to reduced cell and fluid leakage from the vasculature.

- **Cysteinyi leukotriene receptor antagonists (LTRAs)** inhibit leukotrienes (LTs) by blocking the type I receptor (e.g. montelukast – used in asthma, particularly aspirin induced).

- **Desensitization (allergen immunotherapy)** can be used. The principle is that allergy can be prevented by inoculation by giving the allergen in a controlled way. It is indicated for disorders in which the hypersensitivity is IgE mediated, e.g. life-threatening allergy to insect stings, drug allergy and allergic rhinitis. An induction
Anaphylaxis

The term anaphylaxis describes ‘a serious allergic reaction that is rapid in onset and may cause death’. It arises as an acute, generalized IgE-mediated immune reaction involving specific antigen, mast cells and basophils. The reaction requires priming by the allergen, followed by re-exposure. To provoke anaphylaxis, the allergen must be systemically absorbed, either after ingestion or parenteral injection and a range of allergens have been identified:

- foods: nuts (peanuts (protein-arachis hypogaea Ara h 1–3), Brazil, cashew), shellfish (shrimp (allergen Met e 1), lobster), dairy products, egg (and more rarely citrus fruits, mango, strawberry, tomato)
- venoms: wasps, bees, yellow-jackets, hornets
- medications: antisera (tetanus, diphtheria), dextran, latex, some antibiotics.

Anaphylaxis is rare, and the symptom/sign constellation ranges from widespread urticaria to cardiovascular collapse, laryngeal oedema, airway obstruction and respiratory arrest leading to death. Fatal reactions to penicillin occur once every 7.5 million injections; between 1 in 250 and 1 in 125 individuals have severe reactions to bee and wasp stings, and a death takes place every 6.5 million stings; such stings cause between 60 and 80 deaths per year in North America, and 5–10 in the UK. Central to the pathogenesis of anaphylaxis is the activation of mast cells and basophils, with systemic release of some mediators and generation of others. The initial symptoms may appear innocuous: tingling, warmth and itchiness. The ensuing effects on the vasculature give vasodilatation and oedema. The consequence of these may be no more than a generalized flush, with urticaria and angio-oedema. More serious sequelae are hypotension, bronchospasm, laryngeal oedema and cardiac arrhythmia or infarction. Death may occur within minutes. Serum platelet-activating factor (PAF) levels correlate directly with the severity of anaphylaxis whereas PAF acetylhydrolase (the enzyme that inactivates PAF) correlated inversely and was significantly lower in peanut sensitive patients with fatal anaphylactic reactions.

Early recognition and treatment are essential (Emergency Box 3.1).

The best treatment is prevention. Avoidance of triggering foods, particularly nuts and shellfish, may require almost obsessive self-discipline. Patient education is necessary and many are instructed in the self-administration of adrenaline (epinephrine) and carry pre-loaded syringes. Desensitization has a well-established place in the management of this disorder, particularly if exposure is unavoidable or unpredictable, as in insect stings.

Type I hypersensitivity and allergic disease

Autoimmune disease

Autoimmunity is when the immune response turns against self, i.e. recognizes ‘self’ antigens. The vast array of possible TCRs and antibodies that can be generated by the host make it highly probable that at least a small proportion can recognize self (i.e. are autoreactive). Moreover, a degree of auto-reactivity is physiological – the TCR is designed to interact both with the peptide epitope in the HLA molecule binding groove, and with the HLA molecule itself.

The critical event in the development of autoimmune disease is when T and B lymphocytes bearing these recep-
tors become activated. The following are the major checkpoints that the immune system has in place to prevent this:
1. removal of TCRs with very strong affinity for ‘self’ in the thymus
2. the presence of naturally arising regulatory T cells (Tregs)
3. the requirement for a danger signal to licence dendritic cells to activate CD4 T cells.

Autoimmune diseases affect 5% of the population at some stage of their life.

**Failure of Checkpoint 1, thymic education**
During thymic education, TCRs with dangerously high affinity for self are deleted. It has become apparent that such a system relies upon the thymic expression of self antigens. Situations which compromise the expression of a self protein would be expected to favour the development of autoimmunity. In a rare group of patients who develop multiple autoimmune disorders affecting the adrenal and parathyroid glands (Autoimmune Polyglandular Syndrome Type 1; APS Type 1: see p. 1026), there is a defect in the AIRE gene (for autoimmune regulator) which controls thymic expression of a host of self genes. When the gene malfunctions, there is reduced expression of self proteins in the thymus and autoimmune disease is a consequence.

**Failure of Checkpoint 2, regulatory T cells**
An example of Treg failure is the defect in the gene encoding Foxp3, a critical transcription factor in Tregs (see p. 65) that leads to IPEX (see p. 56). IPEX is very rare, but it serves to indicate how Treg defects can lead to autoimmune disease. Laboratory studies in this area are revealing subtle Treg defects in several autoimmune diseases (e.g. type 1 diabetes, multiple sclerosis, rheumatoid arthritis).

**Failure of Checkpoint 3, CD4 T cell activation against an autoantigen (or its mimic)**
For an autoimmune disease to develop, there must be presentation of autoantigens to a naïve, potentially autoreactive CD4 T cell by activated DCs. This could happen in one of two ways:

- Tissue damage due to infection leads to both the release of hidden self antigens and the provision of sufficient danger signals to activate DCs, which in turn activate autoreactive CD4 T cells as well as the pathogen-specific ones. This is often termed ‘bystander activation’.
- A pathogen mimics a self antigen. In the process of making an entirely appropriate immune response against the pathogen, T or B cells are generated that also have the capacity to recognize self. This is termed molecular mimicry.

It is unlikely that for the common autoimmune diseases (Table 3.19) there is a ‘single checkpoint’ explanation. Rather, it is likely that multiple subtle defects, at various checkpoints, are at play.

GBM, glomerular basement membrane.

**Fig. 3.14** Potential mechanisms of immune damage in autoimmune disease.
Mechanisms of tissue damage in autoimmune disease

The scheme shown in Figure 3.14 illustrates potential mechanisms of immune damage in autoimmune disease.

Autoantibodies can cause damage directly, through direct binding to a target cell or structure, with recruitment of complement and other destructive processes. Disease examples of this process include:

- **autoimmune haemolytic anaemia** (autoantibody targets red blood cell autoantigens leading to lysis)
- **myasthenia gravis** (autoantibodies against the acetylcholine receptor cause damage to the neuromuscular junction)
- **Goodpasture’s syndrome** (antiglomerular basement membrane autoantibodies damage glomerular integrity).

Autoantibody binding may not only cause damage – in Graves’ thyroiditis, for example, the antithyroid stimulating hormone receptor antibody stimulates follicular cells to produce thyroid hormones, leading to hyperthyroidism.

Autoantibodies can also bind their antigen in the circulation to form immune complexes. When these become deposited in the tissues, complement and cell-mediated immune reactions are initiated. Immune complexes preferentially deposit in sites such as the kidney glomerulus, leading to chronic kidney disease. This is a feature of SLE, in which the autoantigen within the immune complexes is DNA.

Common autoimmune diseases

There are now over 80 diseases classified as autoimmune. Some of the diseases are very clear cut in their autoimmune origin, but others are not and both major and minor factors must be defined.

**Major criteria:**

- Evidence of autoreactivity (e.g. activated or memory autoreactive T cells or autoantibodies)
- Clinical response to immune suppression
- Passive transfer of the putative immune effector (e.g. autoreactive T cell or autoantibody) causes the disease (hardest criterion to satisfy in man but most stringent).

**Minor criteria:**

- An animal model exists that resembles the human condition, and in which there is a similar loss of immunological tolerance to self
- Evidence that, in the animal model, passive transfer of the putative immune effector reproduces the disease in a naïve animal
- HLA association (frequent indicator that a disease is autoimmune).

cytokines, or to direct immune responses, drugs, toxins or irradiation against a specific target, whether it be a tumour cell or an immune cell involved in a damaging autoimmune response. Natural antiviral mediators, such as the interferons, are already in the clinic as therapies for, amongst other things, chronic viral infection.

### Monoclonal antibody therapy

The combined power of monoclonal antibody (MAb) and recombinant DNA technology has led to a series of ‘designer’ drugs which have been engineered so that they are:

(a) **exquisitely targeted**

(b) **have optimal effector function**, and

(c) **do not carry antigenic segments that may incite a neutralizing response in the host.**

In general this has meant a process of ‘humanizing’ antibodies of mouse origin and selecting an appropriate effector function. For example, a MAb designed to remove a subpopulation of lymphocytes from the patient should have good complement-fixing ability or bind well to receptors on phagocytes, whereas a MAb designed to ‘modulate’ a cell without depletion should have these functions removed. An example of the latter is an anti-CD3 MAb that has modified Fc regions and is designed to functionally downregulate, but not deplete, T cells. Examples of MAbs in current use are shown in Table 3.21.

Others include efalizumab (inhibits T cell activation) in psoriasis; omalizumab (binds to IgE) in asthma; basiliximab and daclizumab (anti-CD25 preventing T cell proliferation) in acute transplant rejection (p. 640).

### Immunosuppressive drugs

**Glucocorticosteroids** (cortisone, hydrocortisone, prednisone and prednisolone) are the most commonly used steroids and have a variety of effects on immune function. These include potent effects on monocyte production of the proinflammatory cytokines IL-1 and TNF-α; blockade of T cell production of IL-2 and IFN-γ; and reduced activation and migration of a range of innate and adaptive immune cells.

**Ciclosporin, tacrolimus and rapamycin** (sirolimus) have similar effects on T cell function. Ciclosporin and tacrolimus are calcineurin inhibitors and inhibit Ca²⁺-dependent second messenger signals in T cells following activation via TCR. By contrast, sirolimus achieves a similar effect but acts at the level of post-activation events in the nucleus.

**Purine analogues** such as azathioprine are also frequently used as anti-inflammatory drugs in conjunction with steroids and act by inhibiting DNA synthesis in dividing adaptive immune cells. Similar in mode of action, but more powerful, is mycophenolate mofetil (MMF).

**Alkylating agents** that interfere with DNA synthesis, such as cyclophosphamide, are also used for immunosuppression.

### Cytokines and anticytokines

Cytokines are pleiotropic agents with powerful proinflammatory and immunosuppressive effects and are attractive targets for therapies that inhibit or enhance their function. In addition to TNF-α targeting, agents that block IL-1 have also been tested in rheumatoid arthritis, although with much less success. Nonetheless, the good safety profile of the drug (recombinant IL-1 receptor antagonist; IL-1ra, Anakinra) prompted its use in other diseases, and a recent study showed a beneficial effect in type 2 diabetes, which may have an innate inflammatory component.

IL-2 and its receptor (CD25) are also obvious candidates for immune therapies, and in addition to blocking function (e.g. through anti-CD25), some IL-2-based strategies are aimed to boost immunity, for example against tumours. Interferons have not only been used to boost proinflammatory immunity, but also as immune modulators (e.g. IFN-β in the autoimmune disease multiple sclerosis), although their efficacy in this respect remains to be fully established.

### Restoring tolerance in autoimmune diseases and allergy

One of the goals for immune-based therapies for autoimmune disease is not to simply achieve immunosuppression, but also to restore immunological tolerance against the relevant autoantigens. In animal models an effective means of achieving this is to administer the autoantigen itself, or key peptide epitopes from it. This is known as antigen-specific or peptide immunotherapy and is under trial in several autoimmune diseases and allergy. Giving antigen without danger signals (i.e. no co-stimulation) could provide an excessive amount of TCR-dependent signal 1 in the absence of signal 2 (p. 59) – this is known to lead to non-responsive T cells. There is also evidence that this safe antigen administration biases T cells towards a regulatory phenotype. The diseases that have the most advanced clinical data are in the field of allergy. For example, administration of cocktails of peptides of the cat allergen Fel d 1 has led to a reduction in detectable skin-prick responses and improved clinical scores.

### Intravenous immunoglobulin

Intravenous immunoglobulin (IVig) is a preparation of polyspecific IgG chemically purified from the plasma of large numbers (>20000) of healthy donors. IVig is used as a
replacement therapy in patients with primary and secondary antibody deficiencies. However, when used for inflammatory conditions there is also a therapeutic benefit, although randomized placebo-controlled studies are few. In the US, IVIg is only recommended for a small number of diseases in addition to antibody deficiency. These include immune-mediated thrombocytopenia; Kawasaki syndrome, chronic inflammatory demyelinating polyneuropathy and post-transfusion purpura. The mechanism of action is not known, but may include blockage of Fc receptors to prevent pathogenic antibodies binding to phagocytes; inhibition of autoantibody synthesis by B cells; inhibition of complement activation; induction of T cell regulation.

This page intentionally left blank
Infection and infectious disease remains the main cause of morbidity and mortality in man, particularly in developing areas where it is associated with poverty and overcrowding.

In the developed world increasing prosperity, universal immunization and antibiotics have reduced the prevalence of infectious disease. However, antibiotic-resistant strains of microorganisms and diseases such as human immunodeficiency virus (HIV) infection, variant Creutzfeldt–Jakob disease (vCJD), avian influenza and severe acute respiratory syndrome (SARS) have emerged. There is increased global mobility, both enforced (as a result of war, civil unrest and natural disaster), and voluntary (for tourism and economic benefit). This has aided the spread of infectious disease and allowed previously localized pathogens such as SARS and West Nile virus to establish themselves world-wide. An increase in the movement of livestock and animals has enabled the spread of zoonotic diseases like monkeypox, while changes in farming and food-processing methods have
contributed to an increase in the incidence of food- and water-borne diseases. Deteriorating social conditions in the inner city areas of our major conurbations have facilitated the resurgence of tuberculosis and other infections. Prisons and refugee camps, where large numbers of people are forced to live in close proximity, often under poor conditions, are providing a breeding ground for devastating epidemics of infectious disease. There are new concerns about the deliberate release of infectious agents such as smallpox or anthrax by terrorist groups or national governments.

In the developing world successes such as the eradication of smallpox have been balanced or outweighed by the new plagues. Infectious diseases cause nearly 25% of all human deaths (Table 4.1). Two billion people – one-third of the world’s population – are infected with tuberculosis (TB), 500 million people catch malaria every year, and 200 million are infected with schistosomiasis. 39.5 million people are living with HIV/AIDS, with 4.3 million new HIV infections in 2006 (65% in sub-Saharan Africa). Infections are often multiple, and there is synergy both between different infections, and between infection and other factors such as malnutrition. Many of the infectious diseases affecting developing countries are preventable or treatable, but continue to thrive owing to lack of money and political will.

The eight Millennium Development Goals (MDG) hope to be achieved by 2015. These are: eradicating extreme poverty and hunger, universal primary education, gender equality and empowerment of women, reduction in child mortality, improvement in maternal health, combating HIV/AIDS, malaria and other diseases, ensuring environment sustainability and developing global partnership for development. The Global Fund was established to combat AIDS, tuberculosis and malaria and has achieved much by providing the means for treatment for TB, insecticide-treated bed nets for malaria and antivirals for HIV. Several other funding streams (governmental, non-governmental and charitable) have also contributed to the fight against infection.

The climate also has consequences on diseases. Both natural climatic events and the gradual global change in weather conditions are affecting the spread and transmission of infections such as malaria and cholera.

### Infectious agents

The causative agents of infectious diseases can be divided into four groups.

**Priors** are the most recently recognized and the simplest infectious agents, consisting of a single protein molecule. They contain no nucleic acid and therefore no genetic information: their ability to propagate within a host relies on inducing the conversion of endogenous prion protein PrP° into a protease-resistant isomorph PrP^res.

**Viruses** contain both protein and nucleic acid, and so carry the genetic information for their own reproduction. However, they lack the apparatus to replicate autonomously, relying instead on ‘hijacking’ the cellular machinery of the host. They are small (usually less than 200 nanometres in diameter) and each virus possesses only one species of nucleic acid (either RNA or DNA).

**Bacteria** are usually, though not always, larger than viruses. Unlike the latter they have both DNA and RNA, with the genome encoded by DNA. They are enclosed by a cell membrane, and even bacteria which have adopted an intracellular existence remain enclosed within their own cell wall. Bacteria are capable of fully autonomous reproduction, and the majority are not dependent on host cells.

**Eukaryotes** are the most sophisticated infectious organisms, displaying subcellular compartmentalization. Different cellular functions are restricted to specific organelles, e.g. photosynthesis takes place in the chloroplasts, DNA transcription in the nucleus and respiration in the mitochondria. Eukaryotic pathogens include unicellular protozoa, fungi (which can be unicellular or filamentous) and multicellular parasitic worms.

Other higher classes, notably the insects and the arachnids, also contain species which can.parasitize man and cause disease: these are discussed in more detail on page 171.

### Host–organism interactions

Each of us is colonized with huge numbers of microorganisms \((10^{14}\ \text{bacteria, plus viruses, fungi, protozoa and worms})\) with which we coexist. The relationship with some of these organisms is symbiotic, in which both partners benefit, while others are commensals, living on the host without causing harm. Infection and illness may be due to these normally harmless commensals and symbiotes evading the body’s defences and penetrating into abnormal sites. Alternatively, disease may be caused by exposure to exogenous pathogenic organisms which are not part of our normal flora.

The symptoms and signs of infection are a result of the interaction between host and pathogen. In some cases, such as the early stages of influenza, symptoms are almost entirely due to killing of host cells by the invading organism. Usually, however, the harmful effects of infection are due to a combination of direct microbial pathogenicity, and the body’s response to infection. In meningococcal septicaemia, for example, much of the tissue damage is caused by cytokines released in an attempt to fight the bacteria. In a few instances, such as chronic South American trypanosomiasis (Chagas’ disease), morbidity is almost entirely immunological, with the parasite itself having little effect once the inflammatory process has been triggered. The molecular mechanisms underlying host–pathogen interactions are discussed in more detail on page 85.
Sources of infection

The endogenous skin and bowel commensals can cause disease in the host, either because they have been transferred to an inappropriate site (e.g. bowel coliforms causing urinary tract infection), or because host immunity has been attenuated (e.g. candidiasis in an immunocompromised host). Many infections are acquired from other people, who may be symptomatic themselves or be asymptomatic carriers. Some bacteria, like the meningococcus, are common transient commensals, but cause invasive disease in a small minority of those colonized. Infection with other organisms, such as the hepatitis B virus, can be followed in some cases by an asymptomatic but potentially infectious carrier state.

Zoonoses are infections that can be transmitted from wild or domestic animals to man. Infection can be acquired in a number of ways: direct contact with the animal, ingestion of meat or animal products, contact with animal urine or faeces, aerosol inhalation, via an arthropod vector, or by inoculation of saliva in a bite wound. Many zoonoses can also be transmitted from person to person. Some zoonoses are listed in Table 4.2.

Most microorganisms do not have a vertebrate or arthropod host but are free-living in the environment. The vast majority of these environmental organisms are non-pathogenic, but a few can cause human disease (Table 4.3). Person-to-person transmission of these infections is rare. Some parasites may have a stage of their life cycle which is environmental (e.g. the free-living larval stage of Strongyloides stercoralis and the hookworms) even though the adult worm requires a vertebrate host. Other pathogens can survive for periods in water or soil and may be transmitted from host to host via this route (see below): these should not be confused with true environmental organisms.

Routes of transmission

Endogenous infection

The body’s own endogenous flora can cause infection if the organism gains access to an inappropriate area of the body. This can happen by simple mechanical transfer, for example colonic bacteria entering the female urinary tract. The non-specific host defences may be breached, for example by cutting or scratching the skin and allowing surface commensals to gain access to deeper tissues; this is frequently the aetiology of cellulitis. There may be more serious defects in host immunity owing to disease or chemotherapy, allowing normally harmless skin and bowel flora to produce invasive disease.

vCJD, variant Creutzfeldt-Jakob disease; SARS, severe acute respiratory syndrome.
Airborne spread
Many respiratory tract pathogens are spread from person to person by aerosol or droplet transmission. Secretions containing the infectious agent are coughed, sneezed or breathed out, and are then inhaled by a new victim. Some enteric viral infections may also be spread by aerosols of faeces or vomit. Environmental pathogens such as Legionella pneumophila, and zoonoses such as psittacosis, are also acquired by aerosol inhalation, while rabies virus may be inhaled in the dust from bat droppings.

Faeco-oral spread
Transmission of organisms by the faeco-oral route can occur by direct transfer (usually in small children), by contamination of clothing or household items (usually in institutions or conditions of poor hygiene), or most commonly via contaminated food or water. Human and animal faecal pathogens can get into the food supply at any stage. Raw sewage is used as fertilizer in many parts of the world, contaminating growing vegetables and fruit. Poor personal hygiene can result in contamination during production, packaging, preparation or serving of foodstuffs. In the western world, the centralization of food supply and increased processing of food has allowed the potential for relatively minor episodes of contamination to cause widely disseminated outbreaks of food-borne infection.

Water-borne faeco-oral spread is usually the result of inadequate access to clean water and safe sewage disposal, and is common throughout the developing world. Worldwide 1.1 billion people have no access to clean water, and 2.6 billion do not have basic sanitation.

Vector-borne disease
Many tropical infections, including malaria, are spread from person to person or from animal to person by an arthropod vector. Vector-borne diseases are also found in temperate climates, but are relatively uncommon. In most cases part of the parasite life cycle takes place within the body of the arthropod, and each parasite species requires a specific vector. Simple mechanical transfer of infective organisms from one host to another can occur, but is rare. Some vector-borne diseases are shown in Table 4.4.

Direct person-to-person spread
Organisms can be passed on directly in a number of ways. Sexually transmitted infections are dealt with on page 175. Skin infections such as ringworm, and ectoparasites such as scabies and head lice, can be spread by simple skin-to-skin contact. Other organisms are passed on by blood- (or occasionally other body fluid) to-blood transmission. Blood-to-blood transmission can occur during sexual contact, from mother to infant peripartum, between intravenous drug users sharing any part of their injecting equipment, when infected medical or other (e.g. tattoo needles) equipment is reused, if contaminated blood or blood products are transfused, or in any sporting or accidental contact when blood is spilled.

Direct inoculation
Infection can occur when pathogenic organisms breach the normal mechanical defences by direct inoculation. Some of the circumstances in which this can occur are covered under endogenous infection and blood-to-blood transmission.

</table>
above. Some environmental organisms may be inoculated by accident: this is a common mode of transmission of tetanus and certain fungal infections. Rabies virus may be inoculated by the bite of an infected animal.

Consumption of infected material
Although many food-related zoonotic infections are due to contamination of food with animal faeces (and are thus, strictly speaking, faeco-oral), several diseases are transmitted directly in animal products. These include some strains of salmonella (e.g. chicken meat), brucellosis (unpasteurized milk), and the prion diseases kuru and vCJD (neural tissue).

Prevention and control
Methods of preventing infection depend upon the source and route of transmission, as described above.

- **Infection control measures.** Poor infection control practice in hospitals and other healthcare environments can cause the transfer of infection from person to person. This may be airborne, via fomites, or a direct contact route. It is essential that all healthcare workers wash or clean their hands before and after patient contact, and whenever necessary they should wear gloves, aprons and other protective equipment. This is particularly necessary when performing invasive procedures, or manipulating indwelling devices such as cannulae.

- **Eradication of reservoir.** In a few diseases, for which man is the only natural reservoir of infection, it may be possible to eliminate disease by an intensive programme of case finding, treatment and immunization. This has been achieved in the case of smallpox. If there is an animal or environmental reservoir complete eradication is unlikely, but local control methods may decrease the risk of human infection (e.g. killing of rodents to control plague, leptospirosis and other diseases).

- **For arthropod-vector-borne infections:**
  - destroying vector species (which may be practical in certain circumstances)
  - taking measures to avoid being bitten (e.g. insect repellent sprays, impregnated bed nets).

- **For food-borne infections.** Improvements in food handling and preparation result in less contamination during processing, transport or preparation. Organisms intrinsically present in food can be killed by appropriate preparation and cooking. Improved surveillance and regulation of the food industry, as well as better health education for the public is necessary.

- **For faeco-oral infections.** Improvements in water supply and sanitation (recognized in the Millennium Development Goals) could dramatically decrease the prevalence of faeco-oral infections.

- **For blood-borne infections.** Prevention of blood transfer, e.g. in blood transfusions and contaminated medical equipment. Donated blood is routinely tested for infection in most developed countries.

- **For infections spread by airborne and direct contact.** Some airborne-transmitted respiratory infections, and some infections spread by direct contact, can be controlled by isolating patients. This is often difficult, but isolation is useful in patients with severe immunodeficiency to protect them from infection.

- **Immunization (see p. 102).**

**Classification of outbreaks**
The type of outbreak has a bearing on public health measures that need to be instituted for its control.

- **Person to person** where infection is passed from one infected individual to another and outbreaks of infection are separated by the incubation period.

- **‘Point source’** is where there is a single source of infection, e.g. food eaten at a social function. All those infected will develop symptoms at the same time, around the expected incubation period.

- **Common source** where there is a single source of infection but over a period of time, e.g. a symptomatic carrier of infection working with food preparation. Many people will be exposed over a long period of time.

**Epidemic.** An increased unusual widespread infection in the community, causing waves of infection. These spread through communities and affect all people who have no active immunity to that infection.

Cases of some infectious diseases should be notified to the public health authorities so that they are aware of cases and outbreaks. Diseases that are notifiable in England and Wales are listed in Table 4.5.

Recent infections endangering public health should also be notified (e.g. SARS, Avian flu).
Infection and Infectious diseases

However, many microorganisms have the potential to produce disease. This may result from inoculation of damaged tissues, tissue invasion, a variety of virulence factors or toxin production.

**Specificity**

Microorganisms are often highly specific with respect to the organ or tissue they infect (Fig. 4.1). For example, a number of viruses are hepatotropic, such as those responsible for hepatitis A, B, C and E and yellow fever. This predilection for specific sites in the body relates partly to the presence of appropriate receptors on different cell types, and partly to the immediate environment in which the organism finds itself; for example, anaerobic organisms colonize the anaerobic colon, whereas aerobic organisms are generally found in the mouth, pharynx and proximal intestinal tract. Other organisms that show selectivity include:

- *Streptococcus pneumoniae* (respiratory tract)
- *Escherichia coli* (urinary and alimentary tract).

---

---

**PRINCIPLES AND BASIC MECHANISMS**

Man constantly interacts with the world of microorganisms from birth to death. The majority cause no harm and some play a role in the normal functioning of the mouth, vagina and intestinal tract. However, many microorganisms have the potential to produce disease. This may result from inoculation of damaged tissues, tissue invasion, a variety of virulence factors or toxin production.

**Specificity**

Microorganisms are often highly specific with respect to the organ or tissue they infect (Fig. 4.1). For example, a number of viruses are hepatotropic, such as those responsible for hepatitis A, B, C and E and yellow fever. This predilection for specific sites in the body relates partly to the presence of appropriate receptors on different cell types, and partly to the immediate environment in which the organism finds itself; for example, anaerobic organisms colonize the anaerobic colon, whereas aerobic organisms are generally found in the mouth, pharynx and proximal intestinal tract. Other organisms that show selectivity include:

- *Streptococcus pneumoniae* (respiratory tract)
- *Escherichia coli* (urinary and alimentary tract).

---

**Fig. 4.1** Sites of infection with common organisms.
Even within a species of bacterium such as *E. coli*, there are clear differences between strains with regard to their ability to cause gastrointestinal disease (see p. 130), which in turn differ from uropathogenic *E. coli* responsible for urinary tract infection.

Within an organ a pathogen may show selectivity for a particular cell type. In the intestine, for example, rotavirus predominantly invades and destroys intestinal epithelial cells on the upper portion of the villus, whereas reovirus selectively enters the body through the specialized epithelial cells, known as M cells, that cover the Peyer’s patches (see p. 274).

**Pathogenesis**

Figure 4.2 summarizes some of the steps that occur during the pathogenesis of infection. In addition, pathogens have developed a variety of mechanisms to evade host defences. For example, some pathogens produce toxins directed at phagocytes – *Staphylococcus aureus* (α-toxin), *Streptococcus pyogenes* (streptolysin) and *Clostridium perfringens* (α-toxin), while others such as *Salmonella* spp. and *Listeria monocytogenes* can survive within macrophages. Several pathogens possess a capsule that protects against complement activation (*Strep. pneumoniae*). Antigenic variation is an additional mechanism for evading host defences that is recognized in viruses (antigenic shift and drift in influenza), bacteria (flagella of salmonella and gonococcal pilil and protozoa (surface glycoprotein changes in *Trypanosoma*).

**Epithelial attachment**

Many bacteria attach to the epithelial substratum by specific organelles called pili (or fimbriae) that contain a surface lectin(s) – a protein or glycoprotein that recognizes specific sugar residues on the host cell. This family of molecules is known as adhesins (see p. 26). Following attachment, some bacteria, such as coagulase-negative staphylococci (*Staph. epidermidis*), produce an extracellular slime layer and recruit additional bacteria, which cluster together to form a biofilm. These biofilms can be difficult to eradicate, and are a frequent cause of medical device-associated infections which affect prosthetic joints and heart valves as well as indwelling catheters. Many viruses and protozoa (e.g. *Plasmodium* spp., *Entamoeba histolytica*) attach to specific epithelial target-cell receptors. Other parasites such as hookworm have specific attachment organs (buccal plates) that firmly grip the intestinal epithelium.

**Colonization**

Following epithelial attachment, pathogens may either remain on the surface epithelium or within the lumen of the organ they have colonized. Tissue invasion may follow.

Invasion may result in:

- an intracellular location for the pathogen (e.g. viruses, *Mycobacterium* spp., *Toxoplasma gondii*, *Plasmodium* spp.)
- an extracellular location for the pathogen (e.g. pneumococci, *E. coli* and *Entamoeba histolytica*)
- invasion directly into the blood or lymph circulation (e.g. schistosome schistosomula and trypanosomes).

Once the pathogen is firmly established in its target tissue, a series of events follows that usually culminates in damage to the host.

**Tissue dysfunction or damage**

Microorganisms produce disease by a number of well-defined mechanisms:

**Cell lysis**

The presence of replicating viruses within a cell may interfere with host cell metabolism such that the cell dies – so-called cytolytic or cytoidal infection.

**Exotoxins and endotoxins**

- *Exotoxins* have many diverse activities including inhibition of protein synthesis (diphtheria toxin), neurotoxicity (*Clostridium tetani* and *C. botulinum*) and enterotoxicity, which results in intestinal secretion of water and electrolytes (*E. coli*, *Vibrio cholerae*). Colonization and secretion in many classical diarrhoeal diseases is the result of virulence-associated genes which encode protein secretion systems (Fig. 4.3).
- *Endotoxin* is a lipopolysaccharide (LPS) in the cell wall of Gram-negative bacteria. It is responsible for many of
**Fig. 4.3** Protein secretion pathways for Gram-negative bacteria. These specialized pathways are necessary for virulence. Types I and II facilitate protein (toxin) secretion into the extracellular space (Type I). Type II does this in two stages. Types III and IV pathways secrete toxins as well as inject toxins directly into the host cells via multiprotein complexes across the bacterial cell envelope and host cell membrane. Type V is a minor variation of Type II. Type VI pathway is unclear but is involved in cytotoxicity. Reproduced with permission from Yarh TL. A critical new pathway for toxin secretion? *Often *Staphylococcus epidermidis.*

the features of septic shock (see p. 899), namely hypotension, fever, intravascular coagulation and, at high-doses, death. The effects of endotoxin are mediated predominantly by release of tumour necrosis factor.

*Staphylococcus aureus* presents an excellent example of the repertoire of microbial virulence. The clinical expression of disease varies according to site, invasion and toxin production and is summarized in Table 4.6. Furthermore, host susceptibility to infection may be linked to genetic or acquired defects in host immunity that may complicate intercurrent infection, injury, ageing and metabolic disturbances (Table 4.7).

**Host response to infection**

**Natural defences**

The natural host defences to infection are those of an intact surface epithelium with local production of secretions, antimicrobial enzymes (e.g. lysozyme in the eye) and in the stomach, gastric acidity. The mucociliary escalator of the large airways is unique to the lung.

**Immunological defences**

Antibody and cell-mediated immune mechanisms play a vital role in combating infection. All organisms can initiate secondary immunological mechanisms, such as complement activation, immune complex formation and antibody-mediated cytolysis of cells. The immunological response to infection is described in Chapter 3.

**Metabolic and immunological consequences of infection**

**Fever**

Body temperature is controlled by the thermoregulatory centre in the anterior hypothalamus in the floor of the third ventricle. Body temperature is maintained at 36.8°C in health, with a diurnal variation of ±0.5°C. Gram-negative bacteria contain lipopolysaccharide (LPS) and peptidoglycan, which is also a component of Gram-positive bacterial cell walls. Toll-like receptors (TLR, see p. 59) on monocytes and den-
The inflammatory response

The inflammatory response is a fundamental biological response to a variety of stimuli including micro-organisms or their products, such as endotoxin which acts on monocytes and macrophages. Non-phagocytic cells (lymphocytes, natural killer cells) are also involved. The release of cytokines, notably TNF-α, IL-1, IL-6 and interferon-γ lead to the release of a cascade of other mediators involved in inflammation and tissue remodelling, such as interleukins prostaglandins, leukotrienes and corticotropic. TNF is therefore responsible for many of the effects of an infection.

The biological behaviour of the pathogen and the consequent host response are responsible for the clinical expression of disease that often allows clinical recognition. The incubation period following exposure can be helpful (e.g. chickenpox 14–21 days). The site and distribution of a rash may be diagnostic (e.g. shingles), while symptoms of cough, sputum and pleuritic pain point to lobar pneumonia. Fever and meningismus characterize classical meningitis. Infection may remain localized or become disseminated and give rise to the sepsis syndrome and disturbances of protein metabolism and acid-base balance (see Ch. 15). Many infections are self-limiting, and immune and non-immune host defence mechanisms will eventually clear the pathogens. This is generally followed by tissue repair, which may result in complete resolution or leave residual damage.

FURTHER READING

APPENDIX TO THE PATIENT WITH A SUSPECTED INFECTION

Infectious diseases can affect any organ or system, and can cause a wide variety of symptoms and signs. Fever is often regarded as the cardinal feature of infection, but not all febrile illnesses are infections, and not all infectious diseases present with a fever. History-taking and examination should aim to identify the site(s) of infection, and also the likely causative organism(s).

History

A detailed history is taken with specific questions about epidemiological risk factors for infection. These are based on the sources of infection and routes of transmission discussed above.

- Travel history: some diseases are more prevalent in certain geographical locations, and many infections common in the tropics are seen rarely if at all in the UK.
- Food and water history: systemic as well as gastroenteric infections can be caught via this route.
- Occupational history.
- Animal contact: domestic, farm and wild animals can all be responsible for zoonotic infection.
- Sexual activity: as well as the traditional sexually transmitted diseases, HIV, hepatitis B and rarely hepatitis C can all be transmitted sexually. Some enteric infections are more common among male homosexuals.
- Intravenous drug use: as well as blood-borne viruses, drug injectors are susceptible to a variety of bacterial and fungal infections due to inoculation. Tattooing, body piercing and receipt of blood products (especially outside the UK) are also risk factors for blood-borne viruses.
- Leisure activities: certain pastimes may predispose to water-borne infections or zoonoses.

Clinical examination

A thorough examination covering all systems is required. Skin rashes and lymphadenopathy are common features of infectious diseases, and the ears, eyes, mouth and throat should also be inspected. Infections commonly associated with a rash are listed in Box 4.1. Rectal, vaginal and penile examination is required in sexually transmitted infections.

The fever pattern may occasionally be helpful, e.g. the tertian fever of falciparum malaria, but too much weight should not be placed on the pattern or degree.

Investigations

In some infections such as chickenpox the clinical presentation is so distinctive that no investigations are normally necessary to confirm the diagnosis. Other cases require investigation.

General investigations (to assess health and identify organ(s) involved)

These will vary depending on circumstances:

- Blood tests. Routine blood count, ESR and C-reactive protein, biochemical profile, urea and electrolytes are performed in the majority of cases (Box 4.2).
- Imaging. X-ray, ultrasound, echocardiography, CT and MR scanning are used to identify and localize infections. Positron emission tomography (PET) and single photon emission tomography (SPECT) have proved useful in localizing infection, especially when combined with CT scanning. However the sensitivity and specificity of these tests in diagnosing infection has yet to be determined, and their use remains limited.

Biopsy or aspiration of tissue for microbiological examination may also be facilitated by ultrasound or CT guidance.

- **Radionuclide scanning** after injection of indium- or technetium-labelled white cells (previously harvested from the patient) may occasionally help to localize infection. It is most effective when the peripheral white cell count is raised, and is of particular value in localizing occult abscesses.

**Microbiological investigations (to identify causative organism)**

Diagnostic services range from simple microscopy to molecular probes. It is often helpful to discuss the clinical problem with a microbiologist to ensure that appropriate tests are performed, and that specimens are collected and transported correctly.

**Microscopy and culture**

Specimens to be sent for microscopy and culture (Box 4.3).

- **Blood and urine** should routinely be sent for bacterial culture regardless of whether fever is present at the time.
- **Cerebrospinal fluid, sputum and biopsy** specimens are sent if clinically indicated.
- **Special culture techniques** are required for fungi, mycobacteria, and some other bacteria such as *Brucella* spp., and the laboratory must be informed if these are suspected.
- **Faecal culture** for viruses is not helpful in the investigation of gastroenteritis – the viruses responsible for this do not grow in routine tissue culture. Antigen or nucleic acid detection techniques (see below) are more appropriate, especially in the investigation of an outbreak of diarrhoea and vomiting. Protozoa should be considered as a cause of diarrhoea in returning travellers, immunocompromised patients, toddlers, men having sex with men, farm workers, and in any cases of prolonged unexplained diarrhoea. Detection of a specific clostridial toxin is a more reliable test for diarrhoea caused by *Clostridium difficile* than culture of the organism itself. Stool culture is a costly routine test and is often requested unnecessarily.

**Immunodiagnostic tests**

These can be divided into two types:

- tests that detect viral or bacterial antigen, using a polyclonal antiserum or a monoclonal antibody
- tests that detect an antibody response to infection (serological tests).

These investigations are valuable in the identification of organisms that are difficult to culture, especially viruses and
Serious infections may require supportive therapy in addition to antibiotics. It is always preferable to have a definite microbial diagnosis before starting treatment, so that an antibiotic with the most appropriate spectrum of activity and site of action can be used. However, some patients are too unwell to wait for results (which in the case of culture may take days). In diseases such as meningitis or septicaemia delay in treatment may be fatal and therapy must be started on an empirical basis. Appropriate samples for culture should be taken before the first dose of antibiotic, and an antibiotic regimen chosen on the basis of the most likely causative organisms. Usually patients are less unwell, and specific therapy can be deferred pending results. Antibiotic therapy is discussed in more detail on page 91.

Special circumstances

Returning travellers. A detailed travel itinerary, including any flight stopovers, should be taken from anyone who is unwell after arriving from another country. Previous travel should also be covered as some infections may be chronic or recurrent. It is necessary to find out not just which countries were visited but also the type of environment: a stay in a remote jungle village carries different health risks from a holiday in an air-conditioned coastal holiday resort. Food and water consumption, bathing and swimming habits, animal and insect contact, and contact with human illness all need to be established. Enquiry should be made about sexual contacts, drug use and medical treatment (especially parenteral) while

**Nucleic acid detection**

Specific genes from many pathogenic microorganisms have been cloned and sequenced. Nucleic acid probes can be designed to detect these sequences, identifying pathogen-specific nucleic acid in body fluids or tissue. The utility of this approach has been greatly enhanced by the development of amplification techniques such as the polymerase chain reaction (PCR), which increases the amount of target DNA/RNA in the sample to be tested.

**Treatment**

Many infections, particularly those caused by viruses, are self-limiting and require no treatment. The mainstay of treatment for most infectious diseases is antimicrobial chemotherapy. The choice of antibiotic should be governed by:

- the clinical state of the patient
- the likely cause of the infection.

PCR, polymerase chain reaction.
In some parts of the world over 90% of professional sex workers are HIV-positive, and hepatitis B and C are very common in parts of Africa and Asia. In addition to the investigations described in the previous section, special tests may be needed depending on the epidemiological risks and clinical signs, and malaria films are mandatory in anyone who is unwell after being in a malarious area. Some of the more common causes of a febrile illness in returning travellers are listed in Table 4.8.

**Immunocompromised patients.** Advances in medical treatment over the past three decades have led to a huge increase in the number of patients living with immunodeficiency states. Cancer chemotherapy, the use of immunosuppressive drugs and the world-wide AIDS epidemic have all contributed to this. The presentation may be very atypical in the immunocompromised patient with few, if any, localizing signs or symptoms. Infection can be due to organisms which are not usually pathogenic, including environmental bacteria and fungi. The normal physiological responses to infection (e.g. fever, neutrophilia) may be diminished or absent. The onset of symptoms may be sudden, and the course of the illness fulminant. A high index of suspicion for infections in people who are known to be immunosuppressed is required. These patients should usually be given early and aggressive antibiotic therapy without waiting for the results of investigations. Samples for culture should be sent before starting treatment, but therapy should not be delayed if this proves difficult. The choice of antibiotics should be guided by the likely causative organisms: these are shown in Box 4.4.

**Injecting drug users.** Parenteral drug use is associated with a variety of local and systemic infections. HIV, HBV and HCV can all be transmitted by sharing injecting equipment. Abscesses and soft tissue infections at the site of injection are common, especially in the groin, and may involve adjacent vascular and bony structures. Systemic infections are also common, most frequently caused by staphylococci and Group A streptococci, but a wide variety of other bacterial and fungal pathogens may be implicated.

</table>
Highly transmissible infections. Relatively few patients with infectious disease present a serious risk to healthcare workers (HCW) and other contacts. However, the appearance of diseases like severe acute respiratory syndrome (SARS), avian influenza, the occasional importation of zoonoses like Lassa fever, and concerns about the bioterrorist use of agents such as smallpox mean that there is still the potential for unexpected outbreaks of life-threatening disease. During the world-wide SARS outbreak in 2003, scrupulous infection control procedures reduced spread of infection. However, in the ‘inter-epidemic’ period it is difficult to maintain the same level of ‘alert’. HCWs should remain vigilant because the early symptoms of many of these diseases are non-specific.

Pyrexia of unknown origin

History, clinical examination and simple investigation will reveal the cause of a fever in most patients. In a small number, however, no diagnosis is apparent despite continuing symptoms. The term pyrexia (or fever) of unknown origin (PUO) is sometimes used to describe this problem. Various definitions have been suggested for PUO: a useful one is ‘a fever persisting for >2 weeks, with no clear diagnosis despite intelligent and intensive investigation’. Patients who are known to have HIV or other immunosuppressing conditions are normally excluded from the definition of PUO, as the investigation and management of these patients is different.

Successful diagnosis of the cause of PUO depends on a knowledge of the likely and possible aetiologies. These have been documented in a number of studies, and are summarized in Box 4.5.

A detailed history and examination is essential, taking into account the possible causes, and the examination should be repeated on a regular basis in case new signs appear. Investigation findings to date should be reviewed, obvious omissions amended and abnormalities followed up. Confirm that the patient does have objective evidence of a raised temperature: this may require admission to hospital if the patient is not already under observation. Some people have an exaggerated circadian temperature variation (usually peaking in the evening), which is not pathological.

The range of tests available is discussed above. Obviously investigation is guided by particular abnormalities on examination or initial test results, but in some cases ‘blind’ investigation is necessary. Some investigations, especially cultures, should be repeated regularly, and serial monitoring of inflammatory markers such as C-reactive protein allows assessment of progress.

Improvements in imaging techniques have diminished the need for invasive investigations in PUO, and scanning has superseded the blind diagnostic laparotomy. Ultrasound, echocardiography, CT, MRI, PET and labelled white cell scanning can all help in establishing a diagnosis if used appropriately: the temptation to scan all patients with PUO from head to toe as a first measure should be avoided. Biopsy of bone marrow (and less frequently liver) may be useful even in the absence of obvious abnormalities, and temporal artery biopsy should be considered in the elderly (see p. 550). Bronchoscopy can be used to obtain samples for microbiological and histological examination if sputum specimens are not adequate. Serological tests have greatly improved the diagnosis of infectious causes of PUO, but these tests should only be ordered and interpreted in the context of the clinical findings and epidemiology.

Treatment of a patient with a persistent fever is aimed at the underlying cause, and if possible only symptomatic treatment should be used until a diagnosis is made. Blind antibiotic therapy may make diagnosis of an occult infection more difficult, and empirical steroid therapy may mask an inflammatory response without treating the underlying cause. In a few patients no cause for the fever is found despite many months of investigation and follow-up. In most of these the symptoms do eventually settle spontaneously, and if no definite cause has been identified after 2 years the long-term prognosis is good.

**ANTIMICROBIAL CHEMOTHERAPY**

Principles of use

Antibiotics are among the safest of drugs, especially those used to treat community infections. They have had a major impact on the life-threatening infections and reduce the morbidity associated with surgery and many common infectious diseases. This in turn is, in part, responsible for the over-prescribing of these agents which has led to concerns with regards to the increasing incidence of antibiotic resistance.
Empirical 'blind' therapy

Most antibiotic prescribing, especially in the community, is empirical. Even in hospital practice, microbiological documentation of the nature of an infection and the susceptibility of the pathogen is generally not available for a day or two. Initial choice of therapy relies on a clinical diagnosis and, in turn, a presumptive microbiological diagnosis. Such 'blind therapy' is directed at the most likely pathogen(s) responsible for a particular syndrome such as meningitis, urinary tract infection or pneumonia. Examples of 'blind therapy' for these three conditions are ceftriaxone, trimethoprim and amoxicillin + erythromycin, respectively. Initial therapy in the severely ill patient is often broad spectrum in order to cover the range of possible pathogens but should be targeted once microbiological information becomes available.

Combination therapy

Combinations of drugs are occasionally required for reasons other than providing broad-spectrum cover. Tuberculosis is initially treated with three or four agents to avoid resistance emerging. Synergistic inhibition is achieved by using penicillin and gentamicin in enterococcal endocarditis or gentamicin and ceftazidime in life-threatening pseudomonas infection.

In the majority of infections there is no firm evidence that bactericidal drugs (penicillins, cephalosporins, aminoglycosides) are more effective than bacteriostatic drugs (tetracyclines), but it is generally considered necessary to use the former in the treatment of bacterial endocarditis and in patients in whom host defence mechanisms are compromised, particularly in those with neutropenia.

Pharmacokinetic factors

To be successful, sufficient antibiotic must penetrate to the site of the infection. Knowledge of the standard pharmacokinetic considerations of absorption, distribution, metabolism and excretion for the various drugs is required. Difficult sites include the brain, eye and prostate, while loculated abscesses are inaccessible to most agents.

Many mild-to-moderate infections can be treated effectively with oral antibiotics provided that the patient is compliant. Parenteral administration is indicated in the severely ill patient to ensure rapid high blood and tissue concentrations of drug. Some antibiotics can only be administered parenterally, such as the aminoglycosides and extended-spectrum cephalosporins. Parenteral therapy is also required in those unable to swallow or where gastrointestinal absorption is unreliable.

Dose and duration of therapy

This will vary according to the nature, severity and response to therapy.

Prolonged treatment (up to 6 weeks) is necessary for some varieties of infective endocarditis, while pulmonary tuberculosis is treated for at least 6 months. In treating many common infections, improvement occurs within 2–3 days; once the patient is afebrile or the leucocytosis has settled, oral administration should be used for those commenced on parenteral therapy. Treatment for 5–7 days is adequate for most infections. Shorter-course therapy (3 days or less) is appropriate for those with symptomatic uncomplicated bacteriuria (cystitis). Minimizing the duration of therapy lowers the risks of adverse reactions and superinfection with Candida spp. or Clostridium difficile, as well as the cost of therapy.

Drugs which are concentrated intracellularly, such as erythromycin, quinolones and tetracyclines, are used in treating mycoplasma, brucella and legionella infections.

Renal and hepatic insufficiency

Many drugs require dose reduction in renal failure to avoid toxic accumulation. This applies to the β-lactams and especially the aminoglycosides and vancomycin. Tetracyclines, other than doxycycline and minocycline, should be avoided. In those with hepatic insufficiency, dose reduction is often required for agents such as isoniazid, ketoconazole, clindamycin, interferon and rifampicin.

Therapeutic drug monitoring

To ensure therapeutic yet non-toxic drug concentrations, serum concentrations of drugs such as the aminoglycosides and vancomycin are monitored, especially in those with impaired or changing renal function. Peak (1 hour post-dose) and trough (pre-dose) serum samples are assayed. However, with the increasing use of once-daily aminoglycoside dosage regimens, random but timed serum assays are being adopted.

Antibiotic chemoprophylaxis

The value of antibiotic chemoprophylaxis has been questioned as there are few controlled trials to prove efficacy (see p. 773). The evidence for chemoprophylaxis against infective endocarditis (IE) is an example. The new guidelines recognize that procedures can cause bacteraemia but not infective endocarditis. Even patients at 'high risk', e.g. previous IE prosthetic heart valves and surgical shunts, do not require prophylaxis (Table 4.9). However, there are a number of indications for which the prophylactic use of antibiotics is still advised. These include surgical procedures where the risk of infection is high (colon surgery) or the consequences of infection are serious (post-splenectomy sepsis). The choice of agent(s) is determined by the likely infectious risk and the established efficacy and safety of the regimen.

Mechanisms of action and resistance to antimicrobial agents

Antibiotics act at different sites of the bacterium. Resistance to an antibiotic can be the result of:

- impaired or altered permeability of the bacterial cell envelope, e.g. penicillins in Gram-negative bacteria
- active expulsion from the cell by membrane efflux systems
- alteration of the target site (e.g. single point mutations in E. coli or a penicillin-binding protein in Strep. pneumoniae leading to acquired resistance – see below)
- specific enzymes which inactivate the drug before or after cell entry (e.g. β-lactamases)
- development of a novel metabolic bypass pathway.

The development or acquisition of resistance to an antibiotic by bacteria invariably involves either a mutation at a single point in a gene or transfer of genetic material from another organism (Fig. 4.4).

Larger fragments of DNA may be introduced into a bacterium either by transfer of ‘naked’ DNA or via a bacteriophage (a virus) DNA vector. Both the former (transformation)

(b) Endocarditis (NICE guidelines for adults and children undergoing interventional procedures March 2008)

- Antibacterial prophylaxis and chlorhexidine mouthwash are not recommended for the prevention of endocarditis in patients undergoing dental procedures.
- Antibacterial prophylaxis is not recommended for the prevention of endocarditis in patients undergoing procedures of the:
  - Upper and lower respiratory tract (including ear, nose and throat procedures and bronchoscopy)
  - Genitourinary tract (including urological, gynaecological and obstetric procedures)
  - Upper and lower gastrointestinal tract.
- Any infection in patients at risk of endocarditis should be investigated promptly and treated appropriately to reduce the risk of endocarditis.
- If patients at risk of endocarditis are undergoing a gastrointestinal or genitourinary tract procedure at a site where infection is suspected, they should receive appropriate antibacterial therapy that includes cover against organisms that cause endocarditis.
- Patients at risk of endocarditis should be:
  - Advised to maintain good oral hygiene
  - Told how to recognize signs of infective endocarditis and advised when to seek expert advice.

* Unless stated, doses are those recommended in adults.
For surgical procedure – see individual procedures in text.

**Fig. 4.4** Some mechanisms for the development of resistance to antimicrobial drugs. These involve either a single point mutation or transfer of genetic material from another organism (transformation, transduction or R factor transfer).
and the latter (transduction) are dependent on integration of this new DNA into the recipient chromosomal DNA. This requires a high degree of homology between the donor and recipient chromosomal DNA.

Finally, antibiotic resistance can be transferred from one bacterium to another by conjugation, when extrachromosomal DNA (a plasmid) containing the resistance factor (R factor) is passed from one cell into another during direct contact. Transfer of such R factor plasmids can occur between unrelated bacterial strains and involve large amounts of DNA and often codes for multiple antibiotic resistance, e.g. as for the quinolones.

Transformation is probably the least clinically relevant mechanism, whereas transduction and R factor transfer are usually responsible for the sudden emergence of multiple antibiotic resistance in a single bacterium. Increasing resistance to many antibiotics has developed (Table 4.10).

**ANTIBACTERIAL DRUGS**

**β-Lactams (penicillins, cephalosporins and monobactams)**

**Penicillins** (Table 4.11)

Structure. The β-lactams share a common ring structure (Fig. 4.5). Changes to the side-chain of benzylpenicillin (penicillin G) render the phenoxymethyl derivative (penicillin V) acid resistant and allow it to be orally absorbed. The presence of an amino group in the phenyl radical of benzylpenicillin increases its antimicrobial spectrum to include many Gram-negative and Gram-positive organisms. More extensive modification of the side-chain (e.g. as in flucloxacinil) renders the drug insensitive to bacterial penicillinase. This is useful in treating infections caused by penicillinase (β-lactamase)-producing staphylococci.

**Mechanisms of action.** β-lactams block bacterial cell wall mucopeptide formation by binding to and inactivating specific penicillin-binding proteins (PBP), which are peptidases involved in the final stages of cell wall assembly and division. Meticillin-resistant *Staph. aureus* (MRSA) (see p. 124) produce a low-affinity PBP which retains its peptidase activity even in the presence of high concentrations of meticillin.

**Indications for use.** Benzylpenicillin can only be given parenterally and is often the drug of choice for serious infections,
notably infective endocarditis, meningococcal, streptococcal, gas gangrene, actinomycosis, anthrax and spirochaetal infections (syphilis, yaws).

Penicillin V is an oral preparation that is used chiefly to treat streptococcal pharyngitis and as prophylaxis against rheumatic fever.

Flucloxacillin is used in infections caused by β-lactamase (penicillinase)-producing staphylococci.

Ampicillin is susceptible to β-lactamase, but its antimicrobial activity includes streptococci, pneumococci and enterococci as well as Gram-negative organisms such as Salmonella spp., Shigella spp., E. coli, H. influenzae and Proteus spp. Drug resistance has, however, eroded its efficacy against these Gram-negatives. It is widely used in the treatment of respiratory tract infections. Amoxicillin has similar activity to ampicillin, but is better absorbed when given by mouth.

The extended-spectrum penicillin, ticarcillin, is active against pseudomonas infections, as is the acylureidopenicillin piperacillin in combination with sulbactam.

Clavulanic acid is a powerful inhibitor of many bacterial β-lactamases and when given in combination with an otherwise effective agent such as amoxicillin (co-amoxiclav) or ticarcillin can broaden the spectrum of activity of the drug. Sulbactam acts similarly and is available combined with ampicillin, while tazobactam in combination with piperacillin is effective in appendicitis, peritonitis, pelvic inflammatory disease and complicated skin infections. The penicillin β-lactamase combinations are also active against β-lactamase-producing staphylococci.

Pivmecillinam has significant activity against Gram-negative bacteria including E. coli, Klebsiella, Enterobacter and Salmonella but no activity against pseudomonas.

Temocillin is active against Gram-negative bacteria, including β-lactamase producers. It is not active against pseudomonas or Acinetobacter spp.

Interactions. Penicillins inactivate aminoglycosides when mixed in the same solution.

Toxicity. Generally, the penicillins are very safe. Hypersensitivity (skin rash [common], urticaria, anaphylaxis), encephalopathy and tubulointerstitial nephritis can occur. Ampicillin also produces a hypersensitivity rash in approximately 90% of patients with infectious mononucleosis who receive this drug. Co-amoxiclav causes a cholestatic jaundice six times more frequently than amoxicillin, as does flucloxacillin.

Cephalosporins and cephamycins (Fig. 4.6)

The cephalosporins have an advantage over the penicillins in that they are resistant to staphylococcal penicillinases (but are still inactive against meticillin-resistant staphylococci) and have a broader range of activity that includes both Gram-negative and Gram-positive organisms, but excludes enterococci and anaerobic bacteria. Ceftazidime and cephirome are active against Pseudomonas aeruginosa. Cefoxitin is a cephamycin with activity against anaerobic bacteria but is no longer available in the UK.

Indications for use (Table 4.12). These potent broad-spectrum antibiotics are useful for the treatment of serious systemic infections, particularly when the precise nature of the infection is unknown. They are commonly used for serious sepsis in postoperative and immunocompromised patients, particularly during cytotoxic chemotherapy of leukaemia and other malignancies. They are used in pneumonia, meningitis, peritonitis and urinary tract infections.

Interactions. There are relatively few interactions.

Toxicity. The toxicity is similar to that of the penicillins but is less common. Some 10% of patients are allergic to both groups of drugs. The early cephalosporins caused proximal tubule damage, although the newer derivatives have fewer nephrotoxic effects.

Monobactams

Aztreonam is currently the only member of this class available. It is a synthetic β-lactam and, unlike the penicillins and cephalosporins, has no ring other than the β-lactam, hence its description as a monobactam.

Its mechanism of action is by inhibition of bacterial cell wall synthesis. It is resistant to most β-lactamases and does not induce β-lactamase production.

Indications for use. Aztreonam’s spectrum of activity is limited to aerobic Gram-negative bacilli. With the exception of urinary tract infections, aztreonam should be used in combination with metronidazole (for anaerobes) and an agent active against Gram-positive cocci (a penicillin or erythromycin). It is a useful alternative to aminoglycosides in combination therapy, largely for the treatment of intra-abdominal sepsis.

Toxicity. As for the β-lactam antibiotics.

Carbapenems

The carbapenems are semisynthetic β-lactams and include imipenem, meropenem and ertapenem. They are currently the most broad spectrum of antibiotics, being active against the majority of Gram-positive and Gram-negative as well as anaerobic bacterial pathogens. Ertapenem, unlike the others, is not active against Pseudomonas aeruginosa or Acinetobacter spp. They differ in their dosage and frequency of administration. Imipenem is partially inactivated in the kidney by enzymatic inactivation and is therefore administered in combination with cilastatin.

Indications for use. They are used for serious nosocomial infections when multiple-resistant Gram-negative bacilli or mixed aerobe and anaerobe infections are suspected.

Toxicity. This is similar to that of β-lactam antibiotics. Nausea, vomiting and diarrhoea occur in less than 5% of

*Unavailable in the UK.

Fig. 4.7  The structure of an aminoglycoside.

cases. Imipenem may cause seizures and should not be used to treat meningitis; meropenem is safe for this indication.

Aminoglycosides

Structure. These antibiotics are polycationic compounds of amino sugars (Fig. 4.7).

Mechanism of action. Aminoglycosides interrupt bacterial protein synthesis by inhibiting ribosomal function (messenger and transfer RNA).

Indications for use. Streptomycin is bactericidal and is rarely used except for the treatment of tuberculosis or the plague. Occasional indications include endocarditis (with penicillin/ampicillin). Neomycin is used only for the topical treatment of eye and skin infections. Even though it is poorly absorbed, prolonged oral administration can produce ototoxicity.

Gentamicin and tobramycin are given parenterally. They are highly effective against many Gram-negative organisms including Pseudomonas spp. They are synergistic with a penicillin against Enterococcus spp. Netilmicin and amikacin have a similar spectrum but are more resistant to the aminoglycoside-inactivating enzymes (phosphorylating, adenylating or acetyllating) produced by some bacteria. Their use should be restricted to gentamicin-resistant organisms.

Interactions. Enhanced nephrotoxicity occurs with other nephrotoxic drugs, ototoxicity with some diuretics, and neuromuscular blockade with curariform drugs.

Toxicity. This is dose-related. Aminoglycosides are nephrotoxic and ototoxic (vestibular and auditory), particularly in the elderly. Therapeutic drug monitoring is necessary in ensuring therapeutic and non-toxic drug concentrations.

Tetracyclines

Structure. These are bacteriostatic drugs possessing a fourring hydronaphthacene nucleus (Fig. 4.8). Included among the tetracyclines are tetracycline, oxytetracycline, demeclocycline, lymecycline, doxycycline and minocycline. Tigecycline is a new injectable glycyclcline which is structurally related to the tetracyclines.

Mechanism of action. Tetracyclines inhibit bacterial protein synthesis by interrupting ribosomal function (transfer RNA).
Tetracyclines

**Indications for use.** Tetracyclines are active against Gram-positive and Gram-negative bacteria but their use is now limited, partly owing to increasing bacterial resistance. Resistance is now common with *Strep, pneumoniae*. A tetracycline is used for the treatment of acne and rosacea. Tetracyclines are also active against *V. cholerae*, *Rickettsia* spp., *Mycoplasma* spp., *Coxiella burnetti*, *Chlamydia* spp. and *Brucella* spp. Tigecycline is active against many organisms resistant to tetracycline and other antibiotics. Most notably, these include vancomycin-resistant enterococci, MRSA and multidrug-resistant Gram-negative bacilli, including *Acinetobacter* spp. Its indications include complicated skin and soft tissue infections and intra-abdominal sepsis.

**Interactions.** The efficacy of tetracyclines is reduced by antacids and oral iron-replacement therapy.

**Toxicity.** Tetracyclines are generally safe drugs, but they may enhance established or incipient renal failure, although doxycycline is safer than others in this group. They cause brown discoloration of growing teeth, and thus these drugs are not given to children or pregnant women. Photosensitivity can occur. Nausea and vomiting are the most frequent adverse effects of tigecycline.

**Macrolides**

**Erythromycin**

**Structure.** Erythromycin consists of a lactone ring with two sugar side-chains, one of which is an aminosugar.

**Mechanism of action.** Erythromycin inhibits protein synthesis by interrupting ribosomal function.

**Indications for use.** Erythromycin has a similar (but not identical) antibacterial spectrum to penicillin and is useful in individuals with penicillin allergy especially in the management of bacterial respiratory and skin and soft tissue infections. It can be given orally or parenterally. It is the preferred agent in the treatment of pneumonias caused by *Legionella* spp. and *Mycoplasma* spp. It is also effective in the treatment of infections due to *Bordetella pertussis* (whooping cough), *Campylobacter* spp. and *Chlamydia* spp.

**Other macrolides**

These include clarithromycin, azithromycin and telithromycin. They have a broad spectrum of activity that includes selective Gram-negative organisms, mycobacteria and *Chlamydia* spp., *Mycoplasma* spp., *Legionella* spp., *Campylobacter* spp., *Chlamydia* spp.

**Chloramphenicol**

**Structure.** Chloramphenicol is the only naturally occurring antibiotic containing nitrobenzene (Fig. 4.9). This structure probably accounts for its toxicity in humans and for its activity against bacteria.

**Mechanism of action.** Chloramphenicol competes with messenger RNA for ribosomal binding. It also inhibits peptidyl transferase.

**Indications for use.** Chloramphenicol is rarely used in developed countries. In developing countries it has been invaluable in the treatment of meningitis and severe infections caused by *Salmonella typhi* and *S. paratyphi* (enteric fevers). *H. influenzae* (meningitis and acute epiglottitis) which are still prevalent in countries where Hib vaccination has not been introduced are also susceptible to chloramphenicol. It is also active against *Yersinia pestis* (plague) and is used topically for the treatment of purulent conjunctivitis. Drug resistance is currently eroding the efficacy of chloramphenicol.

**Interactions.** Chloramphenicol enhances the activity of anticoagulants, phenytoin and some oral hypoglycaemic agents.
Toxicity. Severe irreversible bone marrow suppression is rare but nevertheless now restricts the usage of this drug to only the severely ill patient. Chloramphenicol should not be given to premature infants or neonates because of their inability to conjugate and excrete this drug; high blood levels lead to circulatory collapse and the often fatal ‘grey baby syndrome’.

Fusidic acid

Structure. Fusidic acid has a structure resembling that of bile salts (see p. 322).

Mechanism of action. It is a potent inhibitor of bacterial protein synthesis. Its entry into cells is facilitated by the detergent properties inherent in its structure.

Indications for use. Fusidic acid is mainly used for penicillinase-producing \( \text{Staph. aureus} \) infections such as osteomyelitis (it is well concentrated in bone) or endocarditis, and for other staphylococcal infections accompanied by septicaemia. The drug is well absorbed orally but is relatively expensive and should be used in combination with another staphylococcal agent to prevent resistance emerging.

Resistance. Resistance may occur rapidly and is the reason why fusidic acid is given in combination with another antibiotic.

Toxicity. Fusidic acid may occasionally be hepatotoxic but is generally a safe drug and if necessary can be given during pregnancy.

Sulphonamides and trimethoprim

Structure. The sulphonamides are all derivatives of the prototype sulphamethazine. Trimethoprim is a 2,4-diaminopyrimidine.

Mechanism of action. Sulphonamides block thymidine and purine synthesis by inhibiting microbial folic acid synthesis. Trimethoprim prevents the reduction of dihydrofolate to tetrahydrofolate (see Fig. 8.12).

Indications for use. Sulfamethoxazole is mainly used in combination with trimethoprim (as co-trimoxazole). Its use is now largely restricted to the treatment and prevention of \( \text{Pneumocystis jiroveci} \) (formerly \( \text{P. carinii} \)) infection and listeriosis in developed countries, although it is still in widespread use in developing countries. It may also be used for toxoplasmosis and nocardiosis and as a second-line agent in acute exacerbations of chronic bronchitis and in urinary tract infections. Trimethoprim alone is often used for urinary tract infections and acute-on-chronic bronchitis, as the side-effects of co-trimoxazole are most commonly due to the sulphonamide component. Sulfapyridine in combination with 5-aminosalicylic acid (i.e. sulfasalazine) is now less widely used in inflammatory bowel disease.

Resistance. Resistance to sulphonamides is often plasmid-mediated and results from the production of sulphonamide-resistant dihydropteroate synthase from altered bacterial cell permeability to these agents.

Interactions. Sulphonamides potentiate oral anticoagulants and some hypoglycaemic agents.

Toxicity. Sulphonamides cause a variety of skin eruptions, including toxic epidermal necrolysis, the Stevens–Johnson syndrome, thrombocytopenia, folate deficiency and megaloblastic anaemia with prolonged usage. It can provoke haemolysis in individuals with glucose-6-phosphate dehydrogenase deficiency and therefore should not be used in such people. Co-trimoxazole should also be avoided in the elderly if possible, as deaths have been recorded, probably owing to the sulphonamide component.

Quinolones

The quinolone antibiotics, such as ciprofloxacin, norfloxacin, ofloxacin and levofloxacin, are useful oral broad-spectrum antibiotics, related structurally to nalidixic acid. The latter achieves only low serum concentrations after oral administration and its use is limited to the urinary tract where it is concentrated. Newer quinolones, including moxifloxacin, gemifloxacin and gatifloxacin, have greater activity against Gram-positive pathogens. The structure is shown in Figure 4.10.

Mechanism of action. The quinolone group of bactericidal drugs inhibit bacterial DNA synthesis by inhibiting topoisomerase IV and DNA gyrase, the enzyme responsible for maintaining the superhelical twists in DNA.

Indications for use. The extended-spectrum quinolones such as ciprofloxacin have activity against Gram-negative bacteria, including some \( \text{Pseudomonas aeruginosa} \), and some Gram-positive bacteria (e.g. anthrax, p. 142). They are useful in Gram-negative septicaemia, skin and bone infections, urinary and respiratory tract infections, meningococcal carriage, in some sexually transmitted diseases such as gonorrhoea and non-specific urethritis due to \( \text{Chlamydia trachomatis} \), and in severe cases of travellers’ diarrhoea (see p. 131). The newer oral quinolones provide an alternative to \( \beta \)-lactams in the treatment of community-acquired lower respiratory tract infections.

Resistance. In many countries 30–40% of \( \text{E. coli} \) are resistant. Resistance is also a growing problem among \( \text{Salmonella}, \text{Vibrio cholerae} \) and \( \text{Staphylococcus aureus} \), including MRSA strains.

Interactions. Ciprofloxacin can induce toxic concentrations of theophylline.

![Quinolone](image-url)

**Fig. 4.10** The structure of a quinolone (ciprofloxacin).
Toxicity. Gastrointestinal disturbances, photosensitive rashes and occasional neurotoxicity can occur. Avoid in childhood and pregnancy and in patients taking corticosteroids. Tendon damage, including rupture can occur within 48 hours of use and the drug should be stopped immediately; it should not be used in patients with tendonitis. MRSA and Clostridium difficile infection in hospitals have been linked to high prescribing rates of quinolones.

Oxazolidinones

Structure. The oxazolidinones are a novel class of antibacterial agents of which linezolid (Fig. 4.11) is the first to become available.

Mechanism of action. The oxazolidinones inhibit protein synthesis by binding to the bacterial 23S ribosomal RNA of the 59S subunit, thereby preventing the formation of a functional 70S complex essential to bacterial translation.

Indications for use. Linezolid is active against a variety of Gram-positive pathogens including vancomycin-resistant Enterococcus faecium (unfortunately resistant organisms have already been reported), meticillin-resistant Staph. aureus and penicillin-resistant Strep. pneumoniae. It is also active against group A and group B streptococci. Clinical experience has demonstrated efficacy in a variety of hospitalized patients with severe to life-threatening infections, such as bacteraemia, hospital-acquired pneumonia and skin and soft tissue infections. It can be given both intravenously and by mouth.

Interactions. Linezolid interacts reversibly as a non-selective inhibitor of monoamine oxidase, and has the potential for interacting with serotoninergic and adrenergic agents.

Toxicity. Side-effects include gastrointestinal disturbances, headache, rash, hypertension, reversible thrombocytopenia and occasional reports of optic neuropathy. Safety has not yet been shown in pregnancy.

Nitroimidazoles

Structure. These agents are active against anaerobic bacteria and some pathogenic protozoa. The most widely used drug is metronidazole (Fig. 4.12). Others include tinidazole and nirazolazole.

Mechanism of action. After reduction of their nitro group to a nitrosohydroxyl amino group by microbial enzymes, nitroimidazoles cause strand breaks in microbial DNA.

Indications for use. Metronidazole plays a major role in the treatment of anaerobic bacterial infections, particularly those due to Bacteroides spp. It is also used prophylactically in colonic surgery. It may be given orally, by suppository (well absorbed and cheap) or intravenously (very expensive). It is also the treatment of choice for Clostridium difficile-associated colitis, amoebiasis, giardiasis and infection with Trichomonas vaginalis.

Interactions. Nitroimidazoles can produce a disulfiram-like reaction with ethanol and enhance the anticoagulant effect of warfarin.

Toxicity. Nitroimidazoles are tumorigenic in animals and mutagenic for bacteria, although carcinogenicity has not been described in humans. They cause a metallic taste, and polyneuropathy with prolonged use. They should be avoided in pregnancy.

Glycopeptides

The glycopeptides are antibiotics active against Gram-positive bacteria and act by inhibiting cell wall synthesis.

Vancomycin

Vancomycin is given intravenously for meticillin-resistant Staph. aureus and other multiresistant Gram-positive organisms. It is also used for treatment and prophylaxis against Gram-positive infections in penicillin-allergic patients. It is used for Strep. pneumoniae meningitis when caused by penicillin-resistant strains. By mouth it is an alternative to metronidazole for Clostridium difficile-associated colitis. Glycopeptide-resistant enterococci (GRE) are now seen, as well as vancomycin-resistant Staphylococcus (see p. 124).

Toxicity. Vancomycin can cause otoxicity and nephrotoxicity and thus serum levels should be monitored. Care must be taken to avoid extravasation at the injection site as this causes necrosis and thrombophlebitis. Too rapid infusion can produce symptomatic release of histamine (red man syndrome).

Teicoplanin

This glycopeptide antibiotic is less nephrotoxic than vancomycin. It has more favourable pharmacokinetic properties, allowing once-daily dosage.

Other antibiotics

Clindamycin is not widely used because of its toxic side-effect, antibiotic-associated colitis (pseudomembranous colitis). It is active against Gram-positive cocci including some penicillin-resistant staphylococci. It is increasingly used to treat severe streptococcal or staphylococcal cellulitis. It has the added effect of inhibiting staphylococcal TSST-1 and alpha toxin production. It is also active against anaerobes, especially bacteroides. It is well concentrated in bone and used for osteomyelitis.

Quinupristin and dalfopristin. A combination of these streptogramin antibiotics is used for Gram-positive bacteria which have failed to respond to other antibacterials.

Daptomycin is a lipopeptide with a similar spectrum to vancomycin and is given by i.v. infusion. It is particularly used...
for skin and soft tissue infections due to community-associated MRSA. Muscle toxicity occurs.

**ANTITUBERCULOSIS DRUGS**

These are described on page 866. Rifampicin is also used in other infections apart from tuberculosis.

**ANTIFUNGAL DRUGS** (Table 4.13)

**Polyenes**

Polyenes react with the sterols in fungal membranes, increasing permeability and thus damaging the organism. The most potent is amphotericin, which is used intravenously in severe systemic fungal infections. Nephrotoxicity is a major problem and dosage levels must take background renal function into account. Liposomal amphotericin is less toxic but very expensive. Nystatin is not absorbed through mucous membranes and is therefore useful for the treatment of oral and enteric candidiasis and for vaginal infection. It can only be given orally or as pessaries.

**Azoles**

**Imidazoles** such as ketoconazole, miconazole and clotrimazole are broad-spectrum antifungal drugs. They are predominately fungistatic and act by inhibiting fungal sterol synthesis, resulting in damage to the cell wall. Ketoconazole is active orally but can produce liver damage. It is effective in candidiasis and deep mycoses including histoplasmosis and blastomycosis but not in aspergillosis and cryptococcosis.

Clotrimazole and miconazole are used topically for the treatment of ringworm and cutaneous and genital candidiasis. Econazole is used for the topical treatment of cutaneous and vaginal candidiasis and dermatophyte infections while tioconazole is indicated for fungal nail infections.

**Triazoles.** These include fluconazole, voriconazole and itraconazole. Fluconazole is noted for its ability to enter CSF and is used for candidiasis and for the treatment of central nervous system (CNS) infection with *Cryptococcus neoformans*. Itraconazole fails to penetrate CSF. It is the agent of choice for non-life-threatening blastomycosis and histoplasmosis. It is also moderately effective in invasive aspergillosis. Toxicity is mild. The problem associated with poor absorption of the capsules in the absence of food has been overcome with the liquid formulation. Voriconazole has broad-spectrum activity that includes *Candida*, *Cryptococcus* and *Aspergillus* spp. and other filamentous fungi. It is available for oral and intravenous use. Adverse effects include rash, visual disturbance and abnormalities of liver enzymes. It is indicated for invasive aspergillosis and severe candida infections unresponsive to amphotericin and fluconazole respectively.

**Allylamines**

Terbinafine has broad-spectrum antifungal and also anti-inflammatory activity. It is well absorbed orally and accumulates in keratin. It is useful for the treatment of superficial mycoses such as dermatophyte infections, onychomycosis and cutaneous candidiasis. A topical formulation is also available to treat fungal skin infections.

**Echinocandins**

These act by inhibiting the cell wall polysaccharide, glucan. Caspofungin is active against *Candida* spp. and *Aspergillus* spp. and is indicated for invasive serious aspergillosis unresponsive to other drugs. It is administered intravenously. Other echinocandins include micafungin and anidulafungin approved for the treatment of disseminated candidiasis.

**Other antifungals**

**Flucytosine.** The fluorinated pyrimidine derivative, flucytosine, is used in combination with amphotericin B for cryptococcal meningitis. Side-effects are uncommon, although it may cause bone marrow suppression. It is active when given orally or parenterally.

**Griseofulvin.** Griseofulvin, a naturally occurring antifungal, was formerly widely used for the treatment of more extensive superficial mycoses and onychomycosis for which terbinafine is now the preferred agent.

**Amorolfin.** Amorolfin is available for the topical treatment of fungal skin and nail infections.

**Whitfield’s ointment.** Whitfield’s ointment is a traditional remedy for dermatophyte infection and contains benzoic and salicylic acid. Undecylenic acid (undecenoic) is also used in the treatment of tinea pedis.

**ANTIVIRAL DRUGS**

Drugs for HIV infection are discussed on page 192.

**Nucleoside analogues**

**Aciclovir.** Aciclovir (also known as acycloguanosine, Fig. 4.13a) is an acyclic nucleoside analogue which acts as a chain terminator of herpesvirus DNA synthesis. This drug is converted to aciclovir monophosphate by a virus-encoded thymidine kinase produced by alpha herpesviruses, herpes simplex types 1 and 2 and varicella zoster virus (Table 4.14). Conversion to the triphosphate is then achieved by cellular enzymes. Aciclovir triphosphate acts as a potent inhibitor of viral (but not cellular) DNA polymerase, and also competes with deoxyguanine triphosphate for incorporation into the growing chains of herpesvirus DNA, thereby resulting in
**Fig. 4.13** The structure of antiviral drugs. (a) Aciclovir; (b) cidofovir.

**Ganciclovir.** This guanine analogue is structurally similar to aciclovir, with extension of the acyclic side-chain by a carboxymethyl group. It is active against herpes simplex viruses and varicella zoster virus by the same mechanism as aciclovir. In addition, phosphorylation by a protein kinase encoded by the UL97 gene of cytomegalovirus renders it potently active against this virus. Thus ganciclovir is currently the first-line treatment for cytomegalovirus disease. Intravenous and oral preparations are available as an oral pro-drug, valganciclovir. Unlike aciclovir, ganciclovir has a significant toxicity profile including neutropenia, thrombocytopenia and the likelihood of sterilization by inhibiting spermatogenesis. For this reason, it is reserved for the treatment or prevention of life- or sight-threatening cytomegalovirus infection in immunocompromised patients. Use protective gloves when administering ganciclovir.

**Lamivudine** is a reverse transcriptase inhibitor active against both HIV and hepatitis B. Drug resistance is a problem (see p. 196 and p. 339).

**Entecavir** is a more potent inhibitor of hepatitis B and is active against lamivudine-resistant strains. Telbivudine and emtricitabine are also nucleoside analogue inhibitors of HBV DNA polymerase activity.

**Nucleotide analogues**

**Cidofovir** (Fig. 4.13b). This is a phosphonate derivative of an acyclic nucleoside which is a DNA polymerase chain inhibitor. It is administered intravenously for the treatment of severe cytomegalovirus (CMV) infections in patients with AIDS for whom other drugs are inappropriate. It is given with probenecid, and as it is nephrotoxic, particular attention should be given to hydration and to monitoring renal function.

**Adefovir dipivoxil** is used in the treatment of chronic hepatitis B (see p. 339).

**Pyrophosphate analogues**

**Foscarnet (sodium phosphonoformate)** is a simple pyrophosphate analogue which inhibits viral DNA polymerases. It is active against herpesviruses and its main roles are as a second-line treatment for severe cytomegalovirus disease and for the treatment of aciclovir-resistant herpes simplex infection. It is given intravenously and the potential for severe side-effects, particularly renal damage, limits its use.

**Adamantanes**

**Amantadine.** Amantadine is a synthetic symmetrical amine which is active prophylactically and therapeutically against influenza A virus (it is inactive against influenza B virus). Its prophylactic efficacy is similar to that of influenza vaccine and it is occasionally used to prevent the spread of influenza A in institutions such as nursing homes. Although CNS side-effects such as insomnia, dizziness and headache may occur (it is also used as a treatment for Parkinson’s disease), these are not usually produced by the lower doses currently recommended.

**Neuraminidase inhibitors**

Two drugs that inhibit the action of the neuraminidase of influenza A and B have been introduced. Zanamivir is administered by inhalation and oseltamivir is an oral preparation. Both have been shown to be effective in reducing the

Chain synthesis termination, due to its acyclic structure. This highly specific mode of activity, targeted only to virus-infected cells, means that aciclovir has very low toxicity. Intravenous, oral and topical preparations are available for the treatment of herpes simplex and varicella zoster virus infections (Table 4.14). Treatment does not eliminate the virus so relapses occur.

A pro-drug of aciclovir, valaciclovir, has been developed. Coupling of the amino acid valine to the acyclic side-chain of aciclovir allows better intestinal absorption. The valine is removed by enzymatic action and aciclovir is released into the circulation. A similar pro-drug of a related nucleoside analogue (penciclovir) is the antitherpes drug, famciclovir. The mode of action and efficacy of famciclovir are similar to those of aciclovir.
duration of illness in influenza. Oseltamivir is also available for the prophylaxis of influenza among household contacts of an index case.

**Ribavirin**

This synthetic purine nucleoside derivative which interferes with 5’-capping of messenger RNA, is active against several RNA and DNA viruses, at least in vitro. Its major use is in the treatment of chronic hepatitis C infection in combination with pegylated interferon-α (see p. 344). It is administered orally. Haemolytic anaemia is the most frequent adverse reaction. It is also administered by a small-particle aerosol generator (SPAG) to infants with acute respiratory syncytial virus (RSV) infection. Another indication is in the treatment of Lassa fever virus infection.

**Palivizumab**

This monoclonal antibody is specifically indicated to prevent seasonal respiratory syncytial virus (RSV) infection in infants at high risk of this infection. It is administered by intramuscular injection.

**Interferons**

These are naturally occurring proteins with a multiplicity of actions, including antiviral, immunomodulatory and antiproliferative effects. Interferons are produced by virus-infected cells, macrophages and lymphocytes. Their production is stimulated by a number of factors, including viral nucleic acid. They induce an antiviral state in uninfected cells, through activation of a complex set of biochemical pathways. They have been synthesized commercially by either culture of lymphoblastoid cells or by recombinant DNA technology and are licensed for therapeutic use.

The potency of INF-α has been enhanced by coupling the protein with polyethylene glycol. The resulting PEG interferon given once weekly has been shown to improve the response, and reduce the side-effects, to treatment of hepatitis B and C. When combined with oral ribavirin, selected patients with chronic hepatitis C can be cleared of the virus.

**FURTHER READING**

---

**IMMUNIZATION AGAINST INFECTIOUS DISEASES**

Although effective antimicrobial chemotherapy is available for many diseases, the ultimate aim of any infectious disease control programme is to prevent infection occurring. This is achieved either by:

- eliminating the source or mode of transmission of an infection (see p. 81)
- reducing host susceptibility to environmental pathogens.

**Immunization, immunoprophylaxis and immunotherapy**

Immunization has changed the course and natural history of many infectious diseases. Passive immunization by administering preformed antibody, either in the form of immune serum or purified normal immunoglobulin, provides short-term immunity and has been effective in both the prevention (immunoprophylaxis) and treatment (immunotherapy) of a number of bacterial and viral diseases (Table 4.15). The active immunization schedule currently recommended is summarized in Box 4.6. Long-lasting immunity is achieved only by active immunization with a live attenuated or an inactivated organism, or a subunit thereof (Table 4.16). Active immunization may also be performed with microbial toxin (either native or modified) – that is, a toxoid. Immunization should be kept up to date with booster doses throughout life. Travellers to developing countries, especially if visiting rural areas, should in addition enquire about further specific immunizations.

In 1974 the World Health Organization introduced the Expanded Programme on Immunization (EPI). Twenty years later more than 80% of the world’s children had been immunized against tuberculosis, diphtheria, tetanus, pertussis, polio and measles. Poliomyelitis should shortly be eradicated worldwide, which will match the past success of global smallpox eradication. Introduction of conjugate vaccines against Haemophilus influenzae type b (Hib) has proved highly effective in controlling invasive H. influenzae infection, notably meningitis (see p. 1153).

**Protection for travellers to developing/tropical countries**

There have been a huge increase in the number of people travelling to developing countries, mainly for recreation and leisure. The risk of infection depends on the area to be visited, the type of activity and the underlying health of the traveller. Advice should therefore always be based on an individual assessment.

Protection for travellers can be divided into three categories:

- **Personal protection, e.g.**
  - insect repellents
  - impregnated bed netting
  - avoidance of animals
  - care with food and drink

- **Chemoprophylaxis, e.g. antimalarials**

- **Immunization, e.g.**
  - yellow fever
  - hepatitis A and B
  - typhoid.

Because situations and risks can change rapidly, websites (which can be regularly updated) are often the best source of advice on travel health.
VIRAL INFECTIONS

Introduction
Viruses are much smaller than other infectious agents (see Tables 4.17 and 4.19) and contain either DNA or RNA, not both as in bacteria and other microorganisms. Since they are metabolically inert, they must live intracellularly, using the host cell for synthesis of viral proteins and nucleic acid. Viruses have a central nucleic acid core surrounded by a protein coat that is antigenically unique for a particular virus. The protein coat (capsid) imparts a helical or icosahedral structure to the virus. Some viruses also possess an envelope consisting of lipid and protein.

Outcomes of virus infection of a cell
Replication of viruses within a cell may result in sufficient distortion of normal cell function so as to result in cell death — a cytocidal or cytolytic infection. However, acute cell death is not an inevitable consequence of virus infection of a cell. In a chronic, or persistent, infection, virus replication continues throughout the lifespan of the cell, but does not interfere with the normal cellular processes necessary for cell survival. Hepatitis B and C viruses may interact with cells in this way. Some viruses, e.g. the herpesvirus family, are able to go latent within a cell — in such a state, the virus genome is present within the cell, but there is very little, if any, production of viral proteins, and no production of mature virus particles. Finally, some viruses are able to transform cells, leading to uncontrolled cell division, e.g. Epstein–Barr virus infection of B lymphocytes, resulting in the generation of an immortal lymphoblastoid cell line.

DNA VIRUSES
Details of the structure, size and classification of human DNA viruses are shown in Table 4.17.

ADENOVIRUSES
Over 50 adenovirus serotypes have been identified as human pathogens, infecting a number of different cell types, and therefore resulting in different clinical syndromes. Adenovirus infection commonly presents as an acute pharyngitis, and extension of infection to the larynx and trachea in infants may lead to croup. By school age the majority of children show serological evidence of previous infection. Certain subtypes produce an acute conjunctivitis associated with pharyngitis. In adults, adenovirus causes acute follicular conjunctivitis and rarely pneumonia that is clinically similar to that produced by *Mycoplasma pneumoniae* (see p. 859). Certain adenoviruses (Ads 40 and 41) cause gastroenteritis (see p. 128) without respiratory disease and adenovirus infection may be responsible for acute mesenteric lymphadenitis in children and young adults. Mesenteric adenitis due to adenoviruses may lead to intussusception in infants. Infection in an immunocompromised host, e.g. a bone marrow transplant recipient, may result in multisystem failure failure and fatal disease.

HERPESVIRUSES
Members of the *Herpesviridae* family are causes of a wide range of human diseases. Details are summarized in Table 4.18. The hallmark of all herpesvirus family is the ability of the viruses to establish latent (or silent) infections that then persist for the life of the individual.

Herpes simplex virus (HSV) infection (Fig. 4.14)
Two types of HSV have been identified: HSV-1 is the major cause of herpetic stomatitis, herpes labialis (‘cold sore’), keratoconjunctivitis and encephalitis, whereas HSV-2 causes genital herpes and may also be responsible for systemic infection in the immunocompromised host. These divisions, however, are not rigid, for HSV-1 can give rise to genital herpes and HSV-2 can cause infections in the mouth.

*Signifies primary infection.

**HSV-1**

The portal of entry of HSV-1 infection is usually via the mouth or occasionally the skin. The primary infection may go unnoticed or may produce a severe inflammatory reaction with vesicle formation leading to painful ulcers (gingivostomatitis; see Fig. 4.15). The virus then remains latent, most commonly in the trigeminal ganglia, but may be reactivated by stress, trauma, febrile illnesses and ultraviolet radiation, producing the recurrent form of the disease known as herpes labialis (‘cold sore’). Approximately 70% of the population are infected with HSV-1 and recurrent infections occur in one-third of individuals. Reactivation often produces localized paraesthesiae in the lip before the appearance of a cold sore.

Complications of HSV-1 infection include transfer to the eye (dendritic ulceration, keratitis), acute encephalitis (see p. 1156), skin infections such as herpetic whitlow and erythema multiforme (see p. 1250).

**HSV-2**

The clinical features, diagnosis and management of genital herpes are described on pages 180 and 1231. The virus remains latent in the sacral ganglia and during recurrence can produce a radiculomyelopathy, with pain in the groin, buttocks and upper thighs. Primary anorectal herpes infection is common in men having sex with men (see p. 180).

Neonates may develop primary HSV infection following vaginal delivery in the presence of active genital HSV infection in the mother, particularly if the maternal disease is a primary, rather than a recurrent infection. The disease in the baby varies from localized skin lesions (about 10–15%) to widespread visceral disease often with encephalitis, with a poor prognosis. Caesarean section should therefore be performed if active genital HSV infection is present during labour.

Immune compromised patients such as those receiving intensive cancer chemotherapy or those with the acquired immunodeficiency syndrome (AIDS) may develop disseminated HSV infection involving many of the viscera. In severe cases death may result from hepatitis and encephalitis.

Humoral antibody develops following primary infection, but mononuclear cell responses probably prevent dissemination of disease.

The clinical picture, diagnosis and treatment are described on page 180.
Varicella zoster virus (VZV) infection

VZV produces two distinct diseases, varicella (chickenpox) and herpes zoster (shingles). The primary infection is chickenpox. It usually occurs in childhood, the virus entering through the mucosa of the upper respiratory tract. In some countries (e.g. the Indian subcontinent) a different epidemiological pattern exists with most infections occurring in adulthood. Chickenpox rarely occurs twice in the same individual. Infectious virus is spread from fresh skin lesions by direct contact or airborne transmission and the period of infectivity in chickenpox extends from 2 days before the appearance of the rash until the skin lesions are all at the crusting stage. Following recovery from chickenpox the virus remains latent in dorsal root and cranial nerve ganglia. Reactivation of infection then results in shingles.

Clinical features of chickenpox

Fourteen to twenty-one days after exposure to VZV, a brief prodromal illness of fever, headache and malaise heralds the eruption of chickenpox, characterized by the rapid progression of macules to papules to vesicles to pustules in a matter of hours (Fig. 4.16). In young children the prodromal illness may be very mild or absent. The illness tends to be more severe in older children and can be debilitating in adults. The lesions occur on the face, scalp and trunk, and to a lesser extent on the extremities. It is characteristic to see skin lesions at all stages of development on the same area of skin. Fever subsides as soon as new lesions cease to appear. Eventually the pustules crust and heal without scarring.

Complications of chickenpox include pneumonia, which generally begins 1–6 days after the skin eruption, and bacterial superinfection of skin lesions. Pneumonia is more common in adults than in children and cigarette smokers are at particular risk. Pulmonary symptoms are usually more striking than the physical findings, although a chest radiograph usually shows diffuse changes throughout both lung fields. CNS involvement occurs in about 1 per 1000 cases and most commonly presents as an acute truncal cerebellar ataxia. The immunocompromised are susceptible to disseminated infection with multorgan involvement. Women in pregnancy are prone to severe chickenpox and, in addition, there is a risk of intrauterine infection with structural damage to the fetus (if maternal infection is within the first 20 weeks of pregnancy, the risk of varicella embryopathy is 1–2%).

Fig. 4.16 Chickenpox in an adult. Generalized VZV.

Clinical features of shingles

Shingles (see p. 1231) arises from the reactivation of virus latent within the dorsal root or cranial nerve ganglia. It may occur at all ages but is most common in the elderly, producing skin lesions similar to chickenpox, although classically they are unilateral and restricted to a sensory nerve (i.e. dermatomal) distribution (Fig. 4.17). The onset of the rash of shingles is usually preceded by severe dermatomal pain, indicating the involvement of sensory nerves in its pathogenesis. Virus is disseminated from freshly formed vesicles and may cause chickenpox in susceptible contacts.

The commonest complication of shingles is post-herpetic neuralgia (PHN) (see p. 1157).

Diagnosis

The diseases are usually recognized clinically but can be confirmed by detection of VZV DNA within vesicular fluid using PCR, electronmicroscopy, immunofluorescence or culture of vesicular fluid, and by serology.

Prophylaxis and treatment

Chickenpox usually requires no treatment in healthy children and infection results in lifelong immunity. Aciclovir and derivatives are, however, licensed for this indication in the USA, where the argument for treatment is one of health economics, viz. the sooner the child recovers, the sooner the carer can return to work. However, the disease may be fatal in the immunocompromised, who should therefore be offered protection, after exposure to the virus, with zoster immune immunoglobulin (ZIG).

Anyone with chickenpox who is over the age of 16 years should be given antiviral therapy with aciclovir, or a similar drug, if they present within 72 hours of onset. Prophylactic ZIG is recommended for women in pregnancy exposed to varicella zoster virus and, if chickenpox develops, aciclovir treatment should be given (NB: aciclovir has not been licensed for use in pregnant women). If a woman has chickenpox at term, her baby should be protected by ZIG if delivery occurs within 7 days of the onset of the mother’s rash. An effective live attenuated varicella vaccine is licensed as a routine vaccination of childhood in the USA; it is available on a named-patient basis in the UK, and also for susceptible healthcare workers.

Shingles involving motor nerves, e.g. 7th cranial nerve leading to facial palsy, is also treated with aciclovir (or derivat-
tives thereof) as the duration of lesion formation and time to healing can be reduced by early treatment. Aciclovir, valaciclovir and famciclovir have all been shown to reduce the burden of zoster-associated PHN when treatment is given in the acute phase. Shingles involving the ophthalmic division of the trigeminal nerve has an associated incidence of acute and chronic ophthalmic complications of 50%. Early treatment with aciclovir reduces this to 20% or less. As for chickenpox, all immunocompromised individuals should be given aciclovir at the onset of shingles, no matter how mild the attack appears when it first presents.

Recent evidence suggests that vaccination of all adults over the age of 60, with a dose higher than that used for chickenpox prophylaxis in childhood, reduces shingles-related morbidity and post-herpetic neuralgia.

**Cytomegalovirus (CMV) infection**

Infection with CMV is found world-wide. Clinically significant CMV infection arises particularly in two patient groups – fetuses who acquire the infection transplacentally and are born congenitally infected, and patients who are immunosuppressed, e.g. transplant recipients, or patients with HIV infection. Over 50% of the adult population have serological evidence of latent infection with the virus. As with all herpesviruses, the virus persists for life, usually as a latent infection in which the naked DNA is situated extrachromosomally in the nuclei of the cells in the endothelium of the arterial wall and in T lymphocytes.

**Clinical features**

In healthy adults CMV infection is usually asymptomatic but may cause an illness similar to infectious mononucleosis, with fever, occasionally lymphocytosis with atypical lymphocytes, and hepatitis with or without jaundice. The Paul–Bunnell test for heterophile antibody is negative. Infection may be spread by kissing, sexual intercourse or blood transfusion, and transplacentally to the fetus. Disseminated fatal infection with widespread visceral involvement occurs in the immunocompromised (see p. 202) and may cause encephalitis, retinitis, pneumonitis and diffuse involvement of the gastrointestinal tract.

Intrauterine infection may arise from either primary or reactivated maternal infection. CMV is, by far, the commonest congenital infection – in developed countries, such as the UK, 0.3–1% of all babies are born congenitally infected with CMV. Around 5–10% of such babies have severe disease evident at birth, with a poor prognosis. CNS involvement may cause microcephaly and motor disorders. Jaundice and hepatospleno-megaly are common, and thrombocytopenia and haemolytic anaemia also occur. Periventricular calcification is seen on skull X-ray. A further 5–10% of infected babies are normal at birth, but developmental abnormalities become apparent later, e.g. sensorineural nerve deafness. The remaining 80–85% of infected babies are normal at birth and develop normally.

**Diagnosis**

Most infections are now diagnosed by detection and quantification of CMV DNA or RNA using molecular amplification techniques, in blood or other body fluid samples. The virus can also be identified in tissues by the presence of characteristic intranuclear ‘owl’s eye’ inclusions (Fig. 4.18) on histological staining and by direct immunofluorescence. Culture in human embryo fibroblasts is usually slow but diagnosis can be accelerated by immunofluorescent detection of antigen in the cultures. Serological tests can identify latent (IgG) or primary (IgM) infection.

**Treatment**

In the immunocompetent, infection is usually self-limiting and no specific treatment is required. In the immunosuppressed, ganciclovir (5 mg/kg daily for 14–21 days) reduces retinitis and gastrointestinal damage and can eliminate CMV from blood, urine and respiratory secretions. It is less effective against pneumonitis. In patients who are continually immunocompromised, particularly those with AIDS, maintenance therapy may be necessary. Drug resistance has been reported in AIDS patients and transplant recipients Bone marrow toxicity is common. Valganciclovir, foscarnet and cidofovir are available (see p. 101). Treatment of CMV in neonates is difficult, but ganciclovir therapy of infected babies with evident CNS involvement has been shown to improve long-term hearing outcome.

**Epstein–Barr virus (EBV) infection**

Globally, most individuals are infected with this virus at an early age (0–5 years), at which time clinical symptoms are unusual. Infection at an older age is associated with an acute febrile illness known as infectious mononucleosis (glandular fever), which occurs world-wide in adolescents and young adults. EBV is probably transmitted in saliva and by aerosol.

**Clinical features**

The predominant symptoms of infectious mononucleosis are fever, headache, malaise and sore throat. Palatal petechiae and a transient macular rash are common, the latter occurring in 90% of patients who have received ampicillin (inappropriately) for the sore throat. Cervical lymphadenopathy, particularly of the posterior cervical nodes, and splenomegaly are characteristic. Mild hepatitis is common, but other complications such as myocarditis, meningitis, encephalitis, mesenteric adenitis and splenic rupture are rare.

Although some young adults remain debilitated and depressed for some months after infection, the evidence for reactivation of latent virus in healthy individuals is
controversial, although this is thought to occur in immuno-compromised patients.

Following primary infection, EBV remains latent in resting memory B lymphocytes. It has been shown in vitro that of nearly 100 viral genes expressed during replication, approximately only 10 are expressed in the latently infected B cells.

Severe, often fatal infectious mononucleosis may result from a rare X-linked lymphoproliferative syndrome affecting young boys. Those who survive have an increased risk of hypogammaglobulinaemia and/or lymphoma.

EBV is the cause of oral hairy leucoplakia in AIDS patients and is the major aetiological agent responsible for Burkitt’s lymphoma, undifferentiated nasopharyngeal carcinoma, post-transplant lymphoma, the immunoblastic lymphoma of AIDS patients and some forms of Hodgkin’s lymphoma and gastric cancer. Different levels of expression of EBV latency genes occur in these proliferative conditions caused by the virus, and various co-factors are also involved in their pathogenesis, e.g. in Burkitt’s lymphoma, the commonest tumour of childhood in sub-Saharan Africa, the interplay between EBV infection and the presence of hyperendemic (i.e. present all year-round) malaria appears to be relevant.

**Diagnosis**

EBV infection should be strongly suspected if atypical mononuclear cells (activated CD8 positive T lymphocytes, also known as glandular fever cells) are found in the peripheral blood. It can be confirmed during the second week of infection by a positive Paul–Bunnell reaction, which detects heterophile antibodies (IgM) that agglutinate sheep erythrocytes. False-positives can occur in other conditions such as viral hepatitis, Hodgkin’s lymphoma and acute leukaemia. The Monospot test is a sensitive and easily performed screening test for heterophile antibodies. Specific EBV IgM antibodies indicate recent infection by the virus. Clinically similar illnesses are produced by CMV, toxoplasmosis and acute HIV infection (the so-called seroconversion illness) but these can be distinguished serologically.

**Treatment**

The majority of cases require no specific treatment and recovery is rapid. Corticosteroid therapy is advised when there is neurological involvement (e.g. encephalitis, meningitis, Guillain–Barré syndrome), when there is marked thrombocytopenia or haemolysis, or when the tonsillar enlargement is so marked as to cause respiratory obstruction.

**Human herpesvirus type 6 (HHV-6)**

This human herpesvirus infects CD4+ T lymphocytes, occurs world-wide, and exists as a latent infection in over 85% of the adult population. It is spread by contact with oral secre- tions. The virus causes roseola infantum (exanthem subitum) which presents as a high fever followed by generalized macular rash in infants. HHV-6 is a common cause of febrile convulsions, and aseptic meningitis or encephalitis occur as rare complications. Reactivation in the immunocompromised may lead to severe pneumonia.

**Treatment**

Supportive management only is recommended for the common infantile disease. Ganciclovir can be used in the immunocompromised.

**Human herpesvirus type 7 (HHV-7)**

This virus is similar to HHV-6 in being a T lymphotrophic herpesvirus. It is also present as a latent infection in over 85% of the adult population and it is known to infect CD4+ helper T cells by using the CD4 antigen (the main receptor employed by HIV). The full spectrum of disease due to HHV-7 has not yet been fully characterized, but, like HHV-6, it may cause roseola infantum in infants.

**Human herpesvirus type 8 (Kaposi’s sarcoma-associated herpesvirus)**

This human herpesvirus is strongly associated with the aetiology of classical and AIDS-related Kaposi’s sarcoma. Antibody prevalence is high in those with tumours but relatively low in the general population of most industrialized countries. High rates of infection (>50% population) have been described in central and southern Africa and this matches the geographic distribution of Kaposi’s sarcoma before the era of AIDS. HHV-8 can be sexually transmitted among men having sex with men, through heterosexual sex and through exposure to blood from needle sharing. It is thought that salivary transmission may be the predominant route in Africa. HHV-8 RNA transcripts have been detected in Kaposi’s sarcoma cells and in circulating mononuclear cells from patients with the tumour. This virus also has an aetiological role in two rare lymphoproliferative diseases – multicentric Castleman’s disease (a disorder of the plasma cell type) and primary effusion lymphoma (body-cavity-based lymphoma), which is characterized by pleural, pericardial or peritoneal lymphomatous effusions in the absence of a solid tumour mass.

**PAPOVAVIRUSES**

This virus family comprises the papilloma, polyoma and vacuolar viruses. These viruses tend to produce chronic infections, often with evidence of latency. They are capable of inducing neoplasia in some animal species and were among the first viruses to be implicated in tumorigenesis. Human papillomaviruses, of which there are at least 100 types, are responsible for the common skin and genital warts and certain types (mainly 16 and 18) are the cause of carcinoma of the cervix and some oral cancers (type 16). The realization that cancer of the cervix is an infectious disease has led to the development of papillomavirus vaccines, which have been shown to prevent disease associated with the high-risk HPV types 16 and 18, and have recently been licensed for use in the USA, Australia and Europe. The current recommendations are for vaccination of all girls at age 9–14 years.

For genital warts see page 181.

The human BK virus, a polyomavirus, is generally found in immunocompromised individuals and may be detected in the urine of 15–40% of renal transplant patients. Rarely, this is associated with impairment of function of the transplanted kidney – BK nephropathy. A related virus, JC, is the cause of progressive multifocal leucoencephalopathy (PML) which presents as dementia in the immunocompromised and is due to progressive cerebral destruction resulting from accumulation of the virus in brain tissue. Two further human polyomaviruses, WU and KI, have been recently identified. These may
be associated with respiratory tract infections in young children.

**ERYTHROVIRUSES**

Human erythrovirus B19 (also known as parvovirus) causes erythema infectiosum (fifth disease), a common infection in schoolchildren. The rash is typically on the face (the 'slapped-cheek' appearance). The patient is well and the rash can recur over weeks or months. Asymptomatic infection occurs in 20% of children. Non-specific respiratory tract illness is another common manifestation of infection. Moderately severe self-limiting arthropathy (see p. 535) is common if infection occurs in adulthood, especially in women. Aplastic crisis may occur in patients with chronic haemolysis (e.g. sickle cell disease). Chronic infection with anaemia occurs in immunocompromised subjects. Hydrops fetalis (3% risk) and spontaneous abortion (9% risk) may result from infection during the first and second trimesters of pregnancy.

Bocavirus is a recently identified erythrovirus which accounts for around 3–5% of respiratory tract infections in young children.

**POXVIRUSES**

**Smallpox (variola)**

This disease was eradicated in 1977 following an aggressive vaccination policy and careful detection of new cases coordinated by the World Health Organization. Its possible use in bioterrorism has resulted in the reintroduction of smallpox vaccination in some countries (see p. 959).

**Monkeypox**

This is a rare zoonosis that occurs in small villages in the tropical rainforests in several countries of western and central Africa. Its clinical effects, including a generalized vesicular rash, are indistinguishable from smallpox, but person-to-person transmission is unusual. Most infections occur in children who have not been vaccinated against smallpox. Disease can be severe, with mortality rates of 10–15% in unvaccinated individuals. Serological surveys indicate that several species of squirrel are likely to represent the animal reservoir. The virus was introduced into the USA in 2003 via West African small mammals illegally imported as pets. Widespread infection of prairie dogs resulted, and there were 37 laboratory confirmed cases in humans, only two of which suffered complications (keratitis, encephalopathy).

**Cowpox**

Cowpox produces large vesicles which are classically on the hands in those in contact with infected cows. The lesions are associated with regional lymphadenitis and fever. Cowpox virus has been found in a range of species including domestic and wild cats, and the reservoir is thought to exist in a range of rodents.

**Vaccinia virus**

This is a laboratory virus and does not occur in nature in either humans or animals. Its origins are uncertain but it has been invaluable in its use as the vaccine to prevent smallpox. Vaccination is now not recommended except for laboratory personnel handling certain poxviruses for experimental purposes or in contingency planning to manage a deliberate release of smallpox virus. It is being assessed experimentally as a possible carrier for new vaccines.

**Orf**

This poxvirus causes contagious pustular dermatitis in sheep and hand lesions in humans (see p. 1232).

**Molluscum contagiosum**

This is discussed on page 1232.

**HEPADNA VIRUSES**

These partially double-stranded DNA viruses infect a number of species. The representative virus from this family which infects humans, hepatitis B virus, is discussed, along with other hepatitis viruses, on page 333.

**FURTHER READING**

**RNA VIRUSES (Table 4.19)**

**PICORNAVIRUSES (PICO = SMALL)**

This is a large family of small RNA viruses, which includes the enteroviruses and rhinoviruses which infect humans. The term enterovirus refers to the enteric means of spread of these viruses, i.e. via the faeco-oral route. The enteroviruses include poliovirus types 1–3, coxsackie A and B viruses, echoviruses and enteroviruses (EV) 68–71.

**Poliovirus infection (poliomyelitis)**

Poliomyelitis occurs when a susceptible individual is infected with poliovirus type 1, 2 or 3. These viruses have a propensity for the nervous system, especially the anterior horn cells of the spinal cord and cranial nerve motor neurones. Poliomyelitis is found world-wide but its incidence has decreased dramatically following improvements in sanitation, hygiene and the widespread use of polio vaccines. Spread is usually via the faeco-oral route, as the virus is excreted in the faeces.

**Clinical features**

The incubation period is 7–14 days. Although polio is essentially a disease of childhood, no age is exempt. The clinical manifestations vary considerably.

**Inapparent infection**

Inapparent infection is common and occurs in 95% of infected individuals.

**Abortive poliomyelitis**

Abortive poliomyelitis occurs in approximately 4–5% of cases and is characterized by the presence of fever, sore throat and myalgia. The illness is self-limiting and of short duration.
Non-paralytic poliomyelitis (poliovirus meningitis)
Non-paralytic poliomyelitis has features of abortive poliomyelitis as well as signs of meningeal irritation, but recovery is complete.

Paralytic poliomyelitis
Paralytic poliomyelitis occurs in approximately 0.1% of infected children (1.3% of adults). Several factors predispose to the development of paralysis:

- male sex
- exercise early in the illness
- trauma, surgery or intramuscular injection, which localize the paralysis
- recent tonsillectomy (bulbar poliomyelitis).

This form of the disease is characterized initially by features simulating abortive poliomyelitis. Symptoms subside for 4–5 days, only to recur in greater severity with signs of meningeal irritation and muscle pain, which is most prominent in the neck and lumbar region. These symptoms persist for a few days and are followed by the onset of asymmetric flaccid paralysis without sensory involvement. The paralysis is usually confined to the lower limbs in children under 5 years of age and the upper limbs in older children, whereas in adults it manifests as paraplegia or quadriplegia.

Bulbar poliomyelitis
Bulbar poliomyelitis is characterized by the presence of cranial nerve involvement and respiratory muscle paralysis.
Soft palate, pharyngeal and laryngeal muscle palsies are common.

Aspiration pneumonia, myocarditis, paralytic ileus and urinary calculi are late complications of poliomyelitis.

**Diagnosis**

The diagnosis is a clinical one. Distinction from Guillain–Barré syndrome is easily made by the absence of sensory involvement and the asymmetrical nature of the paralysis in poliomyelitis. Laboratory confirmation and distinction between the wild virus and vaccine strains is achieved by genome detection techniques, virus culture, neutralization and temperature marker tests.

**Treatment**

Treatment is supportive. Bed rest is essential during the early course of the illness. Respiratory support with intermittent positive-pressure respiration is required if the muscles of respiration are involved. Once the acute phase of the illness has subsided, occupational therapy, physiotherapy and occasionally surgery have roles in patient rehabilitation.

**Prevention and control**

Immunization (Box 4.6) has dramatically decreased the prevalence of this disease world-wide and global eradication of the virus, coordinated by the World Health Organization, is expected within the next 1–2 years. The virus remains endemic in only four countries – Nigeria, India, Pakistan and Afghanistan. However, there have been outbreaks in West Africa where cultural taboos have disrupted the polio vaccination campaign and also in the Sudan. Recent studies using inactivated IM poliovirus vaccine (IPV) have revealed greater potency than the original Salk IPV. The greater reliability of IPV in hot climates and the scientific and ethical problems of continuing to use oral polio vaccine (OPV) in countries free from poliomyelitis, mean that IPV has replaced OPV in the routine immunization schedules in many countries.

### Coxsackievirus, echovirus and other enterovirus infections

These viruses are also spread by the faeco-oral route. They each have a number of different types and are responsible for a broad spectrum of disease involving the skin and mucous membranes, muscles, nerves, the heart (Table 4.20) and, rarely, other organs, such as the liver and pancreas. They are frequently associated with pyrexial illnesses and are the most common cause of aseptic meningitis.

#### Herpangina

This disease is mainly caused by Coxsackie A viruses and presents with a vesicular eruption on the fauces, palate and uvula. The lesions evolve into ulcers. The illness is usually associated with fever and headache but is short-lived, recovery occurring within a few days.

#### Hand, foot and mouth disease

This disease is mainly caused by Coxsackievirus A16 or A10. It is also the main feature of infection with enterovirus (EV)71. Oral lesions are similar to those seen in herpangina but may be more extensive in the oropharynx. Vesicles and a maculopapular eruption also appear, typically on the palms of the hands and the soles of the feet, but also on other parts of the body. This infection commonly affects children. Recovery occurs within a week.

#### Neurological disease

Other enteroviruses in addition to poliovirus can cause a broad range of neurological disease, including meningitis, encephalitis, and a paralytic disease similar to poliomyelitis. EV71 has particular predilection for neuroinvasion. Thus, in epidemics of EV71 infection, a variety of serious neuromotor syndromes arise, albeit in a minority of those infected.

#### Heart and muscle disease

Enterovirus infection is a cause of acute myocarditis and pericarditis, from which, in general, there is complete

recovery. However, these viruses can also cause chronic congestive cardiomyopathy and, rarely, constrictive pericarditis.

Skeletal muscle involvement, particularly of the intercostal muscles, is a feature of Bornholm disease, a febrile illness usually due to Coxackievirus B. The pain may be of such an intensity as to mimic pleurisy or an acute abdomen. The infection affects both children and adults and may be complicated by meningitis or cardiac involvement.

Rhinovirus infection

Rhinoviruses are responsible for the common cold (see p. 831). Chimpanzees and humans are the only species to develop the common cold. ICAM-1 is the cellular receptor for rhinovirus and it is only in these two species that the specific binding domain is present. Peak incidence rates occur in the colder months, especially spring and autumn. There are multiple rhinovirus immunotypes (>100), which makes vaccine control impracticable. In contrast to enteroviruses, which replicate at 37°C, rhinoviruses grow best at 33°C (the temperature of the upper respiratory tract), which explains the localized disease characteristic of common colds.

**REOVIRUSES**

Reovirus infection

Reovirus infection occurs mainly in children, causing mild respiratory symptoms and diarrhea. A few deaths have been reported following disseminated infection of brain, liver, heart and lungs.

Rotavirus infection

Rotavirus (Latin *rota* = wheel) is so named because of its electronmicroscopic appearance with a characteristic circular outline with radiating spokes (Fig. 4.19). It is responsible world-wide for both sporadic cases and epidemics of diarrhea, and is currently one of the most common causes of childhood diarrhea. More than 600 000 infected children under the age of 5 years are estimated to die annually in resource-deprived countries, compared with 75–150 in the USA. The prevalence is higher during the winter months in non-tropical areas. Asymptomatic infections are common, and bottle-fed babies are more likely to be symptomatic than those that are breast-fed.

Adults may become infected with rotavirus but symptoms are usually mild or absent. The virus may, however, cause diarrhea in immunosuppressed adults, or outbreaks in patients on care of the elderly wards.

Clinical features

The illness is characterized by vomiting, fever, diarrhea, and the metabolic consequences of water and electrolyte loss.

Diagnosis and differential diagnosis

The diagnosis can be established by PCR for genome detection, or ELISA for the detection of rotavirus antigen in faeces and by electronmicroscopy of faeces. Histology of the jejunal mucosa in children shows shortening of the villi, with crypt hyperplasia and mononuclear cell infiltration of the lamina propria.

Treatment and prevention

Treatment is directed at overcoming the effects of water and electrolyte imbalance with adequate oral rehydration therapy and, when indicated, intravenous fluids (see Box 4.9, p. 132). Antibiotics should not be prescribed. A controlled trial in Egypt in children with rotavirus diarrhea demonstrated faster recovery (31 h versus 75 h) in those given nitazoxanide, a broad-spectrum anti-infective agent, for 3 days compared with placebo.

Rotavirus vaccines

Despite a major setback when the first licensed rotavirus vaccine was rapidly withdrawn from the market in 1999 following reports of increased rates of intussusception, two new vaccines have been developed, and are now licensed for use in many countries. Both are live vaccines. One vaccine contains an attenuated human strain with the relevant antigens being P[8] and G1, while another is based on a bovine parent strain, and comprises five single-gene reassortants each containing a human-strain outer capsid gene encoding the most common human antigenic types (P[8] and G1-4).

**CALICIVIRUSES**

This extensive virus family, named after the cup-shaped (Latin *calyx* = cup) indentations on their viral surface seen by electron microscopy, contains four genera, two of which, the noroviruses and sapoviruses, infect humans and cause gastroenteritis. Norovirus is the major cause of acute non-bacterial gastroenteritis, causing outbreaks in nursing homes, hospitals, schools, leisure centres, restaurants and cruise ships. Transmission is mostly faeco-oral with outbreaks suggesting a common source, such as food and water and fomites. Aerosol transmission also occurs and noroviruses can be detected in vomit. Illness is usually self-limiting (12–48 hours) and mild, consisting of nausea, headache and abdominal cramps, followed by diarrhea and vomiting, which may be the only feature (winter vomiting). Diagnosis is by demonstration of viral nucleic acid in diarrhoeal faeces. Treatment is with oral rehydration solutions (ORS). Prevention can be difficult but hand washing and good hygienic food preparation is required.

*Sapovirus* causes a gastroenteritis, mainly in children. Other viruses associated with gastroenteritis are shown in Table 4.21.
TOGAVIRUSES

This family comprises two genera: the rubiviruses, which include rubella virus; and the alphaviruses, which include some of the arthropod-borne viruses.

Rubella

Rubella (‘German measles’) is caused by a spherical, enveloped RNA virus which is easily killed by heat and ultraviolet light. While the disease can occur sporadically, epidemics are not uncommon. It has a world-wide distribution. Spread of the virus is via droplets; maximum infectivity occurs before and during the time the rash is present.

Clinical features

The incubation period is 14–21 days, averaging 18 days. The clinical features are largely determined by age, with symptoms being mild or absent in children under 5 years.

During the prodrome the patient may develop malaise and fever and mild conjunctivitis and lymphadenopathy. The distribution of the lymphadenopathy is characteristic and involves particularly the suboccipital, postauricular and posterior cervical groups of lymph nodes. Small petechial lesions on the soft palate (Forchheimer spots) are suggestive but not diagnostic. Splenomegaly may be present.

The eruptive or exanthematous phase usually occurs within the first 7 days of the initial symptoms. The rash first appears on the forehead and then spreads to involve the trunk and the limbs. It is pinkish red, macular and discrete, although some of these lesions may coalesce (Fig. 4.20). It usually fades by the second day and rarely persists beyond the third day after its appearance.

Complications

Complications are rare. They include superadded pulmonary bacterial infection, arthralgia (commoner in females), haemorrhagic manifestations due to thrombocytopenia, encephalitis and the congenital rubella syndrome. Rubella affects the fetuses of up to 80% of all women who contract the infection during the first trimester of pregnancy. The incidence of congenital abnormalities diminishes in the second trimester and no ill-effects result from infection in the third trimester.

Congenital rubella syndrome is characterized by the presence of fetal cardiac malformations, especially patent ductus arteriosus and ventricular septal defect, eye lesions (especially cataracts), microcephaly, mental retardation and deafness.

The expanded rubella syndrome consists of the manifestations of the congenital rubella syndrome plus other effects including hepatosplenomegaly, myoclonus, interstitial pneumonia and metaphyseal bone lesions.

Diagnosis and treatment

The diagnosis may be suspected clinically, but laboratory diagnosis is essential to distinguish the illness from other virus infections (e.g. echovirus and drug rashes). This is achieved by the detection of rubella-specific IgM by ELISA in an acute serum sample, preferably confirmed by the demonstration of IgG seroconversion (or a rising titre of IgG) in a subsequent sample taken 14 days later. Viral genome can be detected in throat swabs (or oral fluid samples), urine and, in the case of intrauterine infection, the products of conception.

Treatment is supportive.

Prevention

Human immunoglobulin can decrease the symptoms of this already mild illness, but does not prevent the teratogenic effects. Several live attenuated rubella vaccines have been used with great success in preventing this illness and these have been successfully combined with the measles and mumps (MMR) vaccine. The side-effects of vaccination have been dramatically decreased by using vaccines prepared in human embryonic fibroblast cultures (RA 27/3 vaccine). Use of the vaccine is contraindicated during pregnancy or if there is a likelihood of pregnancy within 3 months of immunization. Inadvertent use of the vaccine during pregnancy has not, however, revealed a risk of teratogenicity.

Arbovirus (arthropod-borne) infection

Arboviruses are zoonotic viruses, with the possible exception of the O’nyong-nyong fever virus of which humans are the only known vertebrate hosts. They are transmitted through the bites of insects, especially mosquitoes and ticks. Over 385 viruses are classified as arboviruses. Culex, Aedes and Anopheles mosquitoes account for the transmission of the majority of these viruses.

Although most arbovirus diseases are generally mild, epidemics are frequent and when these occur the mortality is high. In general, the incubation period is less than 10 days. The illness tends to be biphasic and, as in other viral fevers, pyrexia, conjunctival suffusion, a rash, retro-orbital pain, myalgia and arthralgia are common. Lymphadenopathy is seen in dengue. Lifelong immunity to a particular virus is usual. In some of these viral fevers, haemorrhage is a feature (Table 4.22). Increased vascular permeability, capillary fragility and consumptive coagulopathy have been implicated as causes of the haemorrhage. Encephalitis resulting from cerebral invasion may be prominent in some fevers.

*Most of these are arboviruses. Some (e.g. hantavirus, Lassa fever) have a rodent vector. The source and transmission route of filoviruses is not known.

**Alphaviruses**

The 24 viruses of this group are all transmitted by mosquitoes; eight result in human disease. These viruses are globally distributed and tend to acquire their names from the location where they were first isolated (such as Ross River, Eastern Venezuelan and Western encephalitis viruses) or by the local expression for a major symptom caused by the virus (such as chikungunya, meaning ‘doubled up’). Infection is characterized by fever, headache, maculopapular skin rash, arthralgia, myalgia and sometimes encephalitis.

Major epidemics of chikungunya were reported in India, Sri Lanka and islands in the Indian Ocean (including Reunion, Mauritius and the Seychelles) in 2005 and 2006, with at least 1 million cases and several hundred deaths. The severity of these epidemics is possibly due to a viral strain with mutations resulting in a higher neurovirulence. Several European countries reported cases of chikungunya in returning travellers — including 133 cases in the UK in 2006. The virus may now populate the local Aedes mosquito via increased numbers of travellers who may import virus into countries where it has not previously been described. This has resulted in outbreaks in Italy with over 150 cases and 1 death reported in 2007.

**FLAVIVIRUSES**

There are 60 viruses in this group, some of which are transmitted by ticks and others by mosquitoes.

**Yellow fever**

Yellow fever, caused by a flavivirus, results in an illness of widely varying severity so that the disease is under-reported. It is a disease confined to Africa (90% of cases) and South America between latitudes 15°N and 15°S. For poorly understood reasons, yellow fever has not been reported from Asia, despite the fact that climatic conditions are suitable and the vector, *Aedes aegypti*, is common. The infection is transmitted in the wild by *A. africanus* in Africa and the *Haemagogus* species in South and Central America. Extension of infection to humans (via the mosquito or from monkeys) leads to the occurrence of ‘jungle’ yellow fever. *A. aegypti*, a domestic mosquito which lives in close relationship to humans, is responsible for human-to-human transmission in urban areas (urban yellow fever). Once infected, a mosquito remains so for its whole life.

**Clinical features**

The incubation period is 3–6 days. When the infection is mild, the disease is indistinguishable from other viral fevers such as influenza or dengue.

Three phases in the severe (classical) illness are recognized. Initially the patient presents with a high fever of acute onset, usually 39–40°C, which then returns to normal in 4–5 days. During this time, headache is prominent. Retrobulbar pain, myalgia, arthralgia, a flushed face and suffused conjunctivae are common. Epigastric discomfort and vomiting are present when the illness is severe. Relative bradycardia (Faget’s sign) is present from the second day of illness. The patient then makes an apparent recovery and feels well for several days. Following this ‘phase of calm’ the patient again develops increasing fever, deepening jaundice and hepato-megaly. Ecchymosis, bleeding from the gums, haematemesis and melaena may occur. Coma, which is usually a result of uremia or haemorrhagic shock, occurs for a few hours preceding death. The mortality rate is up to 40% in severe cases. The pathology of the liver shows mid-zone necrosis, and eosinophilic degeneration of hepatocytes (Councilman bodies) (see p. 333).

**Diagnosis and treatment**

The diagnosis is established by a history of travel and vaccination status, and by isolation of the virus (when possible) from blood during the first 3 days of illness. Serodiagnosis is possible, but in endemic areas cross-reactivity with other flaviviruses is a problem.

*Vaccination* is supportive. Bed rest (under mosquito nets), analgesics, and maintenance of fluid and electrolyte balance are required.

**Prevention and control**

Yellow fever is an internationally notifiable disease. It is easily prevented using the attenuated 17D chick embryo vaccine but concerns over safety have arisen because of infection with the 17D virus. Vaccination is not recommended for children under 9 months and immunosuppressed patients unless there are compelling reasons. For the purposes of international certification, immunization is valid for 10 years, but protection lasts much longer than this and probably for life. The WHO Expanded Programme of Immunization includes yellow fever vaccination in endemic areas.

**Dengue**

This is the commonest arthropod-borne viral infection in humans: over 100 million cases occur every year in the tropics, with over 10,000 deaths from dengue haemorrhagic fever. Dengue is caused by a flavivirus and is found mainly in Asia, South America and Africa, although it has been reported from the USA and, more recently, in Italy.

Four different antigenic varieties of dengue virus are recognized and all are transmitted by the daytime-biting *A. aegypti* which breed in standing water in refuse dumps in
inner cities. A. albopictus is a less common transmitter. Humans are infective during the first 3 days of the illness (the viraemic stage). Mosquitoes become infective about 2 weeks after feeding on an infected individual, and remain so for the rest of their lives. The disease is usually endemic. Hetero-

Clinical features
The incubation period is 5–6 days following the mosquito bite. Asymptomatic or mild infections are common. Two clini-
cal forms are recognized (Fig. 4.21).

Classic dengue fever
Classic dengue fever is characterized by the abrupt onset of fever, malaise, headache, facial flushing, retrobulbar pain which worsens on eye movements, conjunctival suffusion and severe backache, which is a prominent symptom. Lymphadenopathy, petechiae on the soft palate and skin rashes may also occur. The rash is transient and morbilliform. It appears on the limbs and then spreads to involve the trunk. Desquamation occurs subsequently. Cough is uncommon. The fever subsides after 3–4 days, the temperature returns to normal for a couple of days, and then the fever returns, together with the features already mentioned, but milder. This biphasic or ‘saddleback’ pattern is considered characteristic. Severe fatigue, a feeling of being unwell and depression are common for several weeks after the fever has subsided.

Dengue haemorrhagic fever (DHF)
Dengue haemorrhagic fever is a severe form of dengue fever and is believed to be the result of two or more sequential infections with different dengue serotypes. It is characterized by the capillary leak syndrome, thrombocytopenia, haemorrhage, hypotension and shock. It is a disease of children and has been described almost exclusively in South East Asia. The disease has a mild start, often with symptoms of an upper respiratory tract infection. This is then followed by the abrupt onset of shock and haemorrhage into the skin and ear, epistaxis, haematemesis and melaena known as the dengue shock syndrome. This has a mortality of up to 44%. Serum complement levels are depressed and there is labora-
tory evidence of a consumptive coagulopathy.

Diagnosis and treatment
Isolation of dengue virus by tissue culture in sera obtained during the first few days of illness is diagnostic.

Rising antibody titres on neutralization (most specific), haemagglutination inhibition ‘ELISA’ or complement-

Fixing antibodies in sequential serum samples.

Blood tests show leucopenia and thrombocytopenia.

Treatment is supportive with analgesics and adequate fluid replacement. Corticosteroids are of no benefit and con-
valescence can be slow. In DHF, blood transfusion may be necessary.

Prevention
Travellers should be advised to sleep under impregnated nets but this is not very effective as the mosquito bites in daytime. Topical insect repellents should be used. Adult mosquitoes should be destroyed by sprays, and breeding sites, e.g. small stagnant water pools, should be eradicated. There is no effective vaccine yet although some are being trialed.

Japanese encephalitis
Japanese encephalitis is a mosquito-borne encephalitis caused by a flavivirus. It has been reported most frequently from the rice-growing countries of South East Asia and the Far East. Culex tritaeniorhynchus is the usual vector and this feeds mainly on pigs as well as birds such as herons and sparrows. Humans are accidental hosts.

As with other viral infections, the clinical manifestations are variable. The incubation period is 5–15 days. Most infec-
tions are asymptomatic. When disease arises, the onset is heralded by severe rigors. Fever, headache and malaise last 1–6 days. Weight loss is prominent. In the acute encephalitic stage the fever is high (38–41°C), neck rigidity occurs and neurological signs such as altered consciousness, hemipa-
resis and convulsions develop. Mental deterioration occurs over a period of 3–4 days and culminates in coma. Mortality varies from 7% to 40% and is higher in children. Residual neurological defects such as deafness, emotional lability and hemiparesis occur in about 70% of patients who have had CNS involvement. Convalescence is prolonged. Antibody detection in serum and CSF by IgM capture ELISA is a useful rapid diagnostic test. Vaccines containing formalin-inactivated viruses derived from mouse brain are effective and available. Treatment is supportive.

**West Nile virus**

In 1999, the West Nile virus was first recognized in the western hemisphere (New York, USA) and it had previously been reported in Africa, Asia and parts of Europe. The outbreak in the USA produced thousands of symptomless infections. In a minority of cases, infection presents as a febrile illness, with a maculopapular rash, with 1% resulting in severe encephalitis. Disease severity and mortality is age-related. The primary hosts of infection are birds. It is spread by mosquitoes and may also infect humans and horses. It can also be transmitted by blood transfusions, breast-feeding and organ donation. Diagnosis is by genome detection in appropriate samples, or specialized serology for the detection of IgM virus-specific antibodies.

**Tick-borne encephalitis virus (TBEV)**

This flavivirus is transmitted by *Ixodes* spp. ticks. It occurs in an area extending from Western Europe to Japan. The tick is the main reservoir for the virus which is transmitted when it feeds on mice and other rodents.

The disease starts 4–28 days after a bite from an infected tick and is biphasic in 80% of patients. Fever, malaise, headache and fatigue are followed, after a symptom free period of about 7 days, by encephalitis. There may be an associated limb paralysis which is due to anterior horn cell involvement mainly of the cervical region. Cranial infection involvement also occurs. TBEV IgM and IgG antibodies are present and the virus can be detected in blood by RT-PCR. Mortality is about 1% but 30% have impairment in neurological function with persistent paralysis in 6%. A preventative vaccine is available.

**BUNYAVIRUSES**

Bunyaviruses belong to a large family of more than 200 viruses, most of which are arthropod-borne.

**Congo–Crimean haemorrhagic fever**

This widespread disease, caused by a virus of the nairovirus genus of Bunyaviruses, is found mainly in Asia and Africa. The primary hosts are cattle and hares and the vectors are the *Hyalomma* ticks. Following an incubation period of 3–6 days there is an influenza-like illness with fever and haemorrhagic manifestations. The mortality is 10–50%.

**Hantaviruses**

Hantaviruses are zoonotic viruses of wild rodents which are spread by aerosolized excreta and not by insect vectors. The most severe form of this infection is Korean haemorrhagic fever (or haemorrhagic fever with renal syndrome – HFRS). This condition has a mortality of 5–10% and is characterized by fever, shock and haemorrhage followed by an oliguric phase. Milder forms of the disease are associated with related viruses (e.g. Puumala virus) and may present as nephropathia epidemica, an acute fever with renal involvement. It is seen in Scandinavia and in other European countries in people who have been in contact with bank voles. In the USA, a hantavirus (transmitted by the deer mouse) termed Sin Nombre was identified as the cause of outbreaks of acute respiratory disease in adults, referred to as hantavirus pulmonary syndrome (HPS). Other hantavirus types and rodent vector systems have been associated with this syndrome.

Diagnosis of hantavirus infection is made by an ELISA technique for specific antibodies.

**Rift Valley fever**

Rift Valley fever, caused by a bunyavirus, is primarily an acute febrile illness of livestock – sheep, goats and camels. It is found in southern and eastern Africa. The vector in East Africa is *Culex pipiens* and in southern Africa, *Aedes caballus,* but can be transmitted by the bite of an infected animal. Following an incubation period of 3–6 days, the patient has an acute febrile illness that is difficult to distinguish clinically from other viral fevers. The temperature pattern is usually biphasic. The initial febrile illness lasts 2–4 days and is followed by a remission and a second febrile episode. Complications are indicative of severe infection and include retinopathy, meningoencephalitis, haemorrhagic manifestations and hepatic necrosis. Mortality approaches 50% in severe forms of the illness. Treatment is supportive. Animals can be vaccinated.

**ORTHOMYXOVIRUSES**

**Influenza**

Three types of influenza virus are recognized: A, B and C, distinguishable by the nature of their internal proteins. The influenza virus is a spherical or filamentous enveloped virus. Haemagglutinin (H), a surface glycoprotein, aids attachment of the virus to the wall of susceptible host cells at specific receptor sites. Cell penetration, probably by pinocytosis, and release of replicated viruses from the cell surface effected by budding through the cell membrane, are facilitated by the action of the enzyme neuraminidase (N) which is also present on the viral envelope. Sixteen H subtypes (H1–H16) and nine N subtypes (N1–N9) have been identified for influenza A viruses but only H1, H2, H3 and N1 and N2 have established stable lineages in the human population since 1918.

- Influenza A is generally responsible for pandemics and epidemics.
- Influenza B often causes smaller or localized and milder outbreaks, such as in camps or schools.
- Influenza C rarely produces disease in humans.

Antigenic shift generates new influenza A subtypes, which emerge at irregular intervals and give rise to influenza pandemics. Possible mechanisms include:

1. Genetic reassortment of the RNA of the virus (which is arranged in eight segments) with that of an avian influenza virus; this requires co-infection of a host with
both human and avian viruses. The pig is one animal in which this may occur. Alternatively, humans may act as the mixing vessel.

2 Trans-species transmission of an avian influenza virus to humans. Viruses transmitted in this way are usually not well adapted to growth in their new host, but adaptation may occur as a result of spontaneous mutations, leading to the emergence of a pandemic strain.

**Antigenic drift** (minor changes in influenza A and B viruses) results from point mutations leading to amino acid changes in the two surface glycoproteins, haemagglutinin (H) and neuraminidase (N), which induce humoral immunity. This enables the virus to evade previously induced immune responses, and is the process whereby annual influenza epidemics arise.

Thus, changes due to antigenic shift or drift render the individual's immune response less able to combat the new variant.

The most serious pandemic of influenza, caused by influenza A/H1N1, occurred in 1918, and was associated with more than 20 million deaths world-wide. In 1957, antigenic shift led to the appearance of influenza A/H2N2, which caused a world-wide pandemic. A further pandemic occurred in 1968 owing to the emergence of Hong Kong influenza A/H3N2, and minor antigenic drifts have caused outbreaks around the world ever since. In 1997, avian influenza A/H5N1 viruses were first isolated from humans, raising the spectre of another pandemic. Over 300 sporadic human A/H5N1 infections have been reported since, mostly from South East Asia, and almost always arising from direct contact with infected chickens, with a mortality of >50%. However, whilst this virus is highly pathogenic to humans, due to the induction of a cytokine storm within the lungs, it still has not evolved to replicate well in human cells. Infected individuals do not therefore shed large quantities of virus from the respiratory tract, and human-to-human spread is unusual. However, anxieties remain that either genetic reassortment will occur in a human co-infected with human A/H1N1 or A/H3N2 viruses, or adaptive mutations will occur within infected human hosts, such that a truly pandemic strain will emerge.

Purified haemagglutinin and neuraminidase from recently circulating strains of influenza A and B viruses are incorporated in current vaccines.

Sporadic cases of influenza and outbreaks among groups of people living in a confined environment are frequent. The incidence increases during the winter months. Spread is mainly by droplet infection but fomites and direct contact have also been implicated.

The clinical features, diagnosis, treatment and prophylaxis of influenza are discussed on page 834.

**PARAMYXOVIRUSES**

These are a heterogeneous group of enveloped viruses with negative single-stranded RNA genomes of varying size that are responsible for a variety of infections.

**Parainfluenza**

Parainfluenza is caused by the parainfluenza viruses types I-IV; these have a world-wide distribution and cause acute respiratory disease. Type IV appears to be less virulent than the other types and has been linked only to mild upper respiratory diseases in children and adults.

Parainfluenza is essentially a disease of children and presents with features similar to the common cold. When severe, a brassy cough with inspiratory stridor and features of laryngotracheitis (croup) are present. Fever is usually present for 2–3 days and may be more prolonged if pneumonia develops. The development of croup is due to submucosal oedema and consequent airway obstruction in the subglottic region. This may lead to cyanosis, subcostal and intercostal recession and progressive airway obstruction. Infection in the immunocompromised is usually prolonged and may be severe. Treatment is supportive with oxygen, humidification and sedation when required. The role of steroids and the antiviral agent ribavirin, is controversial.

**Measles (rubeola)**

Measles is a highly communicable disease that occurs worldwide. With the introduction of aggressive immunization policies, the incidence of measles has fallen dramatically in the West but there are an estimated 0.5 million deaths annually due to measles infection world-wide, mostly in Africa and South East Asia, with mortality being highest in children less than 12 months of age. It is spread by droplet infection and the period of infectivity is from 4 days before until 2 days after the onset of the rash.

**Clinical features**

The incubation period is 8–14 days. Two distinct phases of the disease can be recognized.

**Typical measles**

- **The pre-eruptive and catarrhal stage.** This is the stage of viraemia and viral dissemination. Malaise, fever, rhinorrhea, cough, conjunctival suffusion and the pathognomonic Koplik’s spots are present during this stage. Koplik’s spots are small, greyish, irregular lesions surrounded by an erythematous base and are found in greatest numbers on the buccal mucous membrane opposite the second molar tooth. They occur a day or two before the onset of the rash.

- **The eruptive or exanthematos stage.** This is characterized by the presence of a maculopapular rash that initially occurs on the face, chiefly the forehead, and then spreads rapidly to involve the rest of the body (Fig. 4.22). At first the rash is discrete but later it may

![Fig. 4.22 Measles. Courtesy of Dr MW McKendrick, Royal Hallamshire Hospital, Sheffield.](image-url)
become confluent and patchy, especially on the face and neck. It fades in about 1 week and leaves behind a brownish discoloration.

The most feared complication in an immunocompetent child is acute measles encephalitis, with an incidence of 1/1000 to 1/5000 cases of measles. This is post-infectious, i.e. virus is not present in the brain, and the encephalitis presumably arises through an aberrant cross-reaction of the host immune response to infection. Prognosis is poor, with a high mortality (30%), and severe residual damage in survivors.

Measles carries a high mortality in the malnourished and in those who have other diseases. Complications are common in such individuals and include bacterial pneumonia, bronchitis, otitis media and gastroenteritis. Less commonly, myocarditis, hepatitis and encephalomyelitis may occur. In those who are malnourished or those with defective cell-mediated immunity, the classical maculopapular rash may not develop and widespread desquamation may occur. The virus also causes the rare condition subacute sclerosing panencephalitis, which may follow measles infection occurring early in life (<18 months of age). Persistence of the virus with reactivation pre-puberty results in accumulation of virus in the brain, progressive mental deterioration and a fatal outcome (see p. 1158).

Maternal measles, unlike rubella, does not cause fetal abnormalities. It is, however, associated with spontaneous abortions and premature delivery.

**Diagnosis and treatment**
Most cases of measles are diagnosed clinically but, if necessary, detection of measles-specific IgM in blood or oral fluid, or genome or antigen detection from nasopharyngeal aspirates or throat swabs, can be used to confirm the diagnosis.

Treatment is supportive. Antibiotics are indicated only if secondary bacterial infection occurs.

**Prevention**
A previous attack of measles confers a high degree of immunity and second attacks are uncommon. Normal human immunoglobulin given within 5 days of exposure effectively aborts an attack of measles. It is indicated for previously unimmunized children below 3 years of age, during pregnancy, and in those with debilitating disease.

*Active immunization.* Children in the UK are immunized with the MMR vaccine (Box 4.6) and the mumps vaccine is given in most developing countries. Vaccination is contraindicated in immunosuppressed individuals, during pregnancy, or in those with severe febrile illnesses.

**Mumps**
Mumps is the result of infection with a paramyxovirus. It is spread by droplet infection, by direct contact or through fomites. Humans are the only known natural hosts. The peak period of infectivity is 2–3 days before the onset of the parotitis and for 3 days afterwards.

**Clinical features**
The incubation period averages 18 days. Although no age is exempt, it is primarily a disease of school-aged children and young adults; it is uncommon before the age of 2 years. The prodromal symptoms are non-specific and include fever, malaise, headache and anorexia. This is usually followed by severe pain over the parotid glands, with either unilateral or bilateral parotid swelling (Fig. 4.23). The enlarged parotid glands obscure the angle of the mandible and may elevate the ear lobe, which does not occur in cervical lymph node enlargement. Trismus due to pain is common at this stage. Submandibular gland involvement occurs less frequently.

**Complications**
CNS involvement is the most common extrasalivary gland manifestation of mumps. Clinical meningitis occurs in 5% of all infected patients, and 30% of patients with CNS involvement have no evidence of parotid gland involvement.

Epididymo-orchitis develops in about one-third of patients who develop mumps after puberty. Bilateral testicular involvement results in sterility in only a small percentage of these patients. Pancreatitis, ophoritis, myocardiitis, mastitis, hepatitis and polyarthritis may also occur.

**Diagnosis and treatment**
The diagnosis of mumps is on the basis of the clinical features. In doubtful cases, serological demonstration of a mumps-specific IgM response in an acute blood or oral fluid sample is diagnostic. Virus can be isolated in cell culture from saliva, throat swab, urine and CSF and identified by genome detection or antigen detection by immunofluorescence.

Treatment is supportive. Attention should be given to adequate nutrition and mouth care. Analgesics should be used to relieve pain.

**Prevention**
*Active immunization* Children in the UK are immunized with the MMR vaccine (Box 4.6) and the mumps vaccine is given in most developing countries. Vaccination is contraindicated in immunosuppressed individuals, during pregnancy, or in those with severe febrile illnesses.
Respiratory syncytial virus infection

Respiratory syncytial virus (RSV) is a paramyxovirus that causes many respiratory infections in epidemics each winter. It is a common cause of bronchiolitis in infants, which is complicated by pneumonia in approximately 10% of cases. The infection normally starts with upper respiratory symptoms. After an interval of 1–3 days a cough and low-grade fever may develop. The onset of bronchiolitis is characterized by dyspnoea and hyperexpansion of the chest with subcostal and intercostal recession. The disease may be severe and potentially fatal in babies with underlying cardiac, respiratory (including prematurity) or immunodeficiency disease. RSV infection has been associated with the occurrence of sudden infant death syndrome (SIDS). The virus undergoes antigenic drift, and, consequently, re-infection can occur throughout life. RSV is occasionally the cause of outbreaks of influenza-like illness or pneumonia in the elderly and in the immunocompromised.

Transfer of infection between children in hospital commonly occurs unless infected patients are isolated or cohorted. Meticulous attention to handwashing and other infection control measures reduces the risk of transmission by staff members.

Diagnosis and treatment

Genome detection or immunofluorescence on nasopharyngeal aspirates, virus culture and serology are the usual ways of confirming the diagnosis.

Treatment is generally supportive, but aerosolized ribavirin can be given to severe cases, particularly those with underlying cardiac or respiratory disease.

Prevention

No vaccine is currently available for RSV but high-risk children (including those with bronchopulmonary dysplasia and congenital heart disease) can be protected against severe disease by monthly administration of either a hyperimmune globulin against RSV, or a humanized monoclonal antibody (palivizumab) during the winter months (see p. 101).

Metapneumovirus

Human metapneumovirus (hMPV) is a recently discovered virus causing approximately 10% of lower respiratory tract infections in infants and young children. hMPV infection is clinically indistinguishable from that caused by RSV.

Hendra and Nipah viruses

Hendra virus (formerly called equine morbillivirus) and Nipah virus are zoonotic viruses that have caused disease in humans who have been in contact with infected animals (horses and pigs respectively). The viruses are named after the locations where they were first isolated, Hendra in Australia and Nipah in Malaysia, and both are classified as paramyxoviruses. Hendra virus has caused severe respiratory distress in horses and humans and Nipah virus caused a major outbreak of viral encephalitis (265 cases and 105 deaths) in Malaysia between September 1998 and April 1999. Treatment of these conditions is largely supportive, although there is some evidence that early treatment with ribavirin may reduce the severity of the diseases.

CORONAVIRUSES

Human coronaviruses were first isolated in the mid 1960s and the majority of isolates (related to the reference strains 229E and OC43) have been associated with common colds. In November 2002, an apparently new viral disease occurred in China (Guangdong province) and this spread rapidly in other parts of the Far East and also in Canada (Toronto and Vancouver).

This disease, known as ‘severe acute respiratory syndrome’ (SARS) of which bronchopneumonia has been a major feature, is caused by a previously unknown coronavirus (SARS-CoV). Similarity of this virus to coronaviruses isolated from civet cats, raccoons and ferret badgers indicates the likelihood that SARS is a zoonotic disease. Bats are the likely host species for this virus.

The epidemic was finally brought under control in the summer of 2003 and by then there had been >8000 cases with approximately 800 deaths. In 2004 and 2005, two new coronavirus infections of humans were described – NL63 and HKU1. These are associated with upper respiratory tract symptomatology, such as the common cold.

RHABDOVIRUSES

Rabies

Rabies is a major problem in some countries, with an estimated 55 000 deaths per year world-wide. Established infection is almost invariably fatal. It is caused by a genotype 1, single-stranded RNA virus of the Lyssavirus genus. The rabies virus is bullet-shaped and has spike-like structures arising from its surface containing glycoproteins that cause the host to produce neutralizing, haemagglutination-inhibiting antibodies. The virus has a marked affinity for nervous tissue and the salivary glands. It exists in two major epidemiological settings:

- Urban rabies is most frequently transmitted to humans through rabid dogs and, less frequently, cats.
- Sylvan (wild) rabies is maintained in the wild by a host of animal reservoirs such as foxes, skunks, jackals, mongooses and bats.

With the exception of Australia, New Zealand and the Antarctic, human rabies has been reported from all continents. Transmission is usually through the bite of an infected animal. However, the percentage of rabid bites leading to clinical disease ranges from 10% (on the legs) to 80% (on the head). Other forms of transmission, if they occur, are rare.

Having entered the human body, the virus replicates in the muscle cells near the entry wound. It penetrates the nerve endings and travels in the axoplasm to the spinal cord and brain. In the CNS the virus again proliferates before spreading to the salivary glands, lungs, kidneys and other organs via the autonomic nerves.

There have been only six recorded cases of survival from clinical rabies.

Clinical features

The incubation period is variable and may range from a few weeks to several years; on average it is 1–3 months. In general, bites on the head, face and neck have a shorter incubation period than those elsewhere. In humans, two distinct clinical varieties of rabies are recognized:
furious rabies – the classic variety
• dumb rabies – the paralytic variety.

Furious rabies
The only characteristic feature in the prodromal period is the presence of pain and tingling at the site of the initial wound. Fever, malaise and headache are also present. About 10 days later, marked anxiety and agitation or depressive features develop. Hallucinations, bizarre behaviour and paralysis may also occur. Hyperexcitability, the hallmark of this form of rabies, is precipitated by auditory or visual stimuli. Hydrophobia (fear of water) is present in 50% of patients and is due to severe pharyngeal spasms on attempting to eat or drink. Aerophobia (fear of air) is considered pathognomonic of rabies. Examination reveals hyperreflexia, spasticity, and evidence of sympathetic overactivity indicated by pupillary dilatation and diaphoresis.

The patient goes on to develop convulsions, respiratory paralysis and cardiac arrhythmias. Death usually occurs in 10–14 days.

Dumb rabies
Dumb rabies, or paralytic rabies, presents with a symmetrical ascending paralysis resembling the Guillian–Barre syndrome. This variety of rabies commonly occurs after bites from rabid bats.

Diagnosis
The diagnosis of rabies is generally made clinically. Skin-punch biopsies are used to detect antigen with an immunofluorescent antibody test on frozen section. Viral RNA can be isolated using the reverse transcription polymerase chain reaction (RT-PCR). Isolation of viruses from saliva or the presence of antibodies in blood or CSF may establish the diagnosis. The corneal smear test is not recommended as it is unreliable. The classic Negri bodies are detected at post-mortem in 90% of all patients with rabies; these are eosinophilic, cytoplasmic, ovoid bodies, 2–10 nm in diameter, seen in greatest numbers in the neurones of the hippocampus and the cerebellum. The diagnosis should be made pathologically on the biting animal using RT-PCR, immunofluorescence assay (IFA) or tissue culture of the brain.

Treatment
Once the CNS disease is established, therapy is symptomatic as death is virtually inevitable. The patient should be nursed in a quiet, darkened room. Nutritional, respiratory and cardiovascular support may be necessary.

Drugs such as morphine, diazepam and chlorpromazine should be used liberally in patients who are excitable.

Prevention

Pre-exposure prophylaxis. This is given to individuals with a high risk of contracting rabies, such as laboratory workers, animal handlers and veterinarians. Three doses (1.0 mL) of human diploid (HDCV) or chick embryo cell vaccine given by deep subcutaneous or intramuscular injection on days 0, 7 and 28 provide effective immunity. A reinforcing dose is given after 12 months and additional reinforcing doses are given every 3–5 years depending on the risk of exposure. Vaccines of nervous-tissue origin are still used in some parts of the world. These, however, are associated with significant side-effects and are best avoided if HDCV is available.

Postexposure prophylaxis. The wound should be cleaned carefully and thoroughly with soap and water and left open. Human rabies immunoglobulin should be given immediately (20 IU/kg); half should be injected around the area of the wound and the other half should be given intramuscularly. Five 1.0 mL doses of HDCV should be given intramuscularly: the first dose is given on day 0 and is followed by injections on days 3, 7, 14 and 28. Reaction to the vaccine is uncommon.

Control of rabies
Domestic animals should be vaccinated if there is any risk of rabies in the country. In the UK, control has been by quarantine of imported animals for 6 months and no indigenous case of rabies has been reported for many years. The Pet Travel Scheme (PETS) recently introduced enables certain pet animals to enter or re-enter Great Britain without quarantine if they come from qualifying countries via designated routes, are carried by authorized transport companies, and meet the conditions of the scheme. Wild animals in ‘at risk’ countries must be handled with great care.

RETOVIRUSES

Retroviruses (Table 4.23) are distinguished from other RNA viruses by their ability to replicate through a DNA intermediate using an enzyme, reverse transcriptase.

HIV-1 and the related virus, HIV-2, are further classified as lentiviruses (‘slow’ viruses) because of their slowly progressive clinical effects.

HIV-1 and HIV-2 are discussed on page 184.

HTLV-1 causes adult T cell leukaemia/lymphoma and tropical spastic paraparesis.

ARENAVIRUSES

Arenaviruses are pleomorphic, round or oval viruses with diameters ranging from 50 to 300 nm. The virion surface has club-shaped projections, and the virus itself contains a variable number of characteristic electron-dense granules that represent residual, non-functional host ribosomes. Arenaviruses are responsible for Lassa fever and also for lymphocytic choriomeningitis, Argentinian and Bolivian haemorrhagic fevers.

Lassa fever
This illness was first documented in the town of Lassa, Nigeria, in 1969 and is confined to sub-Saharan West Africa.

*HTLV, human T cell lymphotropic virus.
(Nigeria, Liberia and Sierra Leone). The multimammate rat, Mastomys natalensis, is known to be the reservoir. Humans are infected by ingesting foods contaminated by rat urine or saliva containing the virus. Person-to-person spread by body fluids also occurs. Only 10–30% of infections are symptomatic.

**Clinical features**

The incubation period is 7–18 days. The disease is insidious in onset and is characterized by fever, myalgia, severe backache, malaise and headache. A transient maculopapular rash may be present. A sore throat, pharyngitis and lymphadenopathy occur in over 50% of patients. In severe cases epistaxis and gastrointestinal bleeding may occur – hence the classification of Lassa fever as a viral haemorrhagic fever. The fever usually lasts 1–3 weeks and recovery within a month of the onset of illness is usual. However, death occurs in 15–20% of hospitalized patients, usually from irreversible hypovolaemic shock.

**Diagnosis**

The diagnosis is established by serial serological tests (including the Lassa virus-specific IgM titre) or by genome detection by means of the reverse transcriptase polymerase chain reaction in throat swab, serum or urine.

**Treatment**

Treatment is supportive. In addition, clinical benefit and reduction in mortality can be achieved with ribavirin therapy, if given in the first week.

In non-endemic countries, strict isolation procedures should be used, the patient ideally being nursed in a flexible-film isolator. Specialized units for the management of Lassa fever and other haemorrhagic fevers have been established in the UK. As Lassa fever virus and other causes of haemorrhagic fever (Marburg/Ebola and Congo–Criméan haemorrhagic fever viruses) have been transmitted from patients to staff in healthcare situations, great care should be taken in handling specimens and clinical material from these patients.

**Lymphocytic choriomeningitis (LCM)**

This infection is a zoonosis, the natural reservoir of LCM virus being the house mouse. Infection is characterized by:

- non-nervous-system illness, with fever, malaise, myalgia, headache, arthralgia and vomiting
- aseptic meningitis in addition to the above symptoms.

Occasionally, a more severe form occurs, with encephalitis leading to disturbance of consciousness.

This illness is generally self-limiting and requires no specific treatment.

**FILOVIRUSES**

**MARBURG VIRUS DISEASE AND EBOLA VIRUS DISEASE**

These severe, haemorrhagic, febrile illnesses are discussed together because their clinical manifestations are similar. The diseases are named after Marburg in Germany and the Ebola River region in the Sudan and Zaire where these viruses first appeared. The natural reservoir for these viruses has not been identified and the precise mode of spread from one individual to another has not been elucidated.

Epidemics have occurred periodically in recent years, mainly in sub-Saharan Africa. The mortality from Marburg and Ebola has ranged from 25% to 90% and recovery is slow in those who survive.

The illness is characterized by the acute onset of severe headache, severe myalgia and high fever, followed by prostration. On about the fifth day of illness a non-pruritic maculopapular rash develops on the face and then spreads to the rest of the body. Diarrhoea is profuse and is associated with abdominal cramps and vomiting. Haematemia, melaena or haemoptysis may occur between the seventh and sixteenth day. Hepatosplenomegaly and facial oedema are usually present. In Ebola virus disease, chest pain and a dry cough are prominent symptoms.

Treatment is symptomatic. Convalescent human serum appears to decrease the severity of the attack.

**POSTVIRAL/CHRONIC FATIGUE SYNDROME** (see also p. 1192)

Viral illnesses have been implicated aetologically, including those due to EBV, Coxsackie B viruses, echoviruses, CMV and hepatitis A virus. Non-viral causes such as allergy to Candida spp. have also been proposed. Only a minority of patients have an identifiable precipitating infectious illness.

**TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES (TSE OR PRION DISEASE)**

Transmissible spongiform encephalopathies are caused by the accumulation in the nervous system of a protein, termed a ‘prion’, which is an abnormal isoform PrP<sup>sc</sup> of a normal, host protein (PrP<sup>N</sup>).

Although familial forms of prion disease are known to exist, these conditions can be transmissible, particularly if brain tissue enters another host. There is no convincing evidence for the presence of nucleic acid in association with prions; thus these agents cannot be considered orthodoxy viruses and it is the abnormal prion protein itself that is infectious and can trigger a conversion of the normal protein into the atypical isoform. After infection, a long incubation period is followed by CNS degeneration associated with dementia or ataxia which invariably leads to death. Histology of the brain reveals spongiform change with an accumulation of the abnormal prion protein in the form of amyloid plaques.

The human prion diseases are Creutzfeldt–Jakob disease, including the sporadic, familial, iatrogenic and variant forms of the disease, Gerstmann–Straussler–Scheinker syndrome, familial insomnia and kuru.

- Creutzfeldt–Jakob disease (CJD) usually occurs sporadically world-wide with an annual incidence of one per million of the population. Although, in most cases, the epidemiology remains obscure, transmission to others has occurred as a result of administration of human cadaveric growth hormone or gonadotrophin,
from dura mater and corneal grafting, and in neurosurgery from reuse of contaminated instruments and electrodes (iatrogenic CJD).

- **Variant CJD.** In the UK, knowledge that large numbers of cattle with the prion disease, bovine spongiform encephalopathy (BSE) had gone into the human food chain, led to enhanced surveillance for emergence of the disease in humans. The evidence is convincing, based on transmission studies in mice and on glycosylation patterns of prion proteins, that this has occurred and, to date, there have been approximately 160 confirmed and suspected cases of variant CJD (human BSE) in the UK and 40 in the rest of the world. In contrast to sporadic CJD, which presents with dementia at a mean age of onset of 60 years, variant CJD presents with ataxia, dementia, myoclonus and chorea at a mean age of onset of 29 years. The epidemic curve of vCJD in the UK is shown in Figure 4.24.

- **Gerstmann–Straussler–Scheinker syndrome and fatal familial insomnia** are rare prion diseases usually occurring in families with a positive history. The pattern of inheritance is autosomal dominant with some degree of variable penetrance.

- **Kuru** was described and characterized in the Fore highlanders in NE New Guinea. Transmission was associated with ritualistic cannibalism of deceased relatives. With the cessation of cannibalism by 1960, the disease has gradually diminished and recent cases had all been exposed to the agent before 1960.

The infectious agents of prion disease have remarkable characteristics. In the infected host there is no evidence of inflammatory, cytokine or immune reactions. The agent is highly resistant to decontamination, and infectivity is not reliably destroyed by autoclaving or by treatment with formaldehyde and most other gas or liquid disinfectants. It is very resistant to γ irradiation. Autoclaving at a high temperature (134–137°C for 18 minutes) is used for decontamination of instruments, and hypochlorite (20000 p.p.m. available chlorine) or 1 molar sodium hydroxide are used for liquid disinfecion. Uncertainty about the reliability of any methods for safe decontamination of surgical instruments has necessitated the introduction of guidelines for patient management.

**FURTHER READING**

**BACTERIAL INFECTIONS**

### Classification of bacteria

Bacteria are unicellular organisms (prokaryotes), of which a small fraction are of medical relevance. Unusual infections may result from exposure under circumstances of altered host defences, notably in the severely immunocompromised patient.

Bacteria have traditionally been classified according to the Gram stain which distinguishes Gram-positive from Gram-negative organisms. Using light microscopy, these can then largely be divided into cocci and bacilli (rods). Some have a spiral appearance (spirochaetes) while others, such as *Clostridium* spp., may contain spores (Table 4.24). The cell wall arrangement of Gram-positive cocci contains a phospholipid bilayer surrounded by peptidoglycan made up of repeating units of N-acetylmuramic acid and N-acetylmuramic acid. By contrast, Gram-negative bacilli possess a second outer lipid bilayer containing protein and lipopolysaccharide (endotoxin). Some pathogens are encapsulated, which is an antiphagocytic virulence factor.

Bacteria can often be cultured in broth or on solid agar. Those growing in the absence of oxygen are strict anaerobes (e.g. *Bacteroides* spp.), whilst oxygen-dependent bacteria are known as aerobes (e.g. *Pseudomonas* spp.). Many pathogens can tolerate reduced concentrations of oxygen (e.g. *E. coli*). Some organisms are more demanding in their growth requirements and require special laboratory media (e.g. *Mycoplasma* spp. and *Mycobacterium* spp.); others require more prolonged incubation (e.g. *Brucella* spp.).
Genetic classification is defining bacteria in terms of DNA sequence information and has led to the reclassification of several bacteria. DNA fingerprinting is also being increasingly applied to distinguishing similar isolates, which has applications in defining the epidemiology of infection.

### Diagnosis and management of bacterial infections

The history and examination usually localizes the infection to a specific organ or body site. A systemic response may accompany such localized disease or, in the case of bloodstream infections, be the primary mode of presentation. The microbiological diagnosis is difficult to establish in most community-managed infections, and even in hospital where there is ready access to diagnostic laboratories, only a minority of infections are documented. For these reasons, a clinical approach to bacterial diseases has been adopted.

#### SKIN AND SOFT TISSUE INFECTION

### Superficial infections

Infections of the skin and the soft tissues beneath are common. These are usually fungal (see p. 1232) or bacterial. Although a wide range of bacteria have been recovered from skin and soft tissue infections (Table 4.25), the majority are caused by the Gram-positive cocci *Staphylococcus aureus* and *Streptococcus pyogenes*.

### Staphylococcus aureus

Staphylococci are part of the normal microflora of the human skin and nasopharynx; up to 25% of people are carriers of *S. aureus*, which is the species responsible for the majority of staphylococcal infections. Although soft tissue infections are the most common manifestation of *S. aureus* disease, numerous other sites can be affected (Table 4.6).

The classification of soft tissue infections is complex, because imprecise and overlapping terms are in use. The
strains. Community-associated PVL-producing MRSA and MSSA are becoming an increasingly common cause of invasive soft tissue and lung infections in some countries (notably the USA), although it is unclear whether PVL itself is directly responsible for the increased virulence.

**Meticillin-resistant Staphylococcus aureus (MRSA)**

*S. aureus* are commonly resistant to penicillin, and isolated resistance to other β-lactam antibiotics such as meticillin (now rarely used) and flucloxacillin has been recognized since the development of the first semisynthetic penicillins in the early 1960s. However, in the last 40 years, strains of MRSA with resistance to a much wider range of antibiotics have emerged. In some cases only the glycopeptide antibiotics, vancomycin and teicoplanin, are effective (along with the new agents discussed below), and a few organisms have been isolated with decreased sensitivity even to these.

Vancomycin-insensitive *S. aureus* (VISA) develop because the organism produces a thick cell wall by changing the synthesis of cell wall material. Vancomycin-resistant *S. aureus* (VRSA) acquires resistance by receiving the van A gene from vancomycin-resistant enterococci (see Fig. 4.4).

Apart from the glycopeptides, four newer classes of antibiotics are effective against Gram-positive bacteria, including MRSA: these are the streptogramins (e.g. quinupristin with dalfopristin), the oxazolidinones (e.g. linezolid), tigecycline and daptomycin. They should usually be reserved for multi-resistant organisms. Control of the use of antibiotics in hospitals and good infection control policies are vital to prevent the spread of multiresistant organisms. Scrupulous hygiene on the part of healthcare workers is especially necessary (e.g. hand washing).

MRSA is usually found as a skin commensal, especially in hospitalized patients or nursing home residents. However it can cause a variety of infections in soft tissues and elsewhere, and can cause death. It is particularly associated with surgical wound infections. Eradication of the organism is difficult, and people who are known to be colonized should be isolated from those at risk of significant infection. Topical treatment with antibiotics is often used, but is of limited efficacy. Hand-washing is more effective at controlling spread.

Although MRSA is generally regarded as a hospital-associated organism it is now commonly seen in people away from the hospital setting, both as a colonizer and as a cause of disease. Often the organisms are the typical ‘hospital’ strains of MRSA, and have been acquired directly or indirectly from a healthcare setting (e.g. in workers in care homes). However there is an increasing prevalence in some countries of true community-associated MRSA (CA-MRSA), with no discernible links to hospital or residential care. These CA-MRSA have different resistance profiles to typical hospital strains (often retaining sensitivity to tetracyclines, clindamycin and co-trimoxazole), and are more likely to produce PVL.

**Detection**

Culture takes 24 hours. A new rapid (2 h) real time PCR assay is now available.

**Pasteurellosis**

*Pasteurella multocida* is found in the oropharynx of up to 90% of cats and 70% of dogs. It can cause soft tissue infec-

### Table 4.26 Predisposing factors for skin and soft tissue infection

- Diabetes mellitus
- Chronic lymphoedema
- Peripheral vascular disease
- Venous ulcers
- Steroid treatment
- Malnutrition
- Some immunodeficiency states (e.g. Job’s syndrome)
- Nasal carriage of *Staphylococcus aureus*
tions following animal bites. Although the infection initially resembles other forms of cellulitis, there is a much higher incidence of spread to deeper tissues, resulting in osteomyelitis, tenosynovitis or septic arthritis. The organism is sensitive to penicillin, but as infections following animal bites are often polymicrobial, co-amoxiclav is used.

**Cat scratch disease**

Cat scratch disease is a zoonosis caused by *Bartonella henselae*. Asymptomatic bacteraemia is relatively common in domestic and especially feral cats, and human infection is probably due to direct inoculation from the claws or via cat flea bites. Regional lymphadenopathy appears 1–2 weeks after infection; the nodes become tender and may suppurate. Histology of the nodes shows granuloma formation, and the illness may be mistaken for mycobacterial infection or lymphoma. There are usually few systemic symptoms in immunocompetent patients, although more severe disease may be seen in the immunocompromised. In these patients tender cutaneous or subcutaneous nodules are seen (*bacillary angiomatosis*) which may ulcerate. The lymphadenopathy resolves spontaneously over weeks or months, although surgical drainage of very large suppurating nodes may be necessary. *B. henselae* is sensitive to azithromycin, doxycycline and ciprofloxacin, but drug selection and clinical benefit of treatment is variable according to the primary site of the infection.

**Toxin-mediated skin disease**

A number of skin conditions, although caused by bacteria, are mediated by exotoxins rather than direct local tissue damage.

**Staphylococcal scalded skin syndrome**

The scalded skin syndrome is caused by a toxin-secreting strain of *S. aureus*. It principally affects children under the age of 5. The toxin, exfoliatin, causes intra-epidermal cleavage at the level of the stratum corneum leading to the formation of large flaccid blisters that shear readily. It is a relatively benign condition, and responds to treatment with flucloxacillin.

**Toxic shock syndrome (TSS)**

TSS is usually due to toxin-secreting staphylococci, but toxin-secreting streptococci have also been implicated. Although historically associated with vaginal colonization and tampon use in women, this is not always the case. The exotoxin (normally toxic shock syndrome toxin 1, TSS-T1) causes cytokine release with abrupt onset of fever and shock, with a diffuse macular rash and desquamation of the palms and soles. Many patients are severely ill and mortality is about 5%. Treatment is mainly supportive, although the organism should be eradicated.

**Scarlet fever**

See page 126.

**Deep soft tissue infections**

Infections of the deeper soft tissues are much less common than superficial infections, and tend to be more serious. Usually they are related to penetrating injuries or to surgery, and the causative organisms relate to the nature of the wound.

**Necrotizing fasciitis**

Necrotizing fasciitis is a fulminating, rapidly spreading infection associated with widespread tissue destruction (through all tissue planes) and a high mortality. Historically two forms are described. Type 1, caused by a mixture of aerobic and anaerobic bacteria, is usually seen following abdominal surgery or in diabetics. Type 2, caused by group A streptococci, arises spontaneously in previously healthy people. Other organisms are now also recognized as causing necrotising fasciitis, most notably *Vibrio* species (*V. vulnificans*), associated with sea water in the tropics. All types are characterized by severe pain at the site of initial infection, rapidly followed by tissue necrosis. Infection tracks rapidly along the tissue planes, causing spreading erythema, pain and sometimes crepitus. In patients with fever, toxicity and pain, which is out of proportion to the skin findings, necrotizing fasciitis should be suspected and must be treated aggressively and promptly with antibiotics and urgent surgical exploration with extensive debridement or amputation if necessary. Laboratory investigations show a high CRP, a very raised white count (often over 25 × 10^3/L) and hyponatraemia. Imaging with US/CT may be helpful but should not deter urgent surgical exploration. Multiorgan failure is common and mortality is high. Type 2 necrotizing fasciitis is treated with high doses of benzylpenicillin and clindamycin; type 1 is treated with a broad-spectrum combination, which should include metronidazole.

**Gas gangrene**

Gas gangrene is caused by deep tissue infection with *Clostridium* spp., especially *C. perfringens*, and follows contami-nated penetrating injuries. It is particularly associated with battlefield wounds, but is also seen in intravenous drug users, and following abdominal surgery. The initial infection develops in an area of necrotic tissue caused by the original injury; toxins secreted by the bacteria kill surrounding tissue and enable the anaerobic organism to spread rapidly. Toxins are also responsible for the severe systemic features of gas gangrene. Treatment consists of urgent surgical removal of necrotic tissue, and treatment with benzylpenicillin and clindamycin.

---

**RESPIRATORY TRACT INFECTIONS**

Infections of the respiratory tract are divided into infections of the upper and lower respiratory tract, which are separated by the larynx. In health, the lower respiratory tract is normally sterile owing to a highly efficient defence system (see p. 818). Infections of the upper respiratory tract are particularly common in childhood when they are usually the result of virus infection. The paranasal sinuses and middle ear are contiguous structures and can be involved secondary to viral infections of the nasopharynx. The lower respiratory tract is frequently compromised by smoking, air pollution, aspiration of upper respiratory tract secretions and chronic lung disease, notably chronic obstructive pulmonary disease. Infections of the respiratory tract are defined clinically, sometimes radiologically, as in the case of pneumonia, and by appropriate microbiological sampling.

**Upper respiratory tract infections**

- The common cold (acute coryza) (see p. 831).
- Sinusitis (see p. 1081).
Scarlet fever occurs when the infectious organism (usually a group A streptococcus) produces erythrogenic toxin in an individual who does not possess neutralizing antitoxin antibodies. Infections may be sporadic or epidemic occurring in residential institutions such as schools, prisons and military establishments.

Clinical features
The incubation period of this relatively mild disease, which mainly affects children, is 2–4 days following a streptococcal infection, usually in the pharynx. Regional lymphadenopathy, fever, rigors, headache and vomiting are present. The rash, which blanches on pressure, usually appears on the second day of illness; it initially occurs on the neck but rapidly becomes punctate, erythematous and generalized. It is typically absent from the face, palms and soles, and is prominent in the flexures. The rash usually lasts about 5 days and is followed by extensive desquamation of the skin (Fig. 4.25). The face is flushed, with characteristic circumoral pallor. Early in the disease the tongue has a white coating through which prominent bright red papillae can be seen (‘strawberry tongue’). Later the white coating disappears, leaving a raw-looking, bright red colour (‘raspberry tongue’). The patient is infective for 10–21 days after the onset of the rash, unless treated with penicillin.

Scarlet fever may be complicated by peritonsillar or retropharyngeal abscesses and otitis media.

Diagnosis
The diagnosis is established by the typical clinical features and culture of a throat swab. Elevated antistreptolysin O and anti-DNase B levels in convalescent serum are indicative of streptococcal infection.

Treatment
Penicillin is the drug of choice and is given orally as phenoxymethylpenicillin 500 mg four times daily for 10 days. Individuals allergic to penicillin can be treated effectively with erythromycin 250 mg four times daily for 10 days. Treatment is usually effective in preventing rheumatic fever (see p. 136) and acute glomerulonephritis (see p. 592), which are non-suppurative complications of streptococcal pharyngitis. Unlike acute rheumatic fever, streptococcal nephritis may also complicate streptococcal skin infection.

Prevention
Chemoprophylaxis with penicillin or erythromycin should be given in epidemics.

Diphtheria
Diphtheria caused by Corynebacterium diphtheriae occurs world-wide. Its incidence in the West has fallen dramatically following widespread active immunization, but has re-emerged in the independent states of the former Soviet Union. Transmission is mainly through airborne droplet infection and rarely through fomites.

C. diphtheriae is a Gram-positive bacillus. Only strains which carry the tox + gene, are capable of toxin production. The toxin has two subunits, A and B. Subunit A is responsible for clinical toxicity. Subunit B serves only to transport the toxin component to specific receptors present chiefly on the myocardium and in the peripheral nervous system. Humans are the only natural hosts.

Clinical features
Diphtheria was formerly a disease of childhood but may affect adults in countries where childhood immunization has been interrupted or uptake is poor. The incubation period is 2–7 days. The manifestations may be regarded as local (due to the membrane) or systemic (due to exotoxin). The presence of a membrane, however, is not essential to the diagnosis. The illness is insidious in onset and is associated with tachycardia but only low-grade fever. If complicated by infection with other bacteria such as Strep. pyogenes, fever is high and spiking.

Nasal diphtheria is characterized by the presence of a unilateral, serosanguineous nasal discharge that crusts around the external nares.

Pharyngeal diphtheria is associated with the greatest toxicity and is characterized by marked tonsillar and pharyngeal inflammation and the presence of a membrane. This tough greyish yellow membrane is formed by fibrin, bacteria, epithelial cells, mononuclear cells and polymorphs, and is firmly adherent to the underlying tissue. Regional lymphadenopathy, often tender, is prominent and produces the so-called ‘bull-neck’.

Laryngeal diphtheria is usually a result of extension of the membrane from the pharynx. A husky voice, a brassy cough, and later dyspnoea and cyanosis due to respiratory obstruction are common features.

Clinically evident myocarditis occurs, often weeks later, in patients with pharyngeal or laryngeal diphtheria. Acute circulatory failure due to myocarditis may occur in convalescent individuals around the tenth day of illness and is usually fatal. Neurological manifestations occur either early in the disease (palatal and pharyngeal wall paralysis) or several weeks after its onset (cranial nerve palsies, paraesthesiae, polyneuropathy or, rarely, encephalitis).

Cutaneous diphtheria is uncommon but seen in association with burns and in individuals with poor personal hygiene. Typically the ulcer is punched-out with undermined edges and is covered with a greyish white to brownish adherent membrane. Constitutional symptoms are uncommon.

Diagnosis
This must be made on clinical grounds since therapy is usually urgent and bacteriological results of culture studies and toxin production cannot be awaited.
Treatment
The patient should be isolated and bed rest advised. Antitoxin therapy is the only specific treatment. It must be given promptly to prevent further fixation of toxin to tissue receptors, since fixed toxin is not neutralized by antitoxin. Depending on the severity, 20000–100000 units of horse-serum antitoxin should be administered intramuscularly after an initial test dose to exclude any allergic reaction. Intravenous therapy may be required in a very severe case. There is a risk of acute anaphylaxis after antitoxin administration and of serum sickness 2–3 weeks later (Box 4.7). However, the risk of death outweighs the problems of anaphylaxis. Antibiotics should be administered concurrently to eliminate the organisms and thereby remove the source of toxin production. Benzylpenicillin 1.2 g four times daily is given for 1 week.

The cardiac and neurological complications need intensive therapy. Recovery and rehabilitation can take many weeks.

Prevention
Diphtheria is prevented by active immunization in childhood (see p. 102). Booster doses should be given to those traveling to endemic areas if more than 10 years has elapsed following their primary course of immunization. All contacts of the patient should have throat swabs sent for culture; those with a positive result should be treated with penicillin or erythromycin and active immunization or a booster dose of diphtheria toxoid given.

Pertussis (whooping cough)

Pertussis occurs world-wide. Humans are both the natural hosts and reservoirs of infection. The disease is caused by *Bordetella pertussis* which is a Gram-negative coccobacillus. *B. parapertussis* and *B. bronchiseptica* produce milder infections. Pertussis is highly contagious and is spread by droplet infection. In its early stages it is indistinguishable from other types of upper respiratory tract infection. Epidemic disease occurred in the UK when the safety of the whooping cough vaccine was questioned. Currently, uptake exceeds 95% and the disease is uncommon.

Clinical features

The incubation period is 7–10 days. It is a disease of childhood, with 90% of cases occurring below 5 years of age. However, no age is exempt although in adults it may be unsuspected.

During the catarrhal stage the patient is highly infectious, and cultures from respiratory secretions are positive in over 90% of patients. Malaise, anorexia, mucoid rhinorrhea and conjunctivitis are present. The paroxysmal stage, so called because of the characteristic paroxysms of coughing, begins about a week later. Paroxysms with the classic inspiratory whoop are seen only in younger individuals in whom the lumen of the respiratory tract is compromised by mucus secretion and mucosal oedema. The whoop results from air being forcefully drawn through the narrowed tract. These paroxysms usually terminate in vomiting. Conjunctival suffusion and petechiae and ulceration of the frenulum of the tongue are usual. Lymphocytosis due to the elaboration of a lymphocyte-promoting factor by *B. pertussis* is characteristic; lymphocytes may account for over 90% of the total white blood cell count. This stage lasts approximately 2 weeks and may be associated with several complications, including pneumonia, atelectasis, rectal prolapse and inguinal hernia. Cerebral anoxia may occur, especially in younger children, resulting in convulsions. Bronchiectasis is a rare sequel.

Diagnosis

The diagnosis is suggested clinically by the characteristic whoop and a history of contact with an infected individual. It is confirmed by isolation of the organism. Cultures of swabs (dacron or calcium alginate) of nasopharyngeal secretions result in a higher positive yield than cultures of ‘cough plates’; PCR assays are available.

Treatment

If the disease is recognized in the catarrhal stage, erythromycin will abort or decrease the severity of the infection. In the paroxysmal stage, antibiotics have little role to play in altering the course of the illness.

Prevention and control

Affected individuals should be isolated to prevent contact with others, e.g. in hostels and boarding schools. Pertussis is an easily preventable disease and active immunization is available (Box 4.6). Convulsions and encephalopathy have been reported as rare complications of vaccination but they are probably less frequent than after whooping cough itself. Any exposed susceptible infant should receive prophylactic erythromycin.

Acute epiglottitis (see p. 834)

This has been virtually eliminated among children in those countries which have introduced *Haemophilus influenzae* vaccine, as in the UK. Occasionally, infections are being recognized in adults. The clinical features are described on page 834.

Acute laryngotracheobronchitis (CROUP)

See page 833.

Influenza

See pages 116 and 834.

Lower respiratory tract infections

Pneumonia: community-acquired (see p. 859); hospital-acquired (see p. 862); in immunocompromised persons (see p. 189).

Psittacosis (ornithosis)

Although originally thought to be limited to the psittacine birds (parrots, parakeets and macaws), it is known that the disease is widely spread amongst many species of birds,
including pigeons, turkeys, ducks and chickens (hence the broader term ‘ornithosis’). Human infection is related to exposure to infected birds and is therefore a true zoonosis. The causative organism, *Chlamydia psittaci*, is excreted in avian secretions; it can be isolated for prolonged periods from birds who have apparently recovered from infection. The organism gains entry to the human host by inhalation. For *clinical features and treatment* – see page 860.

**Acinetobacter infection**

This Gram-negative coccobacillus is becoming increasingly prominent in nosocomial infections, particularly as a cause of ventilator-associated pneumonia (see p. 914) and vascular catheter infections. It is a cause of community acquired infections in tropical countries and is associated with wars and natural disasters. The organism is resistant to many antibiotics including carbapenems. Polymyxin and tigecycline are being used but resistance is still a problem.

**Other respiratory infections**

(see also p. 860)

*Chlamydia pneumoniae* causes a relatively mild pneumonia in young adults, clinically resembling infection caused by *Mycoplasma pneumoniae*. Diagnosis can be confirmed by specific IgM serology. Treatment is with erythromycin 500 mg 6-hourly, tetracycline 500 mg every 6–8 hours, or a fluoroquinolone, e.g. ciprofloxacin 500 mg twice daily.

*Other chlamydial infections* include trachoma (see p. 143), lymphogranuloma venereum (see p. 177) and other genital infections.

**Legionnaires’ disease.** This is caused by *Legionella pneumophila* and other *Legionella* spp. It is described on page 860.

**Lung abscess.** See page 836.

**Tuberculosis.** See pages 145 and 863.

---

**GASTROINTESTINAL INFECTIONS**

**Gastroenteritis**

The most common form of acute gastrointestinal infection is gastroenteritis, causing diarrhoea with or without vomiting. Children in the developing world can expect, on average, three to six bouts of severe diarrhoea every year. Although oral rehydration programmes have cut the death toll significantly, at least 2.25 million people die every year as a direct result of diarrhoeal disease. In the western world diarrhoea is both less common and less likely to cause death. However, it remains a major cause of morbidity, especially in the elderly. Other groups who are at increased risk of infectious diarrhoea include travellers to developing countries, homosexual men, and infants in day care facilities. Viral gastroenteritis (see p. 144) is a common cause of diarrhoea and vomiting in young children, but is rarely seen in adults, other than in the context of common source outbreaks, usually due to noroviruses. Protozoal and helmintic gut infections (see p. 160) are rare in the West but relatively common in developing countries. The most common cause of significant adult gastroenteritis world-wide is bacterial infection.

**Mechanisms**

Bacteria can cause diarrhoea in three different ways (Table 4.27). Some species may employ more than one of these methods.

**Mucosal adherence**

Most bacteria causing diarrhoea must first adhere to specific receptors on the gut mucosa. A number of different molecular adhesion mechanisms have been elaborated; for example, adhesions at the tip of the pili or fimbiae which protrude from the bacterial surface aid adhesion. For some pathogens this is merely the prelude to invasion or toxin production but others such as enteropathogenic *Escherichia coli* (EPEC) cause attachment-effacement mucosal lesions on electron microscopy (EM) and produce a secretory diarrhoea directly as a result of adherence. *Enteroaggregative E. coli* (EAggEC)

**FURTHER READING**

adhere in an aggregative pattern with the bacteria clumping on the cell surface and its toxin causes persistent diarrhoea in people in developing countries. Diffusely adhering E. coli (DAEC) adheres in a uniform manner and may also cause diarrhoea seen in children and in developing countries.

**Mucosal invasion**
Invasive pathogens such as *Shigella* spp., enteroinvasive *E. coli* (EIEC) and *Campylobacter* spp. penetrate into the intestinal mucosa. Initial entry into the mucosal cells is facilitated by the production of ‘invasins’, which disrupt the host cell cytoskeleton. Subsequent destruction of the epithelial cells allows further bacterial entry, which also causes the typical symptoms of dysentery: low-volume bloody diarrhoea, with abdominal pain.

**Toxin production** (see Fig. 4.3)
Gastroenteritis can be caused by different types of bacterial toxins:
- **Enterotoxins**, produced by the bacteria adhering to the intestinal epithelium, induce excessive fluid secretion into the bowel lumen, leading to watery diarrhoea, without physically damaging the mucosa, e.g. cholera, enterotoxigenic *E. coli* (ETEC). Some enterotoxins preformed in the food primarily cause vomiting, e.g. *Staph. aureus* and *Bacillus cereus*. A typical example of this is ‘fried rice poisoning’, in which *B. cereus* toxin is present in cooked rice left standing overnight at room temperature.
- **Cytotoxins** damage the intestinal mucosa and, in some cases, vascular endothelium as well (e.g. *E. coli* O157).

**Clinical syndromes**
Bacterial gastroenteritis can be divided on clinical grounds into two broad syndromes: *watery diarrhoea* (usually due to enterotoxins, or adherence), and *dysentery* (usually due to mucosal invasion and damage) (Box 4.8). With some pathogens such as *Campylobacter jejuni* there may be overlap between the two syndromes.

**Management** (see p. 131)

**Salmonella**
Gastroenteritis can be caused by many of the numerous serotypes of salmonella (all of which are members of a single species, *S. choleraesuis*), but the most commonly implicated are *S. enteritidis* and *S. typhimurium*. These organisms, which are found all over the world, are commensals in the bowel of livestock (especially poultry) and in the oviducts of chicken (where the eggs can become infected). They are usually transmitted to man in contaminated foodstuffs and water.

Salmonellae can affect both the large and small bowel, and induce diarrhoea both by production of enterotoxins and by epithelial invasion. The typical symptoms commence abruptly 12–48 hours after infection and consist of nausea, cramping abdominal pain, diarrhoea, and sometimes fever. The diarrhoea can vary from profuse and watery to a bloody dysentery syndrome. Spontaneous resolution usually occurs in 3–6 days, although the organism may persist in the faeces for several weeks. Bacteraemia occurs in 1–4% of cases and is more common in the elderly and the immunosuppressed. Occasionally bacteraemia is complicated by metastatic infection, especially of atheroma on vascular endothelium, with potentially devastating consequences. In healthy adults salmonella gastroenteritis is usually a relatively minor illness, but young children and the elderly are at risk of significant dehydration.

Specific diagnosis is made by culturing the organism from blood or faeces, but management is usually empirical. Antibiotic therapy (ciprofloxacin 500 mg twice daily) may decrease the duration and severity of symptoms, but is rarely warranted (see Box 4.10).

**Campylobacter jejuni**
*C. jejuni* is also a zoonotic infection, existing as a bowel commensal in many species of livestock, e.g. poultry and cattle. It is found world-wide, and is a common cause of childhood gastroenteritis in developing countries. Adults in these countries may be tolerant of the organism, excreting it asymptomatically. In the West it is a common cause of sporadic food-borne outbreaks of diarrhoea, the commonest causes being undercooked meat, e.g. chicken, and contaminated milk products.

Like salmonella, campylobacter can affect large and small bowel and can cause a wide variety of symptoms. The incubation period is usually 2–4 days, after which there is an abrupt onset of nausea, diarrhoea and abdominal cramps. The diarrhoea is usually profuse and watery, but an invasive haemorrhagic colitis is sometimes seen. Bacteraemia is very rare, and infection is usually self-limiting in 3–5 days. Diagnosis is made from stool cultures. If symptoms are severe, azithromycin 500 mg once daily is the drug of choice (see Box 4.10).

**Shigella**
Shigellae are enteroinvasive bacteria which cause classical bacillary dysentery. The principal species causing gastroenteritis are *S. dysenteriae*, *S. flexneri* and *S. sonnei*, which are found with varying prevalence in different parts of the world. All cause a similar syndrome, as a result of damage to the intestinal mucosa. Some strains of *S. dysenteriae* also secrete a cytotoxin affecting vascular endothelium. Although shigellae are found world-wide, transmission is strongly associated with poor hygiene. The organism is spread from
person to person, and only small numbers need to be ingested to cause illness (<200, compared to $10^4$ for campylobacter and $>10^5$ for salmonella). Bacillary dysentery is far more prevalent in the developing world, where the main burden falls on children.

Symptoms start 24–48 hours after ingestion and typically consist of frequent small-volume stools containing blood and mucus. Dehydration is not as significant as in the secretory diarrhoeas, but systemic symptoms and intestinal complications are worse. The illness is usually self-limiting in 7–10 days, but in children in developing countries the mortality may be as high as 20%. Antibiotic treatment decreases the severity and duration of diarrhoea, and possibly reduces the risk of further transmission (see Box 4.10). Resistance to antibiotics is widespread: in some areas amoxicillin or co-trimoxazole may still be effective, but in many places nalidixic acid or ciprofloxacin is needed.

**Enteroinvasive Escherichia coli (EIEC)**

This causes an illness indistinguishable from shigellosis. Definitive diagnosis is made by stool culture.

**Enterohaemorrhagic Escherichia coli (EHEC)**

EHEC (usually serotype O157:H7, and also known as verotoxin-producing E. coli, or VTEC) is a well recognized cause of gastroenteritis in man. It is a zoonosis usually associated with cattle, and there have been a number of major outbreaks (notably in Scotland and Japan) associated with contaminated food. A variety of modes of transmission have been reported, and EHEC is a paradigm for all enteric livestock-associated zoonoses (Fig. 4.26). EHEC secretes a toxin (Shiga-like toxin 1) which affects vascular endothelial cells in the gut and in the kidney. After an incubation period of 12–48 hours it causes diarrhoea (frequently bloody), associated with abdominal pain and nausea. Some days after the onset of symptoms the patient may develop thrombotic thrombocytopenic purpura (see p. 137) or haemolytic uraemic syn-drome (HUS, p. 598). This is more common in children, and may lead to permanent renal damage or death. Treatment is mainly supportive: there is evidence that antibiotic therapy might precipitate HUS by causing increased toxin release.

**Enterotoxigenic Escherichia coli (ETEC)**

ETEC produce both heat-labile and heat-stable enterotoxins which stimulate secretion of fluid into the intestinal lumen. The result is watery diarrhoea of varying intensity, which usually resolves within a few days. Transmission is normally from person to person via contaminated food and water. The organism is common in developing countries, and is a major cause of travellers’ diarrhoea (see below).

**Vibrio**

Cholera, due to *Vibrio cholerae*, is the prototypic pure entero-toxigenic diarrhoea: it is described on page 143.

*Vibrio parahaemolyticus* causes acute watery diarrhoea after eating raw fish or shellfish that has been kept for several hours without refrigeration. Explosive diarrhoea, abdominal cramps and vomiting occurs with a fever in 50%. It is self-limiting, lasting up to 10 days.

**Yersinia**

*Yersinia enterocolitica* infection is a zoonosis of a variety of domestic and wild mammals. Human disease can arise either via contaminated food products, e.g. pork, or from direct animal contact. *Y. enterocolitica* can cause a range of gastroenteric symptoms including watery diarrhoea, dysentery and mesenteric adenitis. The illness is usually self-limiting, but ciprofloxacin may shorten the duration. *Y. pseudotuberculosis* is a much less common human pathogen: it causes mesenteric adenitis and terminal ileitis.

**Staphylococcus aureus**

Some strains of *S. aureus* can produce a heat-stable toxin (enterotoxin B) which causes massive secretion of fluid into the intestinal lumen. It is a common cause of food-borne

---

**Fig. 4.26** Routes of human infection with *E. coli* O157.
gastroenteritis in Europe and the USA, outbreaks usually occurring as a result of poor food hygiene. Because the toxin is preformed in the contaminated food, onset of symptoms is rapid, often within 2–4 hours of consumption. There is violent vomiting, followed within hours by profuse watery diarrhoea. Symptoms have usually subsided within 24 hours.

**Bacillus cereus**

*B. cereus* produces two toxins. One produces watery diarrhoea up to 12 hours after ingesting the organism. The other toxin is preformed in food and causes severe vomiting, e.g. ‘fried rice poisoning’ (see p. 132).

**Clostridial infections**

*Clostridium difficile* causes antibiotic-associated diarrhoea, colitis and pseudomembranous colitis. It is a Gram-positive, anaerobic, spore-forming bacillus and is found as part of the normal bowel flora in 3–5% of the population and even more commonly (up to 20%) in hospitalized people.

**Pathogenesis.** *C. difficile* produces two toxins: toxin A is an enterotoxin while toxin B is cytotoxic and causes bloody diarrhoea. It causes illness either after other bowel commensals have been eliminated by antibiotic therapy or in debilitated patients who have not been on antibiotics. Almost all antibiotics have been implicated but the present increase has been attributed to the overuse of quinolones (e.g. ciprofloxacin). Hospital-acquired infections remain high, partly due to increased person-to-person spread and from fomites (see below). In recent years new strains of *C. difficile* with greater capacity for toxin production have been reported. There have been a number of hospital outbreaks with a high mortality.

**Clinical features.** *C. difficile* diarrhoea can begin anything from 2 days to a month after taking antibiotics. Elderly hospitalized patients are most frequently affected. It is unclear as to why some carriers remain asymptomatic. Symptoms can range from mild diarrhoea to profuse, watery, haemorrhagic colitis, along with lower abdominal pain. The colonic mucosa is inflamed and ulcerated and can be covered by an adherent membrane-like material (pseudomembranous colitis). The disease is usually more severe in the elderly and can cause intractable diarrhoea, leading to death.

**Diagnosis** is made by detecting A or B toxins in the stools by ELISA techniques.

**Treatment** is with metronidazole 400 mg three times daily or oral vancomycin 125 mg four times daily. Causative antibiotics should be discontinued if possible.

**Prevention.** Infection control relies on:

- Responsible use of antibiotics.
- Hygiene, which should involve all health workers, as well as patients and relatives. Washing hands thoroughly using soap and water is essential as alcohol disinfectants do not kill spores.
- Hospital cleaning of surfaces should be performed regularly to try and reduce transmission from fomites.
- Isolation of patients with *C. difficile*.

*Clostridium perfringens* infection is due to inadequately cooked food, usually meat or poultry allowed to cool for a long time, during which the spores germinate. The ingested organism produces an enterotoxin causing watery diarrhoea with severe abdominal pain, usually without vomiting.

**Travellers’ diarrhoea**

Travellers’ diarrhoea is defined as the passage of three or more unformed stools per day in a resident of an industrialized country travelling in a developing nation. Infection is usually food- or water-borne, and younger travellers are most often affected (probably reflecting behaviour patterns). Reported attack rates vary from country to country, but approach 50% for a 2-week stay in many tropical countries. The disease is usually benign and self-limited: treatment with quinolone antibiotics may hasten recovery but is not normally necessary. Prophylactic antibiotic therapy may also be effective for short stays, but should not be used routinely. The common causative organisms are listed in Table 4.28.

**Management of acute gastroenteritis**

In children, untreated diarrhoea has a high mortality due to dehydration, especially in hot climates. Death and serious morbidity are less common in adults but still occur, particularly in developing countries and in the elderly. The mainstay of treatment for all types of gastroenteritis is oral rehydration solutions (ORS): antibiotics have a subsidiary role in some cases (Fig. 4.27; Boxes 4.9 and 4.10 and p. 132). The use and formulation of ORS are discussed under cholera on page 143. It should also be remembered that other diseases, notably urinary tract infections and chest infections in the elderly, and malaria at any age, can present with acute diarrhoea.

**Food poisoning**

Food poisoning is a legally notifiable disease in England and Wales, and is defined as ‘any disease of an infective or toxic nature caused by or thought to be caused by the consumption of food and water’. Not all cases of gastroenteritis are food poisoning, as the pathogens are not always food- or water-borne. Common bacterial causes of food poisoning are listed in Table 4.29. Food poisoning may also be caused by a number of non-infectious organic and inorganic toxins (Table 4.30). Illnesses such as botulism (see p. 134) are also classified as food poisoning, even though they do not primarily cause gastroenteritis. Listeriosis is described on page 138.

The increase in reported food poisoning in developed countries is at least in part due to changes in the production and distribution of food. Livestock raised and slaughtered...

supply encourages widespread and distant transmission of the resulting infections. Kitchen hygiene with careful separation of meat products from salads, along with using the correct temperature for cooking meat are necessary.

Other preventative measures include culling and vaccination of chicken.

**Enteric fever** (see p. 144)

**Other gastrointestinal infections**

Gastric infection with *Helicobacter pylori* is discussed on page 258, Whipple’s disease on page 281, and bacterial peritonitis on page 316.

**INFECTIONS OF THE CARDIOVASCULAR SYSTEM**

- Infective endocarditis (see p. 768).

**INFECTIONS OF THE NERVOUS SYSTEM**

The central and peripheral nervous systems can be affected by a variety of microorganisms including bacteria, viruses (see p. 1156) and protozoa (see p. 157) which cause disease by direct invasion or via toxins. The nervous system is also vulnerable to prion disease (see pp. 121 and 1158).
Bacterial meningitis (see p. 1153)

The most common bacterial disease affecting the central nervous system is acute meningitis, which causes about 175,000 deaths per year, predominantly in the developing world. Epidemic meningitis due to Neisseria meningitidis (usually group A) is common in a broad belt across sub-Saharan Africa and is also seen in parts of Asia. In Europe and North America bacterial meningitis is usually sporadic, with B and C strains predominating. A conjugate vaccine for serogroup C meningococcus has resulted in a fall in the number of cases of meningitis in those countries where it is now part of the childhood immunization schedule, such as the UK.

Streptococcus pneumoniae is the other major cause throughout the world, while tuberculous meningitis (see p. 1155) is common in sub-Saharan Africa and parts of Asia.

Haemophilus influenzae b (Hib) was once a common cause of meningitis in children, but since an effective vaccine has been available, serious H. influenzae infections have become rare in western countries. Many developing countries have also instituted immunization programmes, but invasive H. influenzae infection remains common in some parts of the world.

Other less common causes of meningitis in adults include group B streptococci, Listeria monocytogenes (see p. 138), Staph. aureus and Gram-negative bacilli. These organisms are usually associated with an underlying illness or immuno-compromising condition, or with a cerebrospinal fluid leak.

Cerebral abscess

This is covered on page 1159.

Toxin-mediated infections

Botulism

Clostridium botulinum is a common environmental organism, and produces spores which can survive heating to 100°C. It causes botulism, an illness caused by contamination of canned or bottled foodstuff, in which the anaerobic organism can multiply and elaborate a neurotoxin. After ingestion the toxin causes profound neuromuscular blockade, leading to autonomic and motor paralysis. The first symptoms, occurring 18–24 hours after ingestion, are nausea and diarrhoea. These are followed by cranial nerve palsies and then progressive symmetrical paralysis, leading to respiratory failure.

The diagnosis is usually clinical, and is confirmed by detection of toxin in faeces or in the contaminated food. Treatment is mainly supportive, with mechanical ventilation if necessary. Antitoxin is available in some countries (including the UK); the risk of anaphylaxis is relatively high, and it should only be used in severe cases. A subcutaneous test dose should be given before intravenous or intramuscular injection. Antibiotics have no proven role. The overall mortality from botulism is high, but patients who survive the acute paralysis can make a full recovery.

Botulism may also follow the contamination of wounds, street heroin injection contaminated with C. botulinum, and in infants botulism may be related to bowel colonization by the organism.

Tetanus

Tetanus is also due to a toxin-secreting clostridium: C. tetani. The organism is found in soil, and illness usually results from a contaminated wound. The injury itself may be trivial and disregarded by the individual. It has also complicated intravenous drug use. In developing countries neonatal tetanus follows contamination of the umbilical stump, often after dressing the area with dung.

The organism is not invasive, and clinical manifestations of the disease are due to the potent neurotoxin, tetanosapin. Tetanosapin acts on both the α and δ motor systems at synapses, resulting in disinhibition. It also produces neuromuscular blockade and skeletal muscle spasm, and acts on the sympathetic nervous system. The end result is marked flexor muscle spasm and autonomic dysfunction.

Clinical features

The incubation period varies from a few days to several weeks. The most common form of the disease is generalized tetanus. General malaise is rapidly followed by trismus (lockjaw) due to masseter muscle spasm. Spasm of the facial muscles produces the characteristic grinning expression known as risus sardonicus. If the disease is severe, painful reflex spasms develop, usually within 24–72 hours of the initial symptoms. The interval between the first symptom and the first spasm is referred to as the ‘onset time’. The spasms may occur spontaneously but are easily precipitated by noise, handling of the patient, or by light. Respiration may be impaired because of laryngeal spasm; oesophageal and urethral spasm lead to dysphagia and urinary retention, respectively, and there is arching of the neck and back muscles (opisthotonous). Autonomic dysfunction produces tachycardia, a labile blood pressure, sweating and cardiac arrhythmias. Patients with tetanus are mentally alert.

Death results from aspiration, hypoxia, respiratory failure, cardiac arrest or exhaustion. Mild cases with rigidity usually recover. Poor prognostic indicators include short incubation period, short onset time and extremes of age.

Localized tetanus is a milder form of the disease. Pain and stiffness are confined to the site of the wound, with increased tone in the surrounding muscles. Recovery usually occurs.

Cephalic tetanus is uncommon but invariably fatal. It usually occurs when the portal of entry of C. tetani is the middle ear. Cranial nerve abnormalities, particularly of the seventh nerve, are usual. Generalized tetanus may or may not develop.

Neonatal tetanus is usually due to infection of the umbilical stump. Failure to thrive, poor sucking, grimacing and irritability are followed by the rapid development of intense rigidity and spasms. Mortality approaches 100%. One aim of the WHO Expanded Programme on Immunization (EPI) is to eliminate this condition by immunizing all women of child-bearing age, providing clean delivery facilities and strengthening surveillance in high-risk areas.

Diagnosis

Few diseases resemble tetanus in its fully developed form, and the diagnosis is therefore usually clinical. Rarely, C. tetani is isolated from wounds. Phenothiazine overdosage, strychnine poisoning, meningitis and tetany can occasionally mimic tetanus.

Management

Suspected tetanus. Any wound must be cleaned and debrided if necessary, to remove the source of toxin. Human
treatment. Tetanus immunoglobulin 250 units should be given along with an intramuscular injection of tetanus toxoid. If the patient is already protected a single booster dose of the toxoid is given; otherwise the full three-dose course of adsorbed vaccine is given (see below).

Established tetanus. Management is supportive medical and nursing care. Improvement in this area has contributed more than any other single measure to the decrease in the mortality rate from 60% to nearer 20%. Patients are nursed in a quiet, isolated, well-ventilated, darkened room. Benzodiazepines are used to control spasms and sedate the patient; if the airway is compromised intubation and mechanical ventilation may be necessary. Magnesium sulphate infusion decreases the need for antispasmodics.

Antibiotics and antitoxin should be administered, even in the absence of an obvious wound. Intravenous metronidazole is the drug of choice, although penicillin and cephalosporins are also effective. Human tetanus immunoglobulin (HTIG) 500 IU should be given by intramuscular injection to neutralize any circulating toxin. If HTIG is not available, immune equine tetanus immunoglobulin 10 000 IU should be given intramuscularly; this is probably as effective as HTIG, but there is a high incidence of severe allergic reactions. If the patient recovers, active immunization should be instituted, as immunity following tetanus is incomplete.

Prevention
Tetanus is an eminently preventable disease and all persons should be immunized regardless of age. Those who work in a contaminated environment, such as farmers, are particularly at risk and should have regular booster injections. Active immunization with the alum-adsorbed toxoid should be given. Initially two doses of 0.5 mL of the toxoid are given intramuscularly with an 8-week interval. The third dose is given 6–12 months later as a booster. Subsequent boosters are required at 5-year intervals. Infant immunization schedules in all countries include tetanus (Box 4.6). Protection by passive immunization with either the equine or human anti-tetanus immunoglobulin is short-lived, lasting only about 2 weeks.

### BONE AND JOINT INFECTIONS
- Infective arthritis (see p. 539)
- Osteomyelitis (see p. 541).

### URINARY TRACT INFECTIONS
- Complicated versus uncomplicated infections (see p. 600)
- Acute pyelonephritis (see p. 600)
- Reflux nephropathy (see p. 600)
- Perinephric abscess (renal carbuncle) (see p. 603)
- Bacterial prostatitis (see p. 603)
- Tuberculosis of the urinary tract (see p. 603)

### SYSTEMIC/MULTISYSTEM INFECTIONS

Many infections are confined to a particular body organ or system, owing to the metabolic requirements of the organism, the route of infection or the response of host defences. Other infections can potentially affect several systems or the entire body. Under unusual circumstances such as altered host immunity, infections which are normally circumscribed may become systemic. This section describes those infections which commonly cause multisystem disease in an immunocompetent host.

**Bacteraemia and sepsis syndrome**

*Bacteraemia*, the transient presence of organisms in the blood, can occur in healthy people without causing symptoms. It can follow surgery, dental treatment and even toothbrushing. Bacteraemia can also occur from the bowel or bladder, especially in the presence of local inflammation. Unless a site of metastatic infection is established (such as the heart valves), most organisms are rapidly cleared from the blood.

*Sepsis* is the term used to describe the signs and symptoms of a systemic inflammatory response syndrome (SIRS) to a localized primary site of infection. Viral, bacterial, fungal and parasitic disease can all trigger the sepsis syndrome.

SIRS is not unique to infection and may complicate a variety of events and conditions such as trauma, chronic inflammatory diseases and malignancy (e.g. lymphoma).

*Severe sepsis*. This is the presence of the sepsis syndrome (presence of either a positive blood culture or clinical features of fever, tachypnoea, tachycardia, suspected infection), complicated by organ dysfunction, hypotension or hypoperfusion and manifested by low blood pressure, oliguria, hypoxia, acute confusion and lactic acidosis.

*Septic shock* is defined as the sepsis syndrome plus organ dysfunction and hypotension unresponsive to adequate fluid replacement. Mortality rates often exceed 50%.

Patients presenting with symptoms and signs suggesting sepsis syndrome should be examined for evidence of a source: common sites of infection and responsible organisms are listed in Tables 4.31 and 4.32. Because of the potential to progress to severe sepsis, treatment with antibiotics should usually be started empirically as soon as appropriate cultures have been taken. The choice of agent is governed by the likely pathogen; if there are no clues, a broad-spectrum regimen should be used (e.g. piperacillin plus gentamicin, cefotaxime, with or without metronidazole or imipenem). In hospital units with epidemic MRSA infection, it is common practice to add vancomycin or teicoplanin to this empiric regimen. Antibiotic therapy should be reviewed daily as the illness progresses and the results of investigations

**Table 4.31 Causes of septicemia in a previously healthy adult**
become available. The general management of the sepsis syndrome is covered on page 899.

**Meningococcal septicaemia**

*Neisseria meningitidis* is found world-wide, in five major serogroups. In sub-Saharan Africa and parts of Asia where group A meningococcus is prevalent it usually causes epidemic disease. Groups Y and W can also cause epidemic infection, while groups B and C (which are the predominant strains in Europe and North America) tend to be sporadic. In England and Wales approximately 1500 cases of meningococcal disease are reported annually.

Man is the only known reservoir for the organism, which is carried asymptomatically in the nasopharynx of 5–20% of the general population. Meningococcal disease occurs when the bacteria invade the nasal mucosa and enter the bloodstream: this only happens in a small percentage of those colonized. Invasion depends on both host and bacterial factors. It is more likely to take place soon after colonization has taken place, and following viral upper respiratory infections.

**Clinical features**

Invasive meningococcal infection may cause meningitis, septicemia, or both. Meningitic disease (see p. 899) usually presents with the classical triad of headache, fever and neck stiffness. Vomiting, diminished consciousness and focal neurological signs occur, although some patients, especially in the early stages, only have mild symptoms. Meningococcal septicaemia causes the typical features of septic shock such as fever, myalgia and hypotension (see p. 899), and may be accompanied by a petechial or haemorrhagic rash (Fig. 4.28). In some cases the patient can deteriorate rapidly, with shock, disseminated intravascular coagulation and multigland failure.

**Diagnosis**

The presence of meningitis and septicemia with a typical rash is strongly suggestive of meningococcal disease. Gram-negative diplococci may be seen on Gram stain of CSF or of aspirate from petechiae, and meningococci can also be cultured from CSF or blood, or detected by PCR.

**Management**

*N. meningitidis* is sensitive to benzylpenicillin, third-generation cephalosporins and chloramphenicol; antibiotic treatment for meningococcal meningitis should be started immediately (see Emergency Box 21.1, p. 1154) and continued parenterally for 7 days. Meningococcal septicaemia should be managed in the same way as any other septicemic illness (see p. 905). The mortality from meningococcal septicaemia in developed countries is currently approximately 10%, while that from meningococcal meningitis alone is less than 5% (see below). Mild neurological sequelae (especially vestibular nerve damage) are common, but serious brain damage is relatively unusual.

The meningococcal C conjugate vaccine has led to an overall reduction of meningococcal C disease in the UK. A serogroup B vaccine is not currently available but is under development. A combined A and C vaccine is also available for outbreak control (see p. 423).

For close contacts of a case of meningococcal disease, household and ‘kissing’ contacts should be given prophylaxis with oral rifampicin or ciprofloxacin to eradicate the bacteria from the nasopharynx. In the case of group C disease, contacts should be offered immunization.

**Rheumatic fever**

Rheumatic fever is an inflammatory disease that occurs in children and young adults (the first attack usually occurs at between 5 and 15 years of age) as a result of infection with group A streptococci. It affects the heart, skin, joints and central nervous system. It is common in the Middle and Far East, eastern Europe and South America. It is rare in the UK, western Europe and North America. This decline in the incidence of rheumatic fever (from 10% of children in the 1920s to 0.01% today) parallels the reduction in all streptococcal infections and is largely due to improved hygiene and the use of antibiotics.

Pharyngeal infection with group A streptococcus is followed by the clinical syndrome of rheumatic fever. This is thought to develop because of an autoimmune reaction triggered by molecular mimicry between the cell wall M proteins of the infecting *Streptococcus pyogenes* and cardiac myosin.
and laminin. The condition is not due to direct infection of the heart or to the production of a toxin.

Pathology
All three layers of the heart may be affected. The characteristic lesion of rheumatic carditis is the Aschoff nodule, which is a granulomatous lesion with a central necrotic area occurring in the myocardium. Small, warty vegetations may develop on the endocardium, particularly on the heart valves. A serofibrinous effusion characterizes the acute pericarditis that occurs.

The synovial membranes are acutely inflamed during rheumatic fever, and subcutaneous nodules (which are also granulomatous lesions) are seen in the acute stage of the disease.

Clinical features
The disease presents suddenly, with fever, joint pains, malaise and loss of appetite. Diagnosis relies on the presence of two or more major clinical manifestations or one major manifestation plus two or more minor features. These are known as the modified Jones criteria (Table 4.33).

Carditis manifests as:
- new or changed heart murmurs
- development of cardiac enlargement or cardiac failure
- appearance of a pericardial effusion and ECG changes of pericarditis, myocarditis, AV block or other cardiac arrhythmias.

Non-cardiac features include the following:
- Fever.
- The arthritis associated with rheumatic fever is classically a fleeting migratory polyarthritis affecting large joints such as the knees, elbows, ankles and wrists. Once the acute inflammation disappears, the rheumatic process leaves the joints normal.
- Sydenham's chorea (or St Vitus' dance, see p. 1149) is involvement of the central nervous system that develops late after a streptococcal infection. Sufferers are noticeably 'fidgety' and display spasmodic, unintentional choreiform movements. Speech is often affected.

| ESR, erythrocyte sedimentation rate. |

- Skin manifestations include erythema marginatum, a transient pink rash with slightly raised edges, which occurs in 20% of cases. The erythematous areas found mostly on the trunk and limbs coalesce into crescent- or ring-shaped patches. Subcutaneous nodules, which are painless, pea-sized, hard nodules beneath the skin, may also occur.

Investigations
- **Throat swabs** are cultured for the group A streptococcus.
- Antistreptolysin O titre and antiDNAse B may be elevated.
- ESR and CRP are usually high.
- **Cardiac investigations**, e.g. ECG, echocardiogram.

Treatment
Patients with active arthritis or carditis should be rested in bed. When the clinical syndrome has subsided (e.g. no pyrexia, normal pulse rate, normal ESR, normal white cell count) the patient is mobilized.

Residual streptococcal infections should be eradicated with oral phenoxymethylpenicillin 500 mg four times daily for 1 week. This therapy should be administered even if nasal or pharyngeal swabs do not culture the streptococci.

The arthritis of rheumatic fever responds dramatically to NSAIDs. There is no good evidence that steroids are of benefit, although some experts give high-dose prednisolone if there is severe carditis. Recurrences are most common when persistent cardiac damage is present, and are prevented by the continued administration of oral phenoxymethylpenicillin 250 mg twice daily or intramuscular benzathine penicillin G 1.2 million units monthly until the age of 20 years or for 5 years after the latest attack (see p. 93). Erythromycin is used if the patient is allergic to penicillin. Any streptococcal infection that does develop should be treated promptly.

Prognosis
More than 50% of those who suffer acute rheumatic fever with carditis will later (after 10–20 years) develop chronic rheumatic valvular disease, predominantly affecting the mitral and aortic valves (see Table 13.34).

Leptospirosis
Leptospirosis is a zoonosis caused by the spirochaete *Leptospira interrogans*. There are over 200 serotypes: the main types affecting humans are *L. i. icterohaemorrhagiae* (rodents), *L. i. canicola* (dogs and pigs), *L. i. hardjo* (cattle) and *L. i. pomona* (pigs and cattle). Leptospires are excreted in the animal urine, and enter the host through a skin abrasion or through intact mucous membranes. Leptospirosis can also be caught by ingestion of contaminated water. The organism can survive for many days in warm fresh water, and for up to 24 hours in sea water.

In England and Wales only about 40 cases of leptospirosis are reported every year (although many mild infections probably go undiagnosed), and it remains largely an occupational disease of farmers, vets and others who work with animals. In some parts of the world (e.g. Hawaii, where the annual incidence is about 130/100 000) it is associated with a variety of recreational activities which bring people into
close contact with rodents. Outbreaks of leptospirosis have also been associated with flooding.

**Clinical features**
Weil, in 1886, described a severe illness consisting of jaundice, haemorrhage and renal impairment caused by *L. i. icterohaemorrhagiae*, but fortunately 90–95% of infections are subclinical or cause only a mild fever. The incubation period of leptospirosis is usually 7–14 days, and the illness typically has two phases. A leptospiroaemic phase, which lasts for up to a week, is followed after a couple of days’ interval by an immunological phase. The first phase is characterized by severe headache, malaise, fever, anorexia and myalgia. Most patients have conjunctival suffusion. Hepatosplenomegaly, lymphadenopathy and various skin rashes are sometimes seen. The second phase is usually mild. Fifty per cent of patients have meningism, about a third of whom have a CSF lymphocytosis. The majority of patients recover uneventfully at this stage.

In severe disease there may not be a clear distinction between phases. Following the initial symptoms, patients progressively develop hepatic and renal failure, haemolytic anaemia and circulatory collapse. Cardiac failure and pulmonary haemorrhage may also occur. Even with full supportive care the mortality is around 10%, rising to 15–20% in the elderly.

**Diagnosis**
The diagnosis is usually a clinical one. Leptospires can be cultured from blood or CSF during the first week of illness, but culture requires special media and may take several weeks. A minority of patients may also excrete the organism in their urine from the second week onwards. More usually, the diagnosis is made serologically. Specific IgM antibodies start to appear from the end of the first week and the diagnosis is often made retrospectively with a microscopic agglutination test (MAT) showing a four-fold rise. There is typically a leucocytosis and in severe infection, thrombocytopenia and an elevated creatine phosphokinase.

**Management**
Early antibiotic therapy will limit the progress of the disease, but treatment should still be initiated whatever the stage of the infection. Oral doxycycline may be used in mild cases: intravenous penicillin or erythromycin is given in more severe disease. Intensive supportive care is needed for those patients who develop hepatorenal failure.

**Listeriosis**
*Listeria monocytogenes* is an environmental organism which is widely disseminated in soil and decayed matter. It affects both animals and man: the most common route of human infection is in contaminated foods. The organism can grow at temperatures as low as 4°C, and the most commonly implicated foods are unpasteurized soft cheeses, raw vegetables and chicken pâtés. Listeriosis is a rare but serious infection affecting mainly neonates, pregnant women, the elderly and the immunocompromised. *L. monocytogenes* has also been recognized as a cause of self-limiting foodborne gastroenteritis in healthy adults, but the incidence of this is unknown.

In pregnant women listeria causes a flu-like illness, but infection of the fetus can lead to septic abortion, premature labour and stillbirth. Early treatment of listeria in pregnancy may prevent this, but the overall fetal loss rate is about 50%. In the elderly and the immunocompromised listeria can cause exposure is also common. Person-to-person transmission is rare.

**Clinical features**
The incubation period of acute brucellosis is 1–3 weeks. The onset is insidious, with malaise, headache, weakness, generalized myalgia and night sweats. The fever pattern is classically undulant, although continuous and intermittent patterns are also seen. Lymphadenopathy and hepatosplenomegaly are common; sacro-assiitis, arthritis, osteomyelitis, epididymo-orchitis, meningocerebralitis and endocarditis have all been described.

Untreated brucellosis can give rise to chronic infection, lasting a year or more. This is characterized by easy fatigability, myalgia, and occasional bouts of fever and depression. Splenomegaly is usually present. Occasionally infection can lead to localized brucellosis. Bones and joints, spleen, endocardium, lungs, urinary tract and nervous system may be involved. Systemic symptoms occur in less than one-third.

**Diagnosis**
Blood (or bone marrow) cultures are positive during the acute phase of illness in 50% of patients (higher in *B. melitensis*), but prolonged culture is needed. In chronic disease serological tests are of greater value. The brucella agglutination test, which demonstrates a fourfold or greater rise in titre (>1 in 160) over a 4-week period, is highly suggestive of brucellosis. An elevated serum IgG level is evidence of current or recent infection; a negative test excludes chronic brucellosis. In localized brucellosis antibody titres are low, and diagnosis is usually established by culturing the organisms from the involved site. Species-specific PCR tests are also available.

**Management and prevention**
Brucellosis is treated with a combination of doxycycline 200 mg daily and rifampicin 600–900 mg daily for 6 weeks, but relapses occur. Alternatively, tetracycline can be combined with streptomycin, which is usually given for only the first 2 weeks of treatment. Prevention and control involve careful attention to hygiene when handling infected animals, vaccination with the eradication of infection in animals, and pasteurization of milk. No vaccine is available for use in humans.
mengoencephalitis. Septicaemia and a variety of other focal infections have also been described.

The diagnosis is established by culture of blood, CSF or other body fluids. The treatment of choice for adult listeriosis is ampicillin plus gentamicin. Co-trimoxazole is also effective, but the organism is resistant to cephalosporins.

**Q fever**

*Q* (query) fever is a zoonosis caused by the rickettsia-like organism *Coxiella burnetii*. Infection is widespread in domestic, farm and other animals, birds and arthropods: spread is mainly by ticks. Modes of transmission to humans are by dust, aerosol, and unpasteurized milk from infected cows. The formation of spores means that *C. burnetii* can survive in extreme environmental conditions for long periods. The infective dose is very small, so that minimal animal contact is required. One reported outbreak occurred among inhabitants of a village through which infected sheep had passed. Infection in the UK is rare but has been linked to meat processing.

**Clinical features**

Symptoms begin insidiously 2–4 weeks after infection. Fever is accompanied by flu-like symptoms with myalgia and headache. The acute illness usually resolves spontaneously but pneumonia or hepatitis may develop. Occasional infection can become chronic, with endocarditis, myocarditis, uveitis, osteomyelitis or other focal infections.

*C. burnetii* is an obligate intracellular organism, and does not grow on standard culture media. Diagnosis is made serologically using an immunofluorescent assay. Antibody tests for two different bacterial antigens allow distinction between acute and chronic infection. A PCR assay is now available, but the sensitivity is low.

**Management**

Treatment with doxycycline 200 mg daily for 2 weeks reduces the duration of the acute illness, but it is not known whether this correlates with eradication of the organism. Azithromycin may also be used. For chronic Q fever, including endocarditis, doxycycline is often combined with hydroxychloroquine.

Even prolonged courses of treatment may not clear the infection. A vaccine is available for those at high risk.

**Lyme disease**

Lyme disease is caused by a spirochaete, *Borrelia burgdorferi*, which has at least 11 different genomic species. It is a zoonosis of deer and other wild mammals. The syndrome was first recognized and named following an ‘outbreak’ of arthritis in the town of Lyme, Connecticut, in the mid 1970s. Since then the disease has increased in both incidence and detection: it is now known to be widespread in the USA, Europe, Russia and the Far East. Infection is transmitted from animal to man by ixodid ticks, and is most likely to occur in rural wooded areas in spring and early summer.

**Clinical features**

The first stage of the illness, which follows 7–10 days after infection, is characterized by the skin lesion erythema migrans at the site of the tick bite. This is often accompanied by headache, fever, malaise, myalgia, arthralgia and lymphadenopathy. Many people have no further illness after this. A second stage may follow weeks or months later, when some patients develop neurological symptoms (meningoencephalitis, cranial or polyneuropathies), radiculopathies, cardiac problems (conduction disorders, myocarditis) or arthritis. These manifestations, which are often fluctuant and changing, usually resolve spontaneously over months or years. Some patients, however, develop chronic and persistent neurological disease (e.g. paraparesis) or rheumatological disease (‘late Lyme disease’), although the evidence for persistent infection is lacking (i.e. PCR negative). Acrodermatitis chronica atrophicans, usually on the backs of the hands and feet, can occur if the disease does not resolve spontaneously.

**Diagnosis**

The clinical features and epidemiological considerations are usually strongly suggestive. The diagnosis can only rarely be confirmed by isolation of the organisms from blood, skin lesions or CSF. IgM antibodies are detectable in the first month, and IgG antibodies are invariably present late in the disease. Commercial tests (ELISA, immunofluorescence, haemagglutination) are available but false-positive results do occur. A genuine positive IgG may be a marker of previous exposure rather than of ongoing infection.

**Tularaemia**

Tularaemia is due to infection by *Francisella tularensis*, a Gram-negative organism. It is primarily a zoonosis, acquired mainly from rodents. Infection can be transmitted by arthropod vectors or by handling infected animals, when the microorganisms enter through minor abrasions or mucous membranes. Occasionally infection occurs from contaminated water or from eating uncooked meat. The disease is widely distributed in North America, Northern Europe and Asia. It is relatively rare, occurring mainly in hunters, trappers, and others in close contact with animals.

The incubation period of 2–7 days is followed by a generalized illness. The most common presentation is ulceroglandular tularaemia. A papule occurs at the site of inoculation. This ulcerates and is followed by tender, suppurative lymphadenopathy. Rarely this can be followed by bacteraemia, leading to septicaemia, pneumonia or meningitis. These forms of the disease carry a high mortality if untreated.

Diagnosis is by culture of the organism or by a rising titre seen on a bacterial agglutination test.

Tularaemia should be treated with streptomycin or gentamicin.
LEPROSY

**Skin, Soft Tissue and Eye Disease**

**Leprosy**

Leprosy (Hansen’s disease) is caused by the acid-fast bacillus *Mycobacterium leprae*. Unlike other mycobacteria, it does not grow in artificial media or even in tissue culture. Apart from the nine-banded armadillo, man is the only natural host of *M. leprae*, although it can be grown in the footpads of mice.

The WHO campaign to control leprosy has been hugely successful, with more than 13 million people having been cured of the disease. The number of people with active leprosy has fallen from 5.4 million in 1985 to about 286,000 at the end of 2004, largely as the result of supervised multidrug treatment regimens. The majority of the remaining cases are in India and Brazil, and despite the successes many new infections are occurring in these countries.

The precise mode of transmission of leprosy is still uncertain but it is likely that nasal secretions play a role. Infection is related to poverty and overcrowding. Once an individual has been infected, subsequent progression to clinical disease appears to be dependent on several factors. Males appear to be more susceptible than females, and there is evidence from twin studies of a genetic susceptibility. The main factor, however, is the response of the host's cell-mediated immune system.

Two **polar types** of leprosy are recognized (Fig. 4.29):

- **Tuberculoid leprosy**, a localized disease that occurs in individuals with a high degree of cell-mediated immunity (CMI). The T cell response to the antigen releases interferon which activates macrophages to destroy the bacilli (Th1 response) but with associated destruction of the tissue. The lepromin test (see below) is positive.
- **Lepromatous leprosy**, a generalized disease that occurs in individuals with impaired CMI (Fig. 4.29). Here the tissue macrophages fail to be activated and the bacilli multiply intracellularly. Th2 cytokines are produced. The lepromin test is negative.

The WHO classification of leprosy depends on the number of skin lesions and the number of bacilli detected on the skin smears: **paucibacillary leprosy** has 5 or fewer skin lesions with no bacilli; **multibacillary leprosy** has 6 or more lesions which may have bacilli.

In practice many patients will fall between these two extremes and some may move along the spectrum as the disease progresses or is treated.

**Clinical features**

The incubation period varies from 2 to 6 years, although it may be as short as a few months or as long as 20 years. The onset of leprosy is generally insidious. Acute onset is known to occur. Patients may present with a transient rash, features of an acute febrile illness, evidence of nerve involvement, or with any combination of these. The major signs of leprosy are:

- Skin lesions, usually anaesthetic (generally tuberculoid).
- Thickened peripheral nerves, nerves of predilection which are superficial or lie in fibro-osseous tunnels – ulnar (elbow), median (wrist), radial cutaneous (wrist), common peroneal (knee), posterior tibial and sural (ankle), facial (crossing zygomatic arch) and greater auricular (posterior triangle of the neck).

The spectrum of disease can be divided into five clinical groups:

**Tuberculoid leprosy (TT)**. In tuberculoid leprosy the characteristic, usually single, skin lesion is a hypopigmented, anaesthetic patch with thickened, clearly demarcated edges, central healing, and atrophy. The face, gluteal region and extremities are most commonly affected. The nerve leading to the hypopigmented patch, and the regional nerve trunk, are often thickened and tender. Unlike other parts of the body, a tuberculoid patch on the face is not anaesthetic. Nerve involvement leads to marked muscle atrophy. Tuberculoid lesions are known to heal spontaneously. The prognosis is good.

**Borderline tuberculoid (BT) leprosy**. This resembles TT but skin lesions are usually more numerous, smaller, and may be...
present as small ‘satellite’ lesions around larger ones. Peripheral but not cutaneous nerves are thickened, leading to deformity of hands and feet.

**Borderline (BB) leprosy.** Skin lesions are numerous, varying in size and form (macules, papules, plaques). The annular, rimmed lesion with punched-out, hypopigmented anaesthetic centre is characteristic (Fig. 4.30). There is widespread nerve involvement and limb deformity (Fig. 4.31a).

**Borderline lepromatous (BL) leprosy.** There are a large number of florid asymmetrical skin lesions of variable form, which are strongly positive for acid-fast bacilli. Skin between the lesions is normal and often negative for bacilli.

**lepromatous leprosy (LL).** Although practically every organ can be involved, the changes in the skin are the earliest and most obvious manifestation. Peripheral oedema and rhinitis are the earliest symptoms. The skin lesions predominantly occur on the face, the gluteal region and the upper and lower limbs. They may be macules, papules, nodules or plaques: of these, the macule is the first to appear. Infiltration is most noticeable in the ear lobes. Thinning of the lateral margins of the eyebrows is characteristic. The mucous membranes are frequently involved, resulting in nasal stuffiness, laryngitis and hoarseness of the voice. Nasal septal perforation with collapse of the nasal cartilages produces a saddle-nose deformity. With progression of the disease the typical leonine facies due to infiltration of the skin becomes apparent. Glove and stocking anaesthesia, gynaecomastia, testicular atrophy, ichthyosis and nerve palsies (facial, ulnar, median and radial) develop late in the disease. Neurotrophic atrophy affecting the phalanges leads to the gradual disappearance of fingers (Fig. 4.31b). Nerve involvement is less pronounced than in TT.

**Lepra reactions**

These are immunologically mediated acute reactions that occur in patients with the borderline or lepromatous spectrum of disease, usually during treatment. Two forms are recognized.

**Non-lepromatous lepra reaction (type I lepra reaction).** This is seen following treatment of patients with borderline disease; it is a type IV delayed hypersensitivity reaction. Both upgrading (or reversal) reactions (i.e. a clinical change towards a more tuberculoid form) and downgrading reactions (i.e. a change towards the lepromatous form) can occur. Neurological deficits such as an ulnar nerve palsy may occur abruptly.

**Erythema nodosum leprosum (ENL; type II lepra reaction).** This is a humoral antibody response to an antigen–antibody complex (i.e. a type III immune complex hypersensitivity reaction). It is seen in 50% of patients with treated LL. ENL is characterized by fever, arthralgia, iridocyclitis, crops of painful, subcutaneous erythematous nodules, and other systemic manifestations. It may last from a few days to several weeks.

**Diagnosis**

The diagnosis of leprosy is essentially clinical with:

- hypopigmented/reddish patches with loss of sensation
- thickening of peripheral nerves
- bacterial infections seen in developing and tropical countries

- acid-fast bacilli (AFB) seen on skin-slit smears/biopsy.
- Small slits are made in pinched skin and the fluid obtained is smeared on a slide and stained for AFB.

Patients should be examined for skin lesions in adequate natural light. Occasionally nerve biopsies are helpful. Detection of *M. leprae* DNA is possible in all forms of leprosy using the polymerase chain reaction, and can be used to assess the efficacy of treatment.

**Management**

Multidrug therapy (MDT) is essential because of developing drug resistance (up to 40% of bacilli in some areas are resistant to dapsones). Much shorter courses of treatment are now being used: the current WHO recommended drug regimens for leprosy are shown in Box 4.11 but longer therapy may be required in severe cases. Follow up including skin smears is obligatory.

Patient education is essential. Patients should be taught self-care of their anaesthetic hands and feet to prevent ulcers. If ulcers develop, no weight-bearing should be permitted. Cheap canvas shoes with cushioned insoles are protective.

Leprosy should be treated in specialist centres with adequate physiotherapy and occupational therapy support. Surgery and physiotherapy also play a role in the management of trophic ulcers and deformities of the hands, feet and face.

**Treatment of lepra reactions.** This is urgent, as irreversible eye and nerve damage can occur. Antileprosy therapy must be continued. Type II lepra reactions (ENL) can be treated with analgesics, chloroquine, clofazimine and antipyretics. Thalidomide was previously used for ENL and is effective. However, because of its teratogenicity, it is no longer recommended by WHO. Prednisolone 40–60 mg daily for 3–6 months is effective in type I reactions.

**Prevention**

The prevention and control of leprosy depends on rapid treatment of infected patients, particularly those with LL and BL, to decrease the bacterial reservoir.

**Box 4.11**

Anthrax

Anthrax is caused by *Bacillus anthracis*. The spores of these Gram-positive bacilli are extremely hardy and withstand extremes of temperature and humidity. The organism is capable of toxin production and this property correlates most closely with its virulence. The disease occurs world-wide. Epidemics have been reported in The Gambia, in both North and South America and in southern Europe. Transmission is through direct contact with an infected animal; infection is most frequently seen in farmers, butchers, and dealers in wool and animal hides. Spores can also be ingested or inhaled. There have been cases in the USA due to the deliberate release of anthrax spores as a bioterrorist weapon (see p. 910).

Clinical features

The incubation period is 1–10 days. Cutaneous anthrax is the most common. The small, erythematous, maculopapular lesion is initially painless. It may subsequently vesiculate and ulcerate, with formation of a central black eschar. The illness is self-limiting in the majority of patients, but occasionally perivesicular oedema and regional lymphadenopathy may be marked, and toxæmia can occur.

*Inhalational anthrax* (woolsorter’s disease) follows inhalation of spores, and bioterrorism should be suspected. A febrile illness is accompanied by non-productive cough and retrosternal discomfort; pleural effusions are common. Untreated, the mortality is about 90%, and in the cases in the USA it was 45% despite treatment.

*Gastrointestinal anthrax* is due to consumption of undercooked, contaminated meat. It presents as severe gastroenteritis; haematemesis and bloody diarrhoea can occur. Toxaemia, shock and death may follow.

Diagnosis

The diagnosis is established by demonstrating the organism in smears from cutaneous lesions or by culture of blood and other body fluids. Serological confirmation can be made using ELISAs detecting antibodies to both the organism and a toxin.

Management

Ciprofloxacin is considered the best treatment. In mild cutaneous infections, oral therapy for 2 weeks is adequate but therapy for 60 days was used in the recent outbreaks in the USA. In more severe infections high doses of intravenous antibiotics are needed, along with appropriate supportive care. Any suspected case should be reported to the relevant authority.

Control

Any infected animal that dies should be burned and the area in which it was housed disinfected. Where animal husbandry is poor, mass vaccination of animals may prevent widespread contamination, but needs to be repeated annually. A human vaccine is available for those at high risk, and prophylactic antibiotics may be indicated following exposure. Some countries are establishing public health policies to deal with the deliberate release of anthrax spores.

Mycobacterial ulcer (Buruli ulcer)

Buruli ulcer is seen in humid rural areas of the tropics, especially in Africa. *Mycobacterium ulcerans* is the causative organism. The mode of transmission is thought to be via water bugs, infected by mycobacterium, found in pools and muddy fields. A small subcutaneous nodule at the site of infection gradually ulcerates, involving subcutaneous tissue, muscle and fascial planes. The ulcers are usually large with undermined edges and markedly necrotic bases due to mycolactone (a toxin produced by the mycobacterium). Smears taken from necrotic tissue generally reveal numerous acid-fast bacilli. Until recently the only effective treatment was wide surgical excision with skin grafts, but this is often unavailable in areas where the disease is prevalent. Recent studies using rifampicin and streptomycin have shown significant benefit in some forms of the disease, and further trials are ongoing.

Endemic treponematoses (bejel, yaws and pinta)

These diseases are found in various parts of the tropics and subtropics, mainly in impoverished rural areas. The WHO treated over 50 million cases in the 1950s and 1960s, reducing the prevalence, but subsequently there has been a resurgence of infection. The latest estimate of global prevalence is 2.5 million cases, mainly in South America and Africa (India has recently declared the eradication of yaws). Improvements in sanitation and an increase in living standards will be required to eradicate the diseases completely as organisms are transmitted by bodily contact, usually in children, the organism entering through damaged skin.

Clinical features

**Yaws**

Yaws (caused by *Treponema pertenue*) is the most widespread and common of the endemic treponemal diseases. After an incubation period of weeks or months a primary inflammatory reaction occurs at the inoculation site, from which organisms can be isolated. Dissemination of the organism leads to multiple papular lesions containing treponemes; these skin lesions usually involve the palms and soles. There may also be bone involvement, particularly affecting the long bones and those of the hand.

Approximately 10% of those infected go on to develop late yaws. Bony gummatus lesions may progress to cause gross destruction and disfigurement, particularly of the skull and facial bones, the interphalangeal joints and the long bones. Planter hyperkeratosis is characteristic. Like syphilis, there may be a latent period between the early and late phases of the disease, but visceral, neurological and cardiovascular problems do not occur.

**Bejel (endemic syphilis)**

Bejel is seen in Africa and the Middle East. The causative organism (*Treponema endemicum*) enters through abrasions in the skin directly or by mouth-to-mouth or skin-to-skin contact indirectly. It differs from venereal syphilis in that a primary lesion is not commonly seen. The late stages resemble syphilis, but cardiological and neurological manifestations are rare.

**Pinta**

Pinta, caused by *Treponema carateum*, is restricted mainly to Central and South America. It is milder than the
other trepanomatoses and is confined to the skin. The primary lesion is a pruritic red papule, usually on the hand or foot. It may become scaly but never ulcerates and is generally associated with regional lymphadenopathy. In the later stages similar lesions can continue to occur for up to 1 year, associated with generalized lymphadenopathy. Eventually the lesions heal leaving hyperpigmented or depigmented patches.

**Diagnosis and management**

In endemic areas the diagnosis is usually clinical. The causative organism can be identified from the exudative lesions under dark-ground microscopy. Serological tests for syphilis are positive and do not differentiate between the conditions.

The treatment is with long-acting penicillin (e.g. intramuscular benzathine penicillin, 1.2 million units) given as a single dose. Doxycycline is used when penicillin is ineffective or contraindicated.

**Trachoma**

Trachoma, caused by the intracellular bacterium *Chlamydia trachomatis*, is the most common cause of blindness in the world. It is estimated that there are 150 million current infections, and 6 million people who have been blinded by trachoma. It is a disease of poverty which is found mainly in the tropics and the Middle East: it is entirely preventable. Trachoma commonly occurs in children, and is spread by direct transmission or by flies. Isolated infection is probably self-limiting, and it is repeated infection which leads to chronic eye disease.

**Clinical features**

Infection is bilateral and begins in the conjunctiva, with marked follicular inflammation and subsequent scarring. Scarring of the upper eyelid causes entropion, leaving the cornea exposed to further damage with the eyelashes rubbing against it (trichiasis). The corneal scarring that eventually occurs leads to blindness.

Trachoma may also occur as an acute ophthalmic infection in the neonate.

**Diagnosis and management**

The diagnosis is generally made clinically. However this is an unreliable indicator of active infection. A newly developed near-patient immunodiagnostic dipstick test may help to better target antibiotic therapy.

Systemic therapy with a single dose of azithromycin 20 mg/kg is the treatment of choice; although tetracycline ointment applied locally each day for 6–8 weeks is effective, compliance is poor. In endemic areas repeated courses of therapy are necessary. Once infection has been controlled, surgery may be required for eyelid reconstruction and for treatment of corneal opacities.

**Prevention**

Community health education, improvements in water supply and sanitation (pit latrines) and earlier case reporting could have a substantial impact on disease prevalence. This is reflected in the WHO ‘SAFE’ approach to trachoma: surgery, antibiotics, facial cleanliness, environmental improvement. A WHO target is global eradication by 2020.

---

**Bacterial infections seen in developing and tropical countries**

**GASTROINTESTINAL INFECTIONS**

**Cholera**

Cholera is caused by the curved, flagellated Gram-negative bacillus, *Vibrio cholerae*. The organism is killed by temperatures of 100°C in a few seconds but can survive in ice for up to 6 weeks. One major pathogenic serogroup possesses a somatic antigen (O1) with two biotypes: classical and El Tor. The El Tor biotype replaced the classical biotype as the major cause of the seventh pandemic which began in the 1960s. Infection with the El Tor biotype generally causes milder symptoms, but can still cause severe and life-threatening disease.

The fertile, humid Gangetic plains of West Bengal have traditionally been regarded as the home of cholera. However, a series of pandemics have spread the disease across the world, usually following trade routes. The seventh pandemic currently affects large areas of Asia and sub-Saharan Africa. A new serogroup (O139 Bengal) is responsible for many cases in Bangladesh, India and South East Asia.

Transmission is by the faeco-oral route. Contaminated water plays a major role in the dissemination of cholera, although contaminated foodstuffs and contact carriers may contribute in epidemics. Achlorhydria or hypochlorhydria facilitates passage of the cholera bacilli into the small intestine. Here they proliferate, elaborating an exotoxin which produces massive secretion of isotonic fluid into the intestinal lumen (see p. 306). Cholera toxin also releases serotonin (5-HT) from enterochromaffin cells in the gut, which activates a neural secretory reflex in the enteric nervous system. This may account for at least 50% of cholera toxin’s secretory activity. *V. cholerae* also produces other toxins (zona occludens toxin, ZOT, and accessory cholera toxin, ACT) which contribute to its pathogenic effect.

**Clinical features**

The incubation period varies from a few hours to 6 days. The majority of patients with cholera have a mild illness that cannot be distinguished clinically from diarrhoea due to other infective causes. In severe cases there is abrupt onset of profuse painless diarrhoea, followed by vomiting. As the illness progresses the typical ‘rice water’ stool, flecked with mucus, may be seen. There is massive fluid loss, and if this is not replaced the features of hypovolaemic shock (cold clammy skin, tachycardia, hypotension and peripheral cyanosis) and dehydration (sunken eyes, hollow cheeks and a diminished urine output) appear. The patient, though apathetic, is usually lucid. Muscle cramps may be severe. Children may present with convulsions owing to hypoglycaemia.

---

**FURTHER READING**

With adequate treatment the prognosis is good, with a gradual return to normal clinical and biochemical parameters in 1–3 days.

**Diagnosis**

This is largely clinical. Examination of freshly passed stools may demonstrate rapidly motile organisms (although this is not diagnostic, as *Campylobacter jejuni* may give a similar appearance). A rapid dipstick test is now also available. Stool and rectal swabs should be taken for culture to confirm the diagnosis and to establish antibiotic sensitivity. Cholera should always be reported to the appropriate public health authority.

**Management**

The mainstay of treatment is rehydration, and with appropriate and effective rehydration therapy mortality has decreased to less than 1%. Oral rehydration is usually adequate, but intravenous therapy is occasionally required.

*Oral rehydration solutions (ORS)* are based on the observation that glucose (and other carbohydrates) enhance sodium and water absorption in the small intestine, even in the presence of secretory loss due to toxins. Additions such as amylase-resistant starch to glucose-based ORS have been shown to increase the absorption of fluid. Cereal-based electrolyte solutions have been found to be as effective as sugar/salt ORS, and actually reduce stool volume as well as rehydrating. The WHO recommends the use of reduced osmolarity ORS for all types of diarrhea, although concerns remain about the risk of hyponatraemia. Suitable solutions for rehydration are listed in Box 4.9 (see p. 132).

Mildly dehydrated individuals are given ORS 50 mL/kg in the first 4 hours, followed by a maintenance dose of 100 mL/kg daily until the diarrhoea stops. For moderate dehydration, ORS 100 mL/kg is given within the first 4 hours followed by 10–15 mL/kg/hour.

*Intravenous rehydration* is required only for severely dehydrated individuals with features of collapse. Several litres of intravenous fluid (Ringers lactate) are usually required to overcome the features of shock. Maintenance of hydration is effectively carried out by oral rehydration solutions.

Three-day courses of tetracycline or erythromycin have been used to help to eradicate the infection, decrease stool output, and shorten the duration of the illness. Drug resistance is becoming an increasing problem, and a single dose of ciprofloxacin or azithromycin (each 1 g) is a better choice if available.

*Immunization* is now recommended by the WHO in potential or actual outbreak situations. Live attenuated and killed vaccine (both oral) are available: neither protect against the O139 strain. Cholera prophylaxis with tetracycline 500 mg twice daily for 3 days for adults, or 125 mg daily for children, is effective if the organism is sensitive, but may encourage the spread of resistance. The best preventative measures, however, are good hygiene and improved sanitation.

**Enteric fever**

Over 17 million new cases of enteric fever occur world-wide, mainly in India and Africa, causing 600000 deaths per year. Enteric fever is an acute systemic illness characterized by fever, headache and abdominal discomfort. *Typhoid*, the typical form of enteric fever, is caused by *Salmonella typhi*. A similar but generally less severe illness known as paratyphoid is due to infection with *S. paratyphi* A, B or C. Man is the only natural host for *S. typhi*, which is transmitted in contaminated food or water. The incubation period is 10–14 days.

**Clinical features**

After ingestion, the bacteria invade the small bowel wall via Peyer’s patches, from where they spread to the regional lymph nodes and then to the blood. The onset of illness is insidious and non-specific, with intermittent fever, headache and abdominal pain. Physical findings in the early stages include abdominal tenderness, hepatosplenomegaly, lymphadenopathy and a scanty maculopapular rash (“rose spots”). Without treatment (and occasionally even after treatment) serious complications can arise, usually in the third week of illness. These include meningitis, lobar pneumonia, osteomyelitis, intestinal perforation and intestinal haemorrhage. The fourth week of the illness is characterized by gradual improvement, but in developing countries up to 30% of those infected will die, and 10% of untreated survivors will relapse. This compares with a mortality rate of 1–2% in the USA.

After clinical recovery 5–10% of patients will continue to excrete *S. typhi* for several months: these are termed convalescent carriers. Between 1% and 4% will continue to carry the organism for more than a year: this is chronic carriage. The usual site of carriage is the gall bladder, and chronic carriage is associated with the presence of gallstones. However, in parts of the Middle East and Africa where urinary schistosomiasis is prevalent, chronic carriage of *S. typhi* in the urinary bladder is also common.

**Diagnosis**

The definitive diagnosis of enteric fever requires the culture of *S. typhi* or *S. paratyphi* from the patient. Blood culture is positive in most cases in the first 2 weeks. Culture of intestinal secretions, faeces and urine is also used, although care must be taken to distinguish acute infection from chronic carriage. Bone marrow culture is more sensitive than blood culture, but is rarely required except in patients who have already received antibiotics. Leucopenia is common but nonspecific. Serological tests such as the Widal antigen test are of little practical value, are easily misinterpreted, and should not be used.

**Management**

Increasing antibiotic resistance is seen in isolates of *S. typhi*, especially in the Indian subcontinent. Chloramphenicol, cotrimoxazole and amoxicillin may all still be effective in some cases, but quinolones (e.g. ciprofloxacin 500 mg twice daily) are now the treatment of choice, although increased resistance to these agents is being seen: in such cases azithromycin may be effective. (Infection from the Indian subcontinent, Middle East and South East Asia is often resistant to multiple antibacterial agents.) The patient’s temperature may remain elevated for several days after starting antibiotics, and this alone is not a sign of treatment failure. Prolonged antibiotic therapy may eliminate the carrier state, but in the presence of gall bladder disease it is rarely effective. Cholecystectomy is not usually justified on clinical or public health grounds.

**Prevention**

This is mainly through improved sanitation and clean water. Travellers should avoid drinking untreated water, *ice in drinks* and eating ice creams. Vaccination with injectable
inactivated or oral live attenuated vaccines gives partial protection.

**SYSTEMIC INFECTIONS**

**Tuberculosis**

Tuberculosis is caused by *Mycobacterium tuberculosis*, and occasionally *M. bovis* or *M. africanum*. These are slow-growing bacteria, and unlike other mycobacteria, are facultative intracellular organisms. The prevalence of tuberculosis increases with poor social conditions, inadequate nutrition and overcrowding. In developing countries it is most commonly acquired in childhood.

The impact of tuberculosis in the developing world has been magnified in the past 20 years by the emergence of the HIV pandemic (see p. 184) (Fig. 4.32).

Widespread misuse of antibiotics, combined with the breakdown of healthcare systems in parts of Africa, Russia and East Europe, has led to the emergence of drug-resistant tuberculosis. Multidrug-resistant tuberculosis (MDRTB) is caused by bacteria that are resistant to both rifampicin and isoniazid, two drugs which form the mainstay of treatment. It is now widespread in many parts of the world, including Asia, Eastern Europe and Africa. Extensively drug resistant TB (XDRTB) is additionally resistant to quinolones and injectable second line agents. MDRTB, and especially XDRTB, are very difficult to treat, and carry significant mortality even with the best medical care (see p. 866).

In most people, the initial primary tuberculosis is asymptomatic or causes only a mild illness. The focus of the disease heals.

Occasionally the primary infection progresses locally to a more widespread lesion. Haematogenous spread at this stage may give rise to miliary tuberculosis.

Tuberculosis in the adult may be the result of reactivation of old disease (post-primary tuberculosis), primary infection, or more rarely reinfection.

Pulmonary tuberculosis is the most common form; this is described on page 863, along with the chemotherapeutic regimens. Tuberculosis also affects other parts of the body:

- The gastrointestinal tract, mainly the ileocaecal area, but occasionally the peritoneum, producing ascites (see p. 318).
- The genitourinary system. The kidneys are most commonly involved, but tuberculosis can also cause painless, craggy swellings in the epididymis, and salpingitis, tubal abscesses and infertility in females.
- The central nervous system, causing tuberculous meningitis and tuberculomas (see p. 1155).
- The skeletal system, causing septic arthritis and osteomyelitis.
- The skin, giving rise to lupus vulgaris.
- The eyes, where it can cause choroiditis or iridocyclitis.
- The pericardium, producing constrictive pericarditis (see p. 795).
- The adrenal glands, causing destruction and producing Addison’s disease.
- Lymph nodes. This is a common mode of presentation, especially in young adults and children. Any group of lymph nodes may be involved, but hilar and paratracheal lymph nodes are the most common. Initially the nodes are firm and discrete but later they become matted and can suppurate with sinus formation. Scrofula is the term used to describe massive cervical lymph node enlargement with discharging sinuses. Mycobacterial lymph node disease may also be caused by non-tuberculous mycobacteria.

---

**Fig. 4.32** Tuberculosis – geographical distribution. From Frieden TR, Sterling TR, Munsiff SS et al. Tuberculosis. *Lancet* 2003; 362: 888, with permission from Elsevier.
Non-tuberculous mycobacterial infections

The majority of mycobacterial species are environmental organisms, and are rarely pathogenic. Some have been found to cause disease in man, particularly in immunocompromised patients or those with pre-existing chronic lung disease (Table 4.34).

Plague

Plague is caused by *Yersinia pestis*, a Gram-negative bacillus. Sporadic cases of plague (as well as occasional epidemics) occur worldwide: about 2000 cases per year are reported to the WHO, with a 10% mortality. The majority of cases are seen in sub-Saharan Africa, although the disease is occasionally seen in developed countries in people undertaking outdoor pursuits. The main reservoirs are woodland rodents, which transmit infection to domestic rats (*Rattus rattus*). The usual vector is the rat flea, *Xenopsylla cheopis*. These fleas bite humans when there is a sudden decline in the rat population. Occasionally, spread of the organisms may be through infected faeces being rubbed into skin wounds, or through inhalation of droplets.

Clinical features

Four clinical forms are recognized: bubonic, pneumonic, septicemic and cutaneous.

*Bubonic plague*

This is the most common form and occurs in about 90% of infected individuals. The incubation period is 2–7 days. The onset of illness is acute, with high fever, chills, headache, myalgia, nausea, vomiting and, when severe, prostration. This is rapidly followed by the development of lymphadenopathy (buboes), most commonly involving the inguinal region. Characteristically these are matted and tender, and suppurate in 1–2 weeks.

*Pneumonic plague*

This is characterized by the abrupt onset of features of a fulminating pneumonia with bloody sputum, marked respiratory distress, cyanosis and death in almost all affected patients.

*Septicaemic plague*

This presents as an acute fulminating infection with evidence of shock and disseminated intravascular coagulation (DIC). If left untreated, death usually occurs in 2–5 days. Lymphadenopathy is unusual.

Cutaneous plague

This presents either as a pustule, eschar or papule or an extensive purpura, which can become necrotic and gangrenous.

Diagnosis

This is based on clinical and epidemiological and laboratory findings. Microscopy (on blood or lymph node aspirate), or a rapid antigen detection test can provide a presumptive diagnosis in an appropriate clinical setting. Blood or lymph node culture, or paired serological tests, are required for confirmation.

Management

Treatment is urgent and should be instituted before the results of culture studies are available. The treatment of choice is intramuscular streptomycin 1 g twice daily or gentamicin 1 mg/kg i.v. three times daily for 10 days. Oral tetracycline 500 mg four times daily and chloramphenicol are also effective.

Prevention

Prevention of plague is largely dependent on the control of the flea population. Outhouses, or huts, should be sprayed with insecticides that are effective against the local flea. During epidemics rodents should not be killed until the fleas are under control, as the fleas will leave dead rodents to bite humans. Tetracycline 500 mg four times daily for 7 days is an effective chemoprophylactic agent. A partially effective formalin-killed vaccine is available for use by travellers to plague-endemic areas.

Relapsing fevers

These conditions are so named because, after apparent recovery from the initial infection, one or more recurrences may occur after a week or more without fever. They are caused by spirochaetes of the genus *Borrelia*.

Clinical features

*Louse-borne relapsing fever* (caused by *B. recurrentis*) is spread by body lice, and only humans are affected. Classically it is an epidemic disease of armies and refugees,
although it is also endemic in the highlands of Ethiopia, Yemen and Bolivia. Lice are spread from person to person when humans live in close contact in impoverished conditions. Infected lice are crushed by scratching, allowing the spirochaete to penetrate through the skin. Symptoms begin 3–10 days after infection and consist of a high fever of abrupt onset with rigor, generalized myalgia and headache. A petechial or ecchymotic rash may be seen. The general condition then deteriorates, with delirium, hepatosplenomegaly, jaundice, haemorrhagic problems and circulatory collapse. Although complete recovery may occur at this time, the majority experience one or more relapses of diminishing intensity over the weeks following the initial illness. The severity of the illness varies enormously, and some cases have only mild symptoms. However, in some epidemics mortality has exceeded 50%.

Tick-borne relapsing fever is caused by *B. duttoni* and other *Borreia* species, spread by soft (argasid) ticks. Rodents are also infected, and humans are incidental hosts, acquiring the spirochaete from the saliva of the infected tick. This disease is mainly found in countries where traditional mud huts are the form of shelter, and is a common cause of febrile illness in parts of Africa. The illness is generally similar to the louse-borne disease, although neurological involvement is more common.

### Diagnosis and management

Spirochaetes can be demonstrated microscopically in the blood during febrile episodes: organisms are more numerous in louse-borne relapsing fever. Treatment is usually with tetracycline or doxycycline (see p. 96). A severe Jarisch–Herxheimer reaction (see p. 179) occurs in many patients, often requiring intensive nursing care and intravenous fluids.

### Prevention

Control of infection relies on elimination of the vector. Ticks live for years and remain infected, passing the infection to their progeny. These reservoirs of infection should be controlled by spraying houses with insecticides and by reducing the number of rodents. Patients infested with lice should be deloused by washing with a suitable insecticide. All clothes must be thoroughly disinfected.

### Typhus

Typhus is the collective name given to a group of diseases caused by *Rickettsia* species (Table 4.35). *Rickettsiae* (and the closely related *Orientia*) are small intracellular bacteria that are spread to humans by arthropod vectors, including body lice, fleas, hard ticks and larval mites. *Rickettsiae* inhabit the alimentary tract of these arthropods and the disease is spread to the human host by inoculation of their faeces through broken human skin, generally produced by scratching. *Rickettsiae* multiply intracellularly and can enter most mammalian cells, although the main lesion produced is a vasculitis due to invasion of endothelial cells of small blood vessels. Multisystem involvement is usual.

#### Clinical features

**Typhus fever group**

**Epidemic typhus**

The vector of epidemic typhus is the human body louse, and like louse-borne relapsing fever, epidemics are associated with war and refugees. Outbreaks have occurred in Africa, Central and South America, and Asia.

The incubation period of 1–3 weeks is followed by an abrupt febrile illness associated with profound malaise and generalized myalgia. Headache is severe and there may be conjunctivitis with orbital pain. A measles-like eruption appears around the fifth day. At the end of the first week, signs of meningoencephalitis appear and CNS involvement may progress to coma. At the height of the illness, splenomegaly, pneumonia, myocarditis and gangrene at the peripheries may be evident. Oliguric renal failure occurs in fulminating disease, which is usually fatal. Recovery begins in the third week but is generally slow. The disease may recur many years after the initial attack owing to rickettsiae that lie dormant in lymph nodes. The recrudescence is known as Brill-Zinsser disease. The factors that precipitate recurrence are not clearly defined, although other infections may play a role.

**Endemic (murine) typhus**

This is an infection of rodents that is inadvertently spread to humans by rat fleas. The disease closely resembles epidemic typhus but is much milder and rarely fatal.

**Scrub typhus**

Found throughout Asia and the Western Pacific, this disease is spread by larval trombiculid mites (chiggers). An eschar (a black, crusted, necrotic papule) can often be found at the site of the bite. The clinical illness is very variable, ranging from a mild illness to fulminating and potentially fatal disease.

</table>
The more severe cases resemble epidemic typhus. Unlike other types of typhus the organism is passed on to subsequent generations of mites, which consequently act as both reservoir and vector.

**Spotted fever group**
A variety of *Rickettsia* species, collectively known as the spotted fever group rickettsiae, cause the illnesses known as spotted fevers. In all except for *rickettsial pox* (which is transmitted by a rodent mite) the vector is a hard tick. Although the causative organism and the name of the illness vary from place to place the clinical course is common to all. After an incubation period of 4–10 days an eschar may develop at the site of the bite in association with regional lymphadenopathy. There is abrupt onset of fever, myalgia and headache, accompanied by a maculopapular rash which may become petechial. Neurological, haematological and cardiovascular complications occur as in epidemic typhus, although these are uncommon.

**Diagnosis**
The diagnosis is generally made on the basis of the history and clinical course of the illness. It can be confirmed serologically or by PCR.

**Treatment and prevention**
Doxycycline or tetracycline given for 5–7 days is the treatment of choice. Ciprofloxacin is also effective. Doxycycline 200 mg weekly protects against scrub typhus; it is reserved for highly endemic areas. Rifampicin is also used when resistance to tetracycline has occurred. Seriously ill patients need intensive care. Control of typhus is achieved by eradication of the arthropod vectors. Lice and fleas can be eradicated from clothing by insecticides (0.5% malathion or DDT). Control of rodents is necessary in endemic typhus and some of the spotted fevers. Areas of vegetation infested with trombiculid mites can be cleared by chemical spraying from the air. Bites from ticks and mites should be avoided by wearing protective clothing on exposed areas of the body. The likelihood of infection from ticks is related to the duration of feeding, and in high-risk areas the body should be inspected twice a day as the bites are painless, and any ticks should be removed (see p. 139).

**Bartonellosis and ehrlichiosis**
*Bartonella* spp. and *Ehrlichia* spp. are intracellular bacteria closely related to the rickettsiae. A number of human diseases can be caused by these organisms; like rickettsial disease, infection is usually spread from animals via an arthropod vector (Table 4.36).

**Carrión’s disease**
This disease is restricted mainly to the habitat of its main vector, the sandfly, in the river valleys of the Andes mountains at an altitude of 500–3000 m. Two clinical presentations are seen, which may occur alone or consecutively. *Oroya fever* is an acute febrile illness causing myalgia, arthralgia, severe headache and confusion, followed by a haemolytic anaemia. *Verruga peruana* consists of eruptions of reddish-purple haemangiomatosus nodules, resembling bacillary angiomatosis. It may follow 4–6 weeks after Oroya fever, or be the presenting feature of infection. Spontaneous resolution may occur over a period of months or years. Carrión’s disease is frequently complicated by superinfection, especially with *Salmonella* spp.

The diagnosis is made by culturing bacilli from blood or peripheral lesions. Serological tests have been developed but are not widely available.

Treatment with chloramphenicol or tetracycline is very effective in acute disease, but less so in verruga peruana.

**Cat-scratch disease and bacillary angiomatosis**
These are described on page 125.

**Trench fever**
Trench fever is caused by *Bartonella quintana*, and transmitted by human body lice. It is mainly seen in refugees and the homeless. It is characterized by cyclical fever (typically every 5 days), chills and headaches, accompanied by myalgia and pretibial pain. The disease is usually self-limiting but it can be treated with erythromycin or doxycycline if symptoms are severe.

**Melioidosis**
The term melioidosis refers to infections caused by the Gram-negative bacteria *Burkholderia pseudomallei*. This environmental organism, which is found in soil and surface water, is distributed widely in the tropics and subtropics. The majority of clinical cases of melioidosis occur in South East Asia. Infection follows inhalation or direct inoculation. More than half of all patients with melioidosis have predisposing underlying disease: it is particularly common in diabetics.

| Table 4.36 Human infections caused by *Bartonella* spp. and *Ehrlichia* spp. |
| --- | --- | --- | --- |
| Disease | Organism | Reservoir | Vector |
| **Bartonella** | | | |
| Carrión’s disease | *Bartonella bacilliformis* | Unknown | Sandfly |

| Trench fever | *B. quintana* | Human | Body louse |
| **Ehrlichia** | | | |
| Human ehrlichiosis | *Ehrlichia chafeensis* | Deer | Hard ticks |
| ‘Human granulocytic ehrlichia’ (HE) | *Anaplasma phagocytophilum* | Small mammals and deer | Hard ticks |

*Formerly known as *Ehrlichia phagocytophilia*. 
B. pseudomallei causes a wide spectrum of disease, and the majority of infections are probably subclinical. Illness may be acute or chronic, localized or disseminated, but one form of the disease may progress to another and individual patients may be difficult to categorize. The most serious form is septicaemic melioidosis, which is often complicated by multiple metastatic abscesses: this is frequently fatal. Serological tests are available, but definitive diagnosis depends on isolating the organism from blood or appropriate tissue. B. pseudomallei has extensive intrinsic antibiotic resistance. The most effective agent is ceftazidime, which is given intravenously for 2–4 weeks; this should be followed by several months of co-amoxiclav to prevent relapses.

Actinomycosis
Actinomyces spp. are Gram-positive, branching higher bacteria which are normal mouth and intestine commensals; they are particularly associated with poor mouth hygiene. Actinomyces have a world-wide distribution but are a rare cause of disease in the West.

Clinical features
- Cervicofacial actinomycosis, the most common form, usually occurs following dental infection or extraction. It is often indolent and slowly progressive, associated with little pain, and results in induration and localized swelling of the lower part of the mandible. Sinuses and tracts develop with discharge of ‘sulphur’ granules.
- Thoracic actinomycosis follows inhalation of organisms, usually into a previously damaged lung. The clinical picture is not distinctive and is often mistaken for malignancy or tuberculosis. Symptoms such as fever, malaise, chest pain and haemoptysis are present. Empyema occurs in 25% of patients and local extension produces chest-wall sinuses with discharge of ‘sulphur’ granules.
- Abdominal actinomycosis most frequently affects the caecum. Characteristically, a hard indurated mass is felt in the right iliac fossa. Later, sinuses develop. The differential diagnosis includes malignancy, tuberculosis, Crohn’s disease and amoeboma. The incidence of pelvic actinomycosis appears to be increasing with wider use of intrauterine contraceptive devices.

Occasionally actinomycosis becomes disseminated to involve any site.

Diagnosis and management
Diagnosis is by microscopy and culture of the organism. Treatment often involves surgery as well as antibiotics: penicillin is the drug of choice. Intravenous penicillin 2.4 g 4-hourly is given for 4–6 weeks, followed by oral penicillin for some weeks after clinical resolution. Tetracyclines are also effective.

Nocardia infections
Nocardia spp. are Gram-positive branching bacteria, which are found in soil and decomposing organic matter. N. asteroides, and less often N. brasiliensis, are the main human pathogens.

Clinical features
Mycetoma is the most common illness. This is a result of local invasion by Nocardia spp. and presents as a painless swelling, usually on the sole of the foot (Madura foot). The swelling of the affected part of the body continues inexorably. Nodules gradually appear which eventually rupture and discharge characteristic ‘grains’, which are colonies of organisms. Systemic symptoms and regional lymphadenopathy are rare. Sinuses may occur several years after the onset of the first symptom. A similar syndrome may be produced by other branching bacteria, and also by species of eumycete fungi such as Madurella mycetomi (see p. 153).

Pulmonary disease, which follows inhalation of the organism, presents with cough, fever and haemoptysis: it is usually seen in the immunocompromised. Pleural involvement and empyema occur. In severely immunosuppressed patients initial pulmonary infection may be followed by disseminated disease.

Diagnosis and management
The diagnosis is often difficult to establish, as Nocardia is not easily detected in sputum cultures or on histological section. Severe pulmonary or disseminated infection may require parenteral treatment. Co-trimoxazole, linezolid, ceftriaxone and amikacin have all been used successfully, but in vitro sensitivities are variable and there is no consensus on the best treatment.

Fungal infections

Fungal infections

Fungal infections

Systemic fungal infections

FURTHER READING

Fungal infections

Clinical features
Morphologically, fungi can be grouped into three major categories:
- yeasts and yeast-like fungi, which reproduce by budding
- moulds, which grow by branching and longitudinal extension of hyphae
- dimorphic fungi, which behave as yeasts in the host but as moulds in vitro (e.g. Histoplasma capsulatum and Sporothrix schenckii).

Despite the fact that fungi are ubiquitous, systemic fungal infections are uncommon which contrasts to superficial fungal infections of the skin, nails and orogenital mucosae (see p. 1232). Systemic mycoses are increasing in selected populations of patients such as the immunocompromised (e.g. on corticosteroids) and transplant patients, those managed in high-dependency units and in those with severe immunodeficiency, including HIV. Fungal infections are transmitted by inhalation of spores or by contact with the skin. Fungi do not produce endotoxin, but exotoxin (e.g. aflatoxin) production has been documented in vitro. Fungi may also produce allergic pulmonary disease. Some fungi such as Candida albicans are human commensals. Diseases are usually divided into systemic, subcutaneous or superficial (Table 4.37).

Fungal infections

Systemic fungal infections

Candidiasis
Candidiasis is the most common fungal infection in humans and is predominantly caused by Candida albicans although
other species of *Candida* are increasingly recognized. Candida are small asexual fungi. Most species that are pathogenic to humans are normal oropharyngeal and gastrointestinal commensals. Candidiasis is found world-wide.

**Clinical features**

Any organ in the body can be invaded by candida, but vaginal infection and oral thrush are the most common forms. This latter is seen in the very young, in the elderly, following antibiotic therapy and in those who are immunosuppressed. Candidal oesophagitis presents with painful dysphagia. Cutaneous candidiasis typically occurs in intertriginous areas. It is also a cause of paronychia. Balanitis and vaginal infection are also common (see p. 182).

*Candida albicans* is a rare manifestation, usually occurring in children, and is associated with a T cell defect. It presents with hyperkeratotic plaque-like lesions on the skin, especially the face, and on the fingernails. It is associated with several endocrinopathies, including hypothyroidism and hypoparathyroidism. Dissemination of candidiasis may lead to haematogenous spread, with meningitis, pulmonary involvement, endocarditis or osteomyelitis.

**Diagnosis and treatment**

The fungi can be demonstrated in scrapings from infected lesions, tissue secretions or in invasive disease, from blood cultures.

Treatment varies depending on the site and severity of infection. Oral lesions respond to nystatin, oral amphotericin B or fluconazole. For systemic infections, parenteral therapy with amphotericin B, fluconazole, voriconazole or caspofungin is necessary. Polysymptomatic patients often complaining of widespread candidiasis have a psychiatric disorder (see p. 1194).

**Histoplasmosis**

Histoplasmosis is caused by *Histoplasma capsulatum*, a non-encapsulated, dimorphic fungus. Spores can survive in moist soil for several years, particularly when it is enriched by bird and bat droppings. Histoplasmosis occurs worldwide but is only commonly seen in Ohio and the Mississippi river valleys where over 80% of the population have been subclinically exposed. Transmission is mainly by inhalation of the spores, particularly when clearing out attics, barns and bird roosts or exploring caves.

**Clinical features**

Figure 4.33 summarizes the pathogenesis, main clinical forms and sequelae of *Histoplasma* infection. Primary pulmonary histoplasmosis is usually asymptomatic. The only

**Fig. 4.33 Histoplasma infection.** Summary of pathogenesis, main clinical forms and sequelae.
evidence of infection is conversion of a histoplasmin skin test from negative to positive, and radiological features similar to those seen with the Ghon primary complex of tuberculosis. Calcification in the lungs, spleen and liver occurs in patients from areas of high endemicity. When symptomatic, primary pulmonary histoplasmosis generally presents as a mild influenza-like illness, with fever, chills, myalgia and cough. The systemic symptoms are pronounced in severe disease.

Complications such as atelectasis, secondary bacterial pneumonia, pleural effusions, erythema nodosum and erythema multiforme also occur.

**Chronic pulmonary histoplasmosis** is clinically distinguishable from pulmonary tuberculosis (see p. 864). It is usually seen in American white males over the age of 50 years. Radiologically, pulmonary cavities, infiltrates and characteristic fibrous streaking from the periphery towards the hilum are seen.

The presentation of disseminated histoplasmosis resembles disseminated tuberculosis clinically. Fever, lymphadenopathy, hepatosplenomegaly, weight loss, leucopenia and thrombocytopenia are common. Rarely, features of meningitis, hepatitis, hypoadrenalism, endocarditis and peritonitis may dominate the clinical picture.

**Diagnosis**

Definitive diagnosis is possible only by culturing the fungi or by demonstrating them on histological sections. The histoplasmin skin test is of limited diagnostic value and can be negative in acute disseminated disease. *H. capsulatum* glycoprotein can be detected in the urine and serum in those with acute pulmonary and disseminated infection. Antibodies usually develop within 3 weeks of the onset of illness and are best detected by complement-fixation or immunodiffusion.

**Management**

Only symptomatic acute pulmonary histoplasmosis, chronic histoplasmosis and acute disseminated histoplasmosis require therapy. Itraconazole or ketoconazole are indicated for moderate disease. Severe infection is treated with intravenous amphotericin B for 1–2 weeks followed by itraconazole for a total of 12 weeks. Methylprednisolone is recommended for those who develop respiratory complications. Patients with AIDS usually require treatment with parenteral amphotericin B followed by maintenance therapy with itraconazole 200 mg twice daily where HAART is unavailable. Surgical excision of histoplasmosas (pulmonary granuloma due to *H. capsulatum*) or chronic cavitary lung lesions and release of adhesions following mediastinitis are often required.

**African histoplasmosis**

This is caused by *Histoplasma duboisii*, the spores of which are larger than those of *H. capsulatum*. Skin lesions (e.g. abscesses, nodules, lymph node involvement and lytic bone lesions) are prominent. Pulmonary lesions do not occur. Treatment is similar to that for *H. capsulatum* infection.

**Aspergillosis**

Aspergillosis is caused by one of several species of dimorphic fungi of the genus *Aspergillus*. Of these, *A. fumigatus* is the most common, although *A. flavus* and *A. niger* are also recognized. These fungi are ubiquitous in the environment and are commonly found on decaying leaves and trees. Humans are infected by inhalation of the spores. Disease manifestation depends on the dose of the spores inhaled as well as the immune response of the host. Three major forms of the disease are recognized:

- Bronchopulmonary allergic aspergillosis (see p. 875) shows symptoms suggestive of bronchial asthma.
- Aspergillosa (see p. 876) is sometimes referred to as a pulmonary mycetoma.
- Invasive aspergillosis, which occurs in immunosuppressed patients and presents as acute pneumonia, meningitis or an intracerebral abscess, lytic bone lesions, and granulomatous lesions in the liver; less commonly endocarditis, paranasal *Aspergillus* granuloma or keratitis may occur. Urgent treatment with intravenous voriconazole or amphotericin B is required. Caspofungin provides another alternative for refractory disease.

The diagnosis and treatment are described in more detail on page 875.

**Cryptococcosis**

Cryptococcosis is caused by the yeast-like fungus, *Cryptococcus neoformans*. It has a world-wide distribution and appears to be spread by birds, especially pigeons, in their droppings. The spores gain entry into the body through the respiratory tract, where they elicit a granulomatous reaction. Pulmonary symptoms are, however, uncommon; meningitis which usually occurs in those with HIV or lymphoma is the usual mode of presentation and often develops subacutely. Less commonly, lung cavitation, hilar lymphadenopathy, pleural effusions and occasionally pulmonary fibrosis occur. Skin and bone involvement is rare.

**Diagnosis and treatment**

This is established by demonstrating the organisms in appropriately stained tissue sections. A positive latex cryptococcal agglutinin test performed on the CSF is diagnostic of cryptococcosis.

Amphotericin B (0.7–1.0 mg/kg daily i.v.) alone or in combination with fluconosine (100–200 mg/kg daily) for 2 weeks followed by fluconosine 400 mg daily. Therapy should be continued for 8 weeks if meningitis is present. Fluconosine has greater CSF penetration and is used when toxicity is encountered with amphotericin B and fluconosine and as maintenance therapy in immunocompromised patients, especially those with HIV (see p. 200).

**Coccidioidomycosis**

Coccidioidomycosis is caused by the non-budding spherical form (spherule) of *Coccidioides immitis*. This is a soil saprophyte and is found in the southern USA, Central America and parts of South America. Humans are infected by inhalation of the thick-walled barrel-shaped spores called arthrospores. Occasionally epidemics of coccidioidomycosis have been documented following dust storms.

**Clinical features**

The majority of patients are asymptomatic and the infection is only detected by the conversion of a skin test using
coccidioidin (extract from a culture of mycelial growth of *C. immitis*) from negative to positive. Acute pulmonary coccidioidomycosis presents, after an incubation period of about 10 days, with fever, malaise, cough and expectoration. Erythema nodosum, erythema multiforme, phylctenular conjunctivitis and, less commonly, pleural effusions may occur. Complete recovery is usual.

Pulmonary cavitation with haemoptysis, pulmonary fibrosis, meningitis, lytic bone lesions, hepatosplenomegaly, skin ulcers and abscesses may occur in severe disease.

**Diagnosis**

Because of the high infectivity of this fungus, and consequent risk to laboratory personnel, serological tests (rather than culture of the organism) are widely used for diagnosis. These include the highly specific latex agglutination and precipitin tests (IgM) which are positive within 2 weeks of infection and decline thereafter. Other tests include complement fixation, ELISA and radioimmunoassay.

A complement-fixation test (IgG) performed on the CSF is diagnostic of coccidioidomycosis meningitis and becomes positive within 4–6 weeks and remains so for many years.

**Treatment**

Mild pulmonary infections are self-limiting and require no treatment, but progressive and disseminated disease requires urgent therapy. Ketoconazole, itraconazole or fluconazole for 6 months is the treatment of choice for primary pulmonary disease with more prolonged courses for cavitating or fibronodular disease. Fluconazole in high-dose (600–1000 mg daily) is given for meningitis. Itraconazole provides an alternative. Surgical excision of cavitatory pulmonary lesions or localized bone lesions may be necessary.

**Blastomycosis**

Blastomycosis is a systemic infection caused by the biphasic fungus *Blastomyces dermatitidis*. Although initially believed to be confined to certain parts of North America, it has been reported from South America, India and the Middle East.

**Clinical features**

Blastomycosis primarily involves the skin, where it presents as non-itchy papular lesions that later develop into ulcers with red verrucous margins. The ulcers are initially confined to the exposed parts of the body but later involve the unexposed parts as well. Atrophy and scarring may occur. Pulmonary involvement presents as a solitary lesion resembling a malignancy or gives rise to radiological features similar to the primary complex of tuberculosis. Systemic symptoms such as fever, malaise, cough and weight loss are usually present. Bone lesions are common and present as painful swellings.

**Diagnosis and treatment**

The diagnosis is confirmed by demonstrating the organism in histological sections or by culture, although results can be negative in 30–50% of cases. Enzyme immunoassay may be helpful although there is some cross-reactivity of antibodies to blastomycosis with histoplasma.

Itraconazole is preferred for treating mild to moderate disease in the immunocompetent for periods up to 6 months. Ketoconazole or fluconazole are also used. In severe or unresponsive disease and in the immunocompromised, amphothericin B is indicated.

**Mucormycosis**

_Invasive zygomycosis (mucormycosis)_ is rare and is caused by several fungi, including *Mucor* spp., *Rhizopus* spp. and *Absidia* spp. It occurs in severely ill patients. The hallmark of the disease is vascular invasion with marked haemorrhagic necrosis.

_Rhinocerebral mucormycosis_ is the most common form. Nasal stuffiness, facial pain and oedema, and necrotic, black nasal turbinates are characteristic. It is rare and is mainly seen in diabetics with ketoacidosis.

Subcutaneous _zygomycosis_ presents as a brawny, woody infiltration involving the limbs, neck and trunk and rarely the pharynx and orbital regions in immunosuppressed patients.

Other forms include pulmonary and disseminated infection (immunosuppressed) and gastrointestinal infection (in malnutrition).

_Treatment_ is with amphothericin B and sometimes judicious debridement. Oral saturated potassium iodide has been used in the subcutaneous variety.

---

**SUBCUTANEOUS INFECTIONS**

**Sporotrichosis**

Sporotrichosis is due to the saprophytic fungus *Sporothrix schenckii*, which is found world-wide. Infection usually follows cutaneous inoculation, at the site of which a reddish, non-tender, maculopapular lesion develops – referred to as ‘plaque sporotrichosis’. Pulmonary involvement and disseminated disease rarely occur.

_Treatment_ with itraconazole 100–200 mg/day for 3–6 months is usually curative.

**Subcutaneous zygomycosis**

Subcutaneous zygomycosis, a disease seen in the tropics, is caused by several filamentous fungi of the _Basidiobolus_ genus. The disease usually remains confined to the subcutaneous tissues and muscle fascia. It presents as a brawny, woody infiltration involving the limbs, neck and trunk. Less commonly, the pharyngeal and orbital regions may be affected in immunocompromised patients and especially those with poorly controlled diabetes mellitus. It is locally erosive and can prove fatal. Amphothericin B is the drug of choice.
Protozoal infections

Chromoblastomycosis

Chromoblastomycosis (chromomycosis) is caused by fungi of various genera including Phialophora, Wangella and Fonsecaea. These are found mainly in tropical and subtropical countries. It presents initially as a small papule, usually at the site of a previous injury. This persists for several months before ulcerating. The lesion later becomes warty and encrusted and gradually spreads. Satellite lesions may be present. Itching is frequent. The drug of choice is amphoteri-cin B in combination with itraconazole or voriconazole. Cryosurgery is used to remove local lesions.

Mycetoma (Madura foot)

Mycetoma may be due to subcutaneous infection with fungi (Eumycetes spp.) or bacteria (see p. 149). It is largely confined to the tropics. Infection results in local swelling which may discharge through sinuses. Bone involvement may follow.

Treatment includes surgical debridement with ketoconazole or antibacterials, such as co-trimoxazole, according to the aetiological agent.

Pneumocystis jiroveci (formerly P. carinii) infection

Genetic analysis has shown this organism to be homologous with fungi. It exists as a trophozoite which is probably motile and reproduces by binary fission. After invasion the tropho-zoite wall thickens and forms a cyst. On maturation further division takes place to yield eight merozoites which after cell wall rupture develop into trophozoites. Infection probably occurs in infancy but in otherwise healthy infants it remains undetected. It is usually cleared from the lungs. Pneumocystis jiroveci disease in adults is associated with immunodeficiency states, particularly AIDS, and is discussed on page 200.

FURTHER READING

SUPERFICIAL INFECTIONS

Dermatophytosis

Dermatophytooses are chronic fungal infections of keratinous structures such as the skin, hair or nails. Trichophyton spp., Microsporum spp., Epidermophyton spp. and Candida spp. can also infect keratinous structures.

Malassezia infection

Malassezia spp. are found on the scalp and greasy skin and are responsible for seborrhoeic dermatitis, pityriasis versicolor (hypo- or hyperpigmented rash on trunk) and Malassezia folliculitis (itchy rash on back).

Treatment is with topical antifungals or oral ketoconazole if infection is refractory or more extensive.

PROTOZOAL INFECTIONS

Protozoa are unicellular eukaryotic organisms. They are more complex than bacteria, and belong to the animal kingdom. Although many protozoa are free-living in the environment some have become parasites of vertebrates, including man, often developing complex life cycles involving more than one host species. In order to be transmitted to a new host, some protozoa transform into hardy cyst forms which can survive harsh external conditions. Others are transmitted by an arthropod vector, in which a further replication cycle takes place before infection of a new vertebrate host.

BLOOD AND TISSUE PROTOZOA

Malaria

Human malaria can be caused by four species of the genus Plasmodium: P. falciparum, P. vivax, P. ovale, P. malariae. Occasionally other species of malaria usually found in pri-mates can affect man. Malaria probably originated from animal malarials in central Africa, but was spread around the globe by human migration. Public health measures and changes in land use have eradicated malaria in most developed countries, although the potential for malaria transmission still exists in many areas. Five hundred million people are infected every year, and over one million die yearly. Twenty five thousand international travellers per year are infected.

Epidemiology

Malaria is transmitted by the bite of female anopheline mos-quitoes. The parasite undergoes a temperature-dependent cycle of development in the gut of the insect, and its geographical range therefore depends on the presence of the appropriate mosquito species and on adequate temperature. The disease occurs in endemic or epidemic form throughout the tropics and subtropics except for some areas above 2000 m (Fig. 4.34). Australia, the USA and most of the Medi-terranean littoral are also malaria-free. In hyperendemic areas (51–75% rate of parasitaemia, or palpable spleen in children 2–9 years of age) and holoendemic areas (>75% rate) where transmission of infection occurs year round, the bulk of the mortality is seen in infants. Those who survive to adulthood acquire significant immunity; low-grade parasitaemia is still present, but causes few symptoms. In mesoendemic areas (11–50%) there is regular seasonal transmission of malaria. Mortality is still mainly seen in infants, but older children and adults may develop chronic ill health due to repeated infec-tions. In hypoendemic areas (0–10%), where infection occurs in occasional epidemics, little immunity is acquired and the whole population is susceptible to severe and fatal disease.

Malaria can also be transmitted in contaminated blood transfusions. It has occasionally been seen in injecting drug users sharing needles and as a hospital-acquired infection related to contaminated equipment. Rare cases are acquired outside the tropics when mosquitoes are transported from endemic areas (‘airport malaria’), or when the local mosquito population becomes infected by a returning traveller.

Parasitology

The female mosquito becomes infected after taking a blood meal containing gametocytes, the sexual form of the malarial
Infection and Infectious diseases

parasite (Fig. 4.35). The developmental cycle in the mosquito usually takes 7–20 days (depending on temperature), culminating in infective sporozoites migrating to the insect’s salivary glands. The sporozoites are inoculated into a new human host, and those which are not destroyed by the immune response are rapidly taken up by the liver. Here they multiply inside hepatocytes as merozoites: this is pre-erythrocytic (or hepatic) sporogony. After a few days the infected hepatocytes rupture, releasing merozoites into the blood from where they are rapidly taken up by erythrocytes. In the case of *P. vivax* and *P. ovale*, a few parasites remain dormant in the liver as hypnozoites. These may reactivate at any time subsequently, causing relapsing infection.

Inside the red cells the parasites again multiply, changing from merozoite, to trophozoite, to schizont, and finally appearing as 8–24 new merozoites. The erythrocyte ruptures, releasing the merozoites to infect further cells. Each cycle of this process, which is called erythrocytic schizogony, takes about 48 hours in *P. falciparum*, *P. vivax* and *P. ovale*, and about 72 hours in *P. malariae*. *P. vivax* and *P. ovale* mainly attack reticulocytes and young erythrocytes, while *P. malariae* tends to attack older cells; *P. falciparum* will parasitize any stage of erythrocyte.

A few merozoites develop not into trophozoites but into gametocytes. These are not released from the red cells until taken up by a feeding mosquito to complete the life cycle.

Pathogenesis

The pathology of malaria is related to anaemia, cytokine release, and in the case of *P. falciparum*, widespread organ damage due to impaired microcirculation. The anaemia seen in malaria is multifactorial (Table 4.38). In *P. falciparum*
malaria, red cells containing schizonts adhere to the lining of capillaries in the brain, kidneys, gut, liver and other organs. As well as causing mechanical obstruction these schizonts rupture, releasing toxins and stimulating further cytokine release.

After repeated infections partial immunity develops, allowing the host to tolerate parasitaemia with minimal ill effects. This immunity is largely lost if there is no further infection for a couple of years. Certain genetic traits also confer some immunity to malaria. People who lack the Duffy antigen on the red cell membrane (a common finding in West Africa) are not susceptible to infection with *P. vivax*. Certain haemoglobinopathies (including sickle cell trait) also give some protection against the severe effects of malaria: this may account for the persistence of these otherwise harmful mutations in tropical countries. Iron deficiency may also have some protective effect. The spleen appears to play a role in controlling infection, and splenectomized people are at risk of overwhelming malaria. Some individuals appear to have a genetic predisposition for developing cerebral malaria following infection with *P. falciparum*. Pregnant women are especially susceptible to severe disease.

**Clinical features**

Typical malaria is seen in non-immune individuals. This includes children in any area, adults in hypoendemic areas, and any visitors from a non-malarious region.

The normal incubation period is 10–21 days, but can be longer. The most common symptom is fever, although malaria may present initially with general malaise, headache, vomiting or diarrhoea. At first the fever may be continual or erratic: the classical tertian or quartan fever only appears after some days. The temperature often reaches 41°C, and is accompanied by rigors and drenching sweats.

**P. vivax or P. ovale infection**

The illness is relatively mild. Anaemia develops slowly, and there may be tender hepatosplenomegaly. Spontaneous recovery usually occurs within 2–6 weeks, but hypnozoites in the liver can cause relapses for many years after infection. Repeated infections often cause chronic ill health due to anaemia and hyperreacrive splenomegaly.

**P. malariae infection**

This also causes a relatively mild illness, but tends to run a more chronic course. Parasitaemia may persist for years, with or without symptoms. In children, *P. malariae* infection is associated with glomerulonephritis and nephrotic syndrome.

**P. falciparum infection**

This causes, in many cases, a self-limiting illness similar to the other types of malaria, although the paroxysms of fever are usually less marked. However it may also cause serious complications (Box 4.12), and the vast majority of malaria deaths are due to *P. falciparum*. Patients can deteriorate rapidly, and children in particular progress from reasonable health to coma and death within hours. A high parasitaemia (>1% of red cells infected) is an indicator of severe disease, although patients with apparently low parasite levels may also develop complications. *Cerebral malaria* is marked by diminished consciousness, confusion and convulsions, often progressing to coma and death. Untreated it is universally fatal. *Blackwater fever* is due to widespread intravascular haemolysis, affecting both parasitized and unparasitized red cells, giving rise to dark urine.

**Hyperreactive malarial splenomegaly (tropical splenomegaly syndrome, TSS)**

This is seen in older children and adults in areas where malaria is hyperendemic. It is associated with an exaggerated immune response to repeated malaria infections, and is characterized by anaemia, massive splenomegaly and elevated IgM levels. Malaria parasites are scanty or absent. TSS usually responds to prolonged treatment with prophylactic antimalarial drugs.

**Diagnosis**

Malaria should be considered in the differential diagnosis of anyone who presents with a febrile illness in, or having recently left, a malarious area. Falciparum malaria is unlikely to present more than 3 months after exposure, even if the patient has been taking prophylaxis, but vivax malaria may cause symptoms for the first time up to a year after leaving a malarious area.

Diagnosis is usually made by identifying parasites on a Giemsa-stained thick or thin blood film (thick films are more difficult to interpret, and it may be difficult to speciate the parasite, but they have a higher yield). At least three films should be examined before malaria is declared unlikely. Quantitative buffy coat analysis (QBC) is quicker but less accurate. Rapid antigen detection tests are available for near-patient use. In many endemic areas malaria is overdiagnosed on clinical grounds and it is necessary to make a
definite diagnosis wherever possible. Serological tests are of no diagnostic value.

Parasitaemia is common in endemic areas, and the presence of parasites does not necessarily mean that malaria is the cause of the patient’s symptoms. Further investigation, including a lumbar puncture, may be needed to exclude bacterial infection.

Management

The drug of choice for susceptible parasites is chloroquine (Box 4.13). *P. vivax*, *P. ovale* and *P. malariae* are almost always sensitive to this drug, the only exception being some strains of *P. vivax* from Oceania. Following successful treatment of *P. vivax* or *P. ovale* malaria, it is necessary to give a 2- to 3-week course of primaquine (15 mg daily) to eradicate the hepatic hypnozoites and prevent relapse. This drug can precipitate haemolysis in patients with G6PD deficiency (see p. 413).

SP, Fansidar = pyrimethamine/sulfadoxine; Malarone = atovaquone/proguanil; Coartemether/Riamet = arteether lamalofranline. Chloroquine doses quoted are for base drug. Quinine dose applies to sulphate, hydrochloride or dihydrochloride.

*P. falciparum*. Chloroquine resistance is now found almost world-wide and chloroquine is not recommended. Despite this, cost and availability mean that chloroquine is still the most commonly used antimalarial. In sub-Saharan Africa, older malarial drugs are now ineffective and artemisinin-based combination therapies (ACT) may be used for *P. falciparum* infection (see below).

Treatment should ideally be based on a knowledge of local sensitivity, but this is often not known. In developed countries *P. falciparum* is commonly treated with quinine, usually as quinine sulphate. In mild cases this can be given orally, but in more severe illness it is given by intravenous infusion. Tinnitus and nausea are predictable side-effects of quinine, and do not require dose reduction unless severe. Some resistance to quinine is emerging, and another antimalarial (either Fansidar (pyrimethamine/sulfadoxine) or tetracycline) should be given at the end of the course of quinine.

Other antimalarial drugs include mefloquine, artemisinin derivatives, and a number of fixed-dose combination preparations including Malarone (atovaquone/proguanil), coartemether (artemether/lamalofranline), and Lapsid (chlorproguanil/dapsone). Other (non-fixed dose) combinations are also in use: amodiaquine/sulfadoxine-pyramethamine has been shown to be highly effective in some settings. Despite a number of recent trials it is unclear which combinations are the most effective or sustainable, especially in the poorest developing countries. Combinations containing artemisinin derivatives are widely perceived to be the best treatment and are written into the national policies of many countries, but cost often prevents their use in practice.

**Treatment of severe falciparum malaria.** Severe malaria, indicated by the presence of any of the complications discussed above, or a parasite count above 1% in a non-immune patient, is a medical emergency (Emergency Box 4.1).

- Intravenous artesunate is at least as effective as intravenous quinine, and is a better choice where available. When quinine is used the loading dose should be omitted if the patient has already received quinine or mefloquine.
- Intensive care facilities may be needed, including mechanical ventilation and dialysis.

- Severe anaemia may require transfusion.
- Careful monitoring of fluid balance is essential: both pulmonary oedema and prerenal failure are common.
- Hypoglycaemia can be induced both by the infection itself and by quinine treatment.
- Superadded bacterial infection is common. In very heavy infections (parasitaemia > 10%), there may be a role for exchange transfusion, if the facilities are available.

**Prevention and control**

As with many vector-borne diseases, control of malaria relies on a combination of case treatment, vector eradication, and personal protection from vector bites, e.g. insecticide (permethrin) treated nets. Mosquito eradication is usually achieved either by the use of insecticides, house spraying with DDT, or by manipulation of the habitat (e.g. marsh drainage). After some initial successes, a WHO campaign to eliminate malaria foundered in the mid-1960s. Since then the emergence of both parasite resistance to drugs and mosquito resistance to insecticides has rendered the task more difficult. However, malaria is once again a priority for the WHO, which announced a new ‘Roll Back Malaria’ campaign in 1998. This has had good success in some countries who have co-ordinated programmes, including the use of insecticide-treated bednets and indoor residual spraying with DDT.

Non-immune travellers to malarious areas should take measures to avoid insect bites, such as using insect repellent (diethyltoluamide (DEET) 20–50% in lotions and sprays) and sleeping under mosquito nets. Antimalarial prophylaxis should also be taken in most cases, although this is never 100% effective (Box 4.14). The precise choice of prophylactic regimen depends both on the individual traveller and on the specific itinerary; further details can be found in National Formularies or from travel advice centres. Despite considerable efforts, there is still no effective vaccine available for malaria.

**Trypanosomiasis**

**African trypanosomiasis (sleeping sickness)**

Sleeping sickness is caused by trypanosomes transmitted to humans by the bite of the tsetse fly (genus Glossina). It is endemic in a belt across sub-Saharan Africa, extending to about 14°N and 20°S: this marks the natural range of the tsetse fly. Two subspecies of trypanosome cause human sleeping sickness: *Trypanosoma brucei gambiense* (‘Gambian sleeping sickness’), and *T. b. rhodesiense* (‘Rhodesian sleeping sickness’).

**Epidemiology**

*Sleeping sickness due to T. b. gambiense* is found from Uganda in Central Africa, west to Senegal and south as far as Angola. Man is the major reservoir, and infection is transmitted by riverine Glossina species (e.g. *G. palpalis*).

*Sleeping sickness due to T. b. rhodesiense* occurs in East and Central Africa from Ethiopia to Botswana. It is a zoonziosis of both wild and domestic animals. In endemic situations it is maintained in game animals and transmitted by savanna flies such as *G. morsitans*. Epidemics are usually related to cattle, and the vectors are riverine flies.

Political upheavals during the 1990s disrupted established treatment and control programmes, resulting in major epidemics in Angola, the Democratic Republic of Congo and Uganda. By 1997 as many as 500000 people were affected by sleeping sickness. A concerted control programme has now brought this number down to about 70000.

**Parasitology**

Tsetse flies bite during the day, and unlike most arthropod vectors both males and females take blood meals. An infected insect may deposit metacyclic trypanostigotes (the infective form of the parasite) into the subcutaneous tissue. These cause local inflammation (‘trypanosomal chancre’) and regional lymphadenopathy. Within 2–3 weeks the organisms invade the bloodstream, subsequently spreading to all parts of the body including the brain.

**Clinical features**

*T. b. gambiense* causes a chronic, slowly progressive illness. Episodes of fever and lymphadenopathy occur over months or years, and hepatosplenomegaly may develop. Eventually infection reaches the central nervous system, causing headache, behavioural changes, confusion and daytime somnolence. As the disease progresses patients may develop tremors, ataxia, convulsions and hemiplegias; eventually coma and death supervene. Histologically there is a lymphocytic meningoencephalitis, with scattered trypanosomes visible in the brain substance.

*T. b. rhodesiense* sleeping sickness is a much more acute disease. Early systemic features may include myocarditis, hepatitis and serous effusions, and patients can die before the onset of CNS disease. If they survive, cerebral involvement occurs within weeks of infection, and is rapidly progressive.

**Diagnosis**

Trypanosomes may be seen on Giemsa-stained smears of thick or thin blood films, or of lymph node aspirate. Blood films are usually positive in *T. b. rhodesiense*, but may be negative in *T. b. gambiense*. Serological tests may increase the yield. Serological tests are useful for screening for infection: the card agglutination test for trypanosomiasis (CATT) is a robust and easy-to-use field assay. Examination of cerebrospinal fluid is essential in patients with evidence of trypanosomal infection. CNS involvement causes lymphocytosis and elevated protein in the CSF, and parasites may be seen in concentrated specimens.
Management
The treatment of sleeping sickness had remained largely unchanged for more than 40 years, but there have been recent improvements in the management of *T. b. gambiense* infection. In both forms, treatment is usually effective if given before the onset of CNS involvement. The drug of choice in early trypanosomiasis is suramin, given intravenously at a dose of 20 mg/kg at 5- to 7-day intervals up to a total dose of 5 g. Severe reactions are relatively common, and a test dose of 100 mg is usually given prior to this regimen. A single dose of suramin should be given to patients with parasitaemia prior to lumbar puncture, to avoid inoculation into the CSF.

The only effective drugs which penetrate the CSF in trypanocidal concentrations were the arsenicals, of which the most widely used is melarsoprol. These are given intravenously; a variety of dosing schedules are in use. Melarsoprol is extremely toxic: 2-10% of patients develop an acute encephalopathy, with a 50-75% mortality, and peripheral neuropathy and hepatorenal toxicity are also common. Prednisolone 1 mg/kg/day decreases the treatment-related mortality by 50% in *T. b. gambiense* infection; it has not been fully assessed in *T. b. rhodesiense* disease. Between 3% and 6% of patients relapse following melarsoprol treatment. In *T. b. gambiense* sleeping sickness, eflornithine (difluoromethylornithine) is effective, clearing parasites from blood and CSF; it has a variable effect on *T. b. rhodesiense* infection. Eflornithine is much less toxic than the arsenical drugs, but was prohibitively expensive. It is now being donated free of charge by the manufacturer, allowing widespread use.

Control
The morbidity and mortality of sleeping sickness could be considerably reduced by early detection and treatment of cases. Control programmes have been effective in some areas, but many have been discontinued because of lack of funding or political upheaval. As in many vector-borne diseases, prevention depends largely on elimination, control or avoidance of the vector. Again this requires considerable coordination and money, and has only been implemented in a few places.

**South American trypanosomiasis (Chagas’ disease)**
Chagas’ disease is widely distributed in rural areas of South and Central America. It is caused by *Trypanosoma cruzi*, which is transmitted to humans in the faeces of bloodsucking reduvid bugs (also called cone-nose, or assassin bugs). Faeces infected with *T. cruzi* trypomastigotes are rubbed in through skin abrasions, mucosa or conjunctiva. The bugs, which live in mud or thatch buildings, feed on a variety of vertebrate hosts (e.g. rats, opossums) at night, defecating as they do so.

The parasites spread in the bloodstream, before entering host cells and multiplying. Cell rupture releases them back into the circulation, where they can be taken up by a feeding bug. Further multiplication takes place in the insect gut, completing the trypanosome life cycle. Human infection can also occur via contaminated blood transfusion, or occasionally by transplacental spread.

Clinical features
**Acute infection**, which usually occurs in children, often passes unnoticed. A firm reddish papule is sometimes seen at the site of entry, associated with regional lymphadenopathy. In the case of conjunctival infection there is swelling of the eyelid, which may close the eye (Romana’s sign). There may be fever, lymphadenopathy, hepatosplenomegaly and rarely meningoencephalitis. Acute Chagas’ disease is occasionally fatal in infants, but normally there is full recovery within a few weeks or months.

After a latent period of many years, 10-30% of people go on to develop *chronic Chagas’ disease*. The pathogenesis of this is unclear: it is possibly due to an autoimmune response triggered by the initial infection, although recent evidence has thrown doubt on this mechanism. The heart is commonly affected, with conduction abnormalities, arrhythmias, aneurysm formation and cardiac dilatation. Gastrointestinal involvement leads to progressive dilatation of parts of the gastrointestinal tract: this commonly results in megaoesophagus (causing dysphagia and aspiration pneumonia) and megacolon (causing severe constipation).

**Diagnosis**
Trypanosomes may be seen on a stained blood film during the acute illness. In chronic disease, parasites may be detected by xenodiagnosis: infection-free reduvid bugs are allowed to feed on the patient, and the insect gut subsequently examined for parasites. Serological tests can detect both acute and chronic Chagas’ disease.

**Management and control**
Nifurtimox is the drug of choice for treating Chagas’ disease, but it is variably available throughout the world. Benznidazole (5-10 mg/kg/day for 60 days) is also used. The cure rate is about 80% in acute infection. Both are toxic with adverse reactions in up to 50% of patients. The drug treatment of chronic infection is controversial, as most of the tissue damage is thought to be immune-mediated, but there is some recent evidence suggesting that parasite elimination improves the outcome. Antiarrhythmic drugs and pacemakers may be needed in cardiac disease, and surgical treatment is sometimes needed for gastrointestinal complications.

In the long term, prevention of Chagas’ disease relies on improved housing and living conditions. In the interim, local vector control programmes may be effective and the countries of the ‘Southern Cone’ of South America run a successful joint programme to control the disease by spraying houses with insecticide. Impregnated bed nets with pyrethroid and insect repellents should be used.

**Leishmaniasis**
This group of diseases is caused by protozoa of the genus *Leishmania*, which are transmitted by the bite of the female phlebotomine sandfly (Table 4.39). Leishmaniasis is seen in localized areas of Africa, Asia (particularly India and Bangladesh), Europe, the Middle East and South and Central America. Certain parasite species are specific to each geographical area. The clinical picture is dependent on the species of parasite, and on the host’s cell-mediated immune response. Asymptomatic infection, in which the parasite is suppressed or eradicated by a strong immune response, is common in endemic areas, as demonstrated by a high incidence of positive leishmanin skin tests. Symptomatic infection may be confined to the skin (sometimes with spread to the mucous membranes), or widely disseminated throughout the body (visceral leishmaniasis). Relapse of previously
asymptomatic infection is seen in patients who become immunocompromised, especially those with HIV infection.

In some areas leishmaniasis is primarily zoonotic, whereas in others, man is the main reservoir of infection. In the vertebrate host the parasites are found as oval amastigotes (Leishman–Donovan bodies). These multiply inside the macrophages and cells of the reticuloendothelial system, and are then released into the circulation as the cells rupture. Parasites are taken into the gut of a feeding sandfly (genus Phlebotomus in the Old World, genus Lutzomyia in the New World), where they develop into the flagellate promastigote form. These migrate to the salivary glands of the insect, where they can be inoculated into a new host.

**Visceral leishmaniasis**

**Clinical features**

Visceral leishmaniasis (kala azar) is caused by *L. donovani*, *L. infantum* or *L. chagasi*, and is prevalent in localized areas of Asia, Africa, the Mediterranean littoral and South America.

In parts of India, where man is the main host, the disease occurs in epidemics. In most other areas it is endemic, and it is mainly children and visitors to the area who are at risk.

The main animal reservoirs in Europe and Asia are dogs and foxes, while in Africa it is carried by various rodents.

The incubation period is usually 1–2 months, but may be several years. The onset of symptoms is insidious, and the patient may feel quite well despite markedly abnormal physical findings. Fever is common, and although usually low-grade, it may be high and intermittent. The liver, and especially the spleen, become enlarged; lymphadenopathy is common in African kala azar. The skin becomes rough and pigmented. If the disease is not treated, profound pancytopenia develops, and the patient becomes wasted and immunosuppressed. Death usually occurs within a year, and is normally due to bacterial infection or uncontrolled bleeding.

**Diagnosis**

Specific diagnosis is made by demonstrating the parasite in stained smears of aspirates of bone marrow, lymph node, spleen or liver. The organism can also be cultured from these specimens. Specific serological tests are positive in 95% of cases. Pancytopenia, hypoalbuminaemia and hypergammaglobulinaemia are common. The leishmanin skin test is negative, indicating a poor cell-mediated immune response.

**Management**

The most widely used drugs for visceral leishmaniasis are the pentavalent antimony salts (e.g. sodium stibogluconate, which contains 100 mg of antimony per mL), given intravenously or intramuscularly at a dose of 20 mg of antimony per kg for 21 days. In India, meglumine antimonate is used. Resistance to antimony salts is increasing, and relapses may occur following treatment. The drug of choice where resources permit is intravenous amphotericin B (preferably given in the liposomal form). However, this drug is expensive and not widely available in many areas where the disease is prevalent. An oral drug, miltefosine, has been shown in India to be highly effective, and may replace older therapies. Inter-current bacterial infections are common and should be treated with antibiotics. Blood transfusion may occasionally be required.

Successful treatment may be followed in a small proportion of patients by a skin eruption called *post-kala azar dermal leishmaniasis* (PKDL). It starts as a macular maculopapular nodular rash which spreads over the body. It is most often seen in the Sudan and India. There have been reports of PKDL responding to miltefosine.

**Cutaneous leishmaniasis**

Cutaneous leishmaniasis is caused by a number of geographically localized species, which may be zoonotic or anthropo-otic. Following a sandfly bite, leishmania amastigotes multiply in dermal macrophages. The local response depends on the species of leishmania, the size of the inoculum, and the host immune response. Single or multiple painless nodules occur on exposed areas within 1 week to 3 months following the bite. These enlarge and ulcerate with a characteristic erythematous raised border. An overlying crust may develop. The lesions heal slowly over months or years, sometimes leaving a disfiguring scar.

*L. major* and *L. tropica* are found in Russia and Eastern Europe, the Middle East, Central Asia, the Mediterranean littoral and sub-Saharan Africa. The reservoir for *L. major* is desert rodents, while *L. tropica* has a mainly urban distribution with dogs and humans as reservoirs. *L. aethiopica* is found in the highlands of Ethiopia and Kenya, where the animal reservoir is the hyrax. The skin lesions usually heal spontaneously with scarring: this may take a year or more in the case of *L. tropica*. Leishmaniasis recidivans is a rare chronic relapsing form caused by *L. tropica*.

*L. mexicana* is found predominantly in Mexico, Guatemala, Brazil, Venezuela and Panama: infection usually runs a benign course with spontaneous healing within 6 months. *L. braziliensis* infections (which are seen throughout tropical South America) also usually heal spontaneously, but may take longer.

*L. mexicana amazonensis* and *L. aethiopica* may occasionally cause diffuse cutaneous leishmaniasis. This is rare, and is characterized by diffuse infiltration of the skin by Leishman–Donovan bodies. Visceral lesions are absent.

**Diagnosis and treatment**

The diagnosis can often be made clinically in a patient who has been in an endemic area. Giemsa stain on a split-skin

</table>
smear will demonstrate leishmania parasites in 80% of cases. Biopsy tissue from the edge of the lesion can be examined histologically, and parasites identified by PCR; culture is less often successful. The leishmanin skin test is positive in over 90% of cases, but does not distinguish between active and resolved infection. Serology is unhelpful.

Small lesions usually require no treatment. Large lesions or those in cosmetically sensitive sites can sometimes be treated locally, by curettage, cryotherapy or topical antiparasitic agents. In other cases, systemic treatment (as for visceral leishmaniasis) is required, although treatment is less successful as antimicrobials are poorly concentrated in the skin; *L. aethiopica* is not sensitive to antimicrobials.

**Mucocutaneous leishmaniasis**

Mucocutaneous leishmaniasis occurs in 3–10% of infections with *L. b. braziliensis*, and is commonest in Bolivia and Peru. The cutaneous sores are followed months or years later by indurated or ulcerating lesions affecting mucosa or cartilage, typically on the lips or nose (‘espundia’). The condition can remain static, or there may be progression over months or years affecting the nasopharynx, uvula, palate and upper airways.

**Diagnosis and treatment**

Biopsies usually show only very scanty organisms, although parasites can be detected by PCR; serological tests are frequently positive.

Amphotericin B is the treatment of choice if available, although systemic antimonial compounds are widely used; miltefosine may also be effective. Relapses are common following treatment. Patients may die because of secondary bacterial infection, or occasionally laryngeal obstruction.

**Prevention**

Prevention of leishmaniasis relies on control of vectors and/or reservoirs of infection. Insecticide spraying, control of host animals, and treating infected humans may all be helpful. Personal protection against sandfly bites is also necessary, especially in travellers visiting endemic areas. Sandflies are poor fliers and sleeping off the ground helps prevent bites.

**Toxoplasmosis**

Toxoplasmosis is caused by the intracellular protozoan parasite *Toxoplasma gondii*. The sexual form of the parasite lives in the gut of the definitive host, the cat, where it produces oocysts. After a period of maturing in the environment, these oocysts become the source of infection for secondary hosts which may ingest them. In the secondary hosts (which include man, cattle, sheep, pigs, rodents and birds) there is disseminated infection. Following a successful immune response the infection is controlled, but dormant parasites remain encysted in host tissue for many years. The life cycle is completed when carnivorous felines eat infected animal tissue. Humans are infected either from contaminated cat faeces, or by eating undercooked infected meat; transplacental infection may also occur.

Most infections are asymptomatic or trivial. Symptomatic patients usually present with lymphadenopathy, mainly in the head and neck. There may be fever, myalgia and general malaise; occasionally there are more severe manifestations including hepatitis, pneumonia, myocarditis and choroidoretinitis. Lymphadenopathy and fatigue can sometimes persist for months after the initial infection.

Congenital toxoplasmosis may also be asymptomatic, but can produce serious disease. Clinical manifestations include microcephaly, hydrocephalus, encephalitis, convulsions and mental retardation. Choroidoretinitis is common; occasionally this may be the only feature.

Immunocompromised patients, especially those with HIV infection, are at risk of serious infections with *T. gondii*. In acquired immunodeficiency states this is usually due to reactivation of latent disease (see p. 201).

**Diagnosis**

Diagnosis is usually made serologically. IgG antibodies detectable by the Sabin–Feldman dye test remain positive for years; acute infection can be confirmed by demonstrating a rising titre of specific IgM.

**Management**

Acquired toxoplasmosis in an immunocompetent host rarely requires treatment. In those with severe disease (especially eye involvement) sulfadiazine 2–4 g daily and pyrimethamine 25 mg daily are given for 4 weeks, along with folic acid. The management of pregnant women with toxoplasmosis aims to decrease the risk of fetal complications. However there is little good evidence that giving spiramycin either alone or in combination with sulfadiazine (which is the recommended treatment) has any significant effect on the frequency or severity of fetal damage. Infected infants should be treated from birth. The treatment of toxoplasmosis in HIV-positive patients is covered on page 201.

**Babesiosis**

Babesiosis is a tick-borne parasitic disease, diagnosed most commonly in North America and Europe. It is a zoonosis of rodents and cattle, and is occasionally transmitted to humans: infection is more common and more severe in those who are immunocompromised following splenectomy. The causative organisms are the plasmodium-like *Babesia microti* (rodents) and *B. divergens* (cattle).

The incubation period averages 10 days. In patients with normal splenic function, the illness is usually mild. In splenectomized individuals, systemic symptoms are more pronounced and haemolysis is associated with haemoglobinuria, jaundice and renal failure. Examination of a peripheral blood smear may reveal the characteristic plasmodium-like organisms.

The standard treatment was a combination of quinine 650 mg and clindamycin 600 mg orally three times daily for 7 days but a regimen of atovaquone and azithromycin is as effective, with fewer adverse reactions.

**GASTROINTESTINAL PROTOZOA**

The major gastrointestinal parasites of man are shown in Table 4.40.

Amoebiasis

Amoebiasis is caused by Entamoeba histolytica. The organism is pathogenic and can cause amoebic dysentery, resembling bacillary dysentery or acute ulcerative colitis. Complications are unusual, but include toxic dilatation of the colon, chronic infection with stricture formation, severe haemorrhage, amoeboma and amoebic liver abscess. Amoebomas, which develop most commonly in the caecum or rectosigmoid region, are sometimes mistaken for carcinoma. They may bleed, cause obstruction or intussusception. Amoebic liver abscesses often develop in the absence of a recent episode of colitis. Tender hepatomegaly, a high swinging fever and profound malaise are characteristic, although early in the course of the disease both symptoms and signs may be minimal. The clinical features are described in more detail on page 361.

Diagnosis

Microscopic examination of fresh stool or colonic exudate obtained at sigmoidoscopy is the simplest way of diagnosing colonic amoebic infection. To confirm the diagnosis motile trophozoites containing red blood cells must be identified: the presence of amoebic cysts alone does not imply disease. Sigmoidoscopy and barium enema examination may show colonic ulceration but are rarely diagnostic.

The amoebic fluorescent antibody test is positive in at least 90% of patients with liver abscess and in 60–70% with active colitis. Seropositivity is low in asymptomatic cyst passers.

Management

Metronidazole 800 mg three times daily for 5 days is given in amoebic colitis; a lower dose (400 mg three times daily for 5 days) is usually adequate in liver abscess. Tinidazole is also effective: dehydroemetine and chloroquine are rarely used. After treatment of the invasive disease, the bowel should be cleared of parasites with a luminal amoebicide such as diloxanide furoate.

Prevention

Amoebiasis is difficult to eradicate because of the substantial human reservoir of infection. The only progress will be through improved standards of hygiene, sanitation and better access to clean water. Cysts are destroyed by boiling, but chlorine and iodine sterilizing tablets are not always effective.

Giardiasis

Giardia intestinalis is a flagellate (Fig. 4.36) that is found world-wide. It causes small intestinal disease, with diarrhoea and malabsorption. Prevalence is high in many developing countries, and it is the most common parasitic infection in travellers returning to the UK. In certain parts of Europe, and in some rural areas of North America, large water-borne epidemics have been reported. Person-to-person spread may occur in day nurseries and residential institutions. Like E. histolytica, the organism exists both as a trophozoite and a cyst, the latter being the form in which it is transmitted.

The organism sometimes colonizes the small intestine and may remain there without causing detriment to the host. In other cases, severe malabsorption may occur which is thought to be related to morphological damage to the small intestine. The changes in villous architecture are usually mild, partial villous atrophy; subtotal villous atrophy is rare. The mechanism by which the parasite causes alteration in mucosal architecture and produces diarrhoea and intestinal...
malabsorption is unknown: there is evidence that the morphological damage may be immune-mediated. Bacterial overgrowth has also been found in association with giardiasis and may contribute to fat malabsorption.

**Clinical features**

Many individuals excreting giardia cysts have no symptoms. Others become ill within 1–3 weeks after ingesting cysts: symptoms include diarrhea, often watery in the early stage of the illness, nausea, anorexia, and abdominal discomfort and bloating. In most people affected these resolve after a few days, but in some the symptoms persist. Stools may then become paler, with the characteristic features of steatorrhea. If the illness is prolonged, weight loss ensues, which can be marked. Chronic giardiasis frequently seen in developing countries can result in growth retardation in children.

**Diagnosis**

Both cysts and trophozoites can be found in the stool, but negative stool examination does not exclude the diagnosis since the parasite may be excreted at irregular intervals. The parasite can also be seen in duodenal aspirates (obtained either at endoscopy or with an Enterotest capsule), and in histological sections of jejunal mucosa.

**Management**

Metronidazole 2 g as a single dose on 3 successive days will cure the majority of infections, although sometimes a second or third course is necessary. Alternative drugs include tinidazole, mepacrine and albendazole. Preventative measures are similar to those outlined above for *E. histolytica*.

**Cryptosporidiosis**

This organism is found world-wide, cattle being the major natural reservoir. It has also been demonstrated in supplies of drinking water in the UK. The parasite is able to reproduce both sexually and asexually; it is transmitted by oocysts excreted in the faeces.

In healthy individuals cryptosporidiosis is a self-limiting illness. Acute watery diarrhea is associated with fever and general malaise lasting for 7–10 days. In immunocompromised patients, especially those with HIV, diarrhea is severe and intractable (see p. 201).

Diagnosis is usually made by faecal microscopy, although the parasite can also be detected in intestinal biopsies. There is no reliable treatment, although nitazoxanide may be of benefit.

**Balantidiasis**

*Balanidium coli* is the only ciliate that produces clinically significant infection in humans. It is found throughout the tropics, particularly in Central and South America, Iran, Papua New Guinea and the Philippines. It is usually carried by pigs, and infection is most common in those communities that live in close association with swine. Its life cycle is identical to that of *E. histolytica*. *B. coli* causes diarrhea, and sometimes a dysenteric illness with invasion of the distal ileal and colonic mucosa. Trophozoites rather than cysts are found in the stool. Treatment is with tetracycline or metronidazole.

**Blastocystis hominis infection**

*B. hominis* is a strictly anaerobic protozoan pathogen that inhabits the colon. For decades its pathogenicity for humans was questioned, but there is increasing evidence that it may cause diarrhea. It is sensitive to metronidazole.

**Cyclospora cayetanensis infection**

*Cyclospora cayetanensis*, a coccidian protozoal parasite, was originally recognized as a cause of diarrhea in travellers to Nepal. It has been detected in stool specimens from immunocompetent and immunodeficient people world-wide. Infection is usually self-limiting, but can be treated with co-trimoxazole.

**Microsporidiosis**

Protozoa of the phylum *Microspora* can cause diarrhea in patients with HIV/AIDS (see p. 201).

**HELMINTHIC INFECTIONS**

Worm infections are very common in developing countries, causing much disease in both humans and domestic animals. They are frequently imported into industrialized countries. The most common human helminth infections are listed in Table 4.41. Neglected tropical diseases include a group of 13 parasitic and bacterial infections causing major disability amongst the poorest people in the world. They include three soil-transmitted helminth infections – ascarisiasis, hookworm and trichuriasis.

Helminths are the largest internal human parasite. They reproduce sexually, generating millions of eggs or larvae. Nematodes and trematodes have a mouth and intestinal tract, while cestodes absorb nutrients directly through the outer tegument. All worms are motile, although once the adults are established in their definitive site they rarely migrate further. Adult helminths may be very long-lived: up to 30 years in the case of the schistosomes.

Many helminths have developed complex life cycles, involving more than one host. Both primary and intermediate hosts are often highly specific to a particular species of worm. In some cases of human infection man is the primary host, while in others humans are a non-specific intermediary or are coincidentally infected. Multiple infections with different helminths are common in endemic areas. Mass treatment programmes, in which one or more anthelminthic drugs are given on a regular (usually annual) basis, are used to keep the total worm load down (Table 4.42).

**NEMATODES**

Human infections can be divided into:

- Tissue-dwelling worms including the filarial worms, and the Guinea worm *Dracunculus medinensis*.

</table>
Human intestinal worms, including the human hookworms, the common roundworm (Ascaris lumbricoides) and Strongyloides stercoralis, which are the most common helminthic parasites of man. The adult worms live in the human gut, and do not usually invade tissues, but many species have a complex life cycle involving a migratory larval stage.

Zoonotic nematodes which accidentally infect man and are not able to complete their normal life cycle. They often become ‘trapped’ in the tissues, causing a potentially severe local inflammatory response.

**Tissue-dwelling worms**

**Filaria**

Several nematodes belonging to the superfamily Filarioidea can infect humans. The adult worms are long and threadlike, ranging from 2 cm to 50 cm in length; females are generally much larger than males. Larval stages are inoculated into humans by various species of biting flies (each specific to a particular parasite). The adult worms which develop from these larvae mate, producing millions of offspring (microfilariae), which migrate in the blood or skin. These are ingested by feeding flies, in which the remainder of the life cycle takes place. Disease, which may be caused by either the adult worms or by microfilariae, is caused by host immune response to the parasite and is characterized by massive eosinophilia. Adult worms are long-lived (10–15 years), and reinfection is common, so that disease tends to be chronic and progressive.

**Lymphatic filariasis**

Lymphatic filariasis, which may be caused by different species of filarial worm, has a scattered distribution in the tropics and subtropics (Table 4.43). Nearly 1 billion people in developing countries are at risk. Wuchereria bancrofti is transmitted to man by a number of mosquito species, mainly Culex fatigans. Adult female worms (which are 5–10 cm long) live in the lymphatics, releasing large numbers of microfilariae into the blood. Generally this occurs at night, coinciding with the nocturnal feeding pattern of C. fatigans. Non-periodic forms of W. bancrofti, transmitted by day-biting species of mosquito, are found in the South Pacific. Brugia malayi (and the closely related B. timori) are very similar to W. bancrofti, exhibiting the same nocturnal periodicity. The usual vectors are mosquitoes of the genus Mansonia, although other mosquitoes have been implicated.

**Clinical features**

Following the bite of an infected mosquito, the larvae enter the lymphatics and are carried to regional lymph nodes. Here they grow and mature for 6–18 months.

Adult worms produce allergic lymphangitis. The clinical picture depends on the individual immune response, which in turn may depend on factors such as age at first exposure. In endemic areas many people have asymptomatic infection. Sometimes early infection is marked by bouts of fever accompanied by pain, tenderness and erythema along the course of affected lymphatics. Involvement of the spermatic cord and epididymis are common in Bancroftian filariasis. These acute attacks subside spontaneously in a few days, but usually recur. Recurrent episodes cause intermittent lymphatic obstruction, which in time can become fibrotic and irreversible. Obstructed lymphatics may rupture, causing cellulitis and further fibrosis; there may also be chylous pleural effusions and ascites. Over time there is progressive enlargement, coarsening and fissuring of the skin, leading to the classical appearances of elephantiasis. The limbs or scrotum may become hugely swollen. Eventually the adult worms will die, but the lymphatic obstruction remains and tissue damage continues. Elephantiasis takes many years to develop, and is only seen in association with recurrent infection in endemic areas.

Occasionally the predominant features of filarial infection are pulmonary. Microfilariae become trapped in the pulmonary capillaries, generating intense local allergic response. The resulting pneumonitis causes cough, fever, weight loss and shifting radiological changes, associated with a high peripheral eosinophil count. This is known as tropical pulmonary eosinophilia (see p. 874).

**Diagnosis**

The diagnosis of filariasis is usually made on clinical grounds, supported by a high eosinophil count. Serological tests are sensitive, especially in the earlier stages, but can cross-react with other nematodes: they become negative 1–2 years after effective treatment. Microfilariae start to appear in the peripheral blood about a year after infection, and may be detected on a stained nocturnal blood film. Parasitological diagnosis is difficult in established elephantiasis. The clinical picture is usually diagnostic, but similar lymphatic damage may occasionally be caused by silicates absorbed through the feet from volcanic soil (podoconiosis).

Treatment
Diethylcarbamazine (DEC) kills both adult worms and microfilariae. Serious allergic responses may occur as the parasites are killed, and particular care is needed when using DEC in areas endemic for loiasis. Old multi-dose regimens are now being replaced by single-dose treatment (6 mg/kg, usually repeated annually) often in combination with albendazole. Ivermectin is also used. Associated bacterial infections should be treated promptly, and reconstructive surgery may be needed to remove excess tissue. Mass chemotherapy can decrease the prevalence and severity of infection in endemic areas and 80 million people have already been treated under the WHO eradication programme. Early diagnosis and treatment prevent the development of elephantiasis. These approaches must be combined with vector control to achieve permanent results, while individual protection depends on avoidance of mosquito bites.

Loiasis
Loiasis is found in the humid forests of West and Central Africa. The causative parasite, *Loa loa*, is a small (3–7 cm) filarial worm which is found in the subcutaneous tissues. The microfilariae circulate in the blood during the day, but cause no direct symptoms. The vectors are day-biting flies of the genus *Chrysops*.

Adult worms migrate around the body in subcutaneous tissue planes. Worms may be present for years, frequently without causing symptoms. From time to time localized, tender, hot, soft tissue swellings occur due to hypersensitivity (Calabar swellings) often near to a joint. These are produced in response to the passage of a worm and usually subside over a few days or weeks. There may also be more generalized urticaria and pruritus. Occasionally a worm may be seen crossing the eye under the conjunctiva; they may also enter retro-orbital tissue, causing severe pain. Short-term residents of endemic areas often have more severe manifestations of the disease.

Microfilariae may be seen on stained blood films, although these are often negative. Serological tests are relatively insensitive, and cross-react with other microfilariae. There is usually massive eosinophilia. DEC may cause severe allergic reactions (including fever, urticaria, myalgia, and occasionally encephalitis) associated with parasite killing and is being replaced by newer agents. Ivermectin in single doses of 200–400 μg/kg is effective: it may occasionally cause severe reactions. Albendazole, which causes a more gradual reduction in microfilarial load, may be preferable in heavily-infected patients. Mass treatment with either DEC or ivermectin can decrease the transmission of infection, but the mainstay of prevention is vector avoidance and control.

Onchocerciasis
Onchocerciasis (river blindness) affects 18 million people world-wide, of whom 250000 are blind and 500000 visually impaired; most of these are in West and Central Africa, with small foci in the Yemen, and Central and South America. It is the result of infection with *Onchocerca volvulus*. Infection is transmitted by day-biting flies of the genus *Simulium*.

Pathogenesis
Infection occurs when larvae are inoculated into humans by the bite of an infected fly. The worms mature in 2–4 months, and can live for more than 15 years. Adult worms, which can reach lengths of 50 cm (although less than 0.5 mm in diameter), live in the subcutaneous tissues. They may form fibrotic nodules, especially over bony prominences and sites of trauma. Huge numbers of microfilariae are distributed in the skin, and may invade the eyes. Live microfilariae cause relatively little harm, but dead parasites may cause severe allergic reactions, with hyaline necrosis and loss of tissue collagen and elastin. In the eye a similar process causes conjunctivitis, sclerosing keratitis, uveitis and secondary glaucoma. Choroidalretinitis is also occasionally seen.

Clinical features
Symptoms usually start about a year after infection. Initially there is generalized pruritus, with urticaria and fleeting oedema. Subcutaneous nodules (which can be detected by ultrasound) start to appear, and in dark-skinned individuals, hypo- and hyperpigmentation from excoriation and inflammatory changes. Over time more chronic inflammatory changes appear, with roughened, inelastic skin. Superficial lymph nodes become enlarged, and in the groin may hang down in loose folds of skin (‘hanging groin’). Eye disease, which is associated with chronic heavy infection, usually first manifests as itching and conjunctival irritation. This gradually progresses to more extensive eye disease and eventually to blindness.

Diagnosis
In endemic areas the diagnosis can often be made clinically, especially if supported by finding eosinophilia on a blood film. In order to identify parasites, skin snips taken from the iliac crest or shoulder are placed in saline under a cover slip. After 4 hours, microscopy will show microfilariae wriggling free on the slide. If this is negative, DEC can be applied topically under an occlusive dressing: this will provoke an allergic rash in the majority of infected people (modified Mazzotti reaction) but this is not routinely performed as it is unpleasant. Slit-lamp examination of the eyes may reveal the microfilariae. Serological tests are frequently positive in endemic areas, but this does not imply current infection; they may be negative in expatriates with a low worm load.

Management and prevention
Ivermectin, in a single dose of 150 μg/kg, kills microfilariae and prevents their return for 6–12 months. There is little effect on adult worms, so annual (or more frequent) retreatment is needed. In patients co-infected with *Loa loa*, ivermectin may occasionally induce severe allergic reactions, including a toxic encephalopathy.

Since 1974 the WHO Onchocerciasis Control Programme has had a considerable impact on onchocerciasis in West Africa. A combination of vector control measures and, more recently, mass treatment with ivermectin, has led to a decrease in both infection rates and progression to serious disease. Humans are the only host but measures are required over a long period because of the longevity of the worm (10–15 years).

Mansonellosis
*Mansonella perstans* is a filarial worm transmitted by biting midges of the genus *Culicoides*. Small numbers of microfilariae are found in the blood, and although they do not cause serious disease there may be minor allergic reactions and an eosinophilia.
**Dracunculiasis**

Infection with the Guinea worm, *Dracunculus medinensis*, occurs when water fleas (copepods) containing the parasite larvae are swallowed in contaminated drinking water. Ingested larvae mature and the female worm, which can reach over a metre in length, migrates through connective and subcutaneous tissue for 9–18 months before surfacing on the skin. The uterus of the worm ruptures, releasing larvae which are ingested by the small crustacean water fleas, and the cycle is completed.

The diagnosis is clinical.

The traditional treatment, extracting the worm over several days by winding it round a stick, is probably still the most effective. The worm should not be damaged. Antibiotics may be needed to control secondary infection.

Water fleas (and thus infective larvae) can be removed from drinking water by chemical treatment or by simple filtration. Large-scale eradication programmes have been in place for several years and the incidence of infection has fallen from 900,000 cases in 1989 to 10,600 in 2005. The disease is now confined to small areas of Africa, mainly in Sudan and Ghana. Man is the only host of *D. medinensis*, and it should therefore be possible to completely eradicate this parasite.

**Human intestinal nematodes**

Adult intestinal nematodes (also sometimes referred to as soil-transmitted helminths, or geohelminths) live in the human gut. There are two main types of life cycle, both including a soil-based stage. In some cases infection is spread by ingestion of eggs (which often require a period of maturation in the environment), while in others the eggs hatch in the soil and larvae penetrate directly through the skin of a new host. *Ascaris lumbricoides* larvae invade the duodenum and enter the venous system, via which they reach the lungs. They are eventually expectorated and swallowed, entering the intestine where they complete their maturation. *Strongyloides* is also unusual, in that it is the only nematode that is able to complete its life cycle in humans. Larvae may hatch before leaving the colon, and so are able to infect the host by penetrating the intestinal wall and entering the venous system.

**Ascaris (roundworm infection)**

*Ascaris lumbricoides* is a pale yellow worm, 20–35 cm in length (Fig. 4.37). It is found world-wide but is particularly common in poor rural communities, where there is heavy faecal contamination of the immediate environment. Larvae migrate through the tissues to the lungs before being expectorated and swallowed; adult worms are found in the small intestine. Ova are deposited in faeces, and require a 2- to 4-month maturation in the soil before they are infective.

Infection is usually asymptomatic, although heavy infections are associated with nausea, vomiting, abdominal discomfort and anorexia. Worms can sometimes obstruct the small intestine, the most common site being at the ileocaecal valve. They may also occasionally invade the appendix, causing acute appendicitis, or the bile duct, resulting in biliary obstruction and supplicative cholangitis. Larvae in the lung may produce pulmonary eosinophilia. Heavy infection in children, especially those who are already malnourished, may have significant effects on nutrition and development. Serious morbidity and mortality are rare in ascariasis, but the huge number of people infected means that on a global basis roundworm infection causes a significant burden of disease, especially in children.

*Ascaris* eggs can be identified in the stool, and occasionally adult worms emerge from the mouth or the anus. They may also be seen on barium enema studies. Appropriate drug treatments are shown in Box 4.15. Very rarely, surgical or endoscopic intervention may be required for intestinal or biliary obstruction.

---

† Highly effective; ‡ moderately effective; –, ineffective; n/a, drug not used for this indication; no data available.

‡ WHO recommended dose for developing countries; in UK commonly given as 100 mg single dose for threadworm, or 100 mg twice daily for 3 days for whipworm.

†† Once daily for 2 days.
Threadworm (*Enterobius vermicularis*)

*E. vermicularis* is a small (2–12 mm) worm, which is common throughout the world. Larval development takes place mainly in the small intestine, and adult worms are normally found in the colon. The gravid female deposits eggs around the anus causing intense itching, especially at night. Unlike *A. lumbricoides*, the eggs do not require a maturation period in soil, and infection is often directly transmitted from anus to mouth via the hands. Eggs may also be deposited on clothing and bed linen, and are subsequently either ingested or inhaled. Apart from discomfort and local excoriation, infection is usually harmless.

Ova can be collected either using a moistened perianal swab, or by applying adhesive cellophane tape to the perianal skin. They can then be identified by microscopy.

The most commonly used drugs are mebendazole and piperazine (Box 4.15). However, isolated treatment of an affected person is often ineffective. Other family members (especially small children) may also need to be treated, and the whole family should be given advice about personal hygiene. Two courses of treatment 2 weeks apart may break the cycle of autoinfection.

Whipworm (*Trichuris trichiura*)

Infections with whipworm are common world-wide, especially in poor communities with inadequate sanitation. Adult worms, which are 3–5 cm long, inhabit the terminal ileum and caecum, although in heavy infection they are found throughout the large bowel. The head of the worm is embedded in the intestinal mucosa. Ova are deposited in the faeces, and require a maturation period of 3–4 weeks in the soil before becoming infective.

Infection is usually asymptomatic, but mucosal damage can occasionally be so severe that there is colonic ulceration, dysentery or rectal prolapse.

Diagnosis is made by finding ova on stool microscopy, or occasionally by seeing adult worms on sigmoidoscopy. Drug treatment is shown in Box 4.15.

Hookworm infection

Hookworm infections, caused by the human hookworms *Ancylostoma duodenale* and *Necator americanus*, are found world-wide. They are relatively rare in developed countries, but very common in areas with poor sanitation and hygiene: overall about 25% of the world’s population is affected. Hookworm infection is a major contributing factor to anaemia in the tropics. *A. duodenale* is found mainly in East Asia, North Africa and the Mediterranean, while *N. americanus* is the predominant species in South and Central America, South East Asia and sub-Saharan Africa.

Adult worms (which are about 1 cm long) live in the duodenum and upper jejunum, where they are often found in large numbers. They attach firmly to the mucosa using the buccal plate, feeding on blood. Eggs passed in the faeces develop in warm moist soil, producing infective filiform larvae. These penetrate directly through the skin of a new host, and are carried in the bloodstream to the lungs. Having crossed into the alveoli, the parasites are expectorated and then swallowed, thus arriving at their definitive host.

Clinical features

Local irritation as the larvae penetrate the skin (‘ground itch’) may be followed by transient pulmonary signs and symptoms, often accompanied by eosinophilia. Light infections, especially in a well-nourished person, are often asymptomatic. Heavier worm loads may be associated with epigastric pain and nausea, resembling peptic ulcer disease. Chronic heavy infection, particularly on a background of malnourishment, may cause iron deficiency anaemia, and hypoproteinaemia. Heavy infection in children is associated with delays in physical and mental development.

Diagnosis and treatment

The diagnosis is made by finding eggs on faecal microscopy. In infections heavy enough to cause anaemia these will be present in large numbers. The aim of treatment in endemic areas is reduction of worm burden rather than complete eradication: albendazole or mebendazole, which can both be given as a single dose, are the best drugs (Box 4.15). The WHO is promoting mass treatment programmes for schoolchildren in many parts of the world, together with treatment for schistosomiasis where appropriate.

Strongyloidiasis

*Strongyloides stercoralis* is a small (2-mm long) worm which lives in the small intestine. It is found in many parts of the tropics and subtropics, and is especially common in Asia. Eggs hatch in the bowel, and larvae are found in the stool. Usually these are non-infective rhabditiform larvae, which require a further period of maturation in the soil before they can infect a new host, but sometimes this maturation can occur in the large bowel. Infective filiform larvae can therefore penetrate directly through the perianal skin, reinfecting the host. In this way autoinfection may continue for years or even decades. Some war veterans who were imprisoned in the Far East during the Second World War have been found to have active strongyloidiasis over 50 years later. After skin penetration the life cycle is similar to that of the hookworm, except that the adult worms may burrow into the intestinal mucosa, causing a local inflammatory response.

Clinical features

Skin penetration by *S. stercoralis* causes a similar local dermatitis to hookworm. In autoinfection this manifests as a migratory linear weal around the buttocks and lower abdomen (cutaneous larva currens). In heavy infections damage to the small intestinal mucosa can cause malabsorption, diarrhoea and even perforation. There is usually a persistent eosinophilia. In patients who are immunosuppressed (e.g. by corticosteroid therapy or intercurrent illness) filiform larvae may penetrate directly through the bowel wall in huge numbers, causing an overwhelming and usually fatal generalized infection (the strongyloidiasis hyperinfection syndrome). This condition is often complicated by septicaemia due to bowel organisms, and therefore a broad-spectrum antibiotic should always be given.

Diagnosis and treatment

Mottle larvae may be seen on stool microscopy, especially after a period of incubation. Serological tests are also useful. The best drug for treating strongyloidiasis is ivermectin (200 µg/kg daily for 2 days); albendazole (15 mg/kg 12-hourly for 3 days) is also effective.
Zoonotic nematodes

A number of nematodes which are principally parasites of animals may also affect man. The most common are described below.

**Trichinosis**

The normal hosts of *Trichinella spiralis*, the cause of trichinosis, include pigs, bears and warthogs. Man is infected by eating undercooked meat from these animals. Ingested larvae mature in the small intestine, where adults release new larvae which penetrate the bowel wall and migrate through the tissues. Eventually these larvae encyst in striated muscle.

Light infections are usually asymptomatic. Heavier loads of worms produce gastrointestinal symptoms as the adults establish themselves in the small intestine, followed by systemic symptoms as the larvae invade. The latter include fever, oedema and myalgia. Massive infection may occasionally be fatal, but usually the symptoms subside once the larvae encyst.

The diagnosis can usually be made from the clinical picture, associated eosinophilia, and serological tests. If necessary it can be confirmed by muscle biopsy a few weeks after infection. Albendazole (20 mg/kg for 7 days) given early in the course of the illness will kill the adult worms and decrease the load of larvae reaching the tissues. Analgesia and steroids may be needed for symptomatic relief.

**Toxocariasis (visceral larva migrans)**

Eggs of the dog roundworm, *Toxocara canis*, are occasionally ingested by humans, especially children. The eggs hatch and the larvae penetrate the small intestinal wall and enter the mesenteric circulation, but are then unable to complete their life cycle in a ‘foreign’ host. Many are held up in the capillaries of the liver, where they generate a granulomatous response, but some may migrate into other tissues including lungs, striated muscle, heart, brain and eye. In most cases infection is asymptomatic, and the larvae die without causing serious problems. In heavy infections there may be generalized symptoms (fever and urticaria) and eosinophilia, as well as focal signs related to the migration of the parasites. Pulmonary involvement may cause bronchospasm and chest X-ray changes. Ocular infection may produce a granulomatous swelling mimicking a retinoblastoma, while cardiac or neurological involvement may occasionally be fatal. Rarely, larvae survive in the tissues for many years, causing symptoms long after infection.

Isolation of the larvae is difficult, and the diagnosis is usually made serologically. Albendazole 400 mg daily for a week is the most effective treatment.

**Cutaneous larva migrans (CLM)**

CLM is caused by the larvae of the non-human hookworms *Ancylostoma braziliense* and *A. caninum*. Like human hookworms, these hatch in warm moist soil, and then penetrate the skin. In man they are unable to complete a normal life cycle, and instead migrate under the skin for days or weeks until they eventually die. The wandering of the larva is accompanied by a clearly defined, serpiginous, itchy rash, which progresses at the rate of about 1 cm per day. There are usually no systemic symptoms. The diagnosis is purely clinical. Single larvae may be treated with a 15% solution of topical tiabendazole; multiple lesions require systemic therapy with a single dose of albendazole 400 mg or ivermectin 150–200 µg/kg.

**FURTHER READING**

**TREMATODES**

Trematodes (flukes) are flat leaf-shaped worms. They have complex life cycles, often involving fresh water snails and intermediate mammalian hosts. Disease is caused by the inflammatory response to eggs or to the adult worms.

**Water-borne flukes**

**Schistosomiasis**

Schistosomiasis affects over 200 million people in the tropics and subtropics, mostly in sub-Saharan Africa. Chronic infection causes significant morbidity, and after malaria it has the most socioeconomic impact of any parasitic disease. Schistosomiasis is largely a disease of the rural poor, but has also been associated with major development projects such as dams and irrigation schemes.

**Parasitology and pathogenesis**

There are three species of schistosome which commonly cause disease in man: *Schistosoma mansoni*, *S. haematobium* and *S. japonicum*. *S. mekongi* and *S. intercalatum* also affect man but have very restricted distribution (Fig. 4.38). Eggs are passed in the urine or faeces of an infected person, and hatch in fresh water to release the miracidia. These ciliated organisms penetrate the tissue of the intermediate host, a species of water snail specific to each species of schistosome. After multiplying in the snail, large numbers of fork-tailed cercariae are released back into the water, where they can survive for 2–3 days. During this time the cercariae can penetrate the skin or mucous membranes of the definitive host, man. Transforming into schistosomulae, they pass through the lungs before reaching the portal vein, where they mature into adult worms (the male is about 20 mm long, and the female a little larger). Worms pair in the portal vein before migrating to their final destination: mesenteric veins in the case of *S. mansoni* and *S. japonicum*, and the vesicular plexus for *S. haematobium*. Here they may remain for many years, producing vast numbers of eggs. The majority of these are released in urine or faeces, but a small number become embedded in the bladder or bowel wall, and a few are carried in the circulation to the liver or other distant sites.

The pathology of schistosome infection varies with species and stage of infection. In the early stages there may be local and systemic allergic reactions to the migrating parasites. As eggs start to be deposited there may be a local
inflammatory response in the bowel or bladder, while ectopic eggs may produce granulomatous lesions anywhere in the body. Chronic heavy infection, in which large numbers of eggs accumulate in the tissues, leads to fibrosis, calcification, and in some cases, dysplasia and malignant change. Morbidity and mortality are related to duration of infection and worm load, as well as to the species of parasite. Children in endemic areas tend to have the heaviest worm load, because of both increased exposure to infection, and differences in the immune response between adults and children.

Clinical features
Cercarial penetration of the skin may cause local dermatitis (‘swimmer’s itch’). After a symptom-free period of 3–4 weeks, systemic allergic features may develop, including fever, rash, myalgia and pneumonitis (Katayama fever). These allergic phenomena are common in non-immune travellers, but are rarely seen in local populations, who are usually exposed to infection from early childhood onwards. If infection is sufficiently heavy, symptoms from egg deposition may start to appear 2–3 months after infection.

*S. haematobium* infection (bilharzia). The earliest symptom is usually painless terminal haematuria. As bladder inflammation progresses there is increased urinary frequency and groin pain. Obstructive uropathy develops, leading to hydropnephrosis, renal failure and recurrent urinary infection. There is a strong association between chronic urinary schistosomiasis and squamous cell bladder carcinoma. The genitalia may also be affected, and ectopic eggs may cause pulmonary or neurological disease.

*S. mansoni* usually affects the large bowel. Early disease produces superficial mucosal changes, accompanied by blood-stained diarrhoea. Later the mucosal damage becomes more marked, with the formation of rectal polyps, deeper ulceration, and eventually fibrosis and stricture formation. Ectopic eggs are carried to the liver, where they cause an intense granulomatous response. Hepatitis is followed by progressive periportal fibrosis, leading to portal hypertension, oesophageal varices and splenomegaly (see p. 348). Hepatocellular function is usually well preserved.

*S. japonicum*, unlike the other species, infects numerous other mammals apart from man. It is similar to *S. mansoni*, but infects both large and small bowel, and produces a greater number of eggs. Disease therefore tends to be more severe, and rapidly progressive. Hepatic involvement is more common, and neurological involvement is seen in about 5% of cases.

Diagnosis
Schistosomiasis is suggested by relevant symptoms following fresh water exposure in an endemic area. In the early allergic stages the diagnosis can only be made clinically. When egg deposition has started, the characteristic eggs (with a terminal spine in the case of *S. haematobium*, and a lateral spine in the other species) can be detected on microscopy. In *S. haematobium* infection, the best specimen for examination is a filtered mid-day urine sample. Parasites may also be found in semen, and in rectal snip preparations. *S. mansoni* and *S. japonicum* eggs can usually be found in faeces or in a rectal snip. Serological tests are available, and may be useful in the diagnosis of travellers returning from endemic areas, although the test may not become positive for 12 weeks after infection: a parasitological diagnosis should always be made if possible. In chronic disease X-rays, ultrasound examinations and endoscopy may show abnormalities of the bowel or urinary tract, although these are non-specific. Liver biopsy may show the characteristic periportal fibrosis.

Management
The aim of treatment in endemic areas is to decrease the worm load and therefore minimize the chronic effects of egg deposition. It may not always be possible (or even desirable) to eradicate adult worms completely, and reinfection is common. However, a 90% reduction in egg output has been achieved in mass treatment programmes, and in light infections where there is no risk of re-exposure the drugs are usually curative. The most widely used is praziquantel (Table 4.44), which is effective against all species of schistosome, well-tolerated and reasonably cheap.

Prevention
Prevention of schistosomiasis is difficult, and relies on a combination of approaches. Mass treatment of the

---

**Fig. 4.38** Schistosomiasis – geographical distribution.
population (especially children) will decrease the egg load in the community. Health education programmes, the provision of latrines and access to a safe water supply should decrease the contact with infected water. Attempts to eradicate the snail host have generally been unsuccessful, although man-made bodies of water can often be made less ‘snail-friendly’. Travellers should be advised to avoid potentially infected water.

**Food-borne flukes**

Many flukes infect man via ingestion of an intermediate host, often fresh water fish.

**Paragonimiasis**

Over 20 million people are infected with lung flukes of the genus *Paragonimus*. The adult worms (of which the major species is *P. westermani*) live in the lungs, producing eggs which are expectorated or swallowed and passed in the faeces. Miracidia emerging from the eggs penetrate the first intermediate host, a fresh water snail. Larvae released from the snail seek out the second intermediate host, fresh water crustaceans, in which they encyst as metacercariae. Humans and other mammalian hosts become infected after consuming uncooked shellfish. Cercariae penetrate the small intestinal wall, and migrate directly from the peritoneum to the lungs across the diaphragm. Having established themselves in the lung, the adult worms may survive for 20 years.

The common clinical features are fever, cough and mild haemoptysis. In heavy infections the disease may progress, sometimes mimicking pneumonia or pulmonary tuberculosis. Ectopic worms may cause signs in the abdomen or the brain.

The diagnosis is made by detection of ova on sputum or stool microscopy. Radiological appearances are variable and non-specific. Treatment is with praziquantel, and prevention involves avoidance of inadequately cooked shellfish.

**Liver flukes**

The human liver flukes, *Clonorchis sinensis*, *Opisthorchis felineus* and *O. viverrini*, are almost entirely confined to East and South East Asia, where they infect more than 20 million people. Adults live in the bile ducts, releasing eggs into the faeces. The parasite requires two intermediate hosts, a fresh water snail and a fish, and humans are infected by consumption of raw fish. The cycle is completed when excysted worms migrate from the small intestine into the bile ducts.

Infection is often asymptomatic, but may be associated with cholangitis and biliary carcinoma. The diagnosis is made by identifying eggs on stool microscopy. Treatment is with praziquantel, and infection can be avoided by cooking fish adequately.

**Other fluke infections**

Man can also be infected with a variety of animal flukes, notably the liver fluke *Fasciola hepatica*, and the intestinal fluke *Fasciolopsis buski*. Both require a water snail as an intermediate host; cercariae encyst on aquatic vegetation, and then are consumed by animals or man. After ingestion, *F. hepatica* penetrates the intestinal wall before migrating to the liver; during this stage it causes systemic allergic symptoms. After reaching the bile ducts, it causes similar problems to those of the other liver flukes. *F. buski* does not migrate after it excysts, and causes mainly bowel symptoms.

**Treatment**

See Table 4.44.

### CESTODES

Cestodes (tapeworms) are ribbon-shaped worms which vary from a few millimetres to several metres in length. Adult worms live in the human intestine, where they attach to the epithelium using suckers on the anterior portion (scolex). From the scolex arises a series of progressively developing segments, called proglottids. The mature distal segments contain eggs, which may either be released directly into the faeces, or are carried out with an intact detached proglottid. The eggs are consumed by intermediate hosts, after which they hatch into larvae (oncospheres). These penetrate the intestinal wall of the host (pig or cattle) and encyst in the tissues. Man ingests the cysts in undercooked meat, and the cycle is completed when the parasites excyst in the stomach and develop into adult worms in the small intestine. Infections are usually solitary, but several adult tapeworms may coexist. The exceptions to this life cycle are the dwarf tapeworm, *Hymenolepis nana*, which has no intermediate host and is transmitted from person to person by the faecal-oral route, and *Taenia solium*, which produces cysticercosis (see below).

**Taenia saginata**

*T. saginata*, the beef tapeworm, may reach a length of several metres. It is common in all countries where undercooked beef is eaten. The adult worm causes few if any symptoms. Infection is usually discovered when proglottids are found in faeces or on underclothing, often causing considerable anxiety. Ova may also be seen on stool microscopy. Infection can be cleared with a single dose of praziquantel (10 mg/kg). It can be prevented by careful meat inspection, or by thorough cooking of beef.

**Taenia solium and cysticercosis**

*T. solium*, the pork tapeworm, is generally smaller than *T. saginata*, although it can still reach 6 metres in length. It is
particularly common in South America, South Africa, China and parts of South East Asia. As with *T. saginata* infection is usually asymptomatic. The ova of the two species are identical, but the proglottids can be distinguished on inspection.

Pork tapeworm infection is acquired by eating uncooked pork. Cysticercosis, caused by ingestion of cysts rather than the adult worm, follows the ingestion of eggs from contaminated food and water. Faeco-oral autoinfection can occur but is rare. Patients with tapeworms do not usually develop cysticercosis and patients with cysticercosis do not usually harbour tapeworms. Following the ingestion of eggs, the larvae are liberated, penetrate the intestinal wall, and are carried to various parts of the body where they develop into cysticerci. These are cysts, 0.5–1 cm in diameter, containing the scolex of a new adult worm. Common sites for cysticerci include subcutaneous tissue, skeletal muscle and brain.

Superficial cysts may be felt under the skin, but usually cause no significant symptoms. Cysts in the brain can cause a variety of problems including epilepsy, personality change, hydrocephalus and focal neurological signs (see p. 1157). These may only appear many years after infection.

Muscle cysts tend to calcify, and are often visible on X-rays. Cutaneous cysts can be excised and examined. Brain cysts are less prone to calcification, and are only seen on CT or MRI scan. Serological tests may support the diagnosis.

*Treatment* is again with praziquantel or niclosamide. There is no evidence that drug treatment should be accompanied by a purgative, as was previously believed.

**Treatment of cerebral cysticercosis** (see p. 1157) The role of anthelmintics in cysticercosis remains controversial. Even in neurocysticercosis there is little evidence of benefit, although symptomatic patients with viable neurocysts should probably be treated. Albendazole 15 mg/kg daily for 8–20 days is the drug of choice; the alternative is praziquantel 50 mg/kg daily (in divided doses) for 15 days.

Successful treatment is accompanied by increased local inflammation, and corticosteroids should be given during and after the course of anthelmintic. Anticonvulsants should be given for epilepsy, and surgery may be indicated if there is hydrocephalus. Prevention of cysticercosis depends on good hygiene, as well as on the eradication of human *T. solium* infection.

*Diphyllobothrium latum*

Infection with the fish tapeworm, *D. latum*, is common in northern Europe and Japan, owing to the consumption of raw fish. The adult worm reaches a length of several metres, but like the other tapeworms usually causes no symptoms. A megaloblastic anaemia (due to competitive utilization of B₁₂ by the parasite) may occur. Diagnosis and treatment are the same as for *Taenia* species.

**Hydatid disease**

Hydatid disease occurs when humans become an intermediate host of the dog tapeworm, *Echinococcus granulosus*. The adult worm lives in the gut of domestic and wild canines, and the larval stages are usually found in sheep, cattle and camels. Man may become infected either from direct contact with dogs, or from food or water contaminated with dog faeces. After ingestion the parasites excyst, penetrate the small intestine wall, and are carried to the liver and other organs in the bloodstream. A slow-growing, thick-walled cyst is formed, inside which further larval stages of the parasite develop. The life cycle cannot be completed unless the cyst is eaten by a dog. Hydatid disease is prevalent in areas where dogs are used in the control of livestock, especially sheep. It is common in Australia, Argentina, the Middle East and parts of East Africa; small foci of infection are still found in North Wales and rural Scotland.

Symptoms depend mainly on the site of the cyst. The liver is the most common organ affected (60%), followed by the lung (20%), kidneys (3%), brain (1%) and bone (1%). The symptoms are those of a slowly growing benign tumour. Pressure on the bile ducts may cause jaundice. Rupture into the abdominal cavity, pleural cavity or biliary tree may occur. In the latter situation, intermittent jaundice, abdominal pain and fever associated with eosinophilia result. A cyst rupturing into a bronchus may result in its expectoration and spontaneous cure, but if secondary infection supervenes a chronic pulmonary abscess will form. Focal seizures can occur if cysts are present in the brain. Renal involvement produces lumbar pain and haematuria. Calcification of the cyst occurs in about 40% of cases.

A related parasite of foxes, *E. multilocularis*, causes a similar but more severe infection, alveolar hydatid disease. These cysts are invasive and metastases may occur.

The diagnosis and treatment of hydatid liver disease are described on page 361.

**ARTHROPOD ECTOPARASITES**

Arthropods, which include the arachnid ticks and mites as well as insects, may be responsible for human disease in several ways.

**Local hypersensitivity reactions**

Local lesions may be caused by hypersensitivity to allergens in arthropod saliva. This common reaction, known as papular urticaria, is non-specific and is seen in the majority of people in response to the bite of a variety of blood-sucking arthropods including mosquitoes, bugs, ticks, lice and mites. Occasionally tick bites may cause a more severe systemic allergic response, especially in previously sensitized individuals.

Most of these parasites alight on man only to feed, but some species of lice live in very close proximity to the skin: body lice in clothing, and head and pubic lice on human hairs (see p. 1235).

**Resident ectoparasite infections**

Other ectoparasites are actually resident within the skin, causing more specific local lesions.

**Scabies**

See page 1234.

**Jiggers**

Jiggers is due to infection with the jumper flea, *Tunga penetrans*, and is common throughout South America and Africa. The pregnant female flea burrows into the sole of the foot, often between the toes. The egg sac grows to about 0.5 cm in size, before the eggs are discharged onto the ground. The
main danger is bacterial infection or tetanus. The flea should be removed with a needle or scalpel, and the area kept clean until it heals.

**Myiasis**

Myiasis is caused by invasion of human tissue by the larva of certain flies, principally the Tumbu fly, *Cordylobia anthropophaga* (found in sub-Saharan Africa), and the human botfly, *Dermatobia hominis* (Central and South America). The larvae, which hatch from eggs laid on laundry and linen, burrow into the skin to form boil-like lesions: a central breathing orifice may be visible. Again, the main risk is secondary infection. It is not always easy to extract the larva: covering it with petroleum jelly may bring it up in search of air.

**Systemic envenoming**

Many arthropods can cause local or systemic illness through envenoming, i.e. injection of venom.

The main role of arthropods in causing human disease is as vectors of parasitic and viral infections. Some of these infections are shown in Table 4.4, and discussed in detail elsewhere.

### SEXUALLY TRANSMITTED INFECTIONS

Sexually transmitted infections (STIs) are among the most common causes of illness in the world and remain epidemic in all societies. The public health, social and economic consequences are extensive, both for acute infections and their longer-term sequelae. From 1997 to 2006 the number of new HIV diagnoses in the UK tripled, and new diagnoses of sexually transmitted infections (other than HIV) rose by 63%. STIs have become an increasing world-wide problem.

Those most likely to acquire STIs are young people, homo- and bisexual men and black and ethnic minority populations. Changes in incidence reflect high-risk sexual behaviour and inconsistent use of condoms. Increased travel both within and between countries, recreational drug use, alcohol and more frequent partner change are also implicated. Multiple infections frequently coexist, some of which may be asymptomatic and facilitate spread. Many people attend GUM clinics to seek information, advice and checks of their sexual health, but have no active STI.

**Approach to the patient**

Patients presenting with possible STIs are frequently anxious, embarrassed and concerned about confidentiality. Staff must be alert to these issues and respond sensitively. The clinical setting must ensure privacy and reinforce confidentiality.

**History**

The history of the presenting complaint frequently focuses on genital symptoms, the three most common being vaginal discharge (Table 4.45), urethral discharge (Table 4.46) and genital ulceration (Table 4.47). Details should be obtained of any associated fever, pain, itch, malodour, genital swelling, skin rash, joint pains and eye symptoms. All patients should be asked about dysuria, haematuria and loin pain. A full general medical, family and drug history, particularly of any recent antibacterial or antiviral treatment, allergies and use of oral contraceptives, must be obtained. In women, menstrual, contraception and obstetric history should be obtained. Any past or current history of drug misuse should be explored.

A detailed sexual history should be taken and include the number and types of sexual contacts (genital/genital, oral/genital, anal/genital, oral/anal) with dates, partner’s sex, whether regular or casual partner, use of condoms and other forms of contraception, previous history of STIs including dates and treatment received, HIV testing and results and hepatitis B vaccination status.

Enquiries should be made concerning travel abroad to areas where antibiotic resistance is known or where particular pathogens are endemic.

Examination

General examination must include the mouth, throat, skin and lymph nodes in all patients. Signs of HIV infection are covered on page 187. The inguinal, genital and perianal areas should be examined with a good light source. The groins should be palpated for lymphadenopathy and hernias. The pubic hair must be examined for nits and lice. The external genitalia must be examined for signs of erythema, fissures, ulcers, chancres, pigmented or hypopigmented areas and warts. Signs of trauma may be seen.

In men, the penile skin should be examined and the foreskin retracted to look for balanitis, ulceration, warts or tumours. The urethral meatus is located and the presence of discharge noted. Scrotal contents are palpated and the consistency of the testes and epididymis noted. A rectal examination/proctoscopy should be performed in patients with rectal symptoms, those who practise anoreceptive intercourse and patients with prostatic symptoms. A search for rectal warts is indicated in patients with perianal lesions.

In women, Bartholin’s glands must be identified and examined. The cervix should be inspected for ulceration, discharge, bleeding and ectopy and the walls of the vagina for warts. A bimanual pelvic examination is performed to elicit adnexal tenderness or masses, cervical tenderness, and to assess the position, size and mobility of the uterus. Rectal examination and proctoscopy are performed if the patient has symptoms or practises anoreceptive intercourse.

Investigations

Although the history and examination will guide investigation, it must be remembered that multiple infections may coexist, some being asymptomatic. Full screening is indicated in any patient who may have been in contact with an STI.

Asymptomatic STI screening

- A guide for the investigation of asymptomatic patients is given in Table 4.48a.
- All patients attending GUM clinical services should be routinely offered an HIV antibody test as part of the initial screening for sexually transmitted infections.
- Asymptomatic screening for hepatitis viruses identifies patients that fall into groups at increased risk and who, if susceptible, should be offered vaccination.

Screening tests for hepatitis B. Tests should include hepatitis B surface antigen which enables identification of chronic carriers (Hep BSag) and IgG anti-hepatitis B core, a marker of past infection and hence natural immunity. Screening is recommended for: men who have sex with men (MSM) and their sexual partners, sex workers, intravenous drug users and their contacts, recipients of blood/blood products, needle stick recipients, people who have been sexually assaulted, HIV-positive people, sexual partners of those who are HBsAg-positive and individuals from areas where hepatitis B is endemic.

Hepatitis A screening and vaccination should be offered to men who have sex with men in regions where an outbreak of hepatitis A has been reported, injecting drug users, and patients with chronic hepatitis B or C, or other causes of chronic liver disease.

Hepatitis C. Although no vaccine is available, hepatitis C screening is recommended in intravenous drug users, needle stick recipients, patients with HIV and the sexual partners of HCV-positive people.

Investigations for symptomatic patients

The investigations will depend on the clinical presentation. Common presentations include urethral discharge in men, vaginal discharge in women and genital ulceration. Recommended investigations are shown in Table 4.48b.

Treatment, prevention and control

The treatment of specific conditions is considered in the appropriate section. Many GUM clinics keep basic stocks of medication and dispense directly to the patient. Treatment, particularly for those conditions that may be asymptomatic, is a major way to prevent onward transmission.

Tracing the sexual partners of patients is crucial in controlling spread of STIs. The aims are to prevent the spread of infection within the community and to ensure that people with asymptomatic infection are properly treated. Appropriate antibiotic therapy may be offered to those who have had recent intercourse with someone known to have an active infection (epidemiological treatment). Interviewing people about their sexual partners requires considerable tact and sensitivity, and specialist health advisors are available in GUM clinics.

Over half of all STI diagnoses in the UK are in young adults (16–24 years). Prevention starts with education and information. People begin sexual activity at ever-younger ages and education programmes need to include school pupils as well as young adults. Education of health professionals is also crucial. Public health campaigns aimed at informing groups at particular risk are being implemented at a national level. The National Chlamydia Screening Programme in England (NCSP) aims to provide earlier detection and treatment for Chlamydia by providing easy access for under 25s to Chlamydia testing in community settings.

Avoiding multiple partners, correct and consistent use of condoms and avoiding sex with people who have symptoms of infection may reduce the risks of acquiring an STI. For those who change their sexual partners frequently, regular check-ups (approximately 3-monthly) are advisable. Once people develop symptoms they should be encouraged to seek medical advice as soon as possible to reduce complications and spread to others.

Sexual assault

The medical and psychological management of people who have been sexually assaulted requires particular sensitivity and should be undertaken by an experienced clinician in ways that reduce the risks of further trauma. Specialist sexual assault centres exist, providing multidisciplinary medical, forensic and psychological care in secure and sensitive settings. Post-traumatic stress disorder is common. Although most frequently reported by women, both women and men may suffer sexual assault. Investigations for and treatment of sexually transmitted infections in people who have been raped can be carried out in GUM departments. Collection of material for use as evidence, however, should be carried out within 7 days of the assault by a physician trained in forensic medicine and must take place before any other medical examinations are performed.

History

In addition to the general medical, gynaecological and contraceptive history, full details of the assault, including the

* “Dual” NAAT testing of urine for GC, Chlamydia may be used as a screening investigation.

(b) Symptomatic patients

| Men | Genital discharge | Urethral swabs: microscopy, GC culture, Chlamydia NAAT. Trichomonas should be sought in men in whom other pathology has been excluded | Urine: for NAATs for Chlamydia and GC if no urethral swab is obtainable |
| Women | Genital discharge | Cervical swabs: microscopy and culture for GC and Chlamydia NAATs | Urine for Chlamydia. NAAT if cervical/vaginal specimen has not been obtained |

| Additional investigations in men and women with genital ulceration | Material from the ulcer: microscopy for evidence of early syphilis (dark ground microscopy), Donovanosis, chancroid or LGV PCR techniques where available, for herpes, syphilis and LGV Culture for herpes simplex, Haemophilus ducreyi |

Other investigations depending on clinical circumstances may include:

- Cervical cytology
- Pregnancy testing
- Stools for Giardia, Shigella or Salmonella from those practising oral/anal sex
- Smears and swabs from the subpreputial area in men with balanoposthitis (inflammation of glans penis and prepuce) for candidiasis
- Midstream urine for microscopy, culture and sensitivity

EIA, enzyme immunoassay; LGV lymphogranuloma venereum; NAAT, nucleic acid amplification test; TPHA, Treponema pallidum haemagglutination; TPPA, Treponema pallidum particle agglutination assay.
Adapted from UK national guidance, BASHH 2006.

exact sites of penetration, ejaculation by the assailant and condom use should be obtained, together with details of the sexual history both before and after the event.

Examination

Any injuries requiring immediate attention must be dealt with prior to any other examination or investigations. Accurate documentation of any trauma is necessary. Forced oral penetration may result in small palatal haemorrhages. In cases of forced anal penetration, anal examination including proctoscopy should be carried out, noting any trauma.

Investigations

The risk of STI acquisition from rape is variable and depends on the incidence of STI in the population. Ideally a full STI screen at presentation, with appropriate specimens collected from all sites of actual or attempted penetration and a second examination 2 weeks later, is recommended. Nucleic acid
amplification tests (NAATs) for Neisseria gonorrhoea and for Chlamydia trachomatis can be carried out on urine specimens, avoiding the need for invasive examinations. A positive test should be confirmed by another method for medicolegal purposes. Gram-stained slides of urethral, vaginal and rectal specimens for microscopy for gonococci should be performed. Bacterial vaginosis, yeasts and Trichomonas vaginalis (TV) tests should be carried out on vaginal material. Syphilis serology should be requested and a serum saved. Hepatitis B, HIV and hepatitis C testing should be offered. Specimens should be identified as having potential medicolegal implications.

Management
Preventative therapy for gonorrhoea and Chlamydia is advised using a single dose combination of ciprofloxacin 500 mg and azithromycin 1 g. An accelerated course of Hep B vaccine should be offered and may be of value up to 3 weeks after the event. HIV prophylaxis may be offered within 72 hours of the assault, based upon risk assessment. Post-coital oral contraception may be given within 72 hours of assault. Psychological care provision and appropriate referral to support agencies should be arranged. Sexual partners should be screened and treated if necessary. Follow up at 2 weeks should be arranged to review the patient’s needs and the prophylaxis regimens that are in place, with further follow-up as needed. Following sexual assault most people have a range of emotional and psychological reactions and will require varying levels of psychological support. Referral to a specialist centre is recommended.

Clinical features
Up to 50% of women and 10% of men are asymptomatic. The incubation period is 2–14 days with most symptoms occurring between days 2 and 5.

- In men the most common syndrome is one of anterior urethritis causing dysuria and/or urethral discharge (Fig. 4.40). Complications include ascending infection involving the epididymis or prostate leading to acute or chronic infection. In MSM rectal infection may produce proctitis with pain, discharge and itch.

- In women the primary site of infection is usually the endocervical canal. Symptoms include an increased or altered vaginal discharge, pelvic pain due to ascending infection, dysuria and intermenstrual bleeding. Complications include Bartholin’s abscesses and in rare cases a perihepatitis (Fitzhugh–Curtis syndrome) can develop. On a global basis GC is one of the most common causes of female infertility. Rectal infection, due to local spread, occurs in women and is usually asymptomatic, as is pharyngeal infection. Conjunctival infection is seen in neonates born to infected mothers and is one cause of ophthalmia neonatorum.

Disseminated GC leads to arthritis (usually monoarticular or pauciarticular) (see p. 535) and characteristic papular or pustular rash with an erythematous base in association with fever and malaise. It is more common in women.

Diagnosis
N. gonorrhoeae can be identified from infected areas by culture on selective media with a sensitivity of at least 95%. Nucleic acid amplification tests (NAATs) using urine specimens are non-invasive and highly sensitive, although may give false positive results. Microscopy of Gram-stained secretions may demonstrate intracellular, Gram-negative diplococci, allowing rapid diagnosis. The sensitivity ranges from 90% in urethral specimens from symptomatic men to 50% in endocervical specimens. Microscopy should not be used for pharyngeal specimens. Blood culture and synovial fluid investigations should be performed in cases of disseminated GC. Coexisting pathogens such as Chlamydia, Trichomonas and syphilis must be sought.

**CLINICAL SYNDROMES**

HIV/AIDS
This is discussed in the section starting on page 187.

Gonorrhoea (GC)
Neisseria gonorrhoeae is a Gram-negative intracellular diplococcus (Fig. 4.39), which infects epithelium particularly of the urogenital tract, rectum, pharynx and conjunctivae. Humans are the only host and the organism is spread by intimate physical contact. It is very intolerant to drying and although occasional reports of spread by fomites exist, this route of infection is extremely rare.

**Fig. 4.39** Neisseria gonorrhoeae – Gram-negative intracellular diplococci. Courtesy of Dr B Goh.

**Fig. 4.40** Neisseria gonorrhoeae – purulent urethral discharge. Courtesy of Dr B Goh.
Treatment is indicated in those patients who have a positive culture for GC, positive microscopy or a positive NAAT (this should be repeated because of false positives and all positives should be confirmed by cultures). Treatment is given to patients who have had recent sexual intercourse with someone with confirmed GC infection. Although N. gonorrhoeae is sensitive to a wide range of antimicrobial agents, antibiotic-resistant strains have shown a recent significant increase. In the UK, up to 12% of strains show resistance to penicillin, 27% to ciprofloxacin and over 40% resistance to tetracycline. Immediate therapy based on Gram-stained slides is usually initiated in the clinic, prior to culture and sensitivity results. Antibiotic choice is influenced by travel history or details known from contacts.

Single-dose oral therapy with cefixime (400 mg), ceftriaxone i.m. (250 mg) or spectinomycin 2 g i.m. successfully treats uncomplicated anogenital infection. Single-dose oral amoxicillin 3 g with probenecid 1 g, ciprofloxacin (500 mg) or ofloxacin (400 mg) may be used in areas with low prevalence of antibiotic resistance. Quinolones are no longer recommended for therapy in the USA due to recent increases in resistance.

Longer courses of antibiotics are required for complicated infections. There should be at least one follow-up assessment, and culture tests should be repeated at least 72 hours after treatment is complete. All sexual contacts should be notified and then examined and treated as necessary.

**Chlamydia trachomatis (CT)**

The organism has a world-wide distribution. Genital infection with CT is common, with up to 14% of sexually active people below the age of 25 years in the UK infected. It is regularly found in association with other pathogens: 20% of men and 40% of women with gonorrhoea have been found to have coexisting Chlamydia infections. In men 40% of non-gonococcal and postgonococcal urethritis is due to Chlamydia. As CT is often asymptomatic much infection goes unrecognized and untreated, which sustains the infectious pool in the population. The long-term complications associated with Chlamydia infection, especially infertility, impose significant morbidity in the UK. The UK government has introduced a national Chlamydia screening programme in an attempt to decrease the rates of asymptomatic infection.

**Clinical features**

*In men* CT gives rise to an anterior urethritis with dysuria and discharge; infection is asymptomatic in up to 50% and detected by contact tracing. Ascending infection leads to epididymitis. Rectal infection leading to proctitis occurs in men practising anoreceptive intercourse. *In women* the most common site of infection is the endocervix where it may go unnoticed; up to 80% of infection in women is asymptomatic. Symptoms include vaginal discharge, postcoital or intermenstrual bleeding and lower abdominal pain. Ascending infection causes acute salpingitis. Reactive arthritis (see p. 535) has been related to infection with *C. trachomatis*. Neonatal infection, acquired from the birth canal, can result in mucopurulent conjunctivitis and pneumonia.

**Diagnosis**

CT is an obligate intracellular bacterium, which complicates diagnosis. The nucleic acid amplification test (NAAT) is now the diagnostic test of choice and is used as the ‘standard of care’ with a 90–95% sensitivity. Cell culture techniques provide the ‘gold standard’ and are 100% specific, but are expensive and require considerable expertise. Direct diagnostic tests include direct fluorescent antibody (DFA) tests, enzyme immunoassays (EIA), but they are less reliable and none is diagnostic.

In men first-voided urine samples are tested, or urethral swabs obtained. In women endocervical swabs are the best specimens, and up to 20% additional positives will be detected if urethral swabs are also taken. Urine specimens are less reliable than endocervical swabs in women but are useful if a speculum examination is not possible.

Ligase chain reaction (LCR) can be used as an alternative to PCR.

**Treatment**

Tetracyclines or macrolide antibiotics are most commonly used to treat *Chlamydia*. Doxycycline 100 mg 12-hourly for 7 days or azithromycin 1 g as a single dose are both effective for uncomplicated infection. Tetracyclines are contraindicated in pregnancy. Other effective regimens include erythromycin 500 mg four times daily. Routine test of cure is not necessary after treatment with doxycycline or azithromycin, although if symptoms persist or re-infection is suspected then further tests should be taken. NAATs may remain positive for up to 5 weeks after treatment as they pick up material from non-viable organisms. Sexual contacts must be traced, notified and treated, particularly as so many infections are clinically silent.

**Urethritis**

Urethritis is usually characterized in men by a discharge from the urethra, dysuria and varying degrees of discomfort within the penis. In 10–15% of cases there are no symptoms. A wide array of aetiologies can give rise to the clinical picture and are divided into two broad bands: gonococcal or nongonococcal urethritis (NGU). NGU occurring shortly after infection with gonorrhoea is known as postgonococcal urethritis (PGU). Gonococcal urethritis and *Chlamydia* urethritis (a major cause of NGU) are discussed above.

*Trichomonas vaginalis*, *Mycoplasma genitalium*, *Ureaplasma urealyticum* and *Bacteroides* spp. are responsible for a proportion of cases. HSV can cause urethritis in about 30% of cases of primary infection, considerably fewer in recurrent episodes. Other causes include syphilitic chancre and warts within the urethra. Non-sexually transmitted NGU may be due to urinary tract infections, prostatic infection, foreign bodies and strictures.

**Clinical features**

The urethral discharge is often mucoid and worse in the morning. Crusting at the meatus or stains on underwear occur. Dysuria is common but not universal. Discomfort or itch within the penis may be present. The incubation period is 1–5 weeks with a mean of 2–3 weeks. Asymptomatic urethritis is a major reservoir of infection. *Reactive arthritis* (see p. 535) causing conjunctivitis with arthritis occurs, particularly in HLA B27-positive individuals.

**Diagnosis**

NAATs for gonorrhoea and *Chlamydia* should be performed in all men with symptoms of urethritis. In those who are negative, smears should be taken from the urethra when the
patient has not voided urine for at least 4 hours and should be Gram stained and examined under a high-power (×1000) oil-immersion lens. The presence of five or more polymorphonuclear leucocytes per high-power field or a gram-stained preparation from a centrifuged sample of a first passed urine specimen, containing >10 PMNL per high-power is diagnostic. Men who are symptomatic but have no objective evidence of urethritis should be re-examined and tested after holding urine overnight. Cultures for gonorrhoea must be taken together with specimens for Chlamydia testing.

**Treatment**

Therapy for NGU is with either azithromycin 1 g orally as a single dose or doxycycline 100 mg 12-hourly for 7 days. Sexual intercourse should be avoided. The vast majority of patients will show partial or total response. Sexual partners must be traced and treated; *C. trachomatis* can be isolated from the cervix in 50–60% of the female partners of men with PGU or NGU, many of whom are asymptomatic. This causes long-term morbidity in such women, acts as a reservoir of infection for the community, and may lead to re infection in the index case if not treated.

**Recurrent/persistent NGU**

This is a common and difficult clinical problem which is empirically defined as persistent or recurrent symptomatic urethritis occurring 30–90 days following treatment of acute NGU. It can occur in 20–60% of men treated for acute NGU. The usual time for patients to re-present is 2–3 weeks following treatment. Tests for organisms, e.g. *Mycoplasma, Chlamydia* and *Ureaplasma*, are usually negative. It is necessary to document objective evidence of urethritis, check adherence to treatment and establish any possible contact with untreated sexual partners. A further 1 week’s treatment with erythromycin 500 mg four times a day for 2 weeks plus metronidazole 400 mg twice daily for 5 days may be given, and any specific additional infection treated appropriately. If symptoms are mild and all partners have been treated, patients should be reassured and further antibiotic therapy avoided. In cases of frequent recurrence and/or florid unresponsive urethritis, the prostate should be investigated and urethroscopy or cystoscopy performed to investigate possible strictures, periurethral fistulae or foreign bodies.

**Lymphogranuloma venereum (LVG)**

*Chlamydia trachomatis* types LGV 1, 2 and 3 (different biovars or variant prokaryotic strain) are responsible for this sexually transmitted infection. It is endemic in the tropics, with the highest incidences in Africa, India and South East Asia. There has been a recent upsurge in UK-acquired LGV, particularly amongst HIV-infected men who have sex with men (MSM), presenting with rectal symptoms and associated genital ulceration. Many have also been hepatitis C co-infected. The L2 serovar (different antigenic properties) has been the predominant strain. The Health Protection Agency has enhanced LGV surveillance to track the current UK outbreak.

**Clinical features**

There are three characteristic stages. The primary lesion is a painless ulcerating papule on the genitalia occurring 7–21 days following exposure. It is frequently unnoticed. A few days to weeks after this heals, regional lymphadenopathy develops. The lymph nodes are painful and fixed and the overlying skin develops a dusky erythematous appearance. Finally, nodes may become fluctuant (buboes) and can rupture. Acute LGV also presents as proctitis with perirectal abscesses, the appearances sometimes resembling anorectal Crohn’s disease. The destruction of local lymph nodes can lead to lymphoedema of the genitalia.

**Diagnosis**

The diagnosis is often made on the basis of the characteristic clinical picture after other causes of genital ulceration or inguinal lymphadenopathy have been excluded. Syphilis and genital herpes must be excluded. The laboratory investigations have become more sensitive and specific:

- Detection of nucleic acid (DNA). Nucleic acid amplification tests for LGV serovar are now available. Positive samples should be confirmed by real-time PCR for LGV-specific DNA.
- Isolation of *C. trachomatis* from clinical lesions in tissue culture remains the most specific test, however sensitivity is only 75–85%.
- *Chlamydia trachomatis* serology. Complement fixation (CF) tests, single L-type immunofluorescence test and micro-immunofluorescence test (micro-IF) (the latter being the most accurate). A fourfold rise in antibody titre in the course of the illness or a single point titre of >1/64 is considered to be diagnostic.

**Treatment**

Early treatment is critical to prevent the chronic phase. Doxycycline (100 mg twice daily for 21 days) or erythromycin (500 mg four times daily for 21 days) is efficacious. Follow-up should continue until signs and symptoms have resolved, usually 3–6 weeks. Chronic infection may result in extensive scarring and abscess and sinus formation. Surgical drainage or reconstructive surgery is sometimes required. HIV and hepatitis C screening should be recommended. Sexual partners in the 30 days prior to onset should be notified, examined and treated if necessary.

**Syphilis**

Syphilis is a chronic systemic disease, which is acquired or congenital. In its early stages diagnosis and treatment are straightforward but untreated it can cause complex sequelae in many organs and eventually lead to death. There has been a marked increase in the incidence of syphilis over the past decade. A majority of these infections occur in men who have sex with men, many of whom are co-infected with HIV.

The causative organism, *Treponema pallidum* (TP), is a motile spirochaete that is acquired either by close sexual contact or can be transmitted transplacentally. The organism enters the new host through breaches in squamous or columnar epithelium. Primary infection of non-genital sites may occasionally occur but is rare.

Both acquired and congenital syphilis have early and late stages, each of which has classic clinical features (Table 4.49).

- **Primary.** Between 10 and 90 days (mean 21 days) after exposure to the pathogen a papule develops at the site of inoculation. This ulcerates to become a painless, firm chancre. There is usually painless regional lymphadenopathy in association. The primary lesion

may go unnoticed, especially if it is on the cervix or within the rectum. Healing occurs spontaneously within 2–3 weeks.

- **Secondary.** Between 4 and 10 weeks after the appearance of the primary lesion constitutional symptoms with fever, sore throat, malaise and arthralgia appear. Any organ may be affected – leading, for example, to hepatitis, nephritis, arthritis and meningitis. In a minority of cases the primary chancre may still be present and should be sought.

  Signs include:

  - Generalized lymphadenopathy (50%).
  - Generalized skin rashes involving the whole body including the palms and soles but excluding the face (75%) – the rash, which rarely itches, may take many different forms, ranging from pink macules, through coppery papules, to frank pustules (Fig. 4.41).

  - Condylomata lata – warty, plaque-like lesions found in the perianal area and other moist body sites.
  - Superficial confluent ulceration of mucosal surfaces – found in the mouth and on the genitalia, described as ‘snail track ulcers’.
  - Acute neurological signs in less than 10% of cases (e.g. aseptic meningitis).

Untreated early syphilis in pregnant women leads to fetal infection in at least 70% of cases and may result in stillbirth in up to 30%.

- **Latent.** Without treatment, symptoms and signs abate over 3–12 weeks, but in up to 20% of individuals may recur during a period known as early latency, a 2-year period in the UK (1 year in USA). Latent latency is based on reactive syphilis serology with no clinical manifestations for at least 2 years. This can continue for many years before the late stages of syphilis become apparent.

  - **Tertiary.** Late benign syphilis, so called because of its response to therapy rather than its clinical manifestations, generally involves the skin and the bones. The characteristic lesion, the gumma (granulomatous, sometimes ulcerating, lesions), can occur anywhere in the skin, frequently at sites of trauma. Gummata are commonly found in the skull, tibia, fibula and clavicle, although any bone may be involved. Visceral gummata occur mainly in the liver (hepar lobatum) and the testes.

Cardiovascular and neurosyphilis are discussed on pages 767 and 1157.

**Congenital syphilis**

Congenital syphilis usually becomes apparent between the second and sixth week after birth, early signs being nasal discharge, skin and mucous membrane lesions, and failure to thrive. Signs of late syphilis generally do not appear until after 2 years of age and take the form of ‘stigmata’ relating to early damage to developing structures, particularly teeth and long bones. Other late manifestations parallel those of adult tertiary syphilis.

**Investigations for diagnosis**

*Treponema pallidum* is not amenable to in vitro culture – the most sensitive and specific method is identification by dark-ground microscopy. Organisms may be found in variable numbers, from primary chancre and the mucous patches of secondary lesions. Individuals with either primary or secondary disease are highly infectious.

Serological tests used in diagnosis are either treponemal-specific or non-specific (cardiolipin test) (Table 4.50):

- **Treponemal specific.** The *T. pallidum* enzyme immunoassay (EIA). *T. pallidum* haemagglutination or particle agglutination assay (TPHA/TPPA) and fluorescent treponemal antibodies absorbed (FTA-abs) test are both highly specific for treponemal disease but will not differentiate between syphilis and other treponemal infection such as yaws. These tests usually remain positive for life, even after treatment.

  - **Treponemal non-specific.** The Veneraide Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR) tests are non-specific, becoming positive within
3–4 weeks of the primary infection. They are quantifiable tests which can be used to monitor treatment efficacy and are helpful in assessing disease activity. They generally become negative by 6 months after treatment in early syphilis. The VDRL may also become negative in untreated patients (50% of patients with late-stage syphilis) or remain positive after treatment in late stage. False-positive results may occur in other conditions – particularly infectious mononucleosis, hepatitis, *Mycoplasma* infections, some protozoal infections, cirrhosis, malignancy, autoimmune disease and chronic infections.

The EIA is the screening test of choice and can detect both IgM and IgG antibodies. A positive test is then confirmed with the TPHA/TPPA and VDRL/RPR tests. All serological investigations may be negative in early primary syphilis; the EIA IgM and the FTA-abs being the earliest tests to be positive. The diagnosis will then hinge on positive dark-ground microscopy. Treatment should not be delayed if serological tests are negative in such situations.

Examination of the CSF for evidence of neurosyphilis is indicated in those patients with syphilis who demonstrate neurological signs and symptoms, have a high titre of non-treponemal tests (usually taken to be greater than 1:32), those who have any evidence of treatment failure, and HIV co-infected patients with late latent syphilis or syphilis of unknown duration. A chest X-ray should also be performed.

### Treatment

Treponemocidal levels of antibiotic must be maintained in serum for at least 7 days in early syphilis to cover the slow division time of the organism (30 hours). In late syphilis treponemes may divide even more slowly requiring longer therapy.

- **Early syphilis** (primary or secondary) should be treated with long-acting penicillin such as procaine benzylpenicillin (procaine penicillin) (e.g. Jenacillin A which also contains benzylpenicillin) 600 mg intramuscularly daily for 10 days.
- **For late-stage syphilis,** particularly when there is cardiovascular or neurological involvement, the treatment course should be extended for a further week.

For patients sensitive to penicillin, either doxycycline 200 mg daily or erythromycin 500 mg four times daily is given orally for 2–4 weeks depending on the stage of the infection. Non-compliant patients can be treated with a single dose of benzathine penicillin G 2.4 g intramuscularly. Azithromycin is not recommended following evidence of resistance. The diagnosis and management of syphilis in HIV co-infected patients remains unaltered, however if untreated it may advance more rapidly than in HIV-negative patients and have a higher incidence of neurosyphilis. The *Jarisch–Herxheimer reaction*, which is due to release of TNF-α, IL-6 and IL-8, is seen in 50% of patients with primary syphilis and up to 90% of patients with secondary syphilis. It occurs about 8 hours after the first injection and usually consists of mild fever, malaise and headache lasting several hours. In cardiovascular or neurosyphilis the reaction, although rare, may be severe and exacerbate the clinical manifestations. Prednisolone given for 24 hours prior to therapy may ameliorate the reaction but there is little evidence to support its use. Penicillin should not be withheld because of the Jarisch–Herxheimer reaction; since it is not a dose-related phenomenon, there is no value in giving a smaller dose.

The **prognosis** depends on the stage at which the infection is treated. Early and early latent syphilis have an excellent outlook but once extensive tissue damage has occurred in the later stages the damage will not be reversed although the process may be halted. Symptoms in cardiovascular disease and neurosyphilis may therefore persist.

All patients treated for early syphilis must be followed up at regular intervals for the first year following treatment. Serological markers with a fall in titre of the VDRL/RPR of at least fourfold is consistent with adequate treatment for early syphilis. The sexual partners of all patients with syphilis and the parents and siblings of patients with congenital syphilis must be contacted and screened. Babies born to mothers who have been treated for syphilis in pregnancy are retreated at birth.

### Chancroid

Chancroid or soft chancre is an acute STI caused by *Haemophilus ducreyi*. Although a less common cause of genital ulceration than HSV-2, it is prevalent in parts of Africa and Asia. It is rare in the UK with cases usually associated with travel to or partners from endemic areas. Epidemiological studies in Africa have shown an association between genital ulcer disease, frequently chancroid and the acquisition of HIV infection. A new urgency to control chancroid has resulted from these observations.
Clinical features

The incubation period is 3–10 days. At the site of inoculation an erythematous papular lesion forms which then breaks down into an ulcer. The ulcer frequently has a necrotic base, a ragged edge, bleeds easily and is painful. Several ulcers may merge to form giant serpiginous lesions. Ulcers appear most commonly on the prepuce and frenulum in men and can erode through tissues. In women the most commonly affected site is the vaginal entrance and the perineum and lesions sometimes go unnoticed.

At the same time, inguinal lymphadenopathy develops (usually unilateral) and can progress to form large buboes which suppurate.

Diagnosis and treatment

Chancroid must be differentiated from other genital ulcer diseases (see Table 4.47). Co-infection with syphilis and herpes simplex is common. Isolation of H. ducreyi, a fastidious organism, in specialized culture media is definitive but difficult. Swabs should be taken from the ulcer and material aspirated from the local lymph nodes for culture. Polymerase chain reaction (PCR) techniques are available. Gram stains of clinical material may show characteristic coccobacilli, but this is an insensitive test. Detection of antibody to H. ducreyi using EIA may be useful for population surveillance but, at an individual level, lacks sensitivity and specificity. A ‘probable diagnosis’, may be made if the patient has the appropriate clinical picture, without evidence of T. pallidum or herpes simplex infection.

Single-dose regimens include azithromycin 1 g orally or ceftriaxone 250 mg i.m. Other regimens include ciprofloxacin 500 mg twice daily for 3 days, erythromycin 500 mg four times daily for 7 days. Clinically significant plasmid-mediated antibiotic resistance in H. ducreyi is developing.

Patients should be followed up at 3–7 days, when the ulcers should be responding if the treatment is successful.

Sexual partners should be notified, examined and treated epidemiologically, as asymptomatic carriage has been reported.

HIV-infected patients should be closely monitored, as healing may be slower. Multiple-dose regimens are needed in HIV patients since treatment failures have been reported with single-dose therapy.

Donovanosis

Donovanosis is the least common of all STIs in North America and Europe, but is endemic in the tropics and sub tropics, particularly the Caribbean, South East Asia and South India. Infection is caused by Klebsiella granulomatis, a short, encapsulated Gram-negative bacillus. The infection was also known as granuloma inguinale. Although sexual contact appears to be the most usual mode of transmission, the infection rates are low, even between sexual partners of many years’ standing.

Clinical features

In the vast majority of patients, the characteristic, heaped-up ulcerating lesion with prolific red granulation tissue appears on the external genitalia, perianal skin or the inguinal region within 1–4 weeks of exposure. It is rarely painful. Almost any cutaneous or mucous membrane site can be involved, including the mouth and anorectal regions. Extension of the primary infection from the external genitalia to the inguinal regions produces the characteristic lesion, the ‘pseudo-bubo’.

Diagnosis and treatment

The clinical appearance usually strongly suggests the diagnosis but K. granulomatis (Donovan bodies) can be identified intracellularly in scrapings or biopsies of an ulcer. Successful culture has only recently been reported and PCR techniques and serological methods of diagnosis are being developed, but none is routinely available.

Antibiotic treatment should be given until the lesions have healed. A minimum of 3 weeks’ treatment is recommended. Regimens include doxycycline 100 mg twice daily, co-trimoxazole 960 mg twice daily, azithromycin 500 mg daily or 1 g weekly, or ceftriaxone 1 g daily.

Sexual partners should be notified, examined and treated if necessary.

Herpes simplex

(also see p. 1231)

Genital herpes is one of the most common STIs world-wide and the most common ulcerative STI in the UK. Rates have risen substantially, particularly in young adults. Between 2005 and 2006 there has been a 16% increase in diagnoses of genital herpes in 16–19 year olds in the UK. The peak incidence is in 16- to 24-year-olds of both sexes, with women having higher rates of diagnosis than men. Infection, which is lifelong, may be either primary or recurrent. Transmission occurs during close contact with a person who is shedding virus (who may well be asymptomatic). Most genital herpes is due to type 2. Genital contact with oral lesions caused by HSV-1 can also produce genital infection.

Susceptible mucous membranes include the genital tract, rectum, mouth and oropharynx. The virus has the ability to establish latency in the dorsal root ganglia by ascending peripheral sensory nerves from the area of inoculation. It is this ability which allows for recurrent attacks.

Clinical features

Primary genital herpes is usually accompanied by systemic symptoms of varying severity including fever, myalgia and headache. Multiple painful shallow ulcers develop which may coalesce (Fig. 4.42). Atypical lesions are common. Tender inguinal lymphadenopathy is usual. Over a period of 10–14 days the lesions develop crusts and dry. In women with

Fig. 4.42 Herpes simplex rash on the penis. Courtesy of Dr B Goh.
vulval lesions the cervix is almost always involved. Rectal infection may lead to a florid proctitis. Neurological complications can include aseptic meningitis and/or involvement of the sacral autonomic plexus leading to retention of urine. Asymptomatic primary infection has been reported but is rare.

Recurrent attacks occur in a significant proportion of people following the initial episode and are more likely with HSV type 2 infections. Precipitating factors vary, as does the frequency of recurrence. A symptom prodrome is present in some people prior to the appearance of lesions. Systemic symptoms are rare in recurrent attacks.

The clinical manifestations in immunosuppressed patients (including those with HIV) may be more severe, asymptomatic shedding increased, and recurrences occurring with greater frequency. Systemic spread has been documented (see p. 202).

**Diagnosis**
The history and examination can be highly suggestive of HSV infection.

- A firm diagnosis can routinely be made only on the basis of detection of virus from within lesions.
- Culture of virus from lesions used to be the routine approach but is rapidly being replaced by genome detection analysis. For either assay modality, swabs should be taken from the base of lesions and placed in viral transport medium. Virus is most easily isolated from new lesions.
- HSV DNA detection by polymerase chain reaction (PCR) has increased the rates of detection compared with virus culture.
- Real-time PCR assays are highly specific although not available in all laboratories.

Type-specific immune responses can be found 8–12 weeks following primary infection and indicate HSV infection at some time. False negatives may be found early after infection. IgM assays are unreliable.

**Management**

- **Primary.** Saltwater bathing or sitting in a warm bath is soothing and may allow the patient to pass urine with some degree of comfort. Aciclovir 200 mg five times daily, famciclovir 250 mg three times daily or valaciclovir 500 mg twice daily, all for 5 days, are useful if patients are seen whilst new lesions are still forming. If lesions are already crustsing, antiviral therapy will do little to change the clinical course. Secondary bacterial infection occasionally occurs and should be treated. Rest, analgesia and antipyretics should be advised. In rare instances when encephalitis is present, patients are admitted to hospital and aciclovir given intravenously.

- **Recurrence.** Recurrent attacks tend to be less severe and can be managed with simple measures such as saltwater bathing. Psychological morbidity is associated with recurrent genital herpes and frequent recurrences impose strains on relationships; patients need considerable support. Long-term suppressive therapy is given in patients with frequent recurrences. An initial course of aciclovir 400 mg twice daily or valaciclovir 250 mg twice daily for 6–12 months significantly reduces the frequency of attacks, although there may still be some breakthrough. Therapy should be discontinued after 12 months and the frequency of recurrent attacks reassessed.

**HSV in pregnancy**
The potential risk of infection to the neonate needs to be considered in addition to the health of the mother. Infection occurs either transplacentally (very rare) or via the birth canal. If HSV is acquired for the first time during pregnancy, transplacental infection of the fetus may, rarely, occur. Management of primary HSV in the first or second trimester will depend on the woman’s clinical condition and aciclovir can be prescribed in standard doses. Aciclovir, given at a dose of 400 mg three times a day to accommodate altered pharmacokinetics of the drug in late pregnancy, during the last 4 weeks of pregnancy may prevent recurrence at term.

Primary acquisition in the third trimester or at term with high levels of viral shedding usually leads to delivery by caesarean section.

For women with previous infection, the risk for the baby acquiring HSV from the birth canal is very low in recurrent attacks. Only those with genital lesions at the onset of labour are delivered by caesarean section. Sequential cultures during the last weeks of pregnancy to predict viral shedding at term are no longer indicated.

**Prevention and control**
Patients must be advised that they are infectious when lesions are present; sexual intercourse should be avoided during this time or during prodromal stages. Condoms may not be effective as lesions may occur outside the areas covered. Sexual partners should be notified, examined and given information on avoiding infection. Asymptomatic viral shedding is a cause of onward transmission. It is most common in HSV-2, during the first 12 months following infection and in those with frequent symptomatic HSV. Antiviral drugs reduce shedding and onward transmission.

**Human papillomavirus (HPV) warts**
Anogenital warts are amongst the most common sexually acquired infections. The causative agent is human papillomavirus (HPV) especially types 6 and 11 with types 16 and 18 causing a majority of cases of cervical carcinoma (see p. 108). HPV is acquired by direct sexual contact with a person with either clinical or subclinical infection. Genital HPV infection is common, with only a small proportion of those infected being symptomatic. Neonates may acquire HPV from an infected birth canal, which may result either in anogenital warts or in laryngeal papillomas. The incubation period ranges from 2 weeks to 8 months or even longer.

**Clinical features**
Warts develop around the external genitalia in women, usually starting at the fourchette, and involve the perianal region. The vagina may be infected. Flat warts may develop on the cervix and are not easily visible on routine examination. Such lesions are associated with cervical intraepithelial neoplasia. In men the penile shaft and subpreputial space are the most common sites, although warts involve the urethra and meatus. Perianal lesions are more common in men who practise anoreceptive intercourse but they can be found in any patient. The rectum may become involved.
Warts become more florid during pregnancy or in immunosuppressed patients.

**Diagnosis**
The diagnosis is essentially clinical. It is critical to differentiate condylomata lata of secondary syphilis. Unusual lesions should be biopsied if the diagnosis is in doubt. Up to 30% of patients have coexisting infections with other STIs and a full screen must be performed.

**Treatment**
Significant failure and relapse rates are seen with current treatment modalities. Choice of treatment will depend on the number and distribution of lesions. Local agents, including podophyllin extract (15–25% solution, once or twice weekly), podophyllotoxin (0.5% solution or 1.5% cream in cycles) and trichloroacetic acid, are useful for non-keratinized lesions. Those that are keratinized respond better to physical therapy, e.g. cryotherapy, electrocautery or laser ablation. Imiquimod, an immune response modifier, induces a cytokine response when applied to skin infected with HPV (5% cream used three times a week) and is indicated in both types of lesion. Podophyllin, podophyllotoxin and imiquimod are not advised in pregnancy. Patients co-infected with HIV may have a poorer response to treatment and higher rates of intraepithelial neoplasia. Sexual contacts should be examined and treated if necessary. In view of the difficulties of diagnosing subclinical HPV, condoms should be used for up to 8 months after treatment. Because of the association of HPV with cervical intraepithelial neoplasia, women with warts and female partners of men with warts are advised to have regular cervical screening, i.e. every 3 years. Colposcopy may be useful in women with vaginal and cervical warts.

**Prevention/vaccination**
Two vaccines now exist against HPV. One is effective against HPV types 16 and 18 and the second against types 6, 11, 16 and 18. Both vaccines, based on a DNA-free HPV capsid, are strongly immunogenic and act by inducing a neutralizing antibody response and enhancing CD4 memory cell function. They are given over 6 months in three divided doses, with an excellent safety profile. Up to 98% serological responses, maintained for over 4 years, have been reported from early trials. In placebo-controlled clinical trials of the quadrivalent vaccine a highly significant reduction in low- and high-grade cervical dysplasia, vulval pre-cancers and external genital warts has been demonstrated. Vaccination is most beneficial in those who have not yet been exposed to HPV infection, with a recommendation that it be given before people become sexually active. In the UK there is evidence of increasing sexual activity at ever younger ages and vaccination of children is the logical approach. However this has caused considerable ethical debate. Although initially considered to be most useful for women and girls, vaccination of boys to prevent both genital warts and the transmission of oncogenic HPV strains would be a logical public health approach. Routine HPV vaccination commenced in the UK in late 2006, initially for girls of about 12 years of age, with a second catch-up opportunity at about 18 years of age.

**Trichomoniasis**
*Trichomonas vaginalis (TV)* is a flagellated protozoan which is predominantly sexually transmitted. It is able to attach to squamous epithelium and can infect the vagina and urethra. *Trichomonas* may be acquired perinatally in babies born to infected mothers.

Infected women may, unusually, be asymptomatic. Commonly the major complaints are of vaginal discharge, which is offensive and of local irritation. Men usually present as the asymptomatic sexual partners of infected women, although they may complain of urethral discharge, irritation or urinary frequency.

Examination often reveals a frothy yellowish vaginal discharge and erythematous vaginal walls. The cervix may have multiple small haemorrhagic areas which lead to the description ‘strawberry cervix’. *Trichomonas* infection in pregnancy has been associated with preterm delivery and low birth weight.

**Diagnosis and treatment**
Phase-contrast, dark-ground microscopy of a drop of vaginal discharge shows TV swimming with a characteristic motion in 40–80% of female patients. Similar preparations from the male urethra will only be positive in about 30% of cases. Many polymorphonuclear leucocytes are also seen. Culture techniques are good and confirm the diagnosis. *Trichomonas* is sometimes observed on cervical cytology with 60–80% accuracy in diagnosis. New, highly sensitive and specific tests based on polymerase chain reactions are in development.

Metronidazole is the treatment of choice, either 2 g orally as a single dose or 400 mg twice-daily for 7 days. There is some evidence of metronidazole resistance and nimosazole may be effective in these cases. Topical therapy with intravaginal tinidazole can be effective, but if extravaginal infection exists this may not be eradicated and vaginal infection reoccurs. Male partners should be treated, especially as they are likely to be asymptomatic and more difficult to detect.

**Candidiasis**
Vulvovaginal infection with *Candida albicans* is extremely common. The organism is also responsible for balanitis in men. *Candida* can be isolated from the vagina in a high proportion of women of childbearing age, many of whom will have no symptoms.

The role of *Candida* as pathogen or commensal is difficult to disentangle and it may be changes in host environment which allow the organism to produce pathological effects. Predisposing factors include pregnancy, diabetes, and the use of broad-spectrum antibiotics and corticosteroids. Immunosuppression can result in more florid infection.

**Clinical features**
In women, pruritis vulva is the dominant symptom. Vaginal discharge is present in varying degree. Many women have only one or occasional isolated episodes. Recurrent candidiasis (four or more symptomatic episodes annually) occurs in up to 5% of healthy women of reproductive age. Examination reveals erythema and swelling of the vulva with broken skin in severe cases. The vagina may contain adherent curdy discharge. Men may have a florid balanoposthitis. More commonly, self-limiting burning penile irritation immediately after
sexual intercourse with an infected partner is described. Diabetes must be excluded in men with balanoposthitis.

**Diagnosis**

Microscopic examination of a smear from the vaginal wall reveals the presence of spores and mycelia. Culture of swabs should be undertaken but may be positive in women with no symptoms. *Trichomonas* and bacterial vaginosis must be considered in women with itch and discharge.

**Treatment**

*Topical.* Pessaries or creams containing one of the imidazole antifungals such as clotrimazole 500 mg single dose used intravaginally are usually effective. Nystatin is also useful.

*Oral.* The triazole drugs such as fluconazole 150 mg as a single dose or itraconazole 200 mg twice in 1 day are used systemically where topical therapy has failed or is inappropriate. Recurrent candidiasis may be treated with fluconazole 100 mg weekly for 6 months, or clotrimazole pessary 500 mg weekly for 6 months.

The evidence for sexual transmission of *Candida* is slight and there is no evidence that treatment of male partners reduces recurrences in women.

**Bacterial vaginosis**

Bacterial vaginosis (BV) is a disorder characterized by an offensive vaginal discharge. The aetiology and pathogenesis are unclear but a mixed flora of *Gardnerella vaginalis*, anaerobes including *Bacteroides*, *Mobiluncus* spp. and *Mycoplasma hominis* replaces the normal lactobacilli of the vagina. Amines and their breakdown products from the abnormal vaginal flora are thought to be responsible for the characteristic odour associated with the condition. As vaginal inflammation is not part of the syndrome the term vaginosis is used rather than vaginitis. The condition has been shown to be more common in black women than in white. It is not regarded as a sexually transmitted disease.

**Clinical features**

Vaginal discharge and odour are the most common complaints although a proportion of women are asymptomatic. A homogeneous, greyish white, adherent discharge is present in the vagina, the pH of which is raised (greater than 5). Associated complications are ill-defined but may include chorioamnionitis and an increased incidence of premature labour in pregnant women. Whether BV predisposes non-pregnant women to upper genital tract infection is unclear.

**Diagnosis**

Different authors have differing criteria for making the diagnosis of BV. In general it is accepted that three of the following should be present for the diagnosis to be made:

- characteristic vaginal discharge
- the amine test: raised vaginal pH using narrow-range indicator paper (>4.7)
- a fishy odour on mixing a drop of discharge with 10% potassium hydroxide
- the presence of ‘clue’ cells on microscopic examination of the vaginal fluid.

Clue cells are squamous epithelial cells from the vagina, which have bacteria adherent to their surface, giving a granular appearance to the cell. A Gram stain gives a typical reaction of partial stain uptake.

**Treatment**

Metronidazole given orally in doses of 400 mg twice daily for 5–7 days is usually recommended. A single dose of 2 g metronidazole is less effective. Topical 2% clindamycin cream 5 g intravaginally once daily for 7 days is effective.

Recurrence is high, with some studies giving a rate of 80% within 9 months of completing metronidazole therapy. There is debate over the treatment of asymptomatic women who fulfil the diagnostic criteria for BV. The diagnosis should be fully discussed and treatment offered if the woman wishes. Until the relevance of BV to other pelvic infections is elucidated, the treatment of asymptomatic women with BV is not to be recommended. There is no convincing evidence that simultaneous treatment of the male partner influences the rate of recurrence of BV, and routine treatment of male partners is not indicated.

**INFESTATIONS** (see also p. 1235)

**Pediculus pubis**

The pubic louse (*Pthirus pubis*) is a blood-sucking insect which attaches tightly to the pubic hair. They may also attach to eyelashes and eyebrows. It is relatively host-specific and is transmitted only by close bodily contact. Eggs (nits) are laid at hair bases and usually hatch within a week. Although infestation may be asymptomatic the most common complaint is of itch.

**Diagnosis**

Lice may be seen on the skin at the base of pubic and other body hairs. They resemble small scabs or freckles but if they are picked up with forceps and placed on a microscope slide will move and walk away. Blue macules may be seen at the feeding sites. Nits are usually closely adherent to hairs. Both are highly characteristic under the low-power microscope.

As with all sexually transmitted infections, the patient must be screened for coexisting pathogens.

**Treatment**

Both lice and eggs must be killed with 0.5% malathion, 1% permethrin or 0.5% carbaryl. The preparation should be applied to all areas of the body from the neck down and washed off after 12 hours. In a few cases a further application after 1 week may be necessary. For severe infestations, antipruritics may be indicated for the first 48 hours. All sexual partners should be seen and screened.

**Scabies**

This is discussed on page 1234.

184 Infection and Infectious diseases

HUMAN IMMUNE DEFICIENCY VIRUS (HIV) AND AIDS

Epidemiology
In 2007 UNAIDS (Joint United Nations Programme on HIV/AIDS) estimated that over 33 million people world-wide were living with HIV infection, 2.5 million people were newly infected during that year and 2.1 million died. On a daily basis world-wide 6800 people acquire HIV and 5700 die of AIDS. Sub-Saharan Africa remains the most seriously affected, but in some areas the numbers of new diagnoses has stabilized. However, in Eastern Europe and parts of central Asia infection rates are rising exponentially. The human, societal and economic costs are huge – 33% of 15-year-olds in high-prevalence countries in Africa will die of HIV. Effective therapy for HIV has reduced mortality and morbidity but not in the poorer parts of the world. Demographics of the epidemic have varied greatly, influenced by social, behavioural, cultural and political factors.

In the UK death rates from HIV have fallen (down from 4.7% in 1997 to 0.95% in 2006), but new diagnoses continue to rise and total numbers have tripled over the past decade. In 2006 73,000 people were HIV-positive of whom 30% were undiagnosed and unaware of their infection. Men who have sex with men (MSM) and culturally diverse heterosexual populations from sub-Saharan Africa, are the two largest groups of people living with HIV in the UK and accessing treatment and care.

The pattern is changing, with over half the new infections with HIV being acquired heterosexually, 75% of which are associated with high prevalence countries. The proportion of new diagnoses in the UK in heterosexual women has risen from 25% to 40% since 1997. As mortality rates fall so the population of people with HIV is becoming older, further changing the clinical picture.

Routes of acquisition
Despite the fact that HIV can be isolated from a wide range of body fluids and tissues, the majority of infections are transmitted via semen, cervical secretions and blood.

- Sexual intercourse (vaginal and anal). Globally, heterosexual intercourse accounts for the vast majority of infections, and coexistent STIs, especially those causing genital ulceration, enhance transmission. Passage of HIV appears to be more efficient from men to women, and to the receptive partner in anal intercourse, than vice versa. In the UK, sex between men still accounts for over half the infections reported, but there is an increasing rate of heterosexual transmission. In central and sub-Saharan Africa the epidemic has always been heterosexual and more than half the infected adults in these regions are women. South East Asia and the Indian subcontinent are experiencing an explosive epidemic, driven by heterosexual intercourse and a high incidence of other sexually transmitted diseases.

- Mother to child (transplacentally, perinatally, breastfeeding). Vertical transmission is the most common route of HIV infection in children. European studies suggest that, without intervention, 15% of babies born to HIV-infected mothers are likely to be infected, although rates of up to 40% have been reported from Africa and the USA. Increased vertical transmission is associated with advanced disease in the mother, maternal viral load, prolonged and premature rupture of membranes, and chorioamnionitis. Transmission can occur in utero although the majority of infections take place perinatally. Breast-feeding has been shown to double the risk of vertical transmission. In the developed world interventions to reduce vertical transmission, including the use of antiretroviral agents, delivery by caesarean section and the avoidance of breast-feeding have led to a dramatic fall in the numbers of infected children. The lack of access to these interventions in resource-poor countries in which 90% of infections occur is a major issue.

- Contaminated blood, blood products and organ donations. Screening of blood and blood products was introduced in 1985 in Europe and North America. Prior to this, HIV infection was associated with the use of clotting factors (for haemophilia) and with blood transfusions. In some parts of the world where blood products may not be screened, and in areas where the rate of new HIV infections is very high, transfusion-associated transmission continues to occur.

- Contaminated needles (intravenous drug misuse, injections, needle-stick injuries). The practice of sharing needles and syringes for intravenous drug use continues to be a major route of transmission of HIV in both developed countries and parts of South East Asia, Latin America and the states of the former Soviet Union. In some areas, including the UK, successful education and needle exchange schemes have reduced the rate of transmission by this route. Iatrogenic transmission from needles and syringes used in developing countries is reported. Healthcare workers have a risk of approximately 0.3% following a single needle-stick injury with known HIV-infected blood.

There is no evidence that HIV is spread by social or household contact or by blood-sucking insects such as mosquitoes and bed bugs.

The virus
HIV belongs to the lentivirus group of the retrovirus family. There are two types, HIV-1 and HIV-2. HIV-1 is the most frequently occurring strain globally. HIV-2 is almost entirely confined to West Africa, although there is evidence of some spread to Europe, particularly France and Portugal and the
Indian subcontinent. HIV-2 has only 40% structural homology with HIV-1 and although it is associated with immunosuppression and AIDS, appears to take a more indolent course than HIV-1. Many of the drugs that are used in HIV-1 are ineffective in HIV-2. The structure of HIV is shown in Figure 4.43.

Retroviruses are characterized by the possession of the enzyme reverse transcriptase, which allows viral RNA to be transcribed into DNA, and thence incorporated into the host cell genome. Reverse transcription is an error-prone process with a significant rate of mis-incorporation of bases. This, combined with a high rate of viral turnover, leads to considerable genetic variation and a diversity of viral subtypes or clades. On the basis of DNA sequencing, HIV-1 is divided into three groups, which probably represent three zoonotic transfers from the chimpanzee but do not differ clinically in humans.

- **Group M** (major subtypes) [95% of infections worldwide] contains at least 10 subtypes (or clades), which are denoted A–J. There is a predominance of subtype B in Europe, North America and Australia, but areas of central and sub-Saharan Africa have multiple M subtypes. Recombination of viral material generates an array of circulating recombinant forms (CRFs), which increases the genetic diversity that may be encountered.

- **Group N** (new) is mostly confined to parts of West Central Africa (e.g. Gabon).

- **Group O** (outlier subtypes) are highly divergent from group M and are largely confined to small numbers centred on Cameroon.

Connections between genetic diversity and biological effects, in particular pathogenicity, rates of transmission and response to therapy are being sought. Increasing numbers of non B subtypes and recombinant forms are seen in the UK.

**Pathogenesis**

The interrelationship between HIV and the host immune system is the basis of the pathogenesis of HIV disease. The host cellular receptor that is recognized by HIV surface glycoprotein gp120 is the CD4 molecule, which defines the cell populations that are susceptible to infection (Fig. 4.44). The interaction between CD4 and HIV gp120 surface glycoprotein, together with chemokine co-receptors CCR5 and CXCR4 is responsible for HIV entry into cells. Auxiliary viral proteins such as those coded by the Nef gene have a role in influencing host cell membrane proteins and signal transduction pathways. CD4 receptors and HIV surface glycoprotein interactions mediate the process of syncytium formation, which is a cytopathic effect of HIV infection.

Studies of viral turnover in HIV-infected individuals have demonstrated a virus half-life in the circulation of about 6 hours. To maintain observed levels of plasma viraemia, $10^8–10^9$ virus particles need to be released and cleared daily. Virus production by infected cells lasts for about 2 days and is probably limited by the death of the cell, owing to direct HIV effects, linking HIV replication to the process of CD4 destruction and depletion. Studies suggest that immunopathogenesis is a result of defective T cell homeostasis in HIV infection. The progressive and severe depletion of CD4 helper lymphocytes has profound repercussions for the functioning of the immune system (see p. 65). Cell-mediated immunodeficiency, which is the major consequence, leaves the host open to infections with intracellular pathogens, whilst the coexisting antibody abnormalities predispose to infections with capsulated bacteria. HIV also has a direct effect on certain tissues, notably the nervous system. Loss of immunological function also predisposes the host to the development of a variety of malignant tumours.

**Diagnosis and natural history** (Fig. 4.45)

Reduction in HIV-related morbidity and mortality with effective therapy has highlighted the necessity of testing and diagnosis. Increasing the uptake of HIV testing is a major public health objective. The pre-test counselling and consent required prior to HIV testing is straightforward and can be performed by a wide range of healthcare professionals. HIV testing is being considered on a pan European basis. There is increasing use of the newer point of care HIV testing techniques outside traditional medical settings with the aim of reaching a wider population.

The tests

HIV infection is diagnosed either by the detection of virus-specific antibodies (anti-HIV) or by direct identification of viral material.

**Detection of IgG antibody to envelope components.** This is the most commonly used marker of infection. The routine tests used for screening are based on ELISA techniques, which may be confirmed with Western blot assays. Up to 3 months may elapse from initial infection to antibody detection (serological latency, or window period). These antibodies to HIV have no protective function and persist for life. As with all IgG antibodies, anti-HIV will cross the placenta. All babies born to HIV-infected women will thus have the antibody at birth. In this situation, anti-HIV antibody is not a reliable marker of active infection and in uninfected babies will be gradually lost over the first 18 months of life.
This ‘detuned’ after that diagnosis and of Nucleic home results test blood are is test where of in HIV entry and replication in whole test are in a HIV-infected and infection HIV identifies with detectable mothers some patients with positive oral fluid test, in parallel with a less sensitive (detuned) test that identifies later HIV antibodies within 130 days. A positive result on the sensitive test and a negative ‘detuned’ test are indicative of recent infection, whilst positive results on both tests point to an infection that is more than 130 days old. The major application of this is in epidemiological surveillance and monitoring.

IgG antibody to p24 (anti-p24). This can be detected from the earliest weeks of infection and through the asymptomatic phase. It is frequently lost as disease progresses.

**Genome detection assays.** Nucleic acid-based assays that amplify and test for components of the HIV genome are available. These assays are used to aid diagnosis of HIV in the babies of HIV-infected mothers or in situations where serological tests may be inadequate, such as in early infection when antibody may not be present, or in subtyping HIV variants for medicolegal reasons. (See the discussion of viral load monitoring, p. 190.)

Viral p24 antigen (p24ag). This is detectable shortly after infection but has usually disappeared by 8–10 weeks after exposure. It can be a useful marker in individuals who have been infected recently but have not had time to mount an antibody response.

**Isolation of virus in culture.** This is a specialized technique available in some laboratories to aid diagnosis and as a research tool.

**Fig. 4.44** HIV entry and replication in CD4 T lymphocytes. The human immune deficiency virus binds to host CD4 molecules via the envelope glycoprotein gp120. gp120 binding to secondary receptors (chemokine receptors) and subsequent conformational change results in fusion between gp41 and the cell membrane. Entry of the viral capsid is followed by uncoating of RNA. DNA copies are made from both RNA templates (reverse transcriptase). The enzyme DNA polymerase from the host cell leads to formation of dsDNA. In the nucleus the virally encoded DNA is inserted into the host genome (integration). Regulatory proteins control transcription (a process in which an RNA molecule is synthesized from a DNA template). The virus is reassembled in the cytoplasm and budded out from the host cell.

**Fig. 4.45** The immune response to HIV (seroconversion).

Simple and rapid HIV antibody assays are increasingly available, giving results within minutes. Assays that can utilize alternative body fluids to serum/plasma such as oral fluid, whole blood and urine are now available and home testing kits are being developed. These tests are extremely sensitive and may give false positive results, making it necessary to perform a confirmatory test.

A Serologic Testing Algorithm for Recent HIV Seroconversions (STARHS) can be used to identify recently acquired infection. A highly sensitive ELISA that is able to detect HIV antibodies 6–8 weeks after infection is used on blood in
The spectrum of illnesses associated with HIV infection is broad and is the result of direct HIV effects, the drugs used to treat the condition, coexisting morbidity and co-infections as well as HIV-associated immune dysfunction. Several classification systems exist, the most widely used being the 1993 Centers for Disease Control (CDC) classification (Box 4.16).

This classification depends to a large extent on definitive diagnoses of infection, which makes it more difficult to use in those areas of the world without sophisticated laboratory support. As immunosuppression progresses the patient is susceptible to an increasing range of opportunistic infections and tumours, certain of which meet the criteria for the diagnosis of AIDS (Box 4.17).

Since 1993 the definition of AIDS has differed between the USA and Europe. The USA definition includes individuals with CD4 counts below 200 in addition to the clinical classification based on the presence of specific indicator diagnoses shown in Box 4.17. In Europe the definition remains based on the diagnosis of specific clinical conditions with no inclusion of CD4 lymphocyte counts. Where highly active antiretroviral therapy (HAART) is available and started before the development of severe immunosuppression, progression to AIDS is now uncommon.

**Incubation**

The 2–4 weeks immediately following infection are usually silent both clinically and serologically.

**Seroconversion/primary illness**

The majority of HIV seroconversions are usually asymptomatic. In a proportion, a self-limiting non-specific illness occurs 6–8 weeks after exposure. Symptoms include fever, arthralgia, myalgia, lethargy, lymphadenopathy, sore throat, mucosal ulcers and occasionally a transient faint pink maculopapular rash. Neurological symptoms are common, including headache, photophobia, myelopathy and neuropathy and in rare cases encephalopathy. The illness lasts up to 3 weeks and recovery is usually complete.

**Laboratory abnormalities** include lymphopenia with atypical reactive lymphocytes noted on blood film, thrombocytopenia and raised liver enzymes. CD4 lymphocytes may be markedly depleted and the CD4:CD8 ratio reversed. Antibodies to HIV may be absent during this early stage of infection, although the level of circulating viral RNA is high and p24 core protein may be detectable. Patients experiencing a seroconversion illness may have a more rapidly progressive course of infection.

**Clinical latency**

The majority of people with HIV infection are asymptomatic for a substantial but variable length of time. However, the virus continues to replicate and the person is infectious. Studies suggest a median length of 10 years from infection to development of symptomatic disease, although some patients progress much more rapidly and others have remained symptom-free for up to 15 years. Older age is associated with more rapid progression, and genetic factors may play a part. Gender and pregnancy per se do not appear to influence the rate of progression, although women may fare less well for a variety of reasons. A subgroup of patients with asymptomatic infection have persistent generalized lymphadenopathy (PGL), defined as lymphadenopathy (>1 cm) at two or more extra inguinal sites for more than 3 months in the absence of causes other than HIV infection. The nodes are usually symmetrical, firm, mobile and non-tender. There may be associated splenomegaly. The architecture of the nodes shows hyperplasia of the follicles and proliferation of the capillary endothelium. Biopsy is rarely indicated. Similar disease progression has been noted in asymptomatic patients with or without PGL. Nodes may disappear with disease progression.
Symptomatic HIV infection

As HIV infection progresses the viral load rises, the CD4 count falls, and the patient develops an array of symptoms and signs. The clinical picture is the result of direct HIV effects and of the associated immunosuppression.

In an individual patient the clinical consequences of HIV-related immune dysfunction will depend on at least three factors:

- **The microbial exposure of the patient throughout life.**
  Many clinical episodes represent reactivation of previously acquired infection, which has been latent. Geographical factors determine the microbial repertoire of an individual patient. Those organisms requiring intact cell-mediated immunity for their control are most likely to cause clinical problems.

- **The pathogenicity of organisms encountered.** High-grade pathogens such as *Mycobacterium tuberculosis*, *Candida* and the herpes viruses are clinically relevant even when immunosuppression is mild, and will thus occur earlier in the course of the disease. Less virulent organisms occur at later stages of immunodeficiency.

- **The degree of immunosuppression of the host.** When patients are severely immunocompromised (CD4 count < 100/mm³) disseminated infections with organisms of very low virulence such as *M. avium-intracellulare (MAI)* and *Cryptosporidium* are able to establish themselves. These infections are very resistant to treatment, mainly because there is no functioning immune response to clear organisms. This hierarchy of infection allows for appropriate intervention with prophylactic drugs.

**EFFECTS OF HIV INFECTION**

**Neurological disease**

Infection of the nervous tissue occurs at an early stage but clinical neurological involvement increases as HIV advances. This includes *AIDS dementia complex (ADC)*, *sensory polyneuropathy* and *aseptic meningitis* (see p. 1154). These conditions are much less common since the introduction of HAART (highly active antiretroviral therapy). The pathogenesis is thought to be due both to the release of neurotropic products by HIV itself and to cytokine abnormalities secondary to immune dysregulation.

*ADC* has varying degrees of severity, ranging from mild memory impairment and poor concentration through to severe cognitive deficit, personality change and psychomotor slowing. Changes in affect are common and depressive or psychotic features may be present. The spinal cord may show vacuolar myelopathy histologically. In severe cases brain CT scan shows atrophic change of varying degrees. MRI changes consist of white matter lesions of increased density on T2-weighted sections. EEG shows non-specific changes consistent with encephalopathy. The CSF is usually normal, although the protein concentration may be raised. Patients with mild neurological dysfunction may be unduly sensitive to the effects of other insults such as fever, metabolic disturbance or psychotropic medication, any of which may lead to a marked deterioration in cognitive functioning.

*Sensory polyneuropathy* is seen in advanced HIV infection, mainly in the legs and feet, although hands may be affected. Severe forms cause intense pain, usually in the feet, which disrupts sleep, impairs mobility and generally reduces the quality of life.

*Autonomic neuropathy* may also occur with postural hypotension and diarrhoea. Autonomic nerve damage is found in the small bowel. Didanosine and stavudine produce a similar neuropathy as a major toxic side-effect and are best avoided in patients with HIV neuropathy.

HAART has shown startling improvements in cognitive function in many patients with ADC. It may also have a neuroprotective role.

**Eye disease**

Eye pathology is usually seen in the later stages. The most serious is *cytomegalovirus retinitis* (see p. 107), which is sight-threatening. Retinal cotton wool spots due to HIV persist are rarely troublesome but they can be confused with CMV retinitis. Anterior uveitis can present as acute red eye associated with rifabutin therapy for mycobacterial infections in HIV. Steroids used topically are usually effective but modification of the dose of rifabutin is required to prevent relapse. Pneumocystis, toxoplasmosis, syphilis and lymphoma can all affect the retina and the eye may be the site of first presentation.

**Mucocutaneous manifestations**

(see Table 4.51)

The skin is a common site for HIV-related pathology as the site of dendritic and Langerhans’ cells, both target cells for HIV, is disrupted. Delayed-type hypersensitivity, a good indicator of cell-mediated immunity, is frequently reduced or absent even before clinical signs of immunosuppression appear. Pruritus is a common complaint at all stages of HIV. Generalized dry, itchy, flaky skin is typical and the hair may become thin and dry. An intensely pruritic papular eruption favouring the extremities may be found, particularly in patients from African backgrounds. Eosinophilic folliculitis presents with urticarial lesions particularly on the face, arms and legs.

Drug reactions with cutaneous manifestations are frequent, with rashes developing notably to sulphur-containing drugs amongst others (see Fig. 23.39). Recurrent aphthous ulceration, which is severe and slow to heal, is common and can impair the patient’s ability to eat. Biopsy may be indicated to exclude other causes of ulceration. Topical steroids are useful and resistant cases may respond to thalidomide. In addition to the above the skin is a common site of opportunistic infections (see p. 200).

**Haematological complications**

These are common in advanced HIV infection.

- **Lymphopenia** – this progresses as the CD4 count falls.
- **Anaemia of chronic HIV infection** is usually mild, normochromic and normocytic.
- **Neutropenia** is common and usually mild.
- **Isolated thrombocytopenia** may occur early in infection and be the only manifestation of HIV for some time. Platelet counts are often moderately reduced but can fall dramatically to 10–20 × 10^9/L producing easy bleeding and bruising. Circulating antiplatelet antibodies lead to peripheral destruction. Megakaryocytes are increased in the bone marrow but their function is impaired. Effective antiretroviral therapy usually produces a rise in platelet count. Thrombocytopenic patients undergoing dental, medical or surgical procedures may need therapy with human immunoglobulin, which gives a transient rise in platelet count, or be given platelet transfusion. Steroids are best avoided.
- **Pancytopenia** occurs because of underlying opportunistic infection or malignancies, in particular *Mycobacterium avium-intracellularare*, disseminated cytomegalovirus and lymphoma.
- **Other complications.** Myelotoxic drugs include zidovudine (megaloblastic anaemia, red cell aplasia, neutropenia), lamivudine (anaemia, neutropenia), ganciclovir (neutropenia), systemic chemotherapy (pancytopenia) and co-trimoxazole (agranulocytosis).

**Gastrointestinal effects** (see p. 309)

Weight loss and diarrhoea are common in HIV-infected patients. Wasting is a common feature of advanced HIV infection, which although originally attributed to direct HIV effects on metabolism, is usually a consequence of anorexia. There is a small increase in resting energy expenditure in all stages of HIV, but weight and lean body mass usually remain normal during periods of clinical latency when the patient is eating normally.

Gastrointestinal infections are common. An HIV enteropathy has been described with chronic diarrhoea when no other pathogen has been found. Villous atrophy is seen in the small bowel.

Hypochlorhydria is reported in patients with advanced HIV disease and may have consequences for drug absorption and bacterial overgrowth in the gut.

Rectal lymphoid tissue cells are the targets for HIV infection during penetrative anal sex and may be a reservoir for infection to spread through the body.

**Renal complications**

*HIV-associated nephropathy (HIVAN)* (see p. 597), although rare, can cause significant renal impairment, particularly in more advanced disease. It is most frequently seen in black male patients and can be exacerbated by heroin use.

*Nephrotic syndrome* subsequent to focal glomerulosclerosis is the usual pathology, which may be a consequence of HIV cytopathic effects on renal tubular epithelium. The course is usually relentlessly progressive and dialysis may be required.

Many *nephrotoxic drugs* are used in the management of HIV-associated pathology, particularly foscarnet, amphotericin B, pentamidine and sulfadiazine. Tenofovir has been associated with Fanconi’s syndrome.

**Respiratory complications**

The upper airway and lungs serve as a physical barrier to airborne pathogens and any damage will decrease the efficiency of protection, leading to an increase in upper and lower respiratory tract infections. The sinus mucosa may also function abnormally in HIV infection and is frequently the site of chronic inflammation. Response to antibacterial therapy and topical steroids is usual but some patients require surgical intervention. A similar process is seen in the middle ear, which may lead to chronic otitis media.

*Lymphoid interstitial pneumonitis (LIP)* is well described in paediatric HIV infection but is uncommon in adults. There is an infiltration of lymphocytes, plasma cells and lymphoblasts in alveolar tissue. Epstein–Barr virus may be present. The patient presents with dyspnoea, and a dry cough, which may be confused with pneumocystis infection (see p. 861). Reticular nodular shadowing is seen on chest X-ray. Therapy with steroids may produce clinical and histological benefit in some patients.

**Endocrine complications**

Various endocrine abnormalities have been reported, including reduced levels of testosterone and abnormal adrenal function. The latter assumes clinical significance in advanced disease when intercurrent infection superimposed upon borderline adrenal function precipitates clear adrenal insufficiency requiring replacement doses of glucocorticoid and mineralocorticoid. CMV is also implicated in adrenal-deficient states.

**Cardiac complications**

Cardiovascular pathology is increasingly recognized as a cause of morbidity in people with HIV. Although lipid dysregulation has been associated with antiretroviral medication (ARV), the observation has been made that HDL levels are lower in those with untreated HIV infection than in HIV-negative controls. In a large international study (SMART), ischaemic heart disease was more common in those who took intermittent ARV therapy than in those who maintained viral suppression. The pathogenesis is still unclear. Cardiomyopathy, although rare, is associated with HIV, and may lead to congestive cardiac failure. Lymphocytic and necrotic myocarditis have been described. Ventricular biopsy should be performed to ensure other treatable causes of myocarditis are excluded.

### CONDITIONS ASSOCIATED WITH HIV IMMUNODEFICIENCY (see p. 200)

Immune deficiency allows the development of opportunistic infections (OI) (Table 4.52). These are diseases caused by organisms that are not usually considered pathogenic,
unusual presentations of known pathogens, and the occurrence of tumours that may have an oncogenic viral aetiology. Susceptibility increases as the patient becomes more immunosuppressed. CD4 T lymphocyte numbers are used as markers to predict the risk of infection. Patients with CD4 counts above 200 are at low risk for the majority of AIDS-defining OIs. A hierarchy of thresholds for specific infectious risks can be constructed. Mechanisms include defective T cell function against protozoa, fungi and viruses, impaired macrophage function against intracellular bacteria such as Mycobacteria and Salmonella and defective B cell immunity against capsulated bacteria such as Strep. pneumoniae and Haemophilus. Many of the organisms causing clinical disease are ubiquitous in the environment or are already carried by the patient.

Diagnosis in an immunosuppressed patient may be complicated by a lack of typical signs, as the inflammatory response is impaired. Examples are lack of neck stiffness in cryptococcal meningitis or minimal clinical findings in early Pneumocystis jiroveci pneumonia. Multiple pathogens may coexist. Indirect serological tests are frequently unreliable. Specimens should be obtained from the appropriate site for examination and culture in order to make a diagnosis.

**INVESTIGATIONS AND MONITORING OF HIV-INFECTED PATIENTS**

**Initial assessment**

A full medical history, physical examination and laboratory evaluation should be undertaken in all newly diagnosed patients to determine the stage of infection, the presence of co-morbidities and co-infections, and to assess overall physical, mental and sexual health. The initial assessment should also include details of socio-economic situation, relationships, family and social support networks, and substance misuse. Baseline investigations will depend on the clinical setting, but those appropriate for an asymptomatic person in the UK are shown in Box 4.18.

**Box 4.18** Baseline investigations in a newly diagnosed asymptomatic patient with HIV infection

- **Haematology**
  - Full blood count, differential count and film

- **Biochemistry**
  - Serum, liver and renal function
  - Fasting serum lipid profile
  - Fasting blood glucose

- **Immunology**
  - Lymphocyte subsets
  - HLA B*5701 status

- **Virology**
  - HIV antibody (confirmatory)
  - HIV viral load
  - HIV genotype
  - Hepatitis serology (A, B and C)
  - Cytomegalovirus antibody

- **Microbiology**
  - Toxoplasmosis serology
  - Syphilis serology
  - Screen for other sexually transmitted infections

- **Other**
  - Cervical cytology
  - Chest X-ray if indicated

**Monitoring**

Patients are regularly monitored to assess the progression of the infection and its treatment. Clinical examination will identify signs of immunosuppression (such as oral hairy leukoplakia) and detect early evidence of major opportunistic events. Decisions about appropriate intervention can be made.

**Immunological monitoring**

**CD4 lymphocytes.** The absolute CD4 count and its percentage of total lymphocytes falls as HIV progresses. These figures bear a relationship to the risk of the occurrence of HIV-related pathology, with patients with counts below 200 cells at greatest risk. Rapidly falling CD4 counts and those below 350 are an indication for HAART. Factors other than HIV (e.g. smoking, exercise, intercurrent infections and diurnal variation) also affect CD4 numbers. CD4 counts are performed at approximately 3-monthly intervals unless values are approaching critical levels for intervention, in which case they are performed more frequently.

**Virological monitoring**

**Viral load (HIV RNA)**

HIV replicates at a high rate throughout the course of infection, with many billion new virus particles being produced daily. The rate of viral clearance is relatively constant in any individual and thus the level of viraemia is a reflection of the rate of virus replication. This has both prognostic and therapeutic value.

The commonly used term ‘viral load’ encompasses viraemia and HIV RNA levels. Three HIV RNA assays for viral load are in current use:
Results are given in copies of viral RNA per millilitre of plasma, or converted to a logarithmic scale, and there is good correlation between tests. The most sensitive test is able to detect as few as 20 copies of viral RNA per millilitre. Transient increases in viral load are seen following immunisations (e.g. for influenza and *Pneumococcus*) or during episodes of acute intercurrent infection (e.g. *tuberculosis*); and viral load measurements should not be carried out within a month of these events.

By about 6 months after seroconversion to HIV, the viral set-point for an individual is established and there is a correlation between HIV RNA levels and long-term prognosis, independent of the CD4 count. Those patients with a viral load consistently greater than 100,000 copies/mL have a 10 times higher risk of progression to AIDS over the ensuing 5 years than those consistently below 10,000 copies/mL.

HIV RNA is the standard marker of treatment efficacy (see below). Both duration and magnitude of virus suppression are pointers to clinical outcome. None of the currently available therapies appears to be able to suppress viral replication indefinitely, and a rising viral load, in a patient where compliance is assured, indicates drug failure.

Various guidelines exist for viral load monitoring in clinical practice. Baseline measurements are followed by repeat estimations at intervals of 3–4 months, ideally in conjunction with CD4 counts to allow both pieces of evidence to be used together in decision-making. Following initiation of antiretroviral therapy or changes in therapy, effects on viral load should be seen by 4 weeks, reaching a maximum at 10–12 weeks, when repeat viral load testing should be carried out (Fig. 4.45).

Genotype determination

Clear genotype variations exist within HIV, not only between viral subtypes but also with well-identified point mutations associated with antiretroviral drugs. New infections with drug-resistant variants of HIV have been increasing. Viral genotype analysis is recommended for all newly diagnosed patients with HIV. The most appropriate sample is the one closest to the time of diagnosis.

** MANAGEMENT OF THE HIV-INFECTED PATIENT (Box 4.19)**

Since the advent of highly active antiretroviral therapy (HAART) in 1997, management in the resource-rich world has moved away from treating opportunistic conditions in immunosuppressed patients towards delivering long-term, effective suppressive therapy.

Nevertheless, there is still no cure for HIV and patients must live with a chronic, infectious and unpredictable condition. Limitations to efficacy include the inability of current drugs to clear HIV from certain intracellular pools, the occurrence of serious drug side-effects, strict adherence requirements, complex drug–drug interactions and the ongoing emergence of resistant viral strains.

The aims of management in HIV infection are to maintain physical and mental health, improve the quality of life, increase survival rates, restore and improve immune function, avoid onward transmission of the virus and to provide appropriate palliative support as needed. This requires long-term, maximal suppression of HIV activity using antiretroviral medication and management via a multidisciplinary team approach. Confidentiality must be strictly observed and care taken over establishing who is aware of the patient’s diagnosis and who is excluded from that knowledge. Psychological support is needed not only for the patient but also for family, friends and carers. Dietary assessment and advice should be freely accessible. Clear advice on reducing the risk of HIV transmission must be provided and future sexual practices discussed. Information must be available to allow people to make informed choices about childbearing. The implications for existing family members should be considered. General health promotion advice on smoking, alcohol, diet, drug misuse and exercise should be given, particularly in the light of the cardiovascular, metabolic and hepatotoxicity risks associated with HAART (see p. 192).
Antiretroviral drugs (ARVs)

(see Table 4.53)

The treatment of HIV using antiretroviral therapy (HAART) continues to evolve and improve. Increased potency, reduced toxicity, greater convenience of formulation, compounds with different mechanisms of action coupled with improved understanding of drug resistance have combined to make HIV a manageable condition. However, increasing numbers of compounds, the array of drug–drug interactions, for example, combine to make HIV treatment complex, and better clinical outcomes have been linked closely to physician expertise and the numbers of patients under direct care. Regularly updated treatment guidelines are produced in the UK by the British HIV Association (www.BHIVA.org.uk) and in the USA by the Department of Health and Human Services (http://www.aidsinfo.nih.gov/ContentFiles/AdultandAdolescentGL.pdf). The most up-to-date versions can be found on these websites and the current version must be used.

The key practical principles of prescribing ARVs are given in Box 4.20.

Reverse transcriptase inhibitors

- Nucleoside/nucleotide analogues. Nucleoside reverse transcriptase inhibitors (NRTIs) inhibit the synthesis of DNA by reverse transcription and also act as DNA chain terminators. NRTIs need to be phosphorylated intracellularly for activity to occur. These were the first group of agents to be used against HIV, initially as monotherapy and later as dual drug combinations. Usually two drugs of this class are combined to provide the ‘backbone’ of a HAART regimen. Several fixed dose NRTI combinations are available, which helps reduce the pill burden. NRTIs have been associated with mitochondrial toxicity (see p. 198), a consequence of their effect on the human mitochondrial DNA polymerase. Lactic acidosis is a recognized complication of this group of drugs. Nucleotide analogues (nucleotide reverse transcriptase inhibitors (NRTIs)) have a similar mechanism of action but only require two intracellular phosphorylation steps for activity (as opposed to the three steps for nucleoside analogues). Tenofovir, a monophosphorylated thymidine derivative, is the only licensed compound of this group.

- Non-nucleoside analogues. Non-nucleoside reverse transcriptase inhibitors (NNRTIs) interfere with reverse transcriptase by direct binding to the enzyme. They are generally small molecules that are widely disseminated throughout the body and have a long half-life. NNRTIs affect cytochrome P450. They are ineffective against HIV-2. The level of cross-resistance across the class is very high. All have been associated with rashes and elevation of liver enzymes. A second-generation NNRTI, etravirine, has now been developed with activity against viruses resistant to other compounds of the NNRTI class.

Protease inhibitors (PIs)

These act competitively on the HIV aspartyl protease enzyme, which is involved in the production of functional viral proteins, and enzymes. As a consequence, viral maturation is impaired and immature dysfunctional viral particles are produced. Most of the protease inhibitors are active at very low

</tbody>
</table>

Concentrations and in vitro are found to have synergy with reverse-transcriptase inhibitors. However there are differences in toxicity, pharmacokinetics, resistance patterns and also cost, which influence prescribing. Cross-resistance occurs across the PI group, which can make it difficult to use the drugs sequentially. There appears to be no activity against human aspartyl proteases (e.g. renin), although there are clinically significant interactions with the cytochrome P450 system. This is used to therapeutic advantage, ‘boosting’ blood levels of PI by blocking drug breakdown with small doses of ritonavir. PIs have been linked with abnormalities of fat metabolism and control of blood sugar, and some have been associated with deterioration in clotting function in people with haemophilia. Second generation PIs (e.g. darunavir, tipranavir) with activity against viruses resistant to the first generation drugs are now available.

### Fusion inhibitors

Enfuvirtide is the only licensed compound in this class of agents. It is an injectable peptide derived from HIV gp41 that inhibits gp41-mediated fusion of HIV with the target cell. It is synergistic with NRTIs and PIs. Although resistance to enfuvirtide has been described, there is no evidence of cross-resistance with other drug classes. Because it has an extracellular mode of action there are few drug–drug interactions. Side-effects relate to the subcutaneous route of administration in the form of injection site reactions.

### Co-receptor blockers

The only drug available so far is maraviroc (Celsentri), a chemokine receptor antagonist which blocks the cellular CCR5 receptor entry by CCR5 tropic strains of HIV. These strains are found in earlier HIV infection and, with time adaptations (against which maraviroc is ineffective) allow the CXCR4 receptor to become the most dominant form. The drug is metabolized by CYP p450 (3A), giving the potential for drug–drug interactions.

### Integrase inhibitors

These drugs act as a selective inhibitor of HIV integrase, which blocks viral replication by preventing insertion of HIV DNA into the human DNA genome. Three compounds, have so far been developed, although only one, raltegravir, has a European licence. Raltegravir is metabolized by glucuronidation, and does not require retroviral drug boosting. Toxicity profile appears favourable in the short term and long-term durability data is awaited. It is effective in both treatment of experienced and naive patients.

### Starting therapy

Treatment regimens for HIV infection require a long-term commitment to high levels of adherence. Risks of therapy include serious side-effects, drug interactions and the potential for development of resistant viral strains. The full involvement of patients in therapeutic decision-making is essential for success. Various national guidelines and treatment framework exist (e.g. BHIVA Guidelines, DHHS Guidelines and IAS Recommendations). A combination of clinical assessment and laboratory marker data, including viral load and CD4 counts, together with individual circumstances, should guide therapeutic decision-making. The current UK recommendations are shown in Table 4.54. In situations where therapy is recommended but the patient elects not to start, then more intensive clinical and laboratory monitoring is advisable.

Clear clinical benefit has been demonstrated with the use of antiretroviral drugs in advanced HIV disease. Treatment should be recommended for all patients with symptomatic HIV disease, AIDS or a CD4 count that is consistently below
200 cells/mm³. In such situations there is a significant risk of serious HIV-associated morbidity and mortality.

In asymptomatic patients the absolute CD4 count is the key investigation used to guide treatment decisions. Counts below 200 cells/mm³ are strongly associated with disease progression and death. The outcome for patients initiating therapy below 200 CD4 cells/mm³ is not as good as for those who start at higher counts. The UK recommendation is that therapy should be started before the count falls below 200. Due to late presentation of HIV in the UK almost two-thirds of patients initiating ARVs in 2006 had a CD4 count below 200.

There are no randomized trials of when to start therapy in patients with higher CD4 cell counts. The risk of disease progression for individuals with a count greater than 350 is low, and has to be balanced against ARV therapy toxicity and development of resistance. Earlier intervention at higher CD4 counts is being debated but the recommendation remains to begin therapy at a CD4 count between 350 and 201 cells/mm³ and those with a higher risk of disease progression, e.g. with high viral loads (>60,000 copies/mL) or rapidly falling CD4 count (losing more than 80 cells/year). Co-infection with hepatitis C virus is also a factor for earlier intervention (see p. 340).

Treatment for primary HIV infection is only recommended either within a clinical trial or to alleviate symptoms.

Special situations (seroconversion, pregnancy, post-exposure prophylaxis) in which antiretroviral agents may be used are described on page 198.

**Choice of drugs**

The drug regimen used for starting therapy must be individualized to suit each patient’s needs. Treatment is initiated with three drugs, two NRTIs in combination, with either a NNRTI or a boosted protease inhibitor (Tables 4.53 and 4.55).

**Nucleoside reverse transcriptase inhibitor (NRTI)**

Two NRTIs to form a backbone is increasingly influenced by both efficacy and ease of administration. The availability of the once daily one-tablet fixed-dose combinations, *Truvada* (TDF/FTC) and *Kivexa* (ABC/3TC) has led to the majority of patients who are naïve to medication being prescribed one of these as their 2NRTI backbone. Kivexa should only be used in those who are HLA-B*5701 negative. *Combivir* (ZDV/3TC), with a twice-daily dosing schedule and poorer toxicity profile, is now less frequently prescribed. Comparison of Truvada with Combivir showed more virological failure in the Combivir arm. Head to head efficacy data comparing Truvada and Kivexa in naïve patients has demonstrated non-inferiority of Kivexa at viral levels below 100000 copies/mL. In patients with high viral levels Kivexa should be reserved for use when Truvada is contraindicated. *Stavudine* is associated with lipodystrophy and peripheral neuropathy and is rarely used as first line therapy in the UK, although it continues to be used widely in other parts of the world.

**Non-nucleoside reverse transcriptase inhibitor (NNRTI)**

The decision about use of NNRTI or boosted PI will depend on the particular circumstances of each patient but in the UK, based on clinical trial data, an NNRTI-based regimen is most commonly prescribed to treat naïve patients.

Efavirenz is the recommended option in the UK, having demonstrated good durability over time, potency at low CD4 counts and in high viral loads. Efavirenz has the advantage of once-daily dosing but is associated with CNS side-effects such as dysphoria and insomnia, and is contraindicated in pregnancy. A new fixed dose preparation of efavirenz co-formulated with Truvada (Atripla) allows for a ‘one pill once a day’ regimen.

Nevirapine is of equivalent potency to efavirenz but has a higher incidence of hepatotoxicity and rash and is taken twice daily. Toxicity is greater in women and in those with higher CD4 counts. It is contraindicated in women with CD4 counts above 250 cells and in men with counts above 400. However it a useful alternative to efavirenz if CNS side-effects are troublesome and in women with lower CD4 counts who wish to conceive.

Etravirine is a new, second generation NNRTI, active against drug-resistant strains and useful in treatment of experienced patients.
**Protease inhibitor**

This class of drugs have demonstrated excellent efficacy in clinical practice. PIs combined with a low dose of ritonavir (a boosting PI) provides a pharmacokinetic advantage and is now most commonly used in naïve patients. Using this approach, the half-life of the active drug is increased, allowing greater drug exposure, fewer pills with enhanced potency and the risk of resistance minimized. The disadvantage of this approach is a possible risk of greater lipid abnormalities, particularly raised fasting triglycerides.

Either **lopinavir/ritonavir** or **fosamprenavir/ritonavir** (both taken twice daily) are recommended for first line therapy, with **saquinavir/ritonavir** as an alternative. All three regimens commonly cause GI disturbance and lipid abnormalities. **Atazanavir/ritonavir** is a once-daily regimen, but atazanavir (not currently licensed for naïve use in the UK) produces an isolated, unconjugated hyperbilirubinaemia. **Tipranavir** and **darunavir** both active against some PI-resistant strains are currently only used in treatment-experienced patients although trial data is emerging on use of darunavir in naïve patients.

In summary, recent comparative data show that three NNRTIs, although able to produce good levels of viral suppression in treatment-naïve patients, are less efficacious than combining two NNRTIs with either an NNRTI or a PI and are no longer recommended. Despite interest in the use of PI monotherapy in some situations, the current data does not support its use in treatment-naïve patients outside a clinical trial.

**Monitoring therapy** (Box 4.21)

Virological success of HAART is taken to be a viral load of less than 50 copies/mL within 3–6 months of starting therapy. Once therapy has been initiated the viral load should be measured at 4 weeks to assess efficacy. The durability of the virological response is linked both to the rate of viral load fall and the absolute nadir attained. Viral load and CD4 count should be measured at 12 weeks and then at 3-monthly intervals. Regular clinical assessment should include review of adherence to and tolerability of the regimen, weight, blood pressure and urinalysis. Patients should be monitored for drug toxicity, including full blood count, liver and renal function and fasting lipids and glucose levels.

**Drug resistance** (Box 4.22)

Resistance to ARVs results from mutations in the protease and reverse transcriptase genes of the virus. HIV has a rapid turnover with $10^7$ replications occurring per day. The error rate is high, resulting in genetic diversity within the population of virus in an individual, which will include drug-resistant mutants. When drugs only partially inhibit virus replication there will be a selection pressure for the emergence of drug-resistant strains. The rate at which resistance develops depends on the frequency of pre-existing variants and the number of mutations required. Resistance to most NNRTIs and PIs occurs with an accumulation of mutations, whilst a single-point mutation will confer high-level resistance to NNRTIs. There is evidence for the transmission of HIV strains that are resistant to all or some classes of drugs. Studies of primary HIV infection have shown prevalence rates between 2% and 20%. Prevalence of primary mutations associated with drug resistance in chronically infected patients not on treatment ranges from 3% to 10% in various studies.

**HIV antiretroviral drug resistance testing** has become routine clinical management in patients at diagnosis/before starting therapy and for whom therapy is failing. Genotypic assays to determine the genetic structure of the reverse transcriptase (RT) and protease genes of HIV are available. The tests are based on PCR amplification of virus and give an indirect measure of drug susceptibility in the predominant variants. Such assays are limited both by the starting concentration of virus, most assays requiring at least 1000 copies/mL of blood, and by their poor ability to detect minority strains.
For results to be useful in situations where therapy is failing, samples must be analysed when the patient is on therapy, as once the selection pressure of therapy is withdrawn, wild type virus becomes the predominant strain and resistance mutations present earlier may no longer be detectable.

Databases containing nearly all published HIV (amongst others) and protease sequences, and associated resistance patterns, are maintained in real time by Stanford University and can be accessed at http://hivdb.stanford.edu.

Phenotypic assays provide a more direct measure of susceptibility but the complexity of the assays limits availability.

**Drug interactions**

Drug therapy in HIV is highly complex and the potential for clinically relevant drug interactions is substantial. Both PIs and NNRTIs are able to variably inhibit and induce cytochrome P450, influencing both their own and other drug metabolic rates. Both inducers and inhibitors of cytochrome P450 are sometimes prescribed simultaneously. Induction of metabolism may result in sub-therapeutic antiretroviral drug levels with the risk of treatment failure and development of viral resistance, whilst inhibition can raise drug levels to toxic values and precipitate adverse reactions.

Conventional (e.g. rifamycins) and complementary therapies (e.g. St John’s Wort) affect cytochrome P450 activity and may precipitate substantial drug interactions. Therapeutic drug monitoring (TDM) indicating peak and trough plasma levels may be useful in certain settings.

Potential interactions can be checked using the online tool maintained by Liverpool University at www.hiv-druginteractions.org.

**Adherence**

Adherence to treatment is pivotal to success. Levels of adherence below 95% have been associated with poor virological and immunological responses. Poor absorption and low bioavailability mean that for some compounds trough levels are barely adequate to suppress viral replication and missing even a single dose will result in plasma drug levels falling dangerously low. Patchy adherence facilitates the emergence of drug-resistant variants, which in time will lead to virological treatment failure.

Factors implicated in poor adherence may be associated with the medication, with the patient or with the provider. The former include side-effects associated with medications, the degree of complexity and pill burden and inconvenience of the regimen. Patient factors include the level of motivation and commitment to the therapy, psychological well-being, the level of available family and social support, and health beliefs. Supporting adherence is a key part of clinical care and specific guidelines are available (BHIVA 2004). Education of patients about their condition and treatment is a fundamental requirement for good adherence, as is education of clinicians in adherence support techniques. Provision of acute and ongoing multidisciplinary support for adherence within clinical settings should be universal. Medication-alert devices may be useful for some patients.

**Treatment failure**

Failure of antiretroviral treatment, i.e. persistent viral replication causing immunological deterioration and eventual clinical evidence of disease progression, is caused by a variety of factors, e.g. limited drug potency and food or other medi-
cation may compromise drug absorption. There may be drug interactions or limited penetration of drug into sanctuary sites such as the CNS, permitting viral replication. Side-effects and other patient-related elements contribute to poor adherence.

**Changing therapy**

A rise in viral load, a falling CD4 count or new clinical events that imply progression of HIV disease are all reasons to review therapy. Reasons for treatment failure include the emergence of resistant viral strains, poor patient adherence or intolerance/adverse drug reactions. Virological failure, i.e. two consecutive viral loads of greater than 400 copies/mL in a previously fully suppressed patient requires investigation. Viral genotyping should be used to help select future therapy. If a new suitable treatment option is available it should be started as soon as possible.

Treatment failure in highly treatment-experienced patients poses considerable challenges, but new classes of antiretroviral agents with activity against drug-resistant strains of HIV, makes long-term virological suppression a realistic objective, even in heavily pre-treated patients. However, in some situations it may be better to hold back a new drug and await development of another new agent to give the maximum chance of success.

If the patient has a viral load below the limit of detection and a change needs to be made because of intolerance of a particular drug, then a switch to another sensitive drug within the same class should be made. Simplification of complex regimens may be considered if adherence is problematic.

**Stopping therapy**

Antiretroviral drugs may have to be stopped in, for example, cumulative toxicity, or potential drug interactions with medications needed to deal with another more pressing problem. If adherence is poor, stopping completely may be preferable to continuing with inadequate dosing, in order to reduce the development of viral resistance. Poor quality of life and the view of the patient should be discussed.

NNRTIs efavirenz and nevirapine have long half-lives and therefore should be stopped before the other drugs in the mixture to reduce the risk of drug resistance. If this is not possible, lopinavir/ritonavir may be used either in substitution of the NNRTI or as monotherapy for several weeks to cover the period of subtherapeutic levels.

**Structured treatment interruptions (STIs)** were tried to enhance HIV-specific immune responses or to reduce the exposure to drugs and limit adverse events. However, rapid viral rebound, the adverse effects of viral rebound on the immune system and falling CD4 count in already immunosuppressed patients is a major problem.

New data from a large international trial, the SMART study, on intermittent antiretroviral therapy (even with CD4 counts above 250 cells/mL) suggests these patients do less well than those on continuous therapy. Current British guidance does not support treatment interruption as a standard of care.

**Complications of antiretroviral therapy**

Side-effects are a common problem in HAART (Table 4.53). Some are acute and associated with initiation of medication, whilst others emerge after longer-term exposure to drugs.
Allergic reactions

Allergic reactions occur with greater frequency in HIV infection and have been documented with all the antiretroviral drugs. Abacavir is associated with a potentially fatal hypersensitivity reaction, strongly associated with the presence of HLAB*5701, usually within the first 6 weeks of treatment. There may be a discrete rash and often a fever coupled with general malaise and gastrointestinal and respiratory symptoms. The diagnosis is clinical and symptoms resolve when abacavir is withdrawn. Re-challenge with abacavir can be fatal and is contraindicated. In the UK routine screening for the HLAB*5701 allele has reduced the incidence of abacavir hypersensitivity. Allergies to NNRTIs (often in the second or third week of treatment) usually present with a widespread maculopapular pruritic rash, often with a fever and disordered liver biochemical tests. Reactions can resolve even with continuing therapy but drugs should be stopped immediately in any patient with mucous membrane involvement or severe hepatic dysfunction.

Lipodystrophy and metabolic syndrome

A syndrome of lipodystrophy occurs in patients with HIV on HAART comprising characteristic morphological changes and metabolic abnormalities. The main characteristics include a loss of subcutaneous fat in the arms, legs and face (lipoatrophy), deposition of visceral, breast and local fat, raised total cholesterol, HDL cholesterol and triglycerides, and insulin resistance with hyperglycaemia. The syndrome is potentially associated with increased cardiovascular morbidity. The aetiology is unclear although PIs and NRTIs have been implicated. The highest incidence occurs in those taking combinations of NRTIs and PIs. Stavudine and zidovudine are associated with the lipoatrophy component of the process. The syndrome is difficult to treat, and switching or stopping therapy may not always reverse the processes, although switching away from a stavudine and/or PI-based therapy is recommended. Dietary advice and increasing exercise may improve some of the metabolic problems and help body shape. The addition of glitazones, metformin and growth hormone have been tried. Statins and fibrates are recommended to reduce circulating lipids. Pravastatin has fewer interactions with protease inhibitors but simvastatin is contraindicated as it has high levels of drug interactions with PIs. Surgical approaches are useful in improving facial appearance following lipoatrophy. Polylactic acid injections (New-Fill) have provided improvement in some patients.

Mitochondrial toxicity and lactic acidosis

Mitochondrial toxicity, mostly involving the nucleoside analogue class, leads to raised lactate and lactic acidosis, which has in some cases been fatal. NRTIs inhibit gamma DNA polymerase, and other enzymes that are necessary for normal mitochondrial function. Symptoms are often vague and insidious and include anorexia, nausea, abdominal pain and general malaise. Venous lactate is raised, and the anion gap is typically widened. This is a serious condition requiring immediate cessation of antiretroviral therapy and provision of appropriate supportive measures until normal biochemistry is restored. All patients should be alerted to possible symptoms and encouraged to attend hospital promptly.

Bone metabolism

A variety of bone disorders have been reported in HIV, in particular osteopenia, osteoporosis and avascular necrosis.

The prevalence of these conditions has varied widely in different studies. Antiretroviral agents, particularly PIs, have been implicated in the aetiology, although untreated HIV is believed to have a direct impact on bone metabolism.

IRIS

Paradoxical inflammatory reactions (immune reconstitution inflammatory syndrome, IRIS) may occur on initiating HAART. This occurs usually in people who have been profoundly immunosuppressed and begin therapy. As their immune system recovers, they are able to mount an inflammatory response to a range of pathogens, which can include exacerbation of symptoms with new or worsening of clinical signs. Examples include unusual mass lesions or lymphadenopathy associated with mycobacteria, including deteriorating radiological appearances associated with TB infection. Inflammatory retinal lesions in association with cytomegalovirus, deterioration in liver function in chronic hepatitis B carriers and vigorous vesicular eruptions with herpes zoster have also been described.

Specific therapeutic situations

Acute seroconversion

Antiretroviral therapy in patients presenting with an acute seroconversion illness is controversial. This stage of disease may represent a unique opportunity for therapy as there is less viral diversity, and the host immune capacity is still intact. There is evidence to show that the viral load can be reduced substantially by aggressive therapy at this stage, although it rises when treatment is withdrawn. The longer-term clinical sequelae of treatment at this stage remain uncertain. People with severe symptoms during primary HIV infection may gain a clinical improvement on antiretrovirals. If treatment is contemplated in this situation, entry into a clinical trial is sensible.

Pregnancy

Management of HIV-infected pregnant women requires close collaboration between obstetric, medical and paediatric teams. The aim of HIV management is to deliver a healthy, uninfected baby to a healthy mother without prejudicing the future treatment options of the mother. Although considerations of pregnancy must be factored into clinical decision-making, pregnancy per se should not be a contraindication to providing optimum HIV-related care for the woman. HIV-positive women should be advised against breast-feeding, which doubles the risk of vertical transmission. Delivery by caesarean section reduces the risk of transmission but if the patient is on HAART is unnecessary. For women eligible for treatment of their own HIV disease, whether pregnant or not, triple therapy is the regimen of choice. Risk of vertical transmission increases with viral load. Although the fetus will be exposed to more drugs, the chances of reducing the viral load and hence preventing infection are greatest with a potent triple therapy regimen in the mother.

Treatment should start from 12–14 weeks of pregnancy and continue during delivery. Zidovudine is the usual choice with the baby receiving zidovudine for 6 weeks postpartum. The woman should remain on treatment with appropriate monitoring and support.

Women who do not need treatment for themselves should be prescribed a short course of antiretroviral therapy initiated
between 22 and 28 weeks of pregnancy to reduce vertical transmission. Treatment of the mother with zidovudine monotherapy is at variance with the data on combination therapy for adults as described above, but remains a viable option for a selected group of patients (see BHIVA pregnancy guidelines). Efavirenz has been associated with developmental abnormalities in primate models and several retrospective cases of neural tube defects in babies born to women taking efavirenz have been reported. Efavirenz should not be initiated in pregnancy and women who have conceived on the drug should discuss the risks and benefits of continuing or switching with an expert clinician.

Details of adverse effects associated with ARVs in pregnancy is maintained by the antiretroviral pregnancy registry which holds prospective international data and is regularly updated (www.apregistry.com).

Post-exposure prophylaxis
Healthcare workers following occupational exposure to HIV may need antiretroviral therapy. The British recommendation is zidovudine, lamivudine and lopinavir/ritonavir for 4 weeks. Prophylaxis after sexual exposure may be appropriate in certain situations, in particular rape or in HIV-discordant relationships. The choice of drugs will depend on the clinical setting and what is known of the HIV source.

### Opportunistic infections in the HAART era

Since the introduction of HAART in 1996, the USA and Europe have witnessed a sustained fall in opportunistic infection (OI) and mortality. In the USA deaths that included AIDS-related causes decreased from 3.79/100 person-years in 1996 to 0.32/100 person-years in 2004. Death rates across Europe fell fivefold between 1995 and 1998. European data showed a fall in AIDS-defining illnesses (ADI) from 30.7 per 100 patient-years of observation to 2.5 per 100 patient-years between 1994 and 1998, with patients on HAART having a lower rate of ADIs than patients not on HAART. This trend has continued – recent data from Europe demonstrate a 50% lower incidence of AIDS in 1998–2001 than in 1996–1998, irrespective of CD4 count. Potential long-term adverse effects associated with HAART have not altered its effectiveness in treating AIDS. However the decline has been steeper for some OIs than others, suggesting that the immune reconstitution due to HAART may not be functionally equal against all HIV-associated complications. Not all patients have adequate responses to these medications, even if they are available and tolerable. Immune reconstitution with HAART may produce unusual responses to opportunistic pathogens and confuse the clinical picture. Thus prevention and treatment of OIs remains an integral part of the management of HIV infection.

**Prevention of opportunistic infection in HIV-infected patients**

**Avoid infection**
Exposure to certain organisms can be avoided in those known to be HIV infected. Attention to food hygiene will reduce exposure to salmonella, toxoplasmosis and *Cryptosporidium*, and protected sexual intercourse will reduce exposure to herpes simplex virus (HSV), hepatitis B and papillomaviruses. Cytomegalovirus (CMV)-negative patients should be given CMV-negative blood products.

**Immunization strategies** (Box 4.23)
Guidance on the appropriate use of vaccines in HIV is available from www.bhiva.org/files.

Immunization may not be as effective in HIV-infected individuals.

Hepatitis A and B vaccines should be given for those without natural immunity who are at risk, particularly if there is coexisting liver pathology, e.g. hepatitis C.

**Chemoprophylaxis**
In the absence of a normal immune response, many OIs are hard to eradicate using antimicrobials, and the recurrence rate is high. Primary and secondary chemoprophylaxis has reduced the incidence of many OIs. Advantages must be balanced against the potential for toxicity, drug interactions and cost, with each medication added to what are often complex drug regimens.

- **Primary prophylaxis** is effective in reducing the risk of
  - *Pneumocystis jiroveci*, toxoplasmosis and
  - *Mycobacterium avium-intracellulare*.

- **Primary prophylaxis** is **not** normally recommended against cytomegalovirus, herpesviruses or fungi.

With the introduction of HAART and immune reconstitution, ongoing chemoprophylaxis can be discontinued in those patients with CD4 counts that remain consistently above 200 and who have a low viral load. In developing countries unable to obtain HAART, long-term secondary prophylaxis is still advocated. Other less severe but recurrent infections may also warrant prophylaxis (e.g. herpes simplex, candidiasis).

SPECIFIC CONDITIONS ASSOCIATED WITH HIV INFECTION

Fungal infections

Pneumocystis jiroveci (formerly P. carinii) (see p. 861)

This organism most commonly causes pneumonia (PCP) but can cause disseminated infection. It is not usually seen until patients are severely immunocompromised with a CD4 count below 200. The infection remains common although the use of primary prophylaxis in patients with CD4 < 200 has reduced the incidence. The organism damages alveolar epithelium, which impedes gas exchange and reduces lung compliance.

The onset is often insidious over a period of weeks, with a prolonged period of increasing shortness of breath (usually on exertion), non-productive cough, fever and malaise. Clinical examination reveals tachypnoea, tachycardia, cyanosis and signs of hypoxia. Fine cracksles are heard on auscultation, although in mild cases there may be no auscultatory abnormality. In early infection the chest X-ray is normal but the typical appearances are of bilateral perihilar interstitial infiltrates, which can progress to confluent alveolar shadows throughout the lungs. High-resolution CT scans of the chest demonstrate a characteristic ground-glass appearance even when there is little to see on the chest X-ray. The patient is usually hypoxic and desaturates on exercise. Definitive diagnosis rests on demonstrating the organisms in the lungs via bronchoalveolar lavage or by PCR amplification of the fungal DNA from a peripheral blood sample. As the organism cannot be cultured in vitro it must be directly observed either with silver staining or immunofluorescent techniques.

Treatment should be instituted as early as possible. First-line therapy is with intravenous co-trimoxazole (120 mg/kg daily in divided doses) for 21 days. Up to 40% of patients receiving this regimen will develop some adverse drug reaction, including a typical allergic rash. If the patient is sensitive to co-trimoxazole, intravenous pentamidine (4 mg/kg per day) or dapsone and trimethoprim are given for the same duration. Atovaquone or a combination of clindamycin and primaquine is also used. In severe cases (PaO2 less than 9.5 kPa), systemic corticosteroids have been shown to reduce mortality and should be added. Continuous positive airways pressure (CPAP) or mechanical ventilation (see p. 915) is required if the patient remains severely hypoxic or becomes too tired. Pneumothorax not uncommonly complicates the clinical course in an already severely hypoxic patient.

Secondary prophylaxis is required in patients whose CD4 count remains below 200, to prevent relapse, the usual regimen being co-trimoxazole 960 mg three times a week. Patients sensitive to sulphonamide are given dapsone, pyrimethamine or nebulized pentamidine. The last only protects the lungs and does not penetrate the upper lobes particularly efficiently; hence if relapses occur on this regimen they may be either atypical or extrapulmonary.

Cryptococcus (see p. 151)

The most common presentation of cryptococcus infection in the context of HIV is meningitis, although pulmonary and disseminated infections can also occur. The organism, C. neoformans, is widely distributed – often in bird droppings – and is usually acquired by inhalation. The onset may be insidious with non-specific fever, nausea and headache. As the infection progresses the conscious level is impaired and changes in affect may be noted. Fits or focal neurological presentations are uncommon. Neck stiffness and photophobia may be absent as these signs depend on the inflammatory response of the host, which in this setting is abnormal.

Diagnosis is made on examination of the CSF (perform CT scan before lumbar puncture to exclude space-occupying pathology). Indian ink staining shows the organisms directly and CSF cryptococcal antigen is positive at variable titre. It is unusual for the cryptococcal antigen to become negative after treatment, although the levels should fall substantially. Cryptococci can also be cultured from CSF and/or blood.

Factors associated with a poor prognosis include a high organism count in the CSF, a low white cell count in the CSF, and an impaired consciousness level at presentation.

Treatment. Initial treatment is usually with intravenous amphotericin B (0.7 mg/kg per day) ± flucytosine as induction, although intravenous fluconazole (400 mg daily) is useful if renal function is impaired or if amphotericin side-effects are troublesome. Oral fluconazole 200 mg daily can be substituted if the organism is shown to be fully sensitive and the patient is responding, and should be continued lifelong unless the CD4 count is >100 for a 6-month period.

The mortality from a first episode of cryptococcal meningitis is up to 20%. Relapse is very common, possibly from a prostatic reservoir in men.

Candida (see p. 149)

Mucosal infection with Candida is very common in HIV-infected patients. Oral Candida is one of the most common conditions. C. albicans is the usual organism, although C. krusei and C. glabrata occur. Pseudomembranous candidiasis consisting of creamy plaques in the mouth and pharynx is easily recognized but erythematous Candida appears as reddened areas on the hard palate or as atypical areas on the tongue. Angular cheilitis can occur in association with either form. Vulvovaginal Candida is often problematic.

Oesophageal Candida infection produces odynophagia (see p. 255). Fluconazole or itraconazole are the agents of choice. With prolonged exposure to these agents in HIV-infected patients, azole-resistant C. albicans is becoming an increasing problem. Switching azoles may produce a response. Disseminated Candida is uncommon in the context of HIV infection but if present, fluconazole is the preferred drug with amphotericin, voriconazole or capsofungin also used. Itraconazole was formerly used. C. krusei or C. glabrata may colonize patients who have been treated with fluconazole, as it is fluconazole-resistant. Amphotericin is useful in the treatment of this infection and an attempt to type Candida from clinically azole-resistant patients should be made.

Aspergillus (see p. 151)

Infection with Aspergillus fumigatus occurs in advanced HIV disease. Patients with long-standing neutropenia (often due to chemotherapy) and those on ganciclovir therapy for CMV and myelotoxic antiretrovirals, are prone to this infection. Spores are airborne and ubiquitous. Following inhalation, lung infection proceeds to haematogenous spread to other organs. Sinus infection occurs.
The prognosis is very poor, with amphotericin B or voriconazole being the mainstay of therapy. Capsofungin is also effective. It is almost impossible to treat Aspergillus unless the neutrophil count can be sustained, often with granulocyte colony-stimulating factors.

**Histoplasmosis** (see p. 150)

This infection is a well-recognized complication of HIV in the USA where it is endemic in soil. The most common manifestation is with pneumonia, which may be confused with *Pneumocystis jiroveci* in its presentation (see above).

**Mucocutaneous dermatophyte infections**

(Table 4.51)

These infections are common (see p. 1232).

**Protozoal infections**

**Toxoplasmosis** (see p. 160)

*Toxoplasma gondii* most commonly causes encephalitis and cerebral abscess in the context of HIV, usually as a result of reactivation of previously acquired infection. The incidence depends on the rate of seropositivity to toxoplasmosis in the particular population. High antibody levels are found in France (90% of the adult population). About 25% of the adult UK population is seropositive to toxoplasma.

Clinical presentation is of a focal neurological lesion with convulsions, fever, headache and possible confusion. Examination reveals focal neurological signs in more than 50% of cases. Eye involvement with chorioretinitis may also be present. In most but not all cases of *Toxoplasma* serology is positive. Typically CT scan of the brain shows multiple ring-enhancing lesions. A single lesion on CT may be found to be one of several on MRI. A solitary lesion on MRI, however, makes a diagnosis of toxoplasmosis unlikely.

Diagnosis is by brain biopsy, but in most cases an empirical trial of anti-toxoplasmosis therapy is instituted and if this leads to radiological improvement within 3 weeks this is considered diagnostic. The differential diagnosis includes cerebral lymphoma, tuberculosis or focal cryptococcal infection.

Treatment is with pyrimethamine for at least 6 weeks (loading dose 200 mg, then 50 mg daily) combined with sulfadiazine and folic acid. Clindamycin and pyrimethamine may be used in patients allergic to sulphamethoxazole. Anticonvulsants should be given. Lifelong maintenance is required to prevent relapse unless the CD4 count can be restored by HAART.

**Cryptosporidiosis** (see p. 162)

*Cryptosporidium parvum* can cause a self-limiting acute diarrhoea in an immunocompetent individual. In HIV infection it can cause severe and progressive watery diarrhoea which may be associated with anorexia, abdominal pain, nausea and vomiting. Cysts attach to the epithelium of the small bowel wall, causing secretion of fluid into the gut lumen and failure of fluid absorption. It is also associated with sclerosing cholangitis (see p. 372). The cysts are seen on stool specimens using Kinyoun acid-fast stain and are readily identified in small bowel biopsy specimens.

HAART is associated with resolution of symptoms, otherwise treatment is largely supportive. There are no effective antimicrobial agents available other than paromomycin, which may have a limited effect on diarrhoea.

**Microsporidiosis**

*Enterocytozoon bieneusi* and *Septata intestinalis* are a cause of diarrhoea. Spores can be detected in stools using a trichrome or fluorescent stain that attaches to the chitin of the spore surface. HAART and immune restoration can have a dramatic effect and albendazole eradicates the infection.

**Leishmaniasis** (see p. 158)

This occurs in immunosuppressed HIV-infected individuals who have been in endemic areas, which include South America, tropical Africa and much of the Mediterranean. Symptoms are frequently non-specific with fever, malaise, diarrhoea and weight loss. Splenomegaly, anaemia and thrombocytopenia are significant findings. Amastigotes may be seen on bone marrow biopsy or from splenic aspirates. Serological tests exist for *Leishmania* but they are not reliable in this setting.

Treatment is based on sodium stibogluconate (pentavalent antimony) but liposomal amphotericin is the drug of choice if resources permit. Relapse without HAART is common unless long-term secondary prophylaxis is given.

**Viral infections**

**Hepatitis B and C viruses** (see pp. 335 and 340)

Because of the comparable routes of transmission of hepatitis viruses and HIV, co-infection is common, particularly in MSM, drug users and those infected by blood products. A higher prevalence of hepatitis viruses is found in those with HIV infection than in the general population. With the striking improvement in prognosis in HIV since the introduction of HAART, morbidity and mortality of hepatitis co-infection has become increasingly significant and may limit life expectancy in HIV. In co-infected patients the hepatotoxicity associated with certain antiretroviral agents may be potentiated. HBV vaccination (and HAV) should be given.

**Hepatitis B infection** does not appear to influence the natural history of HIV; however, in HIV co-infected patients there is a significantly reduced rate of hepatitis B e antigen (HBeAg) clearance, and the risk of developing chronic infection is increased. HBV reactivation and reinfec-

**Hepatitis C is** associated with more rapid progression of HIV infection, and the CD4 responses to HAART in co-infected patients may be blunted. Hepatitis C progression is both more likely and more rapid in the presence of HIV infection, and the hepatitis C viral load tends to be elevated. The hepatotoxicity associated with HAART is worse in those with HCV co-infection.
Assessment of co-infected patients requires full clinical and laboratory evaluation and staging of both infections. For HCV both viral load and genotype will influence therapeutic decision-making. In HBV infection, detection and quantification of HBV DNA acts as a marker of viral activity, whilst the significance of viral genotype is still uncertain. Liver biopsy is useful to obtain a histological staging of disease.

**Treatment** options in HCV co-infection are similar for those infected with HCV alone, depending on stage of disease and HCV genotype. Pegylated interferon has greater efficacy than standard interferon and is combined with ribavirin. In HIV/HCV co-infected patients those with a CD4 count above 200 have a better chance of success. In general it is preferable to treat HCV first if HIV infection is stable, as this minimizes hepatotoxicity associated with HAART. However, if the CD4 count is low or the patient is at risk of HIV progression, HIV therapy should be instituted first.

**Cytomegalovirus** (see p. 107)

CMV can be a cause of considerable morbidity in HIV-infected individuals, especially in the later stages of disease. The major problems encountered are retinitis, colitis, oesophageal ulceration, encephalitis and pneumonitis. CMV infection is associated with an arteritis, which may be the major pathogenic mechanism. CMV also causes polyradiculopathy and adrenalitis.

**CMV retinitis**

This tends to occur once the CD4 count is below 100 and has been found in up to 30% of AIDS cases. It is the most common cause of eye disease and blindness. Although usually unilateral to begin with, the infection frequently progresses to involve both eyes. Presenting features depend on the area of retina involved (loss of vision being most common with macular involvement) and include floaters, loss of visual acuity, field loss and scotomata, orbital pain and headache.

Examination of the fundus (Fig. 4.46) reveals haemorrhages and exudates, which follow the vasculature of the retina (so called ‘pizza pie’ appearances). The features are highly characteristic and the diagnosis is made clinically. Retinal detachment and papillitis may occasionally occur. If untreated, retinitis spreads within the eye, destroying the retina within its path. Routine fundoscopy should be carried out on all HIV-infected patients to look for evidence of early infection. Any patient with symptoms of visual disturbance should have a thorough examination with pupils dilated, and if no evident pathology is seen a specialist ophthalmologic opinion should be sought.

**Treatment** for CMV should be started as soon as possible with either ganciclovir (10 mg/kg daily) or foscarnet (60 mg/kg 8-hourly) given intravenously for at least 3 weeks, or until retinitis is quiescent. Reactivation is common, leading to blindness. The major side-effect of ganciclovir is myelosuppression, and foscarnet is nephrotoxic. Maintenance therapy may be required until HAART is instituted and has improved immune competence. Valganciclovir, an oral prodrug of ganciclovir, is available which has some long-term benefit when used as maintenance therapy, but has a lower efficacy than intravenous ganciclovir. Ganciclovir can be given directly into the vitreous cavity but regular injections are required. A sustained-release implant of ganciclovir can be surgically inserted into the affected eye. Cidofovir is available for use when the above drugs are contraindicated. It has renal toxicity.

**CMV gastrointestinal conditions**

**CMV colitis** usually presents with abdominal pain, often generalized or in the left iliac fossa, diarrhoea which may be bloody, generalized abdominal tenderness and a low-grade fever. Dilated large bowel may be seen on abdominal X-ray. Sigmoidoscopy shows a friable or ulcerated mucosa; histology shows the characteristic ‘owl’s eye’ cytoplasmic inclusion bodies (Fig. 4.18).

**Treatment** with either intravenous ganciclovir or foscarnet for 3 weeks improves symptoms and the histological changes are reversed. However, relapse is common once therapy is stopped, unless HAART is available. The issue of long-term maintenance therapy in this situation is controversial since, unlike CMV retinitis, repeated attacks of colitis do not necessarily have significant long-term sequelae. Given the complications associated with maintenance anti-CMV therapy there may be no overall benefit.

Other sites along the gastrointestinal tract are also prone to CMV infection, e.g. ulceration of the oesophagus, usually in the lower third, causes odynophagia. CMV can also cause hepatitis.

**CMV neurological conditions**

**CMV polyradiculopathy** usually affects the lumbosacral roots, leading to muscle weakness and sphincter disturbance. The CSF has an increase in white cells, which surprisingly are almost all neutrophils. Although progression may be arrested by anti-CMV medication, functional recovery may not occur.

CMV encephalopathy has clinical similarities to that caused by HIV itself. It tends to respond poorly to therapy.

**Herpesviruses** (see pp. 104 and 1230)

**Herpes simplex primary infection** occurs with greater frequency and severity, presenting in an ulcerative rather than vesicle form in profoundly immunosuppressed individuals. Genital, oral and occasionally disseminated infection is seen. Viral shedding may be prolonged in comparison with immunocompetent patients.
Varicella zoster virus

Varicella zoster can occur at any stage of HIV but tends to be more aggressive and longer-lasting in the more immunosuppressed patient. Multidermatomal zoster may occur.

Therapy with aciclovir is usually effective. Frequent recurrences need suppressive therapy. Aciclovir-resistant strains (usually due to thymidine kinase-deficient mutants) in HIV-infected patients have become more common. Such strains may respond to foscarnet.

Herpesvirus 8 (HHV-8) is the causative agent of Kaposi’s sarcoma (see p. 108).

Epstein–Barr virus (see p. 107)

Patients with HIV have been shown to have high levels of EBV colonization. There are increased EBV titres in oropharyngeal secretions and high levels of EBV-infected B cells. The normal T cell response to EBV is depressed in HIV. EBV is strongly associated with primary cerebral lymphoma and non-Hodgkin’s lymphoma (see below). Oral hairy leucoplaikia caused by EBV is a sign of immunosuppression first noted in HIV but now also recognized in other conditions. It appears intermittently on the lateral borders of the tongue or the buccal mucosa as a pale ridged lesion. Although usually asymptomatic, patients may find it unsightly and occasionally painful. The virus can be identified histologically and on electron microscopy. There is a variable response to aciclovir.

Human papillomavirus (see p. 108)

HPV produces genital, plantar and occasionally oral warts, which may be slow to respond to therapy and recur repeatedly. HPV is associated with the more rapid development of cervical and anal intraepithelial neoplasia, which in time may progress to squamous cell carcinoma of the cervix or rectum in HIV-infected individuals. HPV vaccination is now available (see p. 108).

Polyomavirus (see p. 108)

JC virus, a member of the papovavirus family, which infects oligodendrocytes, causes progressive multifocal leucoencephalopathy (PML). This leads to demyelination particularly within the white matter of the brain. The features are of progressive neurological and/or intellectual impairment, often including hemiparesis or aphasia. The course is usually inexorably progressive but a stuttering course may be seen. Radiologically the lesions are usually multiple and confined to the white matter. They do not enhance with contrast and do not produce a mass effect. MRI (Fig. 4.47) is more sensitive than CT and reveals enhanced signal on T2-weighted images of the lesions. Definitive diagnosis is made on histological and viral examination of brain tissue obtained at biopsy. There is no specific therapy. HAART which enhances the immune response has, however, produced both clinical and radiological remission in a number of cases. Addition of cidofovir to HAART may improve outcome in some patients.

Bacterial infections

Bacterial infection in HIV is common. Cell-mediated immune responses normally control infection against intracellular bacteria, e.g. Mycobacteria. The abnormalities of B cell function associated with HIV lead to infections with encapsulated bacteria, as reduced production of IgG2 cannot protect against the polysaccharide coat of such organisms. These functional abnormalities may be present well before there is a significant decline in CD4 numbers and so bacterial sepsis may be seen at early stages of HIV infection. Streptococcus pneumoniae, Haemophilus influenzae and Moraxella catharralis infections are examples. Bacterial infection is often disseminated and, although usually amenable to standard antibiotic therapy, may reoccur. Long-term prophylaxis is required if recurrent infection is frequent.

Mycobacteria

Mycobacterium tuberculosis (see p. 863)

Many parts of the world with a high prevalence of TB also have high rates of HIV infection, e.g. Africa, both of which are increasing. The respiratory transmission of TB means both HIV-positive and negative people are being infected. TB can cause disease when there is only minimal immunosuppression and thus often appears early in the course of HIV infection. HIV-related TB frequently represents reactivation of latent TB, but there is also clear evidence of newly acquired infection and nosocomial spread in HIV-infected populations.

The pattern of disease differs with immunosuppression.

- Patients with relatively well preserved CD4 counts have a clinical picture similar to that seen in HIV-negative patients with pulmonary infection.
- In more advanced HIV disease, atypical pulmonary presentations without cavitation and prominent hilar lymphadenopathy, or extrapulmonary TB affecting lymph nodes, bone marrow or liver occur. Bacteraemia may be present.

Diagnosis depends on demonstrating the organisms in appropriate tissue specimens. The response to tuberculin testing is blunted in HIV-positive individuals and is unreliable. Sputum microscopy may be negative even in pulmonary infection and culture techniques are the best diagnostic tool.

Treatment. M. tuberculosis infection usually responds well to standard treatment regimens, although the duration of therapy may be extended, especially in extrapulmonary infection. Multidrug resistance and extensive drug resistant TB (see p. 866) is becoming a problem, particularly in the USA where it is becoming a nosocomial danger. Cases from HIV units in the UK have been reported. Compliance with antituberculous therapy needs to be emphasized. Treatment of TB (see below) is not curative and long-term isoniazid prophylaxis may be given. In patients from TB-endemic areas, primary prophylaxis may prevent emergence of infection.
Drug–drug interactions between antiretroviral and antituberculous medications are complex and are a consequence of enzyme induction or inhibition. Rifampicin is a potent inducer of cytochrome P450, which is also the route for metabolism of HIV protease inhibitors. Using both drugs together results in a reduction in circulating protease inhibitor with reduced efficacy and increased potential for drug resistance. Some protease inhibitors themselves block cytochrome P450, which leads to potentially toxic levels of rifampicin and problems such as uveitis and hepatotoxicity. The non-nucleoside reverse transcriptase inhibitor class also interacts variably with rifamycins, requiring dose alterations. Additionally, there are overlapping toxicities between HAART regimens and antituberculous drugs, in particular hepatotoxicity, peripheral neuropathy and gastrointestinal side-effects. Rifabutin has a weaker effect on cytochrome P450 and may be substituted for rifampicin. Dose adjustments must be made for drugs used in this situation to take account of these interactions.

Paradoxical inflammatory reactions (immune reconstitution inflammatory syndrome, IRIS) which can include exacerbation of symptoms, new or worsening clinical signs and deteriorating radiological appearances have been associated with the improvement of immune function seen in HIV-infected patients starting HAART in the face of M. tuberculosis infection. They are most commonly seen in the first few weeks after initiation of HAART in patients recovering from TB and can last several weeks or months. The syndrome does not reflect inadequate TB therapy and is not confined to any particular combination of antiretroviral agents. It is vital to exclude new pathology in this situation. However delaying antiretroviral therapy increases the risks of further opportunistic events. Allowing at least two weeks of antituberculous therapy before commencing HAART allows some reduction in the burden of mycobacteria. If the CD4 count is less than 100 then antiretrovirals should be started at about 2 weeks of anti-TB medication. If the CD4 count is above 200 then initiation of HAART may wait for at least 6 weeks after the start of antituberculous therapy.

Mycobacterium avium-intracellulare
Atypical mycobacteria, particularly M. avium-intracellulare (MAI), generally appear only in the later stages of HIV infection when patients are profoundly immunosuppressed. It is a saprophytic organism of low pathogenicity that is ubiquitous in soil and water. Entry may be via the gastrointestinal tract or lungs with dissemination via infected macrophages. The major clinical features are fevers, malaise, weight loss, anorexia and sweats. Dissemination to the bone marrow causes anaemia. Gastrointestinal symptoms may be prominent with diarrhoea and malabsorption. At this stage of disease patients frequently have other concurrent infections, so differentiating MAI is difficult on clinical grounds. Direct examination and culture of blood, lymph node, bone marrow or liver give the diagnosis most reliably.

Treatment. MAI is typically resistant to standard antituberculous therapies, although ethambutol may be useful. Drugs such as rifabutin in combination with clarithromycin or azithromycin reduce the burden of organisms and in some ameliorate symptoms. A common combination is ethambutol, rifabutin and clarithromycin. Addition of amikacin to a drug regimen may produce a good symptomatic response. Primary prophylaxis with rifabutin or azithromycin may delay the appearance of MAI, but no corresponding increase in survival has been shown.

Infections due to other organisms
Salmonellae (non-typhoidal) (see p. 129) are frequent pathogens in HIV infection. Salmonellae are able to survive within macrophages, this being a major factor in their pathogenicity. Organisms are usually acquired orally and frequently result in disseminated infection. Gastrointestinal disturbance may be disproportionate to the degree of dissemination, and once the pathogen is in the bloodstream any organ may be infected. Salmonella osteomyelitis and cystitis have been reported. Diagnosis is from blood and stool cultures.

Response to standard antibiotic therapy, depending on laboratory sensitivities, is usually good. Recurrent infection is, however, common and long-term prophylaxis may be required.

Education on food hygiene should be provided.

Skin conditions such as folliculitis, abscesses and cellulitis are common and are usually caused by Staph. aureus.

Periodontal disease, which may be necrotizing, causes pain and damage to the gums. It is more common in smokers, but no specific causative agent has been identified. Therapy is with local debridement and systemic antibiotics.

Strongyloides (see p. 167), a nematode found in tropical areas, may produce a hyperinfection syndrome in HIV-infected patients. Larvae are produced which invade through the bowel wall and migrate to the lung and occasionally to the brain. Albendazole or ivermectin may be used to control infection. Gram-negative septicaemia can develop (see p. 899).

Scabies (see p. 1234) may be much more severe in HIV infection. It may be widely disseminated over the body and appear as atypical, crusted papular lesions known as ‘Norwegian scabies’, from which mites are readily demonstrated. Superadded staphylococcal infection may occur. Treatment with conventional agents such as lindane may fail, and ivermectin has been used to good effect in some patients.

Neoplasms
The mortality and morbidity associated with neoplasia in HIV is substantial, non-Hodgkin’s lymphoma being the most significant tumour now, ahead of Kaposi’s sarcoma.

Kaposi’s sarcoma (see p. 1260)
Kaposi’s sarcoma (KS) in association with HIV (epidemic KS) behaves more aggressively than that associated with HIV-negative populations (endemic KS). The incidence has fallen significantly since the introduction of HAART. The tumour is most common in men who have sex with men and others who have acquired HIV sexually, particularly from a partner who has KS, implicating a sexually transmitted cofactor in the pathogenesis. Human herpesvirus 8 (HHV-8) is involved in pathogenesis. KS skin lesions are characteristically pigmented, well circumscribed and occur in multiple sites. It is a multicentric tumour consisting of spindle cells and vascular endothelial cells, which together form slit-like spaces in which red blood cells become trapped. This process is responsible for the characteristic purple hue of the tumour. In addition to the skin lesions, KS affects lymphatics and lymph nodes, the lung and gastrointestinal tract, giving rise to a wide range of symptoms and signs. Most patients with visceral involvement also have skin or mucous membrane
lesions. Visceral KS carries a worse prognosis than that confined to the skin. Kaposi’s sarcoma is seen around the eye (Fig. 4.48), particularly in the conjunctivae, which can lead to periocular oedema.

Initiation of HAART may cause regression of lesions and prevent new ones emerging. Treatment with local radiotherapy gives good results in skin lesions and is helpful in lymph node disease. For patients with aggressive disease, systemic chemotherapy is indicated using combinations of vincristine and bleomycin or the newer liposomal preparations of doxorubicin. Response is often very good although of uncertain duration. Alpha-interferon is also effective.

**Lymphoma**

A significant proportion of patients with HIV develop lymphoma, mostly of the non-Hodgkin’s, large B cell type. These are frequently extranodal, often affecting the brain, lung and gastrointestinal tract. Many of these tumours are strongly associated with Epstein–Barr virus (EBV), with evidence of expression of latent gene nuclear antigens such as EBNA 1–6, some of which are involved in the immortalization of B cells and drive a neoplastic pathway.

HIV-associated lymphomas are frequently very aggressive. Patients often present with systemic ‘B’ syndromes and progress rapidly despite chemotherapy. Primary cerebral lymphoma is variably responsive to radiotherapy but overall carries a poor prognosis. Lymphomas occurring early in the course of HIV infection tend to respond better to therapy and carry a better prognosis, occasionally going into complete remission.

**Squamous cell carcinoma**

Squamous cell carcinoma, especially of the cervix and anus, is associated with HIV. Human papillomavirus infection has a role in the pathogenesis of these malignancies. Women with HIV infection should have yearly cervical cytology for detection of premalignant change.

**PREVENTION AND CONTROL**

As the numbers of new infections continue to rise, appropriate prevention interventions are fundamental to the control of the epidemic. Vaccine development has been hampered by the genetic variability of the virus and the complex immune response that is required from the host. Antiretroviral drugs are not a cure and are accessible only to a privileged minority of the world’s population. However data from discordant couples demonstrate that as well as a treatment strategy, effective antiretroviral medication is able to reduce onward transmission. Pre-exposure prophylaxis with antiretroviral agents has been considered but clinical trials have so far been challenging to design and implement. Use of a tenofovir-based regimen is being considered in a trial setting. Topical microbicides for intravaginal use are proving very slow to develop.

Strategies that have been shown to be effective include treatment of sexually transmitted infections, consistent use of condoms, use of clean needles and syringes for drug users and antiretroviral drugs to reduce mother-to-child transmission.

Medically performed circumcision has been shown in African studies of HIV-negative heterosexual men to reduce the female to male transmission of HIV by at least 50%. Male circumcision in HIV-positive men however has not been demonstrated to reduce male to female transmission.

Screening of blood products has reduced iatrogenic infection in developed countries but is expensive and not globally available.

Partner notification schemes are helpful but are sensitive and controversial. Availability and accessibility of confidential HIV testing provides an opportunity for individual health education and risk reduction to be discussed.

Understanding and changing behaviour is crucial but notoriously difficult, especially in areas that carry as many taboos as sex. HIV and AIDS. Poverty, social unrest and war all contribute to the spread of HIV. Political will, not always readily available, is required if progress in these areas is to occur.

GENERAL ASPECTS

In developing countries, lack of food and poor usage of the available food can result in protein-energy malnutrition (PEM); 50 million pre-school African children have PEM. In developed countries, excess food is available and the most common nutritional problem is obesity.

Diet and disease are interrelated in many ways. Excess energy intake, particularly when high in animal (saturated) fat content, is thought to contribute to a number of diseases, including ischaemic heart disease and diabetes. A relationship between food intake and cancer has been found in many epidemiological studies; an excess of energy-rich foods (i.e. fat and sugar containing), often with physical inactivity, plays a role in the development of certain cancers, while diets high in vegetables and fruits reduce the risk of most epithelial cancers. Numerous carcinogens, either intentionally added to food (e.g. nitrates for preserving foods) or accidental contaminants (e.g. moulds producing aflatoxin and fungi), may also be involved in the development of cancer.

The proportion of processed foods eaten may affect the development of disease. A number of processed convenience foods have a high sugar and fat content and therefore may predispose to dental caries and obesity, respectively. They also have a low fibre content, and dietary fibre is possibly necessary in the prevention of a number of diseases (see p. 211). Some epidemiological data suggest that there are long-term effects of undernutrition, low growth rates in utero being associated with high death rates from cardiovascular disease in adult life.

In 1991 the Department of Health published the dietary reference values for food and energy and nutrients for the United Kingdom. Values were based on the available information including data from the Food and Agriculture Organization (FAO–WHO), United Nations University (UNU) expert committee, so that there is broad agreement on the reference values given. In the UK recommended daily amounts (RDAs) are no longer used, but have been replaced by the reference nutrient intake (RNI) to provide more help in interpreting dietary surveys.

The RNI is roughly equivalent to the previous RDA, and is sufficient or more than sufficient to meet the nutritional needs of 97.5% of healthy people in a population. Most people’s daily requirements are less than this, and so an estimated average requirement (EAR) is also given, which will certainly be adequate for most. A lower reference nutrient intake (LRNI) which fails to meet the requirements of 97.5% of the population is also given. The RNI figures quoted in this chapter are for the age group 19–50 years. These represent values for healthy subjects and are not always appropriate for patients with disease.

WATER AND ELECTROLYTE BALANCE

Water and electrolyte balance is dealt with fully in Chapter 12. About 1 L of water is required in the daily diet to balance insensible losses, but much more is usually drunk, the kidneys being able to excrete large quantities. The daily RNI for sodium is 70 mmol (1.6 g) but daily sodium intake varies in the range 90–440 mmol (2–10 g). These are needlessly high intakes of sodium which are thought by some to play a role in causing hypertension (see p. 798).
**DIETARY REQUIREMENTS**

**Energy**

Food is necessary to provide the body with energy (Fig. 5.1). The SI unit of energy is the joule (J), and 1 kJ = 0.239 kcal. The conversion factor of 4.2 kJ, equivalent to 1.00 kcal, is used in clinical nutrition.

**Energy balance**

Energy balance is the difference between energy intake and energy expenditure. Weight gain or loss is a simple, but accurate, way of indicating differences in energy balance.

**Energy requirements**

There are two approaches to assessing energy requirements for subjects who are weight stable and close to energy balance:

- assessment of energy intake
- assessment of total energy expenditure.

**Energy intake**

This can be estimated from dietary surveys and in the past this has been used to decide daily energy requirements.

**Energy expenditure**

Daily energy expenditure (Fig. 5.2) is the sum of:

- the basal metabolic rate (BMR)
- the thermic effect of food eaten
- occupational activities
- non-occupational activities.

Total energy expenditure can be measured using a double-labelled water technique. Water containing the stable isotopes $^2$H and $^{18}$O is given orally. As energy is expended carbon dioxide and water are produced. The difference between the rates of loss of the two isotopes is used to calculate the carbon dioxide production, which is then used to calculate energy expenditure. This can be done on urine samples over a 2- to 3-week period with the subject ambulatory. The technique is accurate, but it is expensive and requires the availability of a mass spectrometer. An alternative tracer technique for measuring total energy expenditure is to estimate CO$_2$ production by isotopic dilution. A subcutaneous infusion of labelled bicarbonate is administered continuously by a minipump, and urine is collected to measure isotopic dilution by urea, which is formed from CO$_2$. Other methods for estimating energy expenditure, such as heart rate monitors or activity monitors, are also available but are less accurate.

**Basal metabolic rate.** The BMR can be calculated by measuring oxygen consumption and CO$_2$ production, but it is more usually taken from standardized tables (Table 5.1) that require knowledge of the subject’s age, weight and sex.

**Physical activity.** The physical activity ratio (PAR) is expressed as multiples of the BMR for both occupational and non-occupational activities of varying intensities (Table 5.2).

Thus, for example, to determine the daily energy expenditure of a 66-year-old, 50 kg female doctor, with a BMR of 4805 kJ per day spending one-third of a day sleeping, working or...
Dietary requirements

Energy stores

Although virtually all body fat and glycogen are available for oxidation, less than half the protein is available for oxidation. Figure 5.3 shows that fat accounts for the largest reserves of energy in both lean and obese subjects. The size of the stores determines survival during starvation.

Bodyweight

Bodyweight depends on energy balance. Intake depends not only on food availability but also on a number of complex interrelationships that include the stimulus of good food, the role of hunger, metabolic changes (e.g., hypoglycaemia), and the pleasure and habit of eating. Some people are able to keep their bodyweight constant within a few kilograms for many years, but most gradually increase their weight owing to a small but continuous increase of intake over expenditure.

A gain or loss of energy of 25–29 MJ (6000–7000 kcal) would respectively increase or decrease bodyweight by approximately 1 kg.

Protein

In the UK the adult daily RNI for protein is 0.75 g/kg, with protein representing at least 10% of the total energy intake. Most affluent people eat more than this, consuming 80–100 g of protein per day. The total amount of nitrogen excreted in the urine represents the balance between protein breakdown and synthesis. In order to maintain nitrogen balance, at least 40–50 g of protein are needed. The amount of protein oxidized can be calculated from the amount of nitrogen excreted in the urine over 24 hours using the following equation:

![Available energy reserves from different fuels expressed in MJ (upper) and as a percentage of total (lower) in a lean hypothetical 70 kg adult and an obese 140 kg adult.](image)

In the basal state, energy demands for resting muscle are 20% of the total energy required, abdominal viscera 35–40%, brain 20% and heart 10%. There can be more than a 50-fold increase in muscle energy demands during exercise.
In practice, urinary urea is more easily measured and forms 80–90% of the total urinary nitrogen (N). In healthy individuals urinary nitrogen excretion reflects protein intake. However, urine N excretion does not match intake either in catabolic conditions (negative N balance) or during growth or repletion following an illness (positive N balance).

Protein contains many amino acids, of which nine are indispensable (essential): tryptophan, histidine, methionine, threonine, isoleucine, valine, phenylalanine, lysine, leucine. These amino acids cannot be synthesized and must be provided in the diet. The dispensable (non-essential) amino acids can be synthesized in the body, but some may still be needed in the diet unless adequate amounts of their precursors are available. Animal proteins, such as in milk, meat and eggs, are of high nutritional value as they contain a good balance of all indispensable amino acids. Conversely, many proteins from vegetables are deficient in at least one indispensable amino acid.

In developing countries, adequate protein intake is achieved mainly from vegetable proteins. By combining foodstuffs with different low concentrations of indispensable amino acids (e.g. maize with legumes), protein intake can be adequate provided enough vegetables are available.

Loss of protein from the body (negative N balance) occurs not only because of inadequate protein intake, but also owing to inadequate energy intake. When there is loss of energy from the body, more protein is directed towards oxidative pathways and eventually gluconeogenesis for energy. Of all the amino acids, glutamine is quantitatively the most significant in the circulation and in inter-organ exchange. Alanine is released from muscle: it is deaminated and converted into pyruvic acid before entering the citric acid cycle. Homocysteine is a sulphur-containing amino acid which is derived from methionine in the diet. A raised plasma concentration is an independent risk factor for vascular disease (see p. 747).

Amino acids may be utilized to synthesize products other than protein or urea. For example:

- haem requires glycine
- melanin and thyroid hormones require tyrosine
- nucleic acid bases require glutamine, aspartate and glycine
- glutathione, which is part of the defence system against free radicals, requires glutamate, cysteine and glycine.

### Fat

Dietary fat is chiefly in the form of triglycerides, which are esters of glycerol and free fatty acids. Fatty acids vary in chain length and in saturation (Table 5.3). Unsaturated fatty acids are monounsaturated or polyunsaturated. The hydrocarbon molecules related to these double bonds can be in the cis or the trans position, most natural fatty acids in food being in the cis position (Box 5.1).

The essential fatty acids (EFAs) are linoleic and α-linolenic acid, both of which are precursors of prostaglandins. Eicosapentaenoic and docosahexaenoic are also necessary, but can be made to a limited extent in the tissues from linoleic and linolenic, and thus a dietary supply is not essential.

**Box 5.1** Dietary sources of fatty acids

- **Synthesis of triglycerides**, sterols and phospholipids is very efficient, and even with low-fat diets subcutaneous fat stores can be normal.

  Dietary fat provides 37 kJ (9 kcal) of energy per gram. A high fat intake has been implicated in the causation of:

  - cardiovascular disease
  - cancer (e.g. breast, colon and prostate)
  - obesity
  - type 2 diabetes.

The data on causation are largely epidemiological and disputed by many. Nevertheless, it is often suggested that the consumption of saturated fatty acids should be reduced, accompanied by an increase in monounsaturated fatty acids (the ‘Mediterranean diet’) or polyunsaturated fatty acids. Any increase in polyunsaturated fats should not, however, exceed 10% of the total food energy, particularly as this requires a big dietary change.

Increased consumption of hydrogenated vegetable and fish oils in margarines has led to an increased trans fatty acid consumption and their intake should not, on present evidence, increase more than the current estimated average of 5 g per day or 2% of the dietary energy. This is because trans fatty acids (also called trans fats) behave as if they were saturated fatty acids, increasing circulating LDL and decreasing HDL cholesterol concentrations, which in turn increase the risk of cardiovascular disease. For this reason, the US Food and Drug Administration (FDA) ruled that from 2006 the nutrition labels for all conventional foods and supplements must indicate the content of trans fatty acids. Trans fatty acids from partially hydrogenated oils appear to provide no nutritional benefit and considerable potential for harm.
The n-6 polyunsaturated fatty acids (PUFA) are components of membrane phospholipids, influencing membrane fluidity and ion transport. They also have antiarrhythmic, antithrombotic and anti-inflammatory properties, all of which are potentially helpful in preventing cardiovascular disease.

The n-3 PUFA increase circulating high-density lipoprotein (HDL) cholesterol and lower triglycerides, both of which might reduce cardiovascular risk. Some of the actions of n-3 PUFA are mediated by a range of leukotrienes and eicosanoids, which differ in pattern and functions from those produced from n-6 PUFA.

Epidemiological studies and clinical intervention studies suggest that n-3 PUFA may have effects in the secondary prevention of cardiovascular disease and 'all-cause mortality' (e.g. 20–30% reduction in mortality from cardiovascular disease according to some studies). The benefits, which have been noted as early as 4 months after intervention, have been largely attributed to the antiarrhythmic effects of n-3 PUFA, but some work suggests that n-3 PUFA, administered as capsules, can be rapidly incorporated into atheromatous plaques, stabilizing them and preventing rupture. Whether these effects are due directly to n-3 PUFA or other changes in the diet is still debated.

The GISSI Prevention Trial, which followed over 11 000 patients for 3.5 years after a myocardial infarction, administered the fish oils (eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA)) in the form of capsules and demonstrated a striking benefit in reducing mortality. The effects of vitamin E (300 mg α-tocopherol/day) were also studied, but no benefit was found.

The British Nutrition Foundation and the American Heart Association presently recommend a two-fold increase of the current intake of total n-3 PUFA (several fold increase in the intake of fish oils, and a 50% increase in the intake of α-linolenic acid). Implementing this recommendation will mean either a major change in the dietary habits of populations that eat little fish, or ingestion of capsules containing fish oils. Some government agencies have warned of the hazards of these effects are due directly to n-3 PUFA or other changes in the diet is still debated.

The GISSI Prevention Trial, which followed over 11 000 patients for 3.5 years after a myocardial infarction, administered the fish oils (eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA)) in the form of capsules and demonstrated a striking benefit in reducing mortality. The effects of vitamin E (300 mg α-tocopherol/day) were also studied, but no benefit was found.

The British Nutrition Foundation and the American Heart Association presently recommend a two-fold increase of the current intake of total n-3 PUFA (several fold increase in the intake of fish oils, and a 50% increase in the intake of α-linolenic acid). Implementing this recommendation will mean either a major change in the dietary habits of populations that eat little fish, or ingestion of capsules containing fish oils. Some government agencies have warned of the hazards of eating certain types of fish, which increase the risk of mercury poisoning and possibly other toxicities.

The current recommendations for fat intake for the UK are as follows:

- saturated fatty acids should provide approximately 10% of the dietary energy
- cis-monounsaturated acids (mainly oleic acid) should continue to provide approximately 12% of the dietary energy
- cis-polyunsaturated acids should provide 6% of dietary energy, and are derived from n-6 and n-3 polyunsaturated fatty acids, which should provide ~0.5% of total energy intake
- total fat intake should be no more than 35% of the total dietary energy, and restriction to 30% is desirable.

Cholesterol is found in all animal products. Eggs are particularly rich in cholesterol, which is virtually absent from plants. The average daily intake in the UK is 300–500 mg. Cholesterol is also synthesized (see p. 321) and only very high or low dietary intakes will significantly affect blood levels.

**Essential fatty acid deficiency**

Essential fatty acid deficiency may accompany protein-energy malnutrition (PEM), but it has been clearly defined as a clinical entity only in patients on long-term parenteral nutrition given glucose, protein and no fat. Alopecia, thrombocytopenia, anaemia and a dermatitis occur within weeks with an increased ratio of triene (n-9) to tetraene (n-6) in plasma fatty acids.

**Carbohydrate**

Carbohydrates are readily available in the diet, providing 17 kJ (4 kcal) per gram of energy (15.7 kJ (3.75 kcal) per gram monosaccharide equivalent).

Carbohydrate intake comprises the polysaccharide starch, the disaccharides (mainly sucrose) and monosaccharides (glucose and fructose). Carbohydrate is cheap compared with other foodstuffs; a great deal is therefore eaten, usually more than required.

Dietary fibre, which is largely non-starch polysaccharide (NSP) (entirely NSP according to some authorities), is often removed in the processing of food. This leaves highly refined carbohydrates such as sucrose which contribute to the development of dental caries and obesity. Lignin is included in dietary fibre in some classification systems, but it is not a polysaccharide. It is only a minor component of the human diet.

The principal classes of NSP are:

- cellulose
- hemicelluloses
- pectins
- gums.

None of these are digested by gut enzymes. However, NSP is partly broken down in the gastrointestinal tract, mainly by colonic bacteria, producing gas and volatile fatty acids, e.g. butyrate.

All plant food, when unprocessed, contains NSP, so that all unprocessed food eaten will increase the NSP content of the diet. Bran, the fibre from wheat, provides an easy way of adding additional fibre to the diet: it increases faecal bulk and is helpful in the treatment of constipation.

The average daily intake of NSP in the diet is approximately 16 g. NSP deficiency is accepted as an entity by many authorities and it is suggested that the total NSP be increased to up to 30 g daily. This could be achieved by increased consumption of bread, potatoes, fruit and vegetables, with a reduction in sugar intake in order not to increase total calories. Each extra gram of fibre daily adds approximately 3–5 g to the daily stool weight. Pectins and gums have been added to food to slow down monosaccharide absorption, particularly in type 2 diabetes.

Eating a diet rich in plant foods (fruits, vegetables, cereals and whole grain) is generally recommended for general health promotion, including protection against ischaemic heart disease, stroke and certain types of cancers. This has been attributed to a lipid lowering effect, the presence of protective substances, such as vitamin and non-vitamin antioxidants, and other vitamins such as folic acid, which is linked to homocysteine metabolism, a risk factor for cardiovascular disease. Fermentation of fibre in the colon may protect against development of colonic cancer. However, associated lifestyle factors such as low physical activity may also help explain some of those associations.
Health promotion

Many chronic diseases – particularly obesity, diabetes mellitus and cardiovascular disease – cause premature mortality and morbidity and are potentially preventable by dietary change.

Box 5.2 suggests the composition of the ‘ideal healthy diet’. The values given are based on the principle of:

- reducing total fat in the diet, particularly saturated fat
- increasing consumption of fish which contain n-3 (or α-3) polyunsaturated fatty acids
- increasing intake of whole-grain cereals, green and orange vegetables and fruits, leading to an increase in fibre and antioxidants.

Reductions in dietary sodium and cholesterol have also been suggested. There would be no disadvantage in this, and most studies have suggested some benefit.

Fortification of foods with specific nutrients is common. In the UK margarine and milk are fortified with vitamins A and D, flour with calcium, iron, thiamin and niacin, and breakfast cereals with several vitamins and iron. Not all substances used in fortification have nutritive value. For example, Olestra is a polymer of sucrose and six or more triglycerides which has been introduced to combat obesity. It is not absorbed and is therefore used particularly in savoury snack foods (where it has FDA approval) as a ‘fake fat’. Therefore, it results in a reduction in total calories. It has side-effects, e.g. loose stools, abdominal cramps, and its use is being carefully monitored.

The interests of the individual are often different from those associated with government policy. A distinction needs to be made between nutrient goals and dietary guidelines. Nutrient goals refer to the national intakes of nutrients that are considered appropriate for optimal health in the population, whereas dietary guidelines refer to the dietary methods used to achieve these goals. Since dietary habits in different countries vary, dietary guidelines may also differ, even when the nutrient goals are the same. Nutrient goals are based on scientific information that links nutrient intake to disease. Although the information is incomplete, it includes evidence from a wide range of sources, including experimental animal studies, clinical studies and both short-term and long-term epidemiological studies.

Values in parentheses are goals for the intake of populations, as given by the WHO (including populations who are already on low-fat diets). Some of the extreme ranges are not realistic short-term goals for developed countries, e.g. 75% of total energy from carbohydrate and 15% fat. When total energy intake is 2500 kcal (10 500 kJ) per day, 55% of intake comes from carbohydrate (344 g, i.e. 1376 kcal (5679 kJ)) and 30% from fat (83 g, i.e. 747 kcal (3137 kJ)).

### PROTEIN-ENERGY MALNUTRITION (PEM)

**IN DEVELOPED COUNTRIES**

Starvation uncomplicated by disease is relatively uncommon in developed countries, although some degree of undernourishment is seen in very poor areas. Most nutritional problems occurring in the population at large are due to eating wrong combinations of foodstuffs, such as an excess of refined carbohydrate or a diet low in fresh vegetables. Undernourishment associated with disease is common in hospitals and nursing homes, and Table 5.4 gives a list of conditions in which malnutrition is often seen. Surgical complications, with sepsis, are a common cause. Many patients are admitted to hospital undernourished, and a variety of chronic conditions predispose to this state (Table 5.5).

</tbody>
</table>
The majority of the weight loss, leading to malnutrition, is due to poor intake secondary to the anorexia associated with the underlying condition. Disease may also contribute by causing malabsorption and increased catabolism, which is mediated by complex changes in cytokines, hormones, side-effects of drugs, and immobility. The elderly are particularly at risk of malnutrition because they often suffer from diseases and psychosocial problems such as social isolation or bereavement (Table 5.5).

**Pathophysiology of starvation** (Fig. 5.4)

In the first 24 hours following low dietary intake, the body relies for energy on the breakdown of hepatic glycogen to glucose. Hepatic glycogen stores are small and therefore gluconeogenesis is soon necessary to maintain glucose levels. Gluconeogenesis takes place mainly from pyruvate, lactate, glyceral and amino acids, especially alanine and glutamine. The majority of protein breakdown takes place in muscle, with eventual loss of muscle bulk.

**Lipolysis**, the breakdown of the body’s fat stores, also occurs. It is inhibited by insulin, but the level of this hormone falls off as starvation continues. The stored triglyceride is hydrolysed by lipase to glycerol, which is used for gluconeogenesis, and also to non-esterified fatty acids that can be used directly as a fuel or oxidized in the liver to ketone bodies.

As starvation continues, adaptive processes take place to prevent the body’s available protein being completely utilized. There is a decrease in metabolic rate and total body energy expenditure. Central nervous metabolism changes from glucose as a substrate to ketone bodies. Gluconeogenesis in the liver decreases as does protein breakdown in muscle, both of these processes being inhibited directly by ketone bodies. Most of the energy at this stage comes from adipose tissue, with some gluconeogenesis from amino acids, particularly from alanine in the liver, and glutamine in the kidney.

The metabolic response to prolonged starvation differs between lean and obese individuals. One of the major differences concerns the proportion of energy derived from protein oxidation, which determines the proportion of weight loss from lean tissues. This proportion may be up to three times smaller in obese subjects than lean subjects. It can be regarded as an adaptation which depends on the composition of the initial reserves (Fig. 5.3). This means that deterioration in body function is more rapid in lean subjects. Furthermore, survival time is much less in lean subjects (2 months), compared to the obese (can be at least several months).

Following trauma or shock, some of the adaptive changes do not take place. Glucocorticoids and cytokines (see below) indicate severe disease or multiple physical and psychosocial problems; drugs may lead to confusion, sedation, depression and GIT side-effects (including malabsorption of nutrients).

**Fig. 5.4** Metabolism in (a) the fed and (b) the fasted state. NEFA, non-esterified fatty acids.
stimulate the ubiquitin–proteasome pathway in muscle, which is responsible for accelerated proteolysis in muscle in many catabolic illnesses. In starvation there is a decrease in BMR, whilst in inflammatory and traumatic disease the BMR is often increased. These changes all result in continuing gluconeogenesis with massive muscle breakdown, and further reduction in survival time.

Regulation of metabolism
Tissue metabolism is regulated by multiple coordinated processes. Some are rapid involving nerves, whilst others are slower involving circulating substrates and hormones. Factors include:

- **Circulating substrate concentrations.** The uptake and metabolism of ketone bodies, which serve as the major fuel for the brain during prolonged starvation, is primarily determined by the circulatory concentration which can increase up to 5 mmol/L or more. The liver is responsible for producing ketone bodies, the production of which is in turn controlled by the availability of fatty acids derived from adipose tissue. Substrates may also compete with each other for metabolism, for example glucose competes with non-esterified fatty acids for uptake and metabolism in muscle and heart (the glucose–fatty acid cycle) and this is independent of hormones.

- **Blood flow.** The delivery of substrates (and other signals) to tissues depends not only on their circulating concentration but also on the blood flow to tissues. In many tissues there is coupling between metabolic activity and blood flow, with arterioles regulating blood flow to the tissue according to demand, e.g. blood flow to muscle increases during exercise.

- **Signals.** Hormones and other signals, such as cytokines, regulate intracellular metabolism.

In the fed state, insulin/glucagon ratios are high. Insulin promotes synthesis of glycogen, protein and fat, and inhibits lipolysis and gluconeogenesis.

In the fasted state, insulin/glucagon ratios are low. Glucagon acts mainly on the liver and has no action on muscle. It increases glycolysis and gluconeogenesis, as well as increasing ketone body production from fatty acids. It also stimulates lipolysis in adipose tissue. Catecholamines have a similar action to glucagon but also affect muscle metabolism. These agents both act via cyclic adenosine monophosphate (cAMP) to stimulate lipolysis, producing free fatty acids. These agents both act via cyclic adenosine monophosphate (cAMP) to stimulate lipolysis, producing free fatty acids.

**Cytokines** such as IL-1, IL-6 and TNF play a significant role in regulating metabolism. In acute diseases they contribute to the catabolic process, glycogenolysis, and acute-phase protein synthesis. TNF, which inhibits lipoprotein lipase, is a ‘cachexia factor’ in patients with cancer.

It is unclear how these cytokines interact with central feeding pathways to cause anorexia. However, in animal models of both cancer and inflammatory bowel disease, many peripheral and central mediators of appetite are involved. For example, neuropeptide Y levels in the hypothalamus are often inappropriately low, so there is a reduced drive to feeding.

**Clinical features**
Patients are sometimes seen with loss of weight or malnutrition as the primary symptom (failure to thrive in children). Mostly, however, malnourishment is only seen as an accompaniment of some other disease process, such as malignancy. Severe malnutrition is seen mainly with advanced organic disease or after surgical procedures followed by complications. Three key features which help in the detection of chronic protein–energy malnutrition (PEM) in adults are:

1. **The body mass index (BMI):**
   - Probable chronic PEM: < 18.5 kg/m²
   - Possible chronic PEM: 18.5–20 kg/m²
   - Little or no risk of chronic PEM: > 20 kg/m².

   In patients with oedema or dehydration the BMI may be somewhat misleading.

2. **Weight loss in previous 3-6 months:** > 10%, high risk; 5–10%, possible risk; < 5% low/no risk of developing PEM.

3. **Acute disease effect:** Diseases that have resulted or are likely to result in no dietary intake for more than 5 days are associated with a high risk of malnutrition (e.g. prolonged unconsciousness, persistent swallowing problems after a stroke, or prolonged ileus after abdominal surgery).

- **Other factors:**
  - History of decreased food intake/loss of appetite
  - Clothes becoming loosely fitting (weight loss) and a general appearance indicating obvious wasting
  - Physical and psychosocial disturbances likely to have contributed to the weight loss.

These factors act as a link between detection and management (Fig. 5.5, The Malnutrition Universal Screening Tool). If the underlying physical or psychosocial problems are not adequately addressed, treatment may not be successful.

PEM leads to a depression of the immunological defence mechanism, resulting in a decreased resistance to infection. It also detrimentally affects muscle strength and fatigue, reproductive function (e.g. in anorexia nervosa, which is common in adolescent girls; p. 1219), wound healing, and psychological function (depression, anxiety, hypochondriasis, loss of libido).

**Treatment (see also pp. 233 and 236)**
When malnutrition is obvious and the underlying disease cannot be corrected at once, some form of nutritional support is necessary. Nutrition should be given enteral if the gastrointestinal tract is functioning adequately. This can most easily be done by encouraging the patient to eat more often.
Protein-energy malnutrition (PEM) 215

Step 1  
BMI score

Step 3  
Acute disease effect score  
If patient is acutely ill and there has been or is likely to be no nutritional intake for >5 days  
Score 2

Step 4  
Overall risk of malnutrition  
Add scores together to calculate overall risk of malnutrition  
Score 0 = Low Risk  
Score 1 = Medium Risk  
Score 2 or more = High Risk

Step 5  
Management guidelines  
0 = Low Risk  
Routine clinical care  
• Repeat screening  
  Hospital – weekly  
  Care Homes – monthly  
  Community – annually for special groups e.g. those >75 years  
1 = Medium Risk  
Observe  
• Document dietary intake for 3 days if subject in hospital or care home  
• If improved or adequate intake – little clinical concern; if no improvement – clinical concern – follow local policy  
• Repeat screening  
  Hospital – weekly  
  Care Home – at least monthly  
  Community – at least 2–3 months  
2 = High Risk  
Treat*  
• Refer to dietician, Nutritional Support Team or implement local policy  
• Improve and increase overall nutritional intake  
• Monitor and review care plan  
  Hospital – weekly  
  Care Home – monthly  
  Community – monthly  
• Unless detrimental or no benefit is expected from nutritional support e.g. imminent death.

All risk categories:  
• Treat underlying condition and provide help and advice on food choices, eating and drinking when necessary.  
• Record malnutritional risk category.  
• Record need for special diets and follow local policy.

Obesity:  
• Record presence of obesity.  
• Record underlying condition, these are generally controlled before the treatment of obesity.

IN DEVELOPING COUNTRIES

The International Union of Nutritional Sciences, with support from the International Pediatric Association, launched a global Malnutrition Task Force in 2005 to ensure that an integrated system of prevention and treatment of malnutrition is actively supported.

In many areas of the world, people are on the verge of malnutrition due to extreme poverty. In addition, if events such as drought, war or changes in political climate occur, millions suffer from starvation. Although the basic condition of PEM is the same in all parts of the world from whatever cause, malnutrition resulting from long periods of near-total starvation produces unique clinical appearances in children virtually never seen in high-income countries. The term ‘protein–energy malnutrition’ covers the spectrum of clinical conditions seen in adults and children. Children under 5 years may present with:

- **Marasmus** is the childhood form of starvation, which is associated with obvious wasting. The child looks emaciated, there is obvious muscle wasting and loss of body fat. There is no oedema. The hair is thin and dry (Fig. 5.6a). The child is not so apathetic or anorexic as with kwashiorkor. Diarrhoea is frequently present and signs of infection must be looked for carefully.

- **Kwashiorkor** occurs typically in a young child displaced from breast-feeding by a new baby. It is often precipitated by infections such as measles, malaria and diarrhoeal illnesses. The child is apathetic and lethargic with severe anorexia. There is generalized oedema with skin pigmentation and thickening (Fig. 5.6b). The hair is

Fig. 5.5 Malnutrition Universal Screening Tool (MUST). Reproduced with permission from the British Association for Parenteral and Enteral Nutrition (BAPEN): http://www.bapen.org.uk.

Fig. 5.6 Malnourished children: (a) marasmus and (b) kwashiorkor. Courtesy of Dr Paul Kelly.
ceptible to respiratory and gastrointestinal infections, leading to growth retardation and wasting. The body fat and muscle are lost, and the child becomes listless and apathetic. They may complain of coldness and weakness, and may require frequent feeds due to anorexia. They may lead to extreme loss of weight and height, leading to severe malnutrition. In severe cases, the child may lead to death.

The World Health Organization (WHO) classification of severe malnutrition is based on body mass index, with a value less than 16.0 kg/m² indicating malnutrition (severe malnutrition). A low weight-for-height is a measure of thinness (wasting when pathological), and a low height-for-age is a measure of shortness (stunting when pathological). Those with oedema and clinical signs of severe malnutrition are classified as having oedematous malnutrition.

A classification of severe malnutrition by the World Health Organization (Table 5.6) makes no distinction between kwashiorkor and marasmus, because their approach to treatment is similar. The World Health Organization (WHO) classification of chronic undernutrition in children is based on standard deviation (SD) scores. Thus, children with an SD score between −2 and −3 (between 2 and 3 standard deviation scores below the median – corresponding to a value between 0.13 and 2.3 centile) can be regarded as being at moderate risk of undernutrition, and below an SD score of −3, of severe malnutrition. A low weight-for-height is a measure of thinness (wasting when pathological), and a low height-for-age is a measure of shortness (stunting when pathological). Those with oedema and clinical signs of severe malnutrition are classified as having oedematous malnutrition.

Starvation in adults may lead to extreme loss of weight depending upon the severity and duration. They may crave for food, are apathetic and complain of cold and weakness with a loss of subcutaneous fat and muscle wasting. The WHO classification is based on body mass index, with a value less than 18.5 kg/m² indicating malnutrition (severe malnutrition if less than 16.0 kg/m²).

Severely malnourished adults and children are very susceptible to respiratory and gastrointestinal infections, leading to an increased mortality in these groups.

Investigations

These are not always practicable in field work.

Blood tests

a) Anaemia due to folic acid, iron and copper deficiency is often present, but the haematocrit may be high owing to dehydration.

Table 5.6 Classification of childhood malnutrition

<table>
<thead>
<tr>
<th></th>
<th>Moderate malnutrition</th>
<th>Severe malnutrition*</th>
</tr>
</thead>
</table>
| Symmetrical oedema | No                    | Yes (oedematous malnutrition)^
| Weight-for-height | SD score –3 to –2 (70–79)† | SD score below –3 (<70%)‡ (severe wasting)^
| Height-for-age | SD score –3 to –2 (85–89)† | SD score below –3 (<85%)‡ (severe stunting) |

*The diagnoses are not mutually exclusive
†This includes kwashiorkor and marasmic-kwashiorkor in the older classifications. To avoid confusion with the clinical syndrome of kwashiorkor, which includes other features (see text), the term oedematous malnutrition is preferred
‡Percentage of the median National Centre for Health Statistics/WHO reference
§This corresponds to marasmus (without oedema) in the Wellcome classification and to grade II in the Gomez classification. To avoid confusion the term ‘severe’ wasting is preferred

Treatment

Treatment must involve the provision of protein and energy supplements and the control of infection.

Resuscitation and stabilization

The severely ill child will require:

- Correction of fluid and electrolyte abnormalities, but intravenous therapy should be avoided if possible because of the danger of fluid overload.
- Treatment of shock with oxygen.
- Treatment of hypoglycaemia (blood glucose <3 mmol/L), hypothermia (reduce heat loss, and provide additional heat if necessary) and infection (antibiotics) – these often coexist.

The standard WHO oral hydration solution has a high sodium and low potassium content and is not suitable for severely malnourished children. Instead, the rehydration solution for malnutrition (ReSoMal) is recommended. It is commercially available but can also be produced by modification of the standard WHO oral hydration solution.

Infection is common. Diarrhoea is often due to bacterial or protozoal overgrowth; metronidazole is very effective and is often given routinely. Parasites are also common and, as facilities for stool examination are usually not available, mebendazole 100 mg twice daily should be given for 3 days. In high-risk areas, antimarial therapy is given.

Large doses of vitamin A are also given because deficiency of this vitamin is common. After the initial resuscitation, further stabilization over the next few days is undertaken, as indicated in Table 5.7.

Refeeding

This needs to be planned carefully. During the initial treatment of the acute situation, a balanced diet with sufficient protein and energy is given to maintain a steady state. Large increases in energy can lead to heart failure, circulatory collapse and death (refeeding syndrome). Initial feeding involves administration of feeds of low osmolarity and low in lactose (WHO recommendations: 100 kcal/kg/day, 1.0–1.5 g protein/kg/day and 130 mL liquid/kg/day (100 mL/kg/day if the child has marked oedema)). Attempts should be made to give the feeds slowly and frequently (e.g. 2-hourly during days 1–2; 3-hourly during days 3–5; and 4-hourly thereafter), although anorexia is often a problem and can be exacerbated by excessive feeding. If necessary, fluids and food should be given by nasogastric tube. The child is then gradually weaned to liquids and then solids by mouth. All severely malnourished children have vitamin and mineral deficiencies. Although anaemia is common, the WHO recommends giving iron only after the child develops a good appetite and starts gaining weight, because of concern about making the infection worse (iron is a pro-oxidant). The child should be given daily micronutrient supplements for at least 2 weeks. These should include a multivitamin supplement with folic acid, zinc and copper.
Food supplements (and additional vitamins) should be given to ‘at-risk’ groups by adding high-energy food (e.g. milk powder, meat concentrates) to the diet. Pregnancy and lactation are times of high energy requirement and supplements have been shown to be beneficial.

Rehabilitation
Gradually, as the child improves, more energy can be given, and during rehabilitation weight gain is achieved by providing extra energy and protein (‘catch-up weight gain’). Children who have been severely ill need constant attention right through the convalescent period, as often home conditions are poor and feeds are refused. Sensory stimulation and emotional support is a major component of management during both the stabilization and rehabilitation phases.

Adults do not usually suffer such severe malnutrition, but the same general principles of treatment should be followed.

Care setting
There are not enough hospitals or therapeutic feeding centres to cope with the malnutrition problem (even acute malnutrition problems), which emphasizes the need for outpatient and community based programmes. These may involve the use of ready-to-use therapeutic foods, such as energy-dense pastes with minerals and vitamins, without the need to add water, which could potentially contaminate the food.

Prognosis
Children with extreme malnutrition have a mortality of over 50%. By careful management this can be reduced significantly to less than 10%, depending on the availability of facilities and trained staff. Treatment of underlying disease is essential. Brain development takes place in the first years of life, a time when severe PEM frequently occurs. There is evidence that intellectual impairment and behavioural abnormalities occur in severely affected children. Physical growth is also impaired. Probably both of these effects can be alleviated if it is possible to maintain a high standard of living with a good diet and freedom from infection over a long period.

Prevention
Prevention of PEM depends not only on adequate nutrients being available but also on education of both governments and individuals in the importance of good nutrition and immunization (Box 5.3). Short-term programmes are useful for acute shortages of food, but long-term programmes involving improved agriculture are equally necessary. Bad feeding practices and infections are more prevalent than actual shortage of food in many areas of the world. However, good surveillance is necessary to avoid periods of famine.

**Box 5.3** Prevention of protein–energy malnutrition – GOBIF (a WHO priority programme)
- Growth monitoring: The WHO has a simple growth chart that the mother keeps
- Oral rehydration, particularly for diarrhoea
- Breast-feeding supplemented by food after 6 months
- Immunization: against measles, tetanus, pertussis, diphtheria, polio and tuberculosis
- Family planning

**FURTHER READING**

**VITAMINS**
Deficiencies due to inadequate intake associated with PEM (Table 5.8) are commonly seen in the developing countries. This is not, however, invariable. For example, vitamin A deficiency is not seen in Jamaica, but is common in PEM in Hyderabad, India. In the West, deficiency of vitamins is rare.
Vitamin A (retinol) is part of the family of retinoids which is present in food and the body as esters combined with long-chain fatty acids. The richest food source is liver, but it is also found in milk, butter, cheese, egg yolks and fish oils. Retinol or carotene is added to margarine in the UK and other countries.

Beta-carotene is the main carotenoid found in green vegetables, carrots and other yellow and red fruits. Other carotenoids, lycopene and lutein, are probably of little quantitative importance as dietary precursors of vitamin A.

Beta-carotene is cleaved in the intestinal mucosa by carotene dioxygenase, yielding retinaldehyde which can be reduced to retinol. Between a quarter and a third of dietary vitamin A in the UK is derived from retinoids. Nutritionally, 6 μg of β-carotene is equivalent to 1 μg of preformed retinol; vitamin A activity in the diet is given as retinol equivalents.

Function
Retinol is stored in the liver and is transported in plasma bound to an α-globulin, retinol-binding protein (RBP). Vitamin A has several metabolic roles:

- Retinaldehyde in its cis form is found in the opsin proteins in the rods (rhodopsin) and cones (iodopsin) of the retina (p. 1086). Light causes retinaldehyde to change to its trans isomer, and this leads to changes in membrane potentials that are transmitted to the brain.
- Retinol and retinoic acid are involved in the control of cell proliferation and differentiation.
- Retinyl phosphate is a cofactor in the synthesis of most glycoproteins containing mannose.

**Vitamin A deficiency**
World-wide, vitamin A deficiency and xerophthalmia (see below) is the major cause of blindness in young children despite intensive preventative programmes.

Xerophthalmia has been classified by the WHO (Table 5.10). Impaired adaptation followed by night blindness is the first effect. There is dryness and thickening of the conjunctiva and the cornea (xerophthalmia occurs as a result of keratination). Bitot’s spots – white plaques of keratinized epithelial cells – are found on the conjunctiva of young children with vitamin A deficiency. These spots can, however, be seen without vitamin A deficiency, possibly caused by exposure. Corneal softening, ulceration and dissolution (keratomalacia)
eventually occur; superimposed infection is a frequent accompaniment and both lead to blindness.

In PEM, retinol-binding protein along with other proteins is reduced. This suggests vitamin A deficiency, although body stores are not necessarily reduced.

Vitamin A in malnourished children
Vitamin A supplementation (single oral dose of 60 mg retinol palmitate) appears to improve morbidity and mortality from measles. It has also been suggested that a similar supplementation reduces morbidity and/or mortality from diarrhoeal diseases and respiratory infections and improves growth. Despite low circulating concentrations of vitamin A in HIV-infected individuals, supplementation of HIV-infected pregnant women does not appear to reduce the risk of mother-to-child transmission of HIV.

Diagnosis
In parts of the world where deficiency is common, diagnosis is made on the basis of the clinical features, and deficiency should always be suspected if any degree of malnutrition is present. Blood levels of vitamin A will usually be low, but the best guide to the diagnosis is a response to replacement therapy.

Treatment
Urgent treatment with retinol palmitate 30 mg orally should be given on 2 successive days. In the presence of vomiting and diarrhoea, 30 mg of vitamin A is given intramuscularly. Associated malnutrition must be treated, and superadded bacterial infection should be treated with antibiotics. Referral for specialist ophthalmic treatment is necessary in severe cases.

Prevention
Most western diets contain enough dairy products and green vegetables, but vitamin A is added to foodstuffs (e.g. margarine) in some countries. Vitamin A is not destroyed by cooking.

In some developing countries vitamin A supplements are given at the time the child attends for measles vaccination. Food fortification programmes are another approach. Education of the population is necessary and people should be encouraged to grow their own vegetables. In particular, pregnant women and children should be encouraged to eat green vegetables.

Other effects of vitamin A
The effect of β-carotene in cardiovascular and other diseases is discussed below in the section entitled ‘Dietary antioxidants’ (p. 223). Retinoic acid and some synthetic retinoids are used in dermatology (p. 1247).

Possible adverse effects
- **High intakes of vitamin A.** Chronic ingestion of retinol can cause liver and bone damage, hair loss, double vision, vomiting, and other abnormalities. Single doses of 300 mg in adults or 100 mg in children can be harmful.
- **Retinol is teratogenic.** The incidence of birth defects in infants is high with vitamin A intakes of more than 3 mg a day during pregnancy. In pregnancy, extra vitamin A or consumption of liver is not recommended in the UK. However, β-carotene is not toxic.

Vitamin D
See page 559.

Vitamin K
Vitamin K is found as phylloquinone (vitamin K

Function
Vitamin K is a cofactor necessary for the production not only of blood clotting factors (p. 432), but also for proteins necessary in the formation of bone.

Vitamin K is a cofactor for the post-translational carboxylation of specific protein-bound glutamate residues in γ-carboxyglutamate (Gla). Gla residues bind calcium ions to phospholipid templates, and this action on factors II, VII, IX and X, and on proteins C and S, is necessary for coagulation to take place.

Bone osteoblasts contain three vitamin K-dependent proteins, osteocalcin, matrix Gla protein and protein S, which have a role in bone matrix formation. Osteocalcin contains three Gla residues which bind tightly to the hydroxyapatite matrix depending on the degree of carboxylation; this leads to bone mineralization. There is, however, no convincing evidence that vitamin K deficiency or antagonism affects bone other than rapidly growing bone.

Vitamin K deficiency
Vitamin K deficiency results in inadequate synthesis of clotting factors (p. 440), which leads to an increase in the prothrombin time and haemorrhage. Deficiency occurs in the following circumstances:

The newborn
Deficiency occurs in the newborn owing to:
- poor placental transfer of vitamin K
- little vitamin K in breast milk

### Table 5.10 Classification of xerophthalmia by ocular signs

| Night blindness (XN) | Conjunctival xerosis (XIA) | Bitot’s spot (X2) | Corneal xerosis (X2) | Corneal ulceration/keratomalacia <1/3 corneal surface (X3A) | Corneal ulceration/keratomalacia ≥1/3 corneal surface (X3B) | Corneal scar (XS) | Xerophthalmic fundus (XF) |

Deficiency leads to a haemorrhagic disease of the newborn, which can be prevented by prophylactic vitamin K. Vitamin K (phytomenadione 1 mg, i.m.) is given to all neonates after risks have been discussed with parents and consent obtained.

**Cholestatic jaundice**
When bile flow into the intestine is interrupted, malabsorption of vitamin K occurs as no bile salts are available to facilitate absorption and the prothrombin time increases. This can be corrected by giving 10 mg of phytomenadione intramuscularly. (Note that an increased prothrombin time because of liver disease does not respond to vitamin K injection, there being no shortage of vitamin K, just bad liver function.) In patients with chronic cholestasis (e.g. primary biliary cirrhosis) oral therapy using a water-soluble preparation, menadione sodium phosphate 10 mg daily, is used.

**Concomitant vitamin K antagonists**
Oral anticoagulants antagonize vitamin K (p. 445). Antibacterial drugs also interfere with the bacterial synthesis of vitamin K.

### Vitamin E

Vitamin E includes eight naturally occurring compounds divided into tocopherols and tocotrienoles. The most active compound and the most widely available in food is the natural isomer d- (or RRR) α-tocopherol, which accounts for 90% of vitamin E in the human body. Vegetables and seed oils, including soya bean, saffron, sunflower, cereals and nuts, are the main sources. Animal products are poor sources of the vitamin.

Vitamin E is absorbed with fat, transported in the blood largely in low-density lipoproteins (LDL).

An individual’s vitamin E requirement depends on the intake of polyunsaturated fatty acids (PUFAs). Since this varies widely, no daily requirement is given in the UK. The requirement stated in the USA is approximately 7–10 mg per day, but average diets contain much more than this. If PUFAs are taken in large amounts, more vitamin E is required.

**Function**
The biological activity of vitamin E results principally from its antioxidant properties. In biological membranes it contributes to membrane stability. It protects cellular structures against damage from a number of highly reactive oxygen species, including hydrogen peroxide, superoxide and other oxygen radicals. Vitamin E may also affect cell proliferation and growth.

**Vitamin E deficiency**
The first deficiency to be demonstrated was a haemolytic anaemia described in premature infants. Infant formulations now contain vitamin E.

Deficiency is seen only in children with abetalipoproteinaemia (p. 284) and in patients on long-term parenteral nutrition. The severe neurological deficit (gross ataxia) can be prevented by vitamin E injections.

Plasma or serum levels of α-tocopherol can be measured and should be corrected for the level of plasma lipids by expressing the value as milligrams per milligram of plasma lipid.

**Epidemiological data and clinical trials**

Animals fed an atherogenic diet supplemented with α-tocopherol develop many fewer new atheromatous lesions than those fed an atherogenic diet alone; there may be regression of existing lesions.

There is also evidence for vitamin E intake and blood α-tocopherol levels as an independent risk factor for the development of ischaemic heart disease (IHD) in healthy, well-nourished individuals eating a western diet. This has been shown in comparisons of different communities in the WHO ‘MONICA’ observational study.

**Randomized trials** involving vitamin E supplementation have produced conflicting results, possibly due to factors such as short duration of treatment, use of suboptimal doses or without the concurrent administration of vitamin C, although there may be benefit in certain subgroups.

There are very few trials to assess the role of vitamin E in prevention of peripheral vascular disease and for cancer prevention, although there may be some benefit in patients with Alzheimer’s disease.

### WATER-SOLUBLE VITAMINS

Water-soluble vitamins are non-toxic and relatively cheap and can therefore be given in large amounts if a deficiency is possible. The daily requirements of water-soluble vitamins are given in Table 5.8.

#### Thiamin (vitamin B₁)

Thiamin consists of pyrimidine and thiazole rings. The alcohol side-chain is esterified with one, two or three phosphates (Fig. 5.7).

**Function**
Thiamin diphosphate, often called thiamin pyrophosphate (TPP), is an essential cofactor, particularly in carbohydrate metabolism.
Thiamin deficiency
Thiamin deficiency is seen:
- as beriberi, where the only food consumed is polished rice
- in chronic alcohol-dependent patients who are consuming virtually no food at all
- in starved patients (e.g. with carcinoma of the stomach), and in severe prolonged hyperemesis gravidarum, anorexia nervosa and prolonged total starvation in healthy subjects (e.g. fasts for political reasons). It can also occur in patients given parenteral nutrition with little or no thiamin as large doses of glucose increase requirements of thiamine and can precipitate deficiency, e.g. during refeeding.

Beriberi
This is now confined to the poorest areas of South East Asia. It can be prevented by eating undermilled or par-boiled rice, or by fortification of rice with thiamine. The prevention of beriberi needs a general increase in overall food consumption so that the staple diet is varied and contains legumes and pulses, which contain a large amount of thiamin. There are two main clinical types of beriberi which, surprisingly, only rarely occur together.

Dry beriberi usually presents insidiously with a symmetrical polyneuropathy. The initial symptoms are heaviness and stiffness of the legs, followed by weakness, numbness, and pins and needles. The ankle jerk reflexes are lost and eventually all the signs of polyneuropathy that may involve the trunk and arms are found (p. 1172). Cerebral involvement occurs, producing the picture of the Wernicke–Korsakoff syndrome (p. 1174). In endemic areas, mild symptoms and signs may be present for years without unduly affecting the patient.

Wet beriberi causes oedema. Initially this is of the legs, but it can extend to involve the whole body, with ascites and pleural effusions. The peripheral oedema may mask the accompanying features of dry beriberi.

Thiamin deficiency impairs pyruvate dehydrogenase with accumulation of lactate and pyruvate, producing peripheral vasodilatation and eventually oedema. The heart muscle is also affected and heart failure occurs, causing a further increase in the oedema. Initially there are warm extremities, a full, fast, bounding pulse and a raised venous pressure ("high-output state"), but eventually heart failure advances and a poor cardiac output ensues. The electrocardiogram may show conduction defects.

Infantile beriberi occurs, usually acutely, in breast-fed babies at approximately 3 months of age. The mothers show no signs of thiamin deficiency but presumably their body stores must be virtually nil. The infant becomes anorexic, develops oedema and has some degree of aphonia. Tachycardia and tachypnoea develop and, unless treatment is instituted, death occurs quickly.

Diagnosis
In endemic areas the diagnosis of beriberi should always be suspected and if in doubt treatment with thiamine should be instituted. A rapid disappearance of oedema after thiamine (50 mg i.m.) is diagnostic. Other causes of oedema must be considered (e.g. renal or liver disease), and the polyneuropathy is indistinguishable from that due to other causes. The diagnosis is confirmed by measurement of the circulating thiamin concentration or transketolase activity in red cells using fresh heparinized blood. This enzyme is dependent on TPP. The assay is performed with and without added TPP; an increase in activity of 25% with TPP indicates deficiency.

Treatment
Thiamine 50 mg i.m. is given for 3 days, followed by 50 mg of thiamine daily by mouth. The response in wet beriberi occurs in hours, giving dramatic improvement, but in dry beriberi improvement is often slow to occur. In most cases all the B vitamins are given because of multiple deficiency. Infantile beriberi is treated by giving thiamine to the mother, which is then passed on to the infant via the breast milk.

Thiamin deficiency in patients with alcohol dependence or acute illness
In the western world alcohol-dependent patients and those with severe acute illness receiving high carbohydrate infusions without vitamins are the only major groups to suffer from thiamin deficiency. Rarely they develop wet beriberi, which must be distinguished from alcoholic cardiomyopathy. More usually, however, thiamin deficiency presents with polyneuropathy or with the Wernicke–Korsakoff syndrome.

This syndrome, which consists of dementia, ataxia, varying ophthalmoplegia and nystagmus (see p. 1174), presents acutely and should be suspected in all heavy drinkers. If treated promptly it is reversible; if left it becomes irreversible. It is a major cause of dementia in the USA.

Urgent treatment with thiamine 250 mg i.m. or i.v. infusion once daily is given for 3 days, often combined with other B-complex vitamins. Anaphylaxis can occur. Thiamine must always be given before any intravenous glucose infusion.

Riboflavin
Riboflavin is widely distributed throughout all plant and animal cells. Good sources are dairy products, offal and leafy vegetables. Riboflavin is not destroyed appreciably by cooking, but is destroyed by sunlight. Riboflavin is a flavoprotein that is a cofactor for many oxidative reactions in the cell.

There is no definite deficiency, although many communities have low dietary intakes. Studies in volunteers taking a low riboflavin diet have produced:
angular stomatitis or cheilosis (fissuring at the corners of the mouth)

■ a red, inflamed tongue

■ seborrhoeic dermatitis, particularly involving the face (around the nose) and the scrotum or vulva.

Conjunctivitis with vascularization of the cornea and opacity of the lens has also been described. It is probable, however, that many of the above features are due to multiple deficiencies rather than the riboflavin itself.

Riboflavin 5 mg daily can be tried for the above conditions, usually given as the vitamin B complex.

### Niacin

This is the generic name for the two chemical forms, nicotinic acid and nicotinamide, the latter being found in the two pyridine nucleotides, nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP). Both act as hydrogen acceptors in many oxidative reactions, and in their reduced forms (NADH and NADPH) act as hydrogen donors in reductive reactions. Many oxidative steps in the production of energy require NAD, and NADP is equally necessary in the hexose monophosphate shunt (p. 413) for the generation of NADPH, which is necessary for fatty-acid synthesis.

Niacin is found in many foodstuffs, including plants, meat (particularly offal) and fish. Niacin is lost by removing bran from cereals but is added to processed cereals and white bread in many countries.

Niacin can be synthesized in humans from tryptophan, 60 mg of tryptophan being converted to 1 mg of niacin. The amount of niacin in food is given as the 'niacin equivalent', which is equal to the amount of niacin plus one-sixtieth of the tryptophan content. Eggs and cheese contain tryptophan.

Kynureninase and kynurenine hydroxylase, key enzymes in the conversion of tryptophan to nicotinic acid, are both B6 and riboflavin dependent, and deficiency of these B vitamins can also produce pellagra.

### Pellagra

This is rare and is found in people who eat virtually only maize, for example in parts of Africa. Maize contains niacin in the form of niacytin, which is biologically unavailable, and has a low content of tryptophan. In central America, pellagra has always been rare because maize (for the cooking of tortillas) is soaked overnight in calcium hydroxide, which releases niacin. Many of the features of pellagra can be explained purely by niacin deficiency; but some are probably due to multiple deficiencies, including deficiencies of proteins and of other vitamins.

#### Clinical features

The classical features are of dermatitis (Fig. 5.8), diarrhoea and dementia. Although this is an easily remembered triad, not all features are always present and the mental changes are not a true dementia.

■ Dermatitis. In the areas of skin exposed to sunlight, initially there is redness followed by cracks with occasional ulceration. Chronic thickening, dryness and pigmentation develop. The lesions are always symmetrical and often affect the dorsal surfaces of the hands. The perianal skin and vulva are frequently involved. Casal's necklace or collar is the term given to the skin lesion around the neck, which is confined to this area by the clothes worn.

■ Diarrhoea. This is often a feature but constipation is occasionally seen. Other gastrointestinal manifestations include a painful, red, raw tongue, glossitis and angular stomatitis. Recurring mouth infections occur.

■ Dementia. This occurs in chronic disease. In milder cases there are symptoms of depression, apathy and sometimes thought disorders. Tremor and an encephalopathy frequently occur. Hallucinations and acute psychosis are also seen with more severe cases.

Pellagra may also occur in the following circumstances:

■ Isoniazid therapy can lead to a deficiency of vitamin B6, which is needed for the synthesis of nicotinamide from tryptophan. Vitamin B6 is now given concomitantly with isoniazid.

■ In Hartnup’s disease, a rare inborn error, in which basic amino acids including tryptophan are not absorbed by the gut. There is also loss of this amino acid in the urine.

■ In generalized malabsorption (rare).

■ In alcohol-dependent patients who eat little.

■ Very low protein diets given for renal disease or taken as a food fad.

■ In the carcinoid syndrome and phaeochromocytomas, tryptophan metabolism is diverted away from the formation of nicotinamide to form amines.

#### Diagnosis and treatment

In endemic areas this is based on the clinical features, remembering that other vitamin deficiencies can produce similar changes (e.g. angular stomatitis). Nicotinamide (approximately 300 mg daily by mouth) with a maintenance dose of 50 mg daily is given with dramatic improvement in the skin and diarrhoea. Mostly, however, vitamin B complex is given, as other deficiencies are often present.

An increase in the protein content of the diet and treatment of malnutrition and other vitamin deficiencies is essential.
**Vitamin B₉**

Vitamin B₉ exists as pyridoxine, pyridoxal and pyridoxamine, and is found widely in plant and animal foodstuffs. Pyridoxal phosphate is a cofactor in the metabolism of many amino acids. Dietary deficiency is extremely rare. Some drugs (e.g. isoniazid, hydralazine and penicillamine) interact with pyridoxal phosphate, producing B₉ deficiency. The polyneuropathy occurring after isoniazid usually responds to vitamin B₉.

Sideroblastic anaemia may respond to vitamin B₉ (see p. 397). A polyneuropathy has occurred after high doses (>200 mg) given over many months. Vitamin B₉ is used for premenstrual tension: a daily dose of 10 mg should not be exceeded.

**Biotin and pantothenic acid**

Biotin is involved in a number of carboxylase reactions. It occurs in many foodstuffs and the dietary requirement is small. Deficiency is extremely rare and is confined to a few people who consume raw eggs, which contain an antagonist (avidin) to biotin. It has also been reported in patients receiving long-term parenteral nutrition without adequate amounts of biotin. It causes a dermatitis that responds to biotin replacements.

Pantothenic acid is widely distributed in all foods and deficiency in humans has not been described.

**Vitamin C**

Ascorbic acid is a powerful reducing agent controlling the redox potential within cells. It is involved in the hydroxylation of proline to hydroxyproline, which is necessary for the formation of collagen. The failure of this biochemical pathway in vitamin C deficiency accounts for virtually all of the clinical effects seen.

Humans, along with a few other animals (e.g. primates and the guinea-pig), are unusual in not being able to synthesize ascorbic acid from glucose.

Vitamin C is present in all fresh fruit and vegetables. Unfortunately, ascorbic acid is easily leached out of vegetables when they are placed in water and it is also oxidized to dehydro-ascorbic acid during cooking or exposure to copper or alkalis. Potatoes are a good source as many people eat a lot of them, but vitamin C is lost during storage.

It has been suggested that ascorbic acid in high dosage (1–2 g daily) will prevent the common cold. While there is some scientific support for this, clinical trials have shown no significant effect. Vitamin C supplements have also been advocated to prevent atherosclerosis and cancer, but again a clear benefit has not been demonstrated.

**Vitamin C deficiency** is seen mainly in infants fed boiled milk and in the elderly and single people who do not eat vegetables. In the UK it is also seen in Asians eating only rice and chapattis, and in food faddists.

**Scurvy**

In adults the early symptoms of vitamin C deficiency may be non-specific, with weakness and muscle pain. Other features are shown in Table 5.11. In infantile scurvy there is irritability, painful legs, anaemia and characteristic subperiosteal haemorrhages, particularly into the ends of long bones.

**Table 5.11 Clinical features of vitamin C deficiency (scurvy)**

**Diagnosis**

The anaemia is usually hypochromic but occasionally a normochromic or megaloblastic anaemia is seen. The type of anaemia depends on whether iron deficiency (owing to decreased absorption or loss due to haemorrhage) or folate deficiency (folate being largely found in green vegetables) is present.

Plasma ascorbic acid is very low in obvious deficiency and a vitamin C level of less than 11 μmol/L (0.2 mg per 100 mL) indicates vitamin C deficiency. The leucocyte-platelet layer (buffy coat) of centrifuged blood corresponds to vitamin C concentrations in other tissues. The normal level of leucocyte ascorbate is 1.1–2.8 pmol per 10⁶ cells.

**Treatment**

Initially the patient is given 250 mg of ascorbic acid daily and encouraged to eat fresh fruit and vegetables. Subsequently, 40 mg daily will maintain a normal exchangeable body pool of about 900 mg (5.1 mmol).

**Prevention**

Orange juice should be given to bottle-fed infants. The intake of breast-fed infants depends on the mother’s diet. In the elderly, eating adequate fruit and vegetables is the best way to avoid scurvy. Careful surveillance of the elderly, particularly those who live alone, is necessary. Ascorbic acid supplements should only be necessary occasionally.

**Vitamin B₁₂ and folate**

These are dealt with on page 398 and daily requirements are shown in Table 5.8.

**Folate.** In many developed countries, up to 15% of the population have a partial deficiency of 5,10-methylene tetrahydrofolate reductase, a key folate-metabolizing enzyme. This is due to a point mutation and is associated with an increase in neural tube defects and hyperhomocysteinaemia, which may lead to cardiovascular damage. Autoantibodies against folate receptors have been found in serum from women who have had a pregnancy complicated by neural tube defects. However, the role of this in the pathogenesis is unclear.

In the USA and some other countries, enriched cereals are fortified with 1.4 mg/kg grain of folic acid to increase daily requirements.

**Dietary antioxidants**

Free radicals are generated during inflammatory processes, radiotherapy, smoking, and during the course of a wide range of diseases. They may cause uncontrolled damage of
multiple cellular components, the most sensitive of which are unsaturated lipids, proteins and DNA, and they also disrupt the normal replication process. They have been implicated as a cause of a wide range of diseases, including malignant, acute inflammatory and traumatic diseases, cardiovascular disease, neurodegenerative conditions such as Alzheimer’s disease, senile macular degeneration, and cataract. The defence against uncontrolled damage by free radicals is provided by antioxidant enzymes (e.g. catalase, superoxide dismutase) and antioxidants, which may be endogenous (e.g. glutathione) or exogenous (e.g. vitamins C and E, carotenoids). A possible causal link between lack of antioxidants and cardiovascular disease has emerged from epidemiological studies although several RCTs have not confirmed this.

Epidemiological studies

**Dietary intake**

- A high intake of fruits and vegetables has been linked to a reduced risk of heart disease, cerebrovascular disease and total cardiovascular morbidity and mortality.
- A high intake of nuts (rich in vitamin E) and dietary components, e.g. red wine, onions, apples (rich in flavonoids), which are strong scavengers of free radicals, has also been linked to a reduced risk of cardiovascular disease.
- The seasonal variation in cardiovascular disease, which is higher in winter, has been related to decreased intake of fresh fruit and vegetables in winter.
- The decline in cardiovascular disease in the USA since the 1950s has been associated with a simultaneous increase in the intake of fresh fruit and vegetables.

**Status of antioxidant nutrients**

The level of antioxidant nutrients in the circulation has been reported to be inversely related to cardiovascular morbidity and mortality, extent of atherosclerosis assessed by intra-arterial ultrasound, and clinical signs of ischaemic heart disease. The tissue content of lycopene, a marker of vegetable intake, has been reported to be low in patients with myocardial infarction.

Antioxidants, especially vitamin E, have been shown to prevent the initiation and progression of atherosclerotic disease in animals. They also reduce the oxidation of low-density lipoprotein (LDL) in the arterial wall in vitro. Oxidation of LDL is an initial event in the atherosclerotic process (p. 744). However these epidemiological studies show an association rather than a causal link and RCTs comparing the antioxidant against a control group are necessary.

**Randomized controlled trials (RCT)** (see also p. 929)

The results of such trials have been formally evaluated through a series of systematic reviews and meta-analyses.

- For primary or secondary prevention of cardiovascular disease, intervention with β-carotene, α-tocopherol (vitamin E) and ascorbic acid (vitamin C) has demonstrated no significant benefit.
- Vitamin E or β-carotene given in, e.g. stroke and fatal and non-fatal myocardial infarction, has also not yielded benefits.

There is a report of increased risk of intracerebral and subarachnoid haemorrhage in healthy individuals receiving carotene and α-tocopherol.

A meta-analysis has shown a small but significant overall increased risk of cardiovascular death and all-cause mortality in individuals treated with β-carotene (compared to the control group).

An increased risk of developing lung cancer by administering large doses of β-carotene to subjects with a history of heavy smoking.

Although administration of antioxidant nutrients has been proposed in a wide range of acute (e.g. critical illness, pancreatitis) and chronic diseases, the evidence base from randomized RCTs is generally not strong.

In some cases improvement in indices of free radical damage had been demonstrated (e.g. in acute inflammatory conditions), but with little evidence of clinical benefit.

Epidemiological studies are also confounded by other associated variables, e.g. eating a low-fat diet or undertaking more exercise. The latter may be more valuable in the causal pathway than the intake of antioxidants. Diets rich in fresh fruit and vegetables also contain a range of antioxidants that were not tested in the clinical trials. Therefore, the results of large-scale RCTs using various combinations and doses of antioxidant nutrients are currently awaited. In the meantime, the policy of encouraging ‘healthy’ behaviour, which includes increased physical activity and a varied diet rich in fresh fruit and vegetables, and nuts, is still generally recommended both for the population as a whole and for those at risk of cardiovascular disease.

**Homocysteine, cardiovascular disease and B vitamins**

The circulating concentration of the amino acid homocysteine is an independent risk factor for cardiovascular disease (p. 747). A high concentration is related to ischaemic heart disease, stroke, thrombosis, pulmonary embolism, coronary artery stenosis, and heart failure. The strength of the association is similar to smoking or hyperlipidaemia.

Proposed mechanisms, based on experimental evidence, by which homocysteine detrimentally affects vascular function, include:

- the direct damaging effects of homocysteine on endothelial cells of blood vessels
- an increase in blood vessel stiffness
- an increase in blood coagulation.

Homocysteine is not found in food, but results from metabolism within the body which depends on folic acid, vitamin B₁₂ and pyridoxine (vitamin B₆) (Fig. 5.9). Deficiency of one or more of these vitamins is common in the elderly, which would increase the concentration of homocysteine. If an elevated homocysteine concentration was causally linked to cardiovascular disease then it should be possible to lower the risk by administering one or more of these vitamins to lower the homocysteine concentration. Some recent studies, however, suggest that lowering homocysteine concentrations in this way does not reduce the risk of cardiovascular disease.
Iron deficiency is common worldwide, particularly prevalent in women of reproductive age. Dietary iron overload is seen in South African men who cook and brew for men and 10.9 for women) and chloride are discussed.

The daily RNI of copper is 1.2 mg (19

**FURTHER READING**

**MIXERALS**

A number of minerals have been shown to be essential in animals, and an increasing number of deficiency syndromes are becoming recognized in humans. Long-term total parenteral nutrition allowed trace element deficiency to be studied in controlled conditions; now trace elements are always added to long-term parenteral nutrition regimens. It is highly probable (but difficult to study because of multiple deficiencies) that trace-element deficiency is also a frequent companion of all PEM states. Sodium (RNI 70 mmol/day), potassium (RNI 90 mmol/day), magnesium (RNI 12.3 mmol/day for men and 10.9 for women) and chloride are discussed in Chapter 12.

**Iron** (see also p. 393)

The daily RNI for men is 160 μmol (8.7 mg) and for women 260 μmol (14.8 mg). Iron deficiency is common world-wide, affecting both developing and developed countries. It is particularly prevalent in women of reproductive age. Dietary iron overload is seen in South African men who cook and brew in iron pots.

**Copper**

The daily RNI of copper is 1.2 mg (19 μmol). Shellfish, legumes, cereals and nuts are good dietary sources.

**Deficiency**

Menkes’ kinky hair syndrome is a rare condition caused by malabsorption of copper. The Menkes’ disease gene (ATP7A) encodes a copper-transporting ATPase and has a homology to the gene in Wilson’s disease. Infants with this sex-linked recessive abnormality develop growth failure, mental retardation, bone lesions and brittle hair. Anaemia and neutropenia also occur. This condition, which serves as a model for copper deficiency, supports the idea that some of the clinical features seen in PEM are due to copper deficiency. Breast and cow’s milk are low in copper, and supplementation is occasionally necessary when first treating PEM.

**Copper toxicity**

This occurs in Wilson’s disease; see page 357.

**Zinc**

The daily RNI of zinc is 9.5 mg (145 μmol) for men, 7 mg (110 μmol) for women and it is widely available in food. Zinc is involved in many metabolic pathways, often acting as a coenzyme; it is essential for the synthesis of RNA and DNA.

**Deficiency**

Acrodermatitis enteropathica is an inherited disorder caused by malabsorption of zinc. Infants develop growth retardation, severe diarrhoea, hair loss and associated Candida and bacterial infections. This condition provides a model for zinc deficiency. Zinc supplementation results in a complete cure. Deficiency probably also plays a role in PEM and in many diseases in children in the developing world. Zinc supplementation has been shown to be of some benefit in, for example, the prevention of diarrhoeal diseases and acute respiratory infections; it also improves growth.

Zinc levels have also been shown to be low in some patients with malabsorption or skin disease, and in patients with AIDS, but the exact role of zinc in these situations is disputed. Zinc has low toxicity, but high zinc levels from water stored in galvanized containers interfere with iron and copper metabolism. Wound healing is impaired with moderate zinc deficiency and is improved by zinc supplements. Impaired taste and smell, hair loss and night blindness are also features of severe zinc deficiency.

**Iodine**

The daily RNI of iodine is 140 μg (1.1 μmol) for men and women, and it is found in milk, meat and seafoods.

It exists in foodstuffs as inorganic iodides which are efficiently absorbed. Iodine is a constituent of the thyroid hormones (p. 983).

**Deficiency**

Many areas throughout the world lack iodine in the soil, and so iodine deficiency, which impairs brain development, is a WHO priority. Two billion people (one-third children) worldwide have insufficient iodine intake. Endemic goitre occurs in remote areas where the daily intake is below 70 μg, and in those parts 1–5% of babies are born with cretinism. In these areas, iodized oil should be given intramuscularly to all reproductive women every 3–5 years. Salt iodization is now used in many countries and is a simple, cost-effective way to prevent deficiency.

**MINERALS**

A number of minerals have been found to be essential in animals, and an increasing number of deficiency syndromes are becoming recognized in humans. Long-term total parenteral nutrition allowed trace element deficiency to be studied in controlled conditions; now trace elements are always added to long-term parenteral nutrition regimens. It is highly probable (but difficult to study because of multiple deficiencies) that trace-element deficiency is also a frequent companion of all PEM states. Sodium (RNI 70 mmol/day), potassium (RNI 90 mmol/day), magnesium (RNI 12.3 mmol/day for men and 10.9 for women) and chloride are discussed in Chapter 12.

**Iron** (see also p. 393)

The daily RNI for men is 160 μmol (8.7 mg) and for women 260 μmol (14.8 mg). Iron deficiency is common world-wide, affecting both developing and developed countries. It is particularly prevalent in women of reproductive age. Dietary iron overload is seen in South African men who cook and brew in iron pots.

**Copper**

The daily RNI of copper is 1.2 mg (19 μmol). Shellfish, legumes, cereals and nuts are good dietary sources.
Fluoride
In areas where the level of fluoride in drinking water is less than 1 p.p.m. (0.7–1.2 mg/L), dental caries is relatively more prevalent. Fluoridation of the water provides 1–2 mg daily, resulting in a reduction of about 50% of tooth decay in children. There is little fluoride in food except for sea food and tea, the latter providing 70% of the daily intake. Fluoride-containing toothpaste may add up to 2 mg a day.

Excessive fluoride intake in areas where the water fluoride level is above 3 mg/L can result in fluorosis, in which there is infiltration into the enamel of the teeth, producing pitting and discoloration.

Selenium
Clinical deficiency of selenium is rare except in areas of China where Keshan disease, a selenium-responsive cardiomyopathy, occurs. Selenium deficiency may also cause a myopathy. Toxicity has been described with very high intakes.

Calcium (see also p. 558)
In the UK, the daily RNI of calcium is 700 mg (17.5 mmol), but substantially higher values are recommended in the USA. It is found in many foodstuffs, with two-thirds of the intake coming from milk and milk products, and only 5% from vegetables. In the UK most flour is fortified. Calcium absorption from the gastrointestinal tract is vitamin D-dependent. Ninety-nine per cent of body calcium is in the skeleton.

Increased calcium is required in pregnancy and lactation, when dietary intake must be increased. Calcium deficiency is usually due to vitamin D deficiency.

Phosphate (see also p. 559)
The daily RNI of phosphate is the same as that of calcium, i.e. 17.5 mmol. Phosphates are present in all natural foods, and dietary deficiency has not been described. Patients taking large amounts of aluminium hydroxide can, however, develop phosphate deficiency owing to binding in the gut lumen. It can also be seen in total parenteral nutrition. Symptoms include anorexia, weakness and osteoporosis.

Other trace elements
The possible significance of cadmium, chromium, cobalt, manganese, molybdenum, nickel and vanadium is shown in Table 5.12.

NUTRITION AND AGEING
Many animal studies have shown that life expectancy can be extended by restricting food intake. It is, however, not known whether the ageing process in humans can be altered by nutrition.

THE AGEING PROCESS
The process of ageing is not well understood. While wear and tear may play a role, it is an insufficient explanation for the causation of ageing. The ‘programmed’ theories depend on inbuilt biological clocks that regulate lifespan, and involve genes that are responsible for controlling signals that influence various body systems. The ‘error’ theories involve environmental stressors that induce damage (e.g. mitochondrial DNA damage or cross-linking).

The search for a single cause of ageing, e.g. a single gene defect, has been replaced by the view that ageing is a complex multifactorial process that involves an interaction between genetic, environmental, and stochastic (random damage to essential molecules) causes. The following theories have been suggested:

Molecular theories
- **Gene regulation** – ageing, for example, results from changes in expression of genes that regulate both development and ageing. An insulin-like signalling pathway has been linked to the lifespan of worms, flies and mice (activation of a transcription factor in response to reduced insulin-like signalling prolongs lifespan).
- **Codon restriction** – inadequate mRNA translation resulting from inadequate decoding of codons in mRNA.
- **Error catastrophe** – errors in gene expression result in abnormal proteins.
- **Somatic mutation** – cumulative molecular damage mainly to genetic material.
- **Dysdifferentiation** – cumulative random molecular damage detrimentally affects gene expression.

Mutations in genes encoding Lamin A are found in fibroblasts of elderly people and in progeria syndromes.

Cellular theories
- **Cellular senescence-telomere** – an increase in senescent cells occurs from:
  (a) **Loss of telomeres**, which is known to occur with ageing (with each cell division a small amount of DNA is necessarily lost at each end of the chromosome). Activation of the telomerase enzyme regenerates telomeres, prevents senescence (replicative senescence) and immortalizes cell cultures. Cancer cells are known to activate telomerase. Accelerated telomerase shortening occurs in progerias, such as Werner’s syndrome. A recent study has also found that telomere length in leucocytes predicts coronary artery disease in middle-aged men at high risk and these individuals might benefit from statin treatment.
(b) *Damage* due to a variety of other factors, including DNA damage (stress-induced senescence).

- **Free radical** – production of free radicals during oxidative metabolism which damages fat, protein and DNA.
- **Wear and tear** – cumulative damage from normal injury/stress which is unable to repair itself.
- **Apoptosis theory** – programmed cell death due to genetic events.

**System theories**
These theories involve loss in the function of neuroendocrine or immune systems with consequent age-related physiological changes and an increase in autoimmunity.

*Whole body metabolism and energy expenditure theory* proposes that there is a fixed limit to the cumulative energy expenditure and metabolism during a lifetime, so that if this limit is reached quickly the lifespan is short. Energy restriction in rodents reduces energy expenditure and prolongs lifespan, but there is a lack of studies in primates or humans.

**Evolutionary theories**
- **Cumulative mutation** – mutations that accumulate during a lifetime act in older age rather than during the active reproductive period (for which there is evolutionary selection), producing pathology and senescence. The theory was initially based on the observation that Huntington’s disease, a dominant lethal mutation which typically manifests itself between 35 and 55 years, allows affected individuals to reproduce.
- **Disposable soma** – the somatic body is maintained to ensure reproductive success, after which it is disposable. Factors that may enhance reproductive success may have detrimental effects on ageing – a possible example being androgen secretion, which may be beneficial to reproduction but potentially detrimental with development of prostatic cancer and cardiovascular disease in later life.

Several of these theories have strong nutritional components. *Disability and dependency* in older humans are at least partly due to poor nutrition, and correction of deficiencies or nutrient imbalances can prevent the decline in function from falling below the disability threshold (Fig. 5.10). In this way some loss of function may be prevented or reversed, especially if other measures, such as physical activity, which increases muscle mass and strength, are undertaken.

**Early origins of health and disease in older adults**
A low birth weight (and/or length) is associated with reduced height, as well as reduced mass and fat-free mass in adult life. These relationships can occur independently of genetic factors, since the smaller of identical twins becomes a shorter and lighter adult. Relationships have also been reported between growth of the fetus and a variety of diseases and risk factors for disease in adults and older people. These include cardiovascular disease, especially ischaemic heart disease, hypertension, and diabetes, and even obesity and fat distribution. However, the strength of association for some of these conditions is in some cases weak. Animal studies involving dietary modifications (e.g. protein and zinc, even within the normal range) during pregnancy or in early postnatal life have clearly demonstrated effects, such as hypertension. This can persist, not only through the lifetime of the offspring, but also through to their offspring. The extent to which these apply to humans is uncertain, and the mechanisms are poorly understood. Since relationships with cardiovascular disease in old age have also been related to growth in the first few years of life as well as starvation during puberty, it is likely that cumulative environmental stresses, including nutritional, from the time of implantation of the fertilized egg, to fetal and postnatal growth and development, and adult life, summate to produce an overall disease risk (Fig. 5.10).

**Nutritional requirements in the elderly**
These are qualitatively similar to the requirements of younger adults, but as energy expenditure is less, there is a lower energy requirement. However, maintaining physical activity is required for the overall health of the elderly.
The daily energy requirement of ‘elderly people’ (aged 60 and above, irrespective of age) has been set to be approximately 1.5 × BMR. The BMR is reduced, owing to a fall in the fat-free mass, from an average of 60 kg to 50 kg in men and from 40 kg to 35 kg in women. In disease, physical activity is usually decreased. The diet should contain approximately the same proportions of nutrients, and essential nutrients are still required. Although disabilities and diseases are common in older people, the RNIs are intended for healthy people without disease. The nutrient requirements for those with disease are less well defined.

Nutritional deficits in the elderly are common and may be due to many factors, such as dental problems, lack of cooking skills (particularly in widowers), depression and lack of motivation. Significant malnourishment in developed countries is usually secondary to social problems or disease. In the elderly who are in institutions, multiple nutrient deficiencies are common. Vitamin D supplements may be required because often these people do not go into the sunlight. Owing to the high prevalence of osteoporosis in elderly people, daily calcium intake of 1–1.5 g/day is often recommended.

### Further Reading

### Obesity

Obesity is almost invariable in developed countries and almost all people accumulate some fat as they get older. The World Health Organization acknowledges that obesity (body mass index >30 kg/m²) is a world-wide problem which also affects many developing countries. Obesity implies an excess storage of fat, and this can most easily be detected by looking at the undressed patient.

Most patients suffer from simple obesity, but in certain conditions obesity is an associated feature (Table 5.13). Even in the latter situation, the intake of calories must have exceeded energy expenditure over a prolonged period of time. Hormonal imbalance is often incriminated in women (e.g. postmenopause or when taking contraceptive pills), but most weight gain in such cases is usually small and due to water retention.

Not all obese people eat more than the average person, but all obviously eat more than they need.

### Suggested mechanisms

#### Genetic and environmental factors

These have always been difficult to separate when studying obesity. However, feeding experiments in both monoyzotic and dizygotic twins, reared together or apart, suggest that genetic influences account for 70% of the difference in body mass index (BMI) later in life, and that the childhood environment has little or no influence.

These feeding experiments also showed that weight gain did not occur in all pairs of twins, suggesting that environmental factors operate. Genetic factors have led to the discovery of a putative gene, firstly in the obese (ob ob) mouse and now in humans. The ob gene was shown to be expressed solely in both white and brown adipose tissue. The ob gene is found on chromosome 7 and produces a 16 kDa protein called leptin. In the ob ob mouse a mutation in the ob gene leads to production of a non-functioning protein. Administration of normal leptin to these obese mice reduces food intake and corrects the obesity. A similar situation has been described in a very rare genetic condition causing obesity in humans, in which leptin is not expressed.

In massively obese subjects, leptin mRNA in subcutaneous adipose tissue is 80% higher than in controls. Plasma levels of leptin are also very high, correlating with the BMI. Weight loss due to food restriction decreases plasma levels of leptin. However, in contrast to the ob ob mouse, the leptin structure is normal, and abnormalities in leptin are not the prime cause of human obesity.

Leptin secreted from fat cells was thought to act as a feedback mechanism between the adipose tissue and the brain, acting as a ‘lipostat’ (adipostat), controlling fat stores by regulating hunger and satiety (see below). However, many other signals are involved. It is interesting that obesity is largely restricted to humans, and animals that are domesticated or in zoos.

#### Food intake

Many factors related to the home environment, such as finance and the availability of sweets and snacks, will affect food intake. Some individuals eat more during periods of heavy exercise or during pregnancy and are unable to get back to their former eating habits. The increase in obesity in social class 5 can usually be related to the type of food consumed (i.e. food containing sugar and fat). Psychological factors and how food is presented may override complex biochemical interactions.

It has been shown that obese patients eat more than they admit to eating, and over the years a very small daily excess of intake over expenditure can lead to a large accumulation of fat. For example, a 44 kJ (10.5 kcal) daily excess would lead to a 10 kg weight gain over 20 years.
Control of appetite

Appetite is the desire to eat and this usually initiates food intake. Following a meal, satiation occurs. This depends on gastric and duodenal distension and the release of many substances peripherally and centrally.

Following a meal, cholecystokinin (CCK), bombesin, glucagon-like peptide 1 (GLP1), enteroctatin, and somatostatin are released from the small intestine, and glucagon and insulin from the pancreas. All of these hormones have been implicated in the control of satiety. Centrally, the hypothalamus—particularly the lateral hypothalamic area, and paraventricular and arcuate nuclei—plays a key role in integrating signals involved in appetite and bodyweight regulation (Fig. 5.11). There are two main pathways in the arcuate nucleus (see Fig. 5.11):

- The central appetite-stimulating (anorexogenic) pathway in the ventromedial part of the arcuate nucleus, which expresses NPY (neuropeptide Y) and AgRP (agouti-related protein). Animal studies suggest that this pathway also decreases energy expenditure.

- The central appetite-suppressing (anorexogenic) pathway in the dorsolateral part of the arcuate nucleus, which expresses POMC/CART (pro-opiomelanocortin/cocaine-and-amfetamine-regulated transcript). In this pathway, α-MSH (α-melanocyte-stimulating hormone), formed by cleavage of POMC by PC1 (prohormone convertase), exerts its appetite-suppressing effect via the Mc4R (melanocortin-4 receptors) in areas of the brain that regulate food intake and autonomic activity. Animal studies suggest that this pathway also increases energy expenditure.

These pathways interact with each other and feed into the lateral hypothalamus, which communicates with other parts of the brain, and influence the autonomic nervous system and ingestive behaviour. These central pathways are in turn influenced by a variety of peripheral signals which can also be classified as appetite stimulating or appetite suppressing.

Peripheral appetite-suppressing: Leptin and insulin act centrally to activate the appetite-suppressing pathway (whilst also inhibiting the appetite-stimulating pathway). Since these hormones circulate in proportion to adipose tissue mass, they can be regarded as long-term signals, although they probably also modulate short-term signals (insulin also responds acutely to meal ingestion). Peptide YY (PYY) is produced by the L cells of the large bowel and distal small bowel in proportion to the energy ingested. The release of this rapidly responsive (short-acting) signal begins shortly after food intake, suggesting that the initial response involves neural pathways, before ingested nutrients reach the site of PYY production. PYY is thought to reduce appetite, at least partly through inhibition of the appetite-stimulating pathway (NPY/AgRP-expressing neurones).

Peripheral appetite-stimulating: Ghrelin is a 28-amino-acetylated peptide produced by the oxyntic cells of the fundus of the stomach. It is the first known gastrointestinal tract peptide that stimulates appetite by activating the central appetite-stimulating pathway. The circulatory concentration is high before a meal and is reduced rapidly by ingestion of a meal or glucose (cf. peptide YY, which increases after a meal). It may also act as a long-term signal, as its circulating concentration is low before a meal and is increased in several situations in which there is a negative energy balance, e.g. long-term exercise, very low-calorie diets, anorexia nervosa and both cancer and cardiac cachexia (an exception is vertical banded gastric bypass surgery, where its concentration is low rather than high).

The single gene mutations affecting this pathway in humans, e.g. leptin, leptin receptor, POMC, Mc4R, PC1, and SIM1, are rare and recessive, with the exception of the Mc4R, which is common and dominant with incomplete penetrance. It appears that the Mc4R mutation accounts for 2–6% of human obesity. Affected individuals are obese without disturbances in pituitary
function or resting energy expenditure, although children tend to be tall. However, these mutations are of little significance as obesity is predominantly polygenic in origin (the human obesity gene map has already identified several hundreds of candidate genes).

Another system, the endocannabinoid system, is involved in both central and peripheral regulation of food intake and control of energy balance. There are two receptors: endocannabinoid in the brain and CB₂ in the periphery. CB₁ receptors are located in the cerebral cortex, cerebellum and hippocampus.

The present obesity epidemic is mainly due to behaviour and lifestyle changes (although it may be that individuals with certain genes are affected more than others) with a trebling in the prevalence of obesity in the UK over the last 25 years as well as a vast increase in developing countries.

The control of appetite is extremely complex. For example, if one considers only one signal, i.e. leptin, there can be leptin resistance where obese individuals have high circulating leptin but with no reduction of appetite. In contrast, in acute starvation, leptin concentrations decrease to lower levels than expected from the prevailing adipose tissue mass. It is known that cytokines, such as TNF and IL-2, which are elevated in a wide range of inflammatory and traumatic conditions, also suppress appetite, although the exact pathways involved are not entirely clear. Finally, there are a range of transmitters in the central nervous system, some of which appear to inhibit appetite (dopamine, serotonin, γ-aminobutyric acid) and others which stimulate appetite (e.g. opioids).

Energy expenditure

**Basal metabolic rate (BMR)**. BMR in obese subjects is higher than in lean subjects, which is not surprising since obesity is associated with an increase in lean body mass.

**Physical activity**. Obese patients tend to expend more energy during physical activity as they have a larger mass to move. On the other hand, many obese patients decrease their amount of physical activity. The energy expended on walking at 3 miles per hour is only 15.5 kJ/ min (3.7 kcal/min) and therefore increasing exercise plays only a small part in losing weight. Nevertheless, because increased body fat develops insidiously over many years, any change in energy balance is helpful.

**Thermogenesis**

About 10% of ingested energy is dissipated as heat and is unconnected with physical activity. This dietary induced thermogenesis has been reported to be lower in obese and post-obese subjects than in lean subjects.

This would tend to favour energy deposition in obesity and those predisposed to obesity. However, other workers have found no difference in dietary induced thermogenesis between lean and obese subjects.

Brown adipose tissue in animals, when stimulated by cold or food, dissipates the energy derived from ingested food into heat. This can be a major component of overall energy balance in small mammals. However, the importance of brown adipose tissue thermogenesis in adult humans is likely to be very small, and of doubtful clinical significance. β₃-adrenergic receptors are the principal receptors mediating catecholamine-stimulated lipolysis in brown adipose tissue and to a lesser extent at other sites. Drugs with β₃-adrenergic activities have been developed, but side-effects have limited their use.

### Morbidity and mortality

Obese patients are at risk of early death, mainly from diabetes, coronary heart disease and cerebrovascular disease. The greater the obesity, the higher the morbidity and mortality rates. For example, men who are 10% overweight have a 13% increased risk of death, while the increase in mortality for those 20% overweight is 25%. The rise is less in women, and in men over 65 obesity is not an independent risk factor. Weight reduction reduces this mortality and therefore should be strongly encouraged. The benefits are probably greater in more obese subjects (Table 5.14).

### Clinical features

Most patients recognize their own problems, although often they are unaware of the main foods that cause obesity. Many symptoms are related to psychological problems or social pressures, such as the woman who cannot find fashionable clothes to wear.

The degree of obesity can be assessed by comparison with tables of ideal weight for height, from the BMI (Box 5.4), and by measuring skinfold thickness. The latter should be measured over the middle of the triceps muscle; normal values are 20 mm in a man and 30 mm in a woman. A central distribution of body fat (a waist/hip circumference ratio of >1.0 in men and >0.9 in women) is associated with a higher risk of morbidity and mortality than is a more peripheral distribution of body fat (waist/hip ratio <0.85 in men and <0.75 in women). This is because fat located centrally, especially inside the abdomen, is more sensitive to lipolytic stimuli, with the result that the abnormalities in circulating lipids are more severe.

Table 5.15 shows the conditions and complications that are associated with obesity.

The relationship between cardiovascular disease (hypertension or ischaemic heart disease), hyperlipidaemia, smoking, physical exercise and obesity is complex. Difficulties arise in interpreting mortality figures because of the number of factors involved. Many studies do not differentiate

---
between the types of physical exercise taken or take into account the cuff-size artefact in the measurement of blood pressure (an artefact will occur if a large cuff is not used in patients with a large arm). Nevertheless, obesity almost certainly plays a part in all of these diseases and should be treated. An exception is that stopping smoking, even if accompanied by weight gain, is more beneficial than any of the other factors. Physical fitness is also helpful, and there is some evidence to suggest that a fit obese person may have similar or even lower cardiovascular risk than a leaner unfit person.

**Metabolic syndrome**
There are two classification systems which are shown in Table 5.16. The differences are:

- A large waist is an absolute requirement for the International Diabetes Federation (IDF), but not in the ATP III NCEP.
- The IDF criteria use lower cut-off values for waist circumference (close to values of people with a BMI of 25 kg/m²) and lower fasting blood glucose concentrations.

This means that the prevalence of metabolic syndrome will be higher using the IDF criteria. These criteria will identify at-risk patients at an earlier stage. This could lead to further investigations from this initial screening, and institution of preventative as well as therapeutic measures.

Overweight/obesity and insulin resistance, which causes glucose and lipid disturbances, seem to form the basis of many features of the metabolic syndrome. Other classification systems also exist, e.g. using BMI instead of waist circumference.

The metabolic syndrome is a combination of risk factors (Table 5.16). Its clinical role in the prediction of the risk of cardiovascular disease is in doubt as the sum of the combined risk factors in the syndrome does not offer more than the individual factors added together.

**Treatment**

**Dietary control**
This largely depends on a reduction in calorie intake.

The most common diets allow a daily intake of approximately 4200 kJ (1000 kcal), although this may need to be nearer 6300 kJ (1500 kcal) for someone engaged in physical work. Very low calorie diets are also advocated by some, usually over shorter periods of time, but unless they are accompanied by changes in lifestyle, weight regain is likely. Patients must realize that prolonged dieting is necessary for large amounts of fat to be lost. Furthermore, a permanent change in eating habits is required to maintain the new low weight. It is relatively easy for most people to lose the first few kilograms, but long-term success in moderate obesity is poor, with an overall success rate of no more than 10%.

Many dietary regimens aim to produce a weight loss of approximately 1 kg per week. Weight loss will be greater initially owing to accompanying protein and glycoprotein breakdown and consequent water loss. After 3–4 weeks, further
weight loss may be very small because only adipose tissue is broken down and there is less accompanying water loss.

Patients must understand the principles of energy intake and expenditure, and the best results are obtained in educated, well-motivated patients. Constant supervision by healthcare professionals, by close relatives or through membership of a slimming club helps to encourage compliance. It is essential to establish realistic aims. A 10% weight loss, which is regarded by some as a ‘success’ (see Table 5.14) is a realistic initial aim.

An increase in exercise will increase energy expenditure and should be encouraged – provided there is no contraindication – since weight control is usually not achieved without exercise. The effects of exercise are complex and not entirely understood. However, exercise alone will usually produce little long-term benefit. On the other hand there is evidence to suggest that in combination with dietary therapy, it can prevent weight being regained. In addition, regular exercise (30 min daily) will improve general health.

The diet should contain adequate amounts of protein, vitamins and trace elements. A diet of 4200 kJ (1000 kcal) per day should be made up of more than 50 g protein, approximately 100 g of carbohydrate, and 40 g of fat. The carbohydrate should be in the form of complex carbohydrates such as vegetables and fruit rather than simple sugars. Alcohol contains 29 kJ/g (7 kcal/g) and should normally be discouraged. It can be substituted for other foods in the diet, but it often reduces the willpower. With a varied diet, vitamins and minerals will be adequate and supplements are not necessary.

A balanced diet, attractively presented, is of much greater value and safer than any of the slimming regimens often advertised in magazines.

Most obese people oscillate in weight; they often regain the lost weight, but many manage to lose weight again. This ‘cycling’ in bodyweight may play a role in the development of coronary artery disease.

A wide range of diets are available, including low-fat or low-carbohydrate diets, and some suit certain individuals better than others. The following general statements can be made about them:

- All low-calorie diets produce loss of bodyweight and fat, irrespective of dietary composition. Short-term weight loss is faster on low-carbohydrate diets, as a result of greater loss of body water, which is regained after the end of dietary therapy.
- Very low-fat diets are often low in vitamins E, B₁₂, and zinc. Very low-carbohydrate diets may be nutritionally inadequate, and may lead to deficiencies.
- Low-fat diets decrease LDL triglycerides and increase HDL, whereas low-carbohydrate diets produce a greater decrease in HDL and triglyceride, with no change in LDL.
- There are some potential long-term concerns with low-carbohydrate diets (high in fat and protein), including increased risk of osteoporosis, renal stones and atheroma (due to high saturated fat, high trans fat and cholesterol and the lack of fruits, vegetables and whole grains), but long-term studies are lacking.
- Low-energy-density diets, often bulky and rich in fibre and complex carbohydrates, may be more satiating but they are often less palatable than high-energy-density diets which may affect long-term compliance.
- Liquids, e.g. soft drinks, appear to be less satiating than solid foods.
- A recent study has shown that Mediterranean and low-carbohydrate diets are as effective as a low-fat diet for weight loss.

**Behavioural modification**

The aim of behavioural modification is to encourage the patient to take personal responsibility for changing lifestyle, which will determine dietary habits and physical activity. Family therapy may also be useful, especially when it involves obese children. It can be time-consuming and expensive. Cognitive behavioural therapy is even more time-consuming and expensive.

**Drug therapy**

Drugs can be used in the short term (up to 3 months) as an adjunct to the dietary regimen, but they do not substitute for strict dieting.

**Centrally acting drugs:**

- Drugs acting on both serotonergic and noradrenergic pathways, e.g. sibutramine, tesofensine.
- Cannabinoid-1 receptor blockers, e.g. rimonabant (now withdrawn due to depression/suicide risk), acting on the endocannabinoid system.
- Drugs acting on the noradrenergic pathways do suppress appetite but all have been withdrawn in the UK because of cardiovascular side-effects.

**Peripherally acting drugs:**

- Orlistat is an inhibitor of pancreatic and gastric lipases. It reduces dietary fat absorption and aids weight loss. Weight regain occurs after the drug is stopped. It has been used continuously in a large-scale trial for up to 2 years. The patients complain of diarrhoea during treatment and to avoid this take a low-fat diet resulting in weight loss.
- Incretins: Glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP) are being used in type 2 diabetes mellitus (p. 1039). They suppress appetite and are being used in obesity (Fig. 5.11)

A systematic review of long-term pharmacotherapy concluded that there was a paucity of long-term studies with antiobesity agents, and that in weight loss trials of 1-year duration, orlistat and sibutramine appear to be only modestly effective in promoting weight loss (2.7 and 4.3 kg greater weight loss respectively than the control group). Rimonabant produces a greater weight loss (6.7 kg at 1 year compared to a control group) in addition to hypocaloric dieting but it can produce anxiety and severe depression; it does not have FDA approval. Other randomized trials show that a combination of lifestyle modification and pharmacotherapy (sibutramine) produces greater weight loss than either treatment alone.

**Surgical treatment**

Surgery is used in some cases of morbid obesity (BMI >40 kg/m²) or patients with a BMI >35 kg/m² and obesity-
related complications, after conventional medical treatments have failed. A variety of gastrointestinal surgical procedures have been used. They fall into two main groups:

- restrictive procedures, which restrict the ability to eat
- malabsorptive procedures, which reduce the ability to absorb nutrients.

A systematic analysis of bariatric surgical procedures concluded that, in comparison to non-surgical treatments, they produced significantly more weight loss (23–37 kg), which was maintained to 8 years and associated with improvement in quality of life and co-morbidities.

- Roux-en-Y gastric bypass. This procedure incorporates both restrictive and malabsorptive elements (gastro-jejunostomy). This procedure, like other malabsorptive procedures, may result in nutrient deficiencies requiring careful long-term follow-up.
- Bilio-pancreatic diversion (including the duodenal switch variation). This is another malabsorptive procedure that requires long-term evaluation.
- Laparoscopic adjustable gastric banding. This is a restrictive procedure, in which a band is placed around the upper stomach to produce a small proximal pouch and a large distal remnant. It has a perioperative mortality of < 0.5%, and results in loss of about 60% (43–78%) of the excess weight after 3 years, although longer-term follow-up studies are required. Laparoscopic adjustable gastric banding has been reported to produce greater weight loss and fewer side-effects (e.g., vomiting) and operative revisions than vertical banded gastroplasty.
- Liposuction. The removal of large amounts of fat by suction (liposuction) does not deal with the underlying problem and weight regain frequently occurs. There is no reduction in cardiovascular risk factors.

Prevention

Preventing obesity must always be the goal because most obese people find it difficult to maintain any weight loss they have managed to achieve. All health professionals must be aware of the dangers of obesity and encourage children, young as well as older adults, from gaining too much weight. A small gain each year over a long period produces an obese individual for whom treatment is difficult. Public health policies should consider creation of public places to encourage physical activity and fitness, education about the benefits of losing weight or not gaining it through healthy eating and physical activity, and changes in food composition (alternatives to high-fat, high-energy-dense foods).

The present obesity epidemic has resulted from lifestyle changes, and so it is appropriate to promote lifestyle changes, not only as the first line therapy for most overweight and obese individuals, but also in the prevention of overweight and obesity. Lifestyle modification would involve changes in the amount of time watching television and using computers, use of bicycle paths, dietary changes, and educational activities of patients and public, parents and children. All the specific therapies discussed above, including pharmacotherapy, should be part of a package that involves lifestyle modification.

NUTRITIONAL SUPPORT IN THE HOSPITAL PATIENT

Nutritional support is recognized as being necessary in many hospitalized patients. The pathophysiology and hallmarks of malnutrition have been described earlier (p. 213); here the forms of nutritional support that are available are discussed, along with special nutritional requirements in some diseases.

Principles

Some form of nutritional supplementation is required in those patients who cannot eat, should not eat, will not eat or cannot eat enough. All patients should be screened for malnutrition on admission and the findings linked to a care plan, preferably under the supervision of a trained multidisciplinary team. The Council of Europe has produced 10 key characteristics of good nutritional care in hospital (bapen.org.uk). Plans are discussed with patients and consent is taken for any invasive procedure (e.g. nasogastric tube, parenteral nutrition). If the patient is unable to give consent, the healthcare team should act in the patient’s best interest, taking into account previously expressed wishes of the patient and views of the family. It is usually necessary to provide nutritional support for:

- all severely malnourished patients on admission to hospital
- moderately malnourished patients who, because of their physical illness, are not expected to eat for more than 3–5 days
- normally nourished patients expected not to eat for more than 5 days or to eat less than half their intake for more than 8–10 days.
Enteral rather than parenteral nutrition should be used if the gastrointestinal tract is functioning normally.

In the refeeding syndrome, the shifts of water and electrolytes that occur after parenteral and enteral nutrition can be life threatening. Carbohydrate intake stimulates insulin release which leads to cellular uptake of phosphate, potassium and magnesium. Complications include hypophosphataemia, hypokalaemia, hypomagnesaemia and fluid overload because of sodium retention (decreased renal excretion of sodium and water). Patients who have eaten little or nothing for more than 5 days should initially receive no more than 50% of their energy requirements (NICE guidelines).

### Nutritional requirements for adults

- **Water.** Typical requirements are – 2–3 L/day. Increased requirements occur in patients with large-output fistulae, nasogastric aspirates and diarrhoea. Reduced requirements occur in patients with oedema, hepatic failure, renal failure (oliguric and not dialysed) and brain oedema.

- **Energy.** Typical requirements are – 7.5–10.0 MJ/day (1800–2400 kcal/day). Disease increases resting energy expenditure but decreases physical activity. Extra energy is given for repletion and reduced energy for obesity.

- **Protein.** Typically 10–15 g N/day (62–95 g protein/day) or 0.15–0.25 g N/kg/day (0.94–1.56 g protein/kg/day). Extra protein may be needed in severely catabolic conditions, such as extensive burns.

- **Major minerals.** Typical requirements for sodium and potassium are 70–100 mmol/day. Increased requirements occur in patients with gastrointestinal effluents. The excretion of these minerals in various effluents can provide an indication of the additional requirements (Table 12.10). Low requirements may be necessary in those with fluid overload (or patients with hypernatraemia and hyperkalaemia). The requirements of calcium and magnesium are higher for enteral than for parenteral nutrition because only a proportion of these minerals is absorbed by the gut.

- **Trace elements.** For trace elements such as iodide, fluoride and selenium that are well absorbed, the requirements for enteral and parenteral nutrition are similar. For other trace elements, such as iron, zinc, manganese and chromium, the requirements for parenteral nutrition are substantially lower than for enteral nutrition (Fig. 5.12).

- **Vitamins.** Many vitamins are given in greater quantities in patients receiving parenteral nutrition than in those receiving enteral nutrition (Fig. 5.13). This is because patients on parenteral nutrition may have increased requirements, partly because of severe disease, partly because they may already have depleted pools of vitamins, and partly because some vitamins degrade during storage. Vitamin K is usually absent from parenteral nutrition regimens and therefore it may need to be administered separately.

### Enteral nutrition (EN)

Feeds can be given by various routes:

- By mouth (food can be supplemented with solid or liquid supplements with multiple benefits).
- By fine-bore nasogastric tube (Practical Box 5.1)
- Percutaneous endoscopic gastrostomy (PEG) is useful for patients who need enteral nutrition for a prolonged
The procedure should be explained to the patient and consent taken.

Procedure
- Insert fine-bore tube intranasally with wire stylet.
- Confirm position of tube in stomach by aspiration of gastric contents and auscultation of the epigastrium.
- Check by X-ray if aspiration or auscultation is unsuccessful.

Problems
No satisfactory way of keeping nasogastric tubes in place (up to 60% come out).

Main complications
- Regurgitation and aspiration into bronchus.
- Blockage of the nasogastric tube.
- Gastrointestinal side-effects, the most common being diarrhoea.
- Metabolic complications including hyperglycaemia and hypokalaemia, as well as low levels of magnesium, calcium and phosphate.

Diet formulation (see Table 5.17)
A polymeric diet with whole protein and fat can be used, except in patients with severely impaired gastrointestinal function who may require a predigested (i.e. elemental) diet. In these patients, the nitrogen source is purified low-molecular-weight peptides or amino acid mixtures, with sometimes the fat being given partly as medium-chain triglycerides.

Management
Daily amounts of diet vary between 1.5 and 2.5 L, but small amounts are started in patients with suspected poor gastric emptying and severe malnutrition (to avoid the refeeding syndrome).

Hypercatabolic patients require a high supply of nitrogen (15 g daily) and often will not achieve positive nitrogen balance until the primary injury is resolved.

The success of enteral feeding depends on careful supervision of the patient, with monitoring of weight, biochemistry and diet charts.

Parenteral nutrition
Peripheral parenteral nutrition
Specially formulated mixtures for peripheral use are available, with a low osmolality and containing lipid emulsions. Heparin and corticosteroids can be added to the infusion and local application of glyceryl trinitrate patches reduces the occurrence of thrombophlebitis and prolongs catheter life.

Peripheral cannulas can be inserted into a mid arm vein (20 cm) and can last up to 5 days.

Parenteral nutrition via a central venous catheter (PN) (see Practical Box 5.2)
A silicone catheter is placed into a central vein, usually using the infraclavicular approach to the subclavian vein. The skin-entry site should be dressed carefully and not disturbed unless there is a suggestion of catheter-related sepsis.

Complications of catheter placement include central vein thrombosis, pneumothorax and embolism, but the major problem is catheter-related sepsis. Organisms, mainly staphylococci, enter along the side of the catheter, leading to septicemia. Sepsis can be prevented by careful and sterile placement of the catheter, by not removing the dressing over the catheter entry site, and by not giving other substances (e.g. blood products, antibiotics) via the central vein catheter.
Sepsis should be suspected if the patient develops fever and leucocytosis. In two-thirds of cases, organisms can be grown from the catheter tip after removal. Treatment involves removal of the catheter and appropriate systemic antibiotics.

Nutrients
With PN it is possible to provide sufficient nitrogen for protein synthesis and calories to meet energy requirements. Electrolytes, vitamins and trace elements are also necessary. All of these substances are infused simultaneously.

Nitrogen source
Most patients receive at least 11–15 g N per day, in the form of synthetic L-amino acids.

Energy source
This is provided by glucose, with additional calories provided by a fat emulsion. Fat infusions provide a greater number of calories in a smaller volume than can be provided by carbohydrate. Fat infusions are not hypertonic and they also prevent essential fatty acid deficiency.

Essential fatty acid deficiency has been reported in long-term parenteral nutritional regimens without fat emulsions. It causes a scaly skin, hair loss and a delay in healing.

Electrolytes, vitamins and trace elements
(See Figs 5.12 and 5.13.) Initially, the electrolyte status should be monitored on a daily basis and electrolyte solutions given as appropriate. Fat- and water-soluble vitamins and minerals including trace elements should be given routinely.

Administration and monitoring
Peripheral parenteral nutrition. Administered via 3-L bags over 24 hours, with the constituents being premixed under sterile conditions by the pharmacy. Table 5.18 shows the composition which provides 9 g of nitrogen and 1700 calories in 24 hours.

Central venous PN regimen. Most hospitals now use pre-mixed 3-L bags. A standard parenteral nutrition regimen which provides 14 g of nitrogen and 2250 calories over 24 hours is also given in Table 5.18.

Monitoring includes:
- Blood tests. Daily plasma electrolytes and glucose.
- Twice weekly FBC, liver biochemistry and function, calcium, phosphate, and magnesium, zinc and glycerides weekly.
- Nutritional status. Weekly weight and skin fold thickness if appropriate callipers are available.
- Nitrogen balance (p. 210) assessment, but this requires complete collections of urine.

Complications
- Catheter-related (see above)
- Metabolic (e.g. hyperglycaemia – insulin therapy is usually necessary)
- Fluid and electrolyte disturbances
- Hypercalcaemia
- Liver dysfunction
- Nutrient deficiencies (if inadequately provided).

### NUTRITIONAL SUPPORT IN THE HOME PATIENT

In both high- and low-income countries there is considerably more undernutrition in the community than in hospital. However, the principles of care are very similar: detection of malnutrition and the underlying risk factors; treatment of underlying disease processes and disabilities; correction of specific nutrient deficiencies and provision of appropriate nutritional support. This typically begins with dietary advice, and may involve the provision of ‘meals on wheels’ by social services. A systematic review of the use of nutritional supplements in the community came to the following conclusions:

- Supplements are generally of more value in patients with a BMI < 20 kg/m² and children with growth failure (weight for height < 85% of ideal) than in those with better anthropometric indices. They are likely to be of little or no value in patients with little weight loss and a BMI > 20 kg/m². The supplemental energy intake in such subjects largely replaces oral food intake.

- Supplements may be of value in weight-losing patients (e.g. >10% weight loss compared to pre-illness) with a BMI > 20 kg/m², and in children with deteriorating growth performance without chronic protein–energy undernutrition.

- The functional benefits vary according to the patient group. In patients with chronic obstructive airways disease the observed functional benefits were increased respiratory muscle strength, increase in handgrip strength, and an increase in walking distance/duration of exercise. In the elderly the benefits were reduced number of falls, or increase in activities of daily living, and reduced pressure sore surface area. In patients with HIV/AIDS there were changes in immunological function and improved cognition. Patients with liver disease experienced a lower incidence of severe infections and had a lower frequency of hospitalization.
Acceptability and compliance are likely to be better when a choice of supplements (of type, flavour, consistency) and schedule is decided in conjunction with the patient and/or carer. Changes in these may be necessary when there is a change in patterns of daily activities, disease status, and ‘taste fatigue’ with prolonged use of the same supplement.

Nutritional counselling and monitoring are recommended before and after the start of supplements (see also below).

Some patients receive enteral tube feeding and parenteral nutrition at home. At any one point in time in developed countries enteral tube feeding occurs more frequently at home than in hospital. In adults the commonest reason for starting home tube feeding is for swallowing difficulties. This involves patients with neurological disorders, such as motor neurone disease, multiple sclerosis and Parkinson’s disease, but the commonest single diagnosis is cerebrovascular disease. Approximately 2% of patients who have had a stroke in the UK receive home enteral tube feeding (HETF). However, in a British Nutrition survey (1996–2000) of patients with these disorders (apart from Parkinson’s), only 15% in total were able to return to oral feeding after one year. The swallowing capabilities of patients should be assessed regularly in order to avoid unnecessary tube feeding. The patients and/or carers should have adequate training, contacts with appropriate health professions, and a reliable delivery service for feeds and ancillary equipment. They should also be clear about how to manage simple problems associated with the feeding tube, which is usually a gastrostomy tube rather than a nasogastric tube.

Home parenteral nutrition is practised much less frequently, usually under the supervision of specialist centres. The potential value of intestinal transplantation in patients with long-term intestinal failure is still being assessed.

Food allergy is weak, although adverse reactions to food certainly exist. These can be divided into those that involve immune mechanisms (food allergy) and those that do not (food intolerance).

### Food allergy

Food allergy, which is estimated to affect up to about 5% of young children and about 1–2% of adults, may be IgE mediated or non-IgE mediated (T-cell mediated). The IgE-mediated reactions tend to occur early after a food challenge (within minutes to an hour). Adults tend to be allergic to fish, shellfish and peanuts, while children tend to be allergic to cow’s milk, egg white, wheat, and soy. Peanuts are very allergenic and peanut allergy persists throughout life. The following conditions can result from food allergy:

- **Acute hypersensitivity.** An example is urticaria, vomiting or diarrhoea after eating nuts, strawberries or shellfish. These IgE-mediated reactions do not usually produce clinical problems as the patients have already learned to avoid the suspected food. Inadvertent ingestion of the incriminating food can sometimes occur, leading to angioneurotic oedema (p. 1244).
- **Eczema and asthma.** These tend to affect young children and are often due to egg and are IgE mediated.
- **Rhinitis and asthma.** These have been produced by foods such as milk and chocolate, mainly in atopic subjects.
- **Chronic urticaria.** This has been treated successfully by an exclusion diet.
- **Food-sensitive enteropathy.** This may manifest itself as coeliac disease (gluten (wheat) sensitive enteropathy), and cow’s milk enteropathy (in infants) and is T-cell mediated.

### Food intolerance

- **Migraine.** This sometimes follows the intake of foods such as chocolate, cheese and alcohol, which are rich in certain amines, such as tyramine. Patients on monoamine oxidase inhibitors, which are involved in the metabolism of these amines, are particularly vulnerable.
- **Irritable bowel syndrome.** In some patients this seems to be related to ingestion of certain food items, such as wheat, but the mechanisms are not clearly defined.
- **Chinese restaurant syndrome.** Monosodium glutamate, a flavour enhancer used in cooking Chinese food, may produce dizziness, faintness, nausea, sweating and chest pains.
- **Lactose intolerance.** Patients develop abdominal bloating and diarrhoea following ingestion of lactose, which is present in milk (p. 277). This is probably the commonest form of food intolerance world-wide, and may be genetic in origin.
- **Phenylketonuria.** This can also be classified as a form of food intolerance, and is due to lack of phenylalanine hydroxylase, which is necessary for the metabolism of phenylalanine present in dietary protein.

A number of other inborn errors of metabolism can also be regarded as forms of food intolerance.

Food intolerance may be due to a constituent of food (e.g. the histamine in mackerel or canned food, or the tyramine in...
cheeses), chemical mediators released by food (e.g. histamine may be released by tomatoes or strawberries), or toxic chemicals found in food (e.g. the food additive tartrazine).

Many other additives and compounds with certain E numbers have been implicated as causing reactions, but the evidence for this is poor.

There is little or no evidence to suggest that diseases such as arthritis, behaviour and affective disorders and Crohn’s disease are due to ingestion of a particular food.

Multiple vague symptoms such as tiredness or malaise are also not due to food allergy. Most of the patients in this group are suffering from a psychiatric disorder (p. 1192).

Management

- A careful history may help to delineate the causative agent, particularly when the effects are immediate.
- Skin-prick testing with allergen and measurement in the serum of antigen or antibodies have not correlated with symptoms and are usually misleading. ‘Fringe’ techniques such as hair analysis, although widely advertised, are of no value.
- Diagnostic exclusion diets are sometimes used, but they are time-consuming. They can occasionally be of value in identifying a particular food causing problems.
- Dietary challenge consists of the food and the test being given sublingually or by inhalation in an attempt to reproduce the symptoms. Again this may be helpful in a few cases.
- Most people who have acute reactions to food realize it and stop the food, and do not require medical attention. In the remainder of patients, a small minority seem to be helped by modifying their diet, but there is no good scientific evidence to support these exclusion diets.

**FURTHER READING**

**ALCOHOL**

Alcohol is a popular ‘nutrient’ consumed in large quantities all over the world. In many countries, alcohol consumption is becoming a major problem (see p. 1211).

Ethanol (ethyl alcohol) is oxidized, in the steps shown in Box 5.5, to acetaldehyde. Acetaldehyde is then converted to acetate, 90% in the liver mitochondria. Acetate is released into the blood and oxidized by peripheral tissues to carbon dioxide and water.

Alcohol dehydrogenases are found in many tissues and it has been suggested that enzymes present in the gastric

**Box 5.5 The main pathways of ethanol oxidization**

- **Alcohol dehydrogenase:**
  
  \[
  \text{CH}_3\text{CH}_2\text{OH} + \text{NAD}^+ \xrightarrow{\text{ADH}} \text{CH}_3\text{CHO} + \text{NADH} + \text{H}^+ \tag{1}
  \]

  - **The liver microsomal enzyme oxidizing system (MEOS)** including the specific P450 enzyme, CYP2E1, which is induced by ethanol:
    
    \[
    \text{CH}_3\text{CH}_2\text{OH} + \text{NADPH} + \text{H}^+ + \text{O}_2 \xrightarrow{\text{MEOS}} \text{CH}_3\text{CHO} + \text{NADP} + 2\text{H}_2\text{O} \tag{2}
    \]

**Effects of excess alcohol consumption**

Excess consumption of alcohol leads to two major problems, both of which can be present in the same patient:

- alcohol dependence syndrome (p. 1212)
- physical damage to various tissues.

Each unit of alcohol (defined as one half pint of normal beer, one single measure of spirit, or one small glass of wine) contains 8 g of ethanol (Fig. 5.14). All the long-term effects of excess alcohol consumption are due to excess ethanol, irrespective of the type of alcoholic beverage; i.e. beer and spirits are no different in their long-term effects. Short-term effects, such as hangovers, depend on additional substances, particularly other alcohols such as isoamyl alcohol, which are known as congeners. Brandy and bourbon contain the highest percentage of congeners.

The amount of alcohol that produces damage varies and not everyone who drinks heavily will suffer physical damage. For example, only 20% of people who drink heavily develop cirrhosis of the liver. The effect of alcohol on different organs of the body is not the same; in some patients the liver is affected, in others the brain or muscle. The differences may be genetically determined.

Thiamin deficiency contributes to both neurological (confusion, Wernicke–Korsakoff syndrome; see p. 1174) and some of the non-neurological manifestations (cardiomyopathy). Susceptibility to damage of different organs is variable and the figures given in Box 5.6 are given only as a guide to

![Fig. 5.14 Measures of 1 unit of alcohol.](image)
Box 5.6  Guide to sensible drinking of alcohol

Daily maximum
3 units for men
2 units for women

To help achieve this:
Use a standard measure.
Do not drink during the daytime.
Have alcohol-free days each week.

Remember
Health can be damaged without being ‘drunk’. Regular heavy intake is more harmful than occasional binges.
Do not drink to ‘drown your problems’.
In the UK the drink-before-driving limit of alcohol in the blood is 800 mg/L (80 mg%).

Food decreases absorption and therefore results in a lower blood alcohol level.
4–5 units are sufficient to put the blood alcohol level over the legal driving limit in a 70 kg man (less in a lighter person).

In developed countries gastrointestinal symptoms are a common reason for attendance to primary care clinics and to hospital outpatients. Approximately 75% of these consultations are for non-organic symptoms. The clinician’s main task is therefore to recognize when organic disease must be sought or excluded, remembering that 20% of all cancers occur in the gastrointestinal tract (Fig. 6.1).

In developing countries, malnutrition and poor hygiene make infection a more probable diagnosis. The clinician needs to recognize and treat these infections promptly and also help with prevention by encouraging good hygiene.

Dyspepsia and indigestion

Dyspepsia is an inexact term used to describe upper abdominal symptoms such as heartburn, acidity, pain or discomfort, nausea, wind, fullness or belching. Patients refer to all of these as ‘indigestion’, but may also include other symptoms such as constipation and the presence of undigested vegetable material in the stool. ‘Indigestion’ is common; 80% of the population will say they have had indigestion at some time.

‘Alarm’ features are suggestive of serious diseases such as cancer. They are:

- dysphagia
- weight loss
- protracted vomiting
- anorexia
- haematemesis or melaena.

However among patients investigated for dysphagia, anorexia, weight loss and vomiting, only a minority have significant gastrointestinal pathology. Even among patients with a history of vomiting blood or melaena, organic disease is by no means invariable. Nonetheless, concern about missing treatable cancer is so great that most patients with alarm symptoms will be recommended to undergo endoscopy.

Fig. 6.1 Incidence (approximate) of cancers at various sites of the gastrointestinal tract.

GASTROINTESTINAL SYMPTOMS AND SIGNS

FURTHER READING

Dysphagia and odynophagia

These symptoms are described on page 249.

Vomiting

Vomiting centres are located in the lateral reticular formation of the medulla and are stimulated by the chemoreceptor trigger zones (CTZs) in the floor of the fourth ventricle, and also by vagal afferents from the gut. These zones are directly stimulated by drugs, motion sickness and metabolic causes.

There are usually three phases:
- nausea – a feeling of wanting to vomit, often associated with autonomic effects including salivation, pallor and sweating
- retching – a strong involuntary unproductive effort to vomit associated with abdominal muscle contraction
- vomiting – the expulsion of gastric contents through the mouth.

Many gastrointestinal (and non-gastrointestinal) conditions are associated with vomiting (Table 6.1).

- **Large volumes of vomit** and sometimes projectile vomiting suggest gastric outlet or upper intestinal obstruction.
- **Faeculent vomit** suggests low intestinal obstruction or the presence of a gastrocolic fistula.
- **Nausea** and frequent regurgitation of small amounts of gastric contents without other abdominal symptoms are frequently psychogenic.
- **Haematemesis** is vomiting fresh or altered blood (‘coffee-grounds’) (see p. 267).
- **Early-morning nausea and vomiting** is seen in pregnancy, alcohol dependence and some metabolic disorders (e.g. uraemia).

Flatulence

This term describes excessive wind. It is used to indicate belching, abdominal distension, gurgling and the passage of flatus per rectum. Swallowing air (aerophagia) is described on page 311. Some of the swallowed air passes into the intestine where most of it is absorbed, but some remains to be passed rectally. Intestinal bacterial breakdown of food also produces a small amount of gas. Rectal flatus thus consists of nitrogen, carbon dioxide, hydrogen and methane. It is normal to pass rectal flatus up to 20 times per day.

Diarrhoea and constipation

These are common complaints and in the community are not usually due to serious disease. They are described in detail on pages 305 and 295 respectively. Some simple rules are useful; for example, a single episode of diarrhoea is commonly due to dietary indiscretion or anxiety; watery stools of large volume are always due to organic disease; bloody diarrhoea usually implies colonic disease; acute diarrhoea lasting 2–5 days is most often due to an infective cause. Stool cultures can be useful but not always possible.

Patients often consider themselves constipated if their bowels are not open on most days, though normal stool frequency is very variable, from 3 times daily to 3 times a week. The difficult passage of hard stool is also regarded as constipation, irrespective of stool frequency. True constipation with hard stools is rarely due to organic colonic disease.

Abdominal pain

Pain is stimulated mainly by the stretching of smooth muscle or organ capsules. Severe acute abdominal pain can be due to a large number of gastrointestinal conditions, and normally presents as an emergency (see p. 314). An apparent ‘acute abdomen’ can occasionally be due to referred pain from the chest, as in pneumonia, or to metabolic causes, such as diabetic ketoacidosis or porphyria.

Clinical enquiry in patients with abdominal pain should include:
- site, intensity, character, duration and frequency of the pain
- aggravating and relieving factors
- associated symptoms, including non-gastrointestinal symptoms.

Upper abdominal pain

**Epigastric pain** is very common; it is often a dull ache, but sometimes sharp and severe and may be related to food intake. Although functional dyspepsia is the commonest diagnosis, the symptoms of peptic ulcer disease can be identical. **Heartburn** – a burning pain behind the sternum – is a common symptom of reflux.

**Right hypochondrial pain** may originate from the gall bladder or biliary tract. Biliary pain can also be epigastric. **Biliary pain** is typically intermittent, lasts a few hours and remits spontaneously to recur weeks or months later. Hepatic congestion (e.g. in hepatitis or cardiac failure) and sometimes peptic ulcer can present with pain in the right hypochondrium. Chronic, persistent or constant pain in the right (or left) hypochondrium in a well-looking patient is a frequent functional symptom; this chronic pain is not due to gall bladder disease (see p. 368).

Lower abdominal pain

**Acute pain in the left iliac fossa** is usually colonic in origin (e.g. acute diverticulitis). Chronic pain is most commonly associated with functional bowel disorders.

**Lower abdominal pain in women** occurs in a number of gynaecological disorders and the differentiation from GI disease may be difficult.

**Persistent pain in the right iliac fossa** over a long period is not due to chronic appendicitis and is most commonly functional.
Proctalgia fugax is a severe pain deep in the rectum that comes on suddenly but lasts only for a short time. It is not due to organic disease.

Abdominal wall pain
Persistent abdominal pain with localized tenderness which is not relieved by tensing the abdominal muscles appears to arise from the abdominal wall itself. Causes are thought to include nerve entrapment, external hernias and entrapment of internal viscera (commonly omentum) within traumatic ruptures of abdominal wall musculature.

Anorexia and weight loss
Anorexia describes reduced appetite. It is common in systemic disease and may be seen in psychiatric disorders, particularly anorexia nervosa. Anorexia often accompanies cancer but is usually a late symptom and not of diagnostic help. Weight loss is almost always due to reduced food intake and is a frequent accompaniment of gastrointestinal diseases. Weight loss in malabsorption is primarily due to anorexia. Weight loss with a normal or increased dietary intake occurs with hyperthyroidism and other catabolic states. Weight loss should always be assessed objectively as patients’ impressions are unreliable. Appetite and satiety are described on page 229.

CLINICAL EXAMINATION
A systematic general examination is performed, starting with the hands, skin and nutritional status and noting the presence of anaemia or jaundice. Detailed examination of the gastrointestinal tract starts with the mouth and tongue, before examining the abdomen with the patient lying flat.

Examination of the abdomen
Inspection
Abdominal distension, whether due to flatus, fat, fetus, fluid or faeces, must be looked for. Intermittent distension is most commonly a feature of functional bowel disorders.

Palpation
Some abdominal organs may be felt even when normal, usually in thin people, and such organs are usually only just palpable (Fig. 6.2). Reidel’s lobe is an anatomical variant consisting of a palpable enlargement of the lateral portion of the right lobe of the liver. Any palpable mass is carefully felt to evaluate its size, shape and consistency and whether it moves with respiration, to decide which organ is involved.

Figure 6.3a (p. 245) shows a normal CT scan at the level of T12. The hernial orifices should be examined if intestinal obstruction is suspected.

A succussion splash suggests gastric outlet obstruction if the patient has not drunk for 2–3 hours; the splash of fluid in the stomach can be heard with a stethoscope laid on the abdomen when the patient is moved.

Percussion
Abdominal percussion detects the areas of dullness caused by the liver and spleen, ascites or over masses. It can also detect a full bladder. Ascites is a term for excess fluid in the peritoneal cavity. It is detected clinically by central abdominal resonance due to gas within small bowel loops with dullness in the flanks which shifts when the patient lies on their side. This ‘shifting dullness’ is a reliable physical sign, but 1–2 L of fluid must be present. A large ovarian cyst can sometimes produce an enlarged abdomen, but the dullness is more centrally placed than in ascites.

Auscultation
Auscultation is not of great value in abdominal disease, except in the acute abdomen (see p. 314). Abdominal bruits are often present in normal subjects and are rarely clinically significant.

Examination of the rectum and sigmoid colon
A digital examination of the rectum should be performed in all patients with a change in bowel habit, rectal bleeding and prior to proctoscopy or sigmoidoscopy.

Proctoscopy (Practical Box 6.1) is performed in all patients with a history of bright red rectal bleeding to look for anorectal pathology such as haemorrhoids; a rigid sigmoidoscope is too narrow and long to enable adequate examination of the anal canal.

Sigmoidoscopy is part of the routine in-hospital examination in all cases of diarrhoea and in patients with lower abdominal symptoms such as a change in bowel habit or rectal bleeding. The rigid sigmoidoscope allows inspection of a maximum of 20–25 cm of distal colon.

Flexible sigmoidoscopy (FS) (60 cm) allows a more extensive examination, usually up to the splenic flexure, and often with less discomfort. It can be performed in the outpatient department after evacuation of the distal colon using an enema or suppository. FS is useful in patients with increased stool frequency or looseness or rectal bleeding. Most rectal bleeding is due to benign ano-rectal disease (haemorrhoids or fissure-in-ano). Up to 60% of colonic neoplasms occur within the range of FS (see Fig. 6.47, p. 304). It can also be used to biopsy or remove lesions in the sigmoid area seen radiologically, and for the follow-up of patients with distal colitis. If the presenting complaint is constipation with hard stools FS has the same rate of abnormality as in a control population.

Fig. 6.2 The organs sometimes palpable in thin subjects.
Sigmoidoscopy
- The technique using a 25-cm rigid sigmoidoscope is easy to learn, provides valuable information and is safe in competent hands
- No bowel preparation is required
- Explain to the patient the nature of the procedure, obtain consent
- The technique is relatively painless. In the irritable bowel syndrome, the patient’s pain is often reproduced by air insufflation
1. Rectal examination is initially performed
2. The sigmoidoscope is passed into the anus, pointing towards the symphysis pubis. The obturator is removed, and the instrument passed under direct vision to the rectosigmoid junction and beyond if possible (using air insufflation)
3. The mucosa of the anus and rectum is inspected. The normal mucosa is shiny with superficial vessels and no contact bleeding
4. Biopsies can be taken of any lesions that are seen or from apparently normal-looking mucosa, which occasionally shows histological evidence of inflammation

Proctoscopy
1. The proctoscope is passed into the anus and the obturator is removed
2. The patient strains down as the proctoscope is removed
3. Haemorrhoids are seen as purplish veins in the left lateral, right posterior or right anterior positions
4. Fissures may also be seen, but pain often prevents the procedure from being performed

Stool examination
It is occasionally useful to confirm a patient’s account (e.g. passing of blood or steatorrhoea). The shape and size may be helpful (e.g. ‘rabbit dropping’ or ribbon-like stools in the irritable bowel syndrome). Stool charts for recording weight and frequency of defecation are useful in inpatients to follow the progress of diarrhoea.

INVESTIGATIONS

Routine haematology and biochemistry, followed by radiology and endoscopy, are the principal investigations. The investigation of small bowel disease is discussed in more detail on page 276. Manometry is mainly used in oesophageal disease (see p. 250) and anorectal disorders (see p. 295).

Imaging

Full clinical information must be provided before the examination, and ideally the images should be reviewed with the radiologist.

Plain X-rays of the chest and abdomen are chiefly used in the investigation of an acute abdomen. Interpretation depends on analysis of gas shadows inside and outside the bowel. Plain films are particularly useful where obstruction or perforation is suspected, in assessment of the severity and extent of acute colitis and to assess faecal loading in constipation. Calcification may be seen in gall bladder stones and in chronic pancreatitis, though CT is more sensitive for both.

Ultrasound involves no radiation and is the first-line investigation for abdominal distension, e.g. ascites, mass or suspected inflammatory conditions. It can show dilated fluid-filled loops of bowel in obstruction, and thickening of the bowel wall. It can be used to guide biopsies or percutaneous drainage. In the acute abdomen, ultrasound can diagnose cholecystitis, appendicitis, enlarged mesenteric glands and other inflammatory conditions.

Endoscopic ultrasound (EUS) is performed with a gastroscope incorporating an ultrasound probe at the tip. It is used diagnostically for lesions in the oesophageal or gastric wall including the detailed TNM staging of oesophageal/gastric cancer and for the detection and biopsy of pancreatic tumours and cysts.

Endoanal and endorectal ultrasonography are performed to define the anatomy of the anal sphincters (see p. 298), to detect perianal disease and to stage superficial rectal tumours.

Computed tomography involves high-dose radiation. Modern multi-slice fast scanners and techniques involving intraluminal and intravenous contrast provide accurate diagnoses in many cases. Intraluminal contrast may be used and may be positive (Gastrografin or Omnipaque) or negative (usually water). The bowel wall and mesentry are well seen after intravenous contrast especially with negative intraluminal contrast. Clinically unsuspected diseases of other abdominal organs are quite often also revealed (Fig. 6.3a).

CT is widely used as a first-line investigation for the acute abdomen. CT is sensitive for small volumes of gas from a perforated viscus as well as leakage of contrast from the gut lumen.

Inflammatory conditions such as abscesses, appendicitis, diverticulitis, Crohn’s disease and its complications are well demonstrated. In high-grade bowel obstruction CT is usually diagnostic of both the presence and the cause of the obstruction.

CT is widely used in cancer staging and as guidance for biopsy of tumour or lymph nodes.

CT pneumocolon/CT colonography (virtual colonoscopy) after CO₂ insufflation into a previously cleansed colon provides an alternative to colonoscopy for diagnosis of colon mass lesions (Fig. 6.3b). It is being evaluated as a screening test for colon pathology with sensitivities of over 90% for >10 mm polyps.

Unprepared CT is a good test for colon cancer in the frail (often elderly) patient who would have problems with bowel preparation.

Magnetic resonance imaging. MRI uses no radiation and is particularly useful in the evaluation of rectal cancers and abscesses and fistulae in the perianal region. It is also useful in small bowel disease and in hepatobiliary and pancreatic disease.

Positron emission tomography (PET) relies on detection of the metabolism of fluoro-deoxyglucose. It is used for staging oesophageal, gastric and colorectal cancer and in the detection of metastatic and recurrent disease. PET/CT adds additional anatomical information.
Double-contrast barium meal examines the oesophagus, stomach and duodenum. Barium is given to produce mucosal coating. Effervescent granules producing carbon dioxide in the stomach create a double contrast between gas and barium. This test has a high accuracy for the detection of significant pathology – ulcers and cancer – but requires good technique. Gastroscopy is a more sensitive test for small superficial mucosal lesions and for bleeding, and enables biopsy of suspicious areas.

Small bowel meal or follow-through specifically examines the small bowel. Ingested barium passes through the small bowel into the right colon, usually taking about an hour. The fold pattern and calibre of the small bowel are assessed. Specific views of the terminal ileum are usually obtained using compression to separate the loops of bowel and particularly to identify early changes in patients with suspected Crohn’s disease.

Small bowel enema (enteroclysis) is an alternative specific technique for small bowel examination. A tube is passed into the duodenum and a large volume of dilute barium is introduced. It is particularly used to demonstrate strictures or adhesions when there is suspicion of intermittent obstruction.

Barium enema examines the colon and is used for altered bowel habit. Colonoscopy has largely replaced this examination for rectal bleeding, polyps and inflammatory bowel disease. The colon is first thoroughly cleansed with oral laxative preparations. Barium and air or CO₂ are insufflated via a rectal catheter and double-contrast views obtained of the entire colon. Rectal examination and sigmoidoscopy should precede this examination. Some patients find the examination rather difficult to tolerate, particularly the elderly, frail or immobile in whom other tests such as CT should be used.

Absorbable water soluble (Gastrografin or Omnipaque) contrast agents should be used in preference to barium when perforation is suspected anywhere in the gut.

Radioisotopes

Radionuclides are used to a varying degree depending on local enthusiasm, availability and expertise. Some more common indications and techniques are to:

- detect urease activity of Helicobacter pylori – ^13C urea breath test (see p. 260)
- assess oesophageal reflux – gamma camera scan after oral [⁹⁹mTc]technetium–sulphur colloid
- measure rate of gastric emptying – sequential gamma camera scans after oral [⁹⁹mTc]technetium–sulphur colloid or [¹¹¹In-DTPA (indium-labelled diethylene triamine penta-acetic acid)
- demonstrate a Meckel’s diverticulum – gamma camera scan after i.v. [⁹⁹mTc]pertechnetate, which has affinity for gastric mucosa
- assess extent of inflammation and presence of inflammatory collections in inflammatory bowel disease – gamma camera scan after i.v. [⁹⁹mTc]HMPAO (hexamethylpropylene amine oxime) labelled white cells
evaluate neuroendocrine tumours and their metastases
– gamma camera scan after i.v. radiolabelled octreotide
or MIBG (meta-iodobenzylguanidine)

■ assess obscure gastrointestinal bleeding:
– measure faecal loss of i.v. $^{51}$Cr labelled red cells
– gamma camera abdominal scan after i.v. injection of
red cells labelled with $^{99m}$Tc (only useful if the
bleeding is at more than 2 mL/minute)

■ measure albumin loss in the stools (in protein-losing
enteropathy) – following albumin labelled in vivo with i.v.
$^{51}$CrCl$_3$ (this test has been replaced by the measurement of
the intestinal clearance of $\alpha$, antitrypsin)

■ assess bile salt malabsorption (in patients with
unexplained diarrhoea) – gamma camera scan to
measure both isotope retention and faecal loss of orally
administered $^{75}$Selenium-homocholic acid taurine
(SeHCAT) (see p. 308)

■ detect bacterial overgrowth in the small bowel – measure
$^{14}$CO$_2$ in breath following oral $^{14}$C glycocholic acid.

Endoscopy

Video endoscopes have largely replaced fibreoptic instru-
ments. They have a video chip and lens assembly mounted in
the tip of the instrument to relay colour images to a televi-
sion monitor. The tip of the endoscope can be angulated in
all directions. Channels in the instrument are used for air
insufflation, water injection, suction and for the passage of
accessories such as biopsy forceps or brushes for obtaining
tissue, snare for polypectomy and needles for injection
therapies. Permanent photographic or video records of the
procedure can be obtained.

Oesophagogastroduodenoscopy (OGD, ‘gastroscopy’) is
often used as the investigation of choice for upper GI
disorders by gastroenterologists because of easy
access and the possibility of therapy and mucosal
biopsy. Findings include reflux oesophagitis, gastritis,
ulcers and cancer. Relative contraindications include
severe chronic obstructive pulmonary disease, a recent
myocardial infarction, or severe instability of the atlanto-
axial joints. The mortality for diagnostic endoscopy is
0.001% with significant complications in 1:1000, usually
when performed as an emergency (e.g. GI haemorrhage).

Colonoscopy allows good visualization of the whole
colon and terminal ileum. Biopsies can be obtained and
polyps removed. The success rate for reaching the
terminal ileum should be at least 90% after training.
Cancer, polyps and diverticular disease are the
commonest significant findings. Perforation occurs in
1:1000 examinations and in 2% after polypectomy. The
mortality is 0.02% for diagnostic colonoscopy (Practical
Box 6.2).

Balloon enteroscopy can examine the small bowel from
the duodenum to the ileum but specialized
enteroscopes are needed. The indications are limited
(mainly gastrointestinal blood loss), the technique is
time-consuming and the instruments are expensive so it
is available only in a few centres.

Video (wireless) capsule endoscopy is now used for the
evaluation of obscure GI bleeding (after negative
gastroscopy and colonoscopy) and for the detection of
small bowel tumours and occult inflammatory bowel
disease.

![Practical Box 6.2 Gastroscopy and colonoscopy](image)

- Explain the procedure to the patient, including benefits and
  risks
- Discuss need for sedation
- Obtain written informed consent

**Gastroscopy**

1. Patient should be fasted for at least 4 hours
2. Give oxygen and monitor oxygen saturation with an
   oximeter
3. Give lidocaine throat spray or sedation (midazolam ± opiate
   if required)
4. Pass the gastroscope to the duodenum under direct vision
5. Examine during insertion and withdrawal
6. Gastroscopy takes 5–15 minutes, depending on the
   indication and findings
7. Withhold fluid and food until LA/sedation wears off
8. Complications are rare: beware of over-sedation, perforation
   and aspiration
9. Patient must be accompanied home if sedation given

**Colonoscopy**

1. Stop oral iron a week before the procedure
2. Restrict diet to low residue foods for 48 hours; clear fluids
   only for 24 hours
3. Use local bowel cleansing regime, usually starting 24 hours
   beforehand (e.g. two sachets of Picocol and 2–4 bisacodyl
   tablets, or Moviprep 2 litres, or KleanPrep 4 litres, or local
   alternative; more if constipated)
4. Give oxygen and monitor $O_2$ levels
5. Give sedation (midazolam ± opiate) if required by patient
6. Pass the colonoscope to the caecum or ileum under direct
   vision
7. Detailed examination during withdrawal
8. Colonoscopy takes 15–30 minutes, depending on the colon
   anatomy, indication and findings
9. Withhold fluid and food until sedation wears off
10. Observe patient for at least an hour after sedation given
11. Complications are rare: beware of over-sedation, perforation
   and aspiration
12. Patient must be accompanied home if sedation given

THE MOUTH AND SALIVARY GLANDS

The oral cavity extends from the lips to the pharynx and
contains the tongue, teeth and gums. Its primary functions
are mastication, swallowing and speech. Problems in the
mouth are extremely common and, although they may be
trivial, they can produce severe symptoms. Poor dental
hygiene is often a factor.

Stomatitis is inflammation in the mouth from any cause,
such as ill-fitting dentures. Angular stomatitis is inflammation
of the corners of the mouth.

The ‘burning mouth syndrome’ consists of a burning sen-
sation with a clinically normal oral mucosa. It occurs more
commonly in middle-aged and elderly females. It is probably
psychogenic in origin. Halitosis is a common symptom and is
due to poor oral hygiene, anxiety (often when halitosis is
more apparent to the patient than real) and rarer causes, e.g.
oesophageal stricture and pulmonary sepsis.

The mouth

**Recurrent aphthous ulceration**

Idiopathic aphthous ulceration is common and affects up to
25% of the population. Recurrent painful round or ovoid
mouth ulcers are seen with inflammatory halos. They are commoner in females and non-smokers, usually appear first in childhood and tend to reduce in number and frequency before age 40. Other family members may be affected. There is no sign of systemic disease. Minor aphthous ulcers are the most common, are less than 10 mm diameter, have a grey/white centre with a thin erythematous halo and heal within 14 days without scarring. They rarely affect the dorsum of the tongue or hard palate. Major aphthous ulcers (more than 10 mm diameter) often persist for weeks or months and heal with scarring.

The cause is not known. Deficiencies of iron, folic acid or vitamin B12 (with or without gastrointestinal disorders) are sometimes found but are not causally linked. Secondary causes, e.g. Crohn’s disease, should be excluded.

There are no specific effective therapeutic. Sufferers should avoid oral trauma and acidic foods or drinks which cause pain. Topical (1% triamcinolone) or systemic corticosteroids may lessen the duration and severity of the attacks. Chlorhexidine gluconate or tetracycline mouthwash, dapsone, colchicine, thalidomide and azathioprine have all been used with variable effect.

Other causes

See Table 6.2.

Neoplasia (squamous cell carcinoma)

Malignant tumours of the mouth account for 1% of all malignant tumours in the UK. The majority develop on the floor of the mouth or lateral borders of the tongue. Early lesions may be painless, but advanced tumours are easily recognizable as hard indurated ulcers with raised and rolled edges. Aetiological agents include tobacco, heavy alcohol consumption and the areca nut. Premalignant lesions include leucoplakia (single adherent white patch), lichen planus, submucous fibrosis and erythroplakia (a red patch). The previous male predominance has declined. Treatment is by surgical excision but may require extensive neck dissection to remove involved lymph nodes and/or radiotherapy.

Oral white patches

Transient white patches are either due to Candida infection or are very occasionally seen in systemic lupus erythematosus. Oral candidiasis in adults is seen in seriously ill or immunocompromised patients, diabetics and following therapy with broad-spectrum antibiotics or inhaled steroids. Local causes include mechanical, irritative or chemical trauma from drugs (e.g. aspirin).

Persistent white patches can be due to leucoplakia, which is associated with alcohol and (particularly) smoking, and is premalignant. A biopsy should always be taken; histology shows alteration in the keratinization and dysplasia of the epithelium. Treatment is unsatisfactory. Isotretinoin possibly reduces disease progression. Oral lichen planus presents as white striae, which can rarely extend into the oesophagus.

Oral pigmented lesions

Non-neoplastic lesions

Racial pigmentation is scattered and symmetrically distributed. Amalgam tattoo is the most common form of localized oral pigmentation and consists of blue-black macules involving the gingivae and results from dental amalgam sequestering into the tissues. Diseases causing pigmentation include Peutz-Jeghers syndrome and Addison’s disease. Heavy metals, such as lead, bismuth and mercury, and drugs (e.g. phenothiazines and antimalarials) all cause pigmentation of the gums.

Neoplastic lesions

These include melanotic naevi on the hard palate and buccal mucosa. These are rarer in the mouth than on the skin. Malignant melanomas are rare, more common in males, and occur mainly on the upper jaw. The 5-year survival is only 5%.

The tongue

The tongue may be involved in stomatitis with similar lesions to those described above.

Glossitis is a red, smooth, sore tongue associated with B12, folate or iron deficiency. It is also seen in infections due to Candida and in riboflavin and nicotinic acid deficiency.

A black hairy tongue is due to a proliferation of chromogenic microorganisms causing brown staining of elongated filiform papillae. The causes are unknown, but heavy smoking and the use of antiseptic mouthwashes have been implicated.

A geographic tongue is an idiopathic condition occurring in 1–2% of the population and may be familial. There are erythematous areas surrounded by well-defined, slightly raised irregular margins. The lesions are usually painless and the patient should be reassured.

The gums

The gums (gingivae) are the mucous membranes covering the alveolar processes of the mandible and the maxilla. Chronic gingivitis follows the accumulation of bacterial plaque. It resolves when the plaque is removed. It is the most common cause of bleeding gums.

Acute (necrotizing) ulcerative gingivitis (‘Vincent’s angina’) is characterized by the proliferation of spirochaete and fusiform bacteria associated with poor oral hygiene and smoking. Treatment is with oral metronidazole 200 mg three times daily for 3 days, improved oral hygiene and chlorhexidine gluconate mouthwash.

Desquamative gingivitis is a clinical description of smooth, red atrophic gingivae caused by lichen planus or mucous membrane pemphigoid. The diagnosis is confirmed by biopsy.
**Gingival swelling** may be due to inflammation or fibrous hyperplasia. The latter may be hereditary (gingival fibromatosis) or associated with drugs (e.g. phenytoin, ciclosporin, nifedipine). Inflammatory swellings are seen in pregnancy, gingivitis and scurvy. Swelling due to infiltration is seen in acute leukaemia and Wegener’s granulomatosis.

**The teeth**

Dental caries causes tooth decay and ‘cavities’. The main cause in man is *Streptococcus mutans* which is cariogenic only in the presence of dietary sugar. Dental caries can progress to pulpitis and pulp necrosis, and spreading infection can cause dental alveolar abscesses. If there is soft tissue swelling, antibiotics (e.g. amoxicillin or metronidazole) should be prescribed prior to dental intervention.

Erosion of the teeth can result from exposure to acid (e.g. in bulimia nervosa) or, very occasionally, in patients with gastro-oesophageal reflux disease.

**Oral manifestations of HIV infection**

In the UK, 60% of HIV-infected patients have characteristic oral lesions. Lesions strongly associated with HIV infection include candidiasis (with erythema and/or white exudates), erythematous candidiasis, oral hairy leucoplaikia, Kaposi’s sarcoma, non-Hodgkin’s lymphoma, necrotizing ulcerative gingivitis and necrotizing ulcerative periodontitis and are described elsewhere.

All oral lesions are much less common since the introduction of HAART (see p. 192).

**THE SALIVARY GLANDS**

**Excessive salivation** (*ptyalism*) occurs prior to vomiting, but may be secondary to other intraoral pathology. It can be psychogenic.

**Dry mouth** (*xerostomia*) can result from a variety of causes:
- Sjögren’s syndrome
- drugs (e.g. antimuscarinic, antiparkinsonian, antihistamines, lithium, monoamine oxidase inhibitors, tricyclic and related antidepressants, and clonidine)
- radiotherapy
- psychogenic causes
- dehydration, shock and renal failure.

The principles of management are to preserve what flow remains, stimulate flow and replace saliva (glycerine and lemon mouthwash and artificial saliva).

**Sialadenitis**

*Acute sialadenitis* is viral (mumps) or bacterial. Bacterial sialadenitis is a painful ascending infection with *Staphylococcus aureus*, *Streptococcus pyogenes* and *Strep. pneumoniae*, usually secondary to secretory failure. Pus can be expressed from the affected duct.

*Kikuchi disease* is a rare, self-limiting condition which presents with cervical lymphadenopathy, fever and sometimes parotid involvement. The cause is unknown.

**Salivary duct obstruction due to calculus**

Obstruction to salivary flow is usually due to a calculus. There is a painful swelling of the submandibular gland after eating and stones can sometimes be felt in the floor of the mouth. Plain X-ray films and sialography will show the calculus; removal of the obstruction by sialendoscopy gives complete relief.

**Sarcoidosis** (see also p. 868)

Sarcoidosis can involve the major salivary glands as part of Heerfordt’s syndrome (uveo-parotid fever). When combined with lacrimal gland enlargement it is known as the Mikulicz syndrome.

**Neoplasms**

Salivary gland neoplasms account for 3% of all tumours worldwide. The majority occur in the parotid gland. The pleomorphic adenoma is the most common and 15% of these undergo malignant transformation. Malignant tumours classically result in lower motor neurone 7th cranial nerve signs. Recurrence following surgical excision is common.

**THE PHARYNX AND OESOPHAGUS**

**Structure and function**

The oesophagus is a muscular tube approximately 20 cm long that connects the pharynx to the stomach just below the diaphragm. In the upper portion, both the outer longitudinal layer and inner circular muscle layers are striated. In the lower two-thirds of the oesophagus, including the thoracic and abdominal parts containing the lower oesophageal sphincter, both layers are composed of smooth muscle. Diseases of the striated muscle of the upper oesophagus include polymyositis and myasthenia gravis, whereas scleroderma and achalasia involve the distal smooth muscle portion.

The oesophagus is lined by stratified squamous epithelium which extends distally to the squamocolumnar junction where the oesophagus joins the stomach, recognized endoscopically by a zig-zag (‘Z’) line.

The oesophagus is separated from the pharynx by the upper oesophageal sphincter, which is normally closed due to tonic activity of the nerves supplying the cricopharyngeus. The lower oesophageal sphincter (LOS) consists of a 2–4 cm zone in the distal end of the oesophagus that has a high resting tone and, assisted by the diaphragmatic sphincter, is largely responsible for the prevention of gastric reflux.

During swallowing, the bolus of food is voluntarily moved from the mouth to the pharynx. Contraction of the pharynx initiates reflex relaxation of the upper sphincter and food enters the oesophagus. Starting in the pharynx, a primary peristaltic wave progresses down the whole oesophagus. The LOS relaxes when swallowing is initiated, before the arrival of the food bolus carried by the peristaltic wave.

The smooth muscle of the thoracic oesophagus and lower oesophageal sphincter is supplied by vagal autonomic motor nerves consisting of extrinsic preganglionic fibres and...
intramural postganglionic neurones in the myenteric plexus (Fig. 6.4). There are parallel excitatory and inhibitory pathways. The excitatory pathway consisting of preganglionic and postganglionic neurones acts via acetylcholine and also substance P at the postganglionic synapse. The inhibitory pathway comprises preganglionic cholinergic and postganglionic nitricergic neurones (NANC fibres) that release vasoactive intestinal peptide, nitric oxide, ATP and substance P.

**Swallowing**

Between swallows the muscles of the oesophagus are relaxed except for those of the sphincters. The upper oesophageal sphincter remains closed because of tonic activity of its innervation. The lower oesophageal sphincter remains closed due to the unique property of its muscle, illustrated by the tonic contraction of the denervated LOS in achalasia. Transient lower oesophageal sphincter relaxations (TLESRs) occur in normal people, and in more in reflux sufferers.

Swallowing is mediated by a complex reflex involving a swallowing centre in the dorsal motor nucleus of the vagus in the brainstem. Once activated, the swallowing centre neurones send pre-programmed discharges of inhibition followed by excitation to the motor nuclei of the cranial nerves. This results in initial relaxation, followed by distally progressive activation of neurones to the oesophageal smooth muscle and LOS. Pharyngeal and oesophageal peristalsis mediated by this swallowing reflex causes primary peristalsis. Secondary peristalsis arises as a result of stimulation by a food bolus in the lumen, mediated by a local intra-oesophageal reflex. Tertiary contractions indicate pathological non-propulsive contractions resulting from aberrant activation of local reflexes within the myenteric plexus.

**Symptoms of oesophageal disorders**

Major oesophageal symptoms are:

- **Dysphagia**. This term means a sensation of obstruction during the passage of liquid or solid through the pharynx or oesophagus, i.e. within 15 seconds of food leaving the mouth. The characteristics of the progression of dysphagia to solids can be helpful, e.g. intermittent slow progression with a history of heartburn suggests a benign peptic stricture; relentless progression over a few weeks suggests a malignant stricture. The slow onset of dysphagia for solids and liquids at the same time suggests a motility disorder, e.g. achalasia (see p. 253). The causes are shown in Table 6.3.

- **Odynophagia** is pain during the act of swallowing and is suggestive of oesophagitis. Causes include reflux, infection, chemical oesophagitis due to drugs such as bisphosphonates or slow-release potassium, or associated with oesophageal stenosis.

- **Substernal discomfort, heartburn**. This is a common symptom of reflux of gastric contents into the oesophagus. It is usually a retrosternal burning pain that can spread to the neck, across the chest, and when severe can be difficult to distinguish from the pain of ischaemic heart disease. It is often worst lying down at night when gravity promotes reflux, or on bending or stooping.

- **Regurgitation** is the effortless reflux of oesophageal contents into the mouth and pharynx. Uncommon in normal subjects, it occurs frequently in patients with gastro-oesophageal reflux disease or organic stenosis.

Signs of oesophageal disorders
The main sign of oesophageal disease is weight loss due to reduced food intake. Cervical lymphadenopathy with cancer is uncommon. Rarely a pharyngeal pouch may be seen to swell the neck during drinking.

Investigation of oesophageal disorders
- Barium swallow and meal.
- Oesophagoscopy.
- Manometry (Fig. 6.5) is performed by passing a catheter through the nose into the oesophagus and measuring the pressures generated within the region of the lower oesophageal sphincter (LOS) and body of oesophagus. It is the gold standard for the assessment of oesophageal motor activity. It is not a primary investigation and should be performed only when the diagnosis has not been achieved by history, barium radiology or endoscopy. Recordings are usually made over a short time period, or much more rarely for up to 24 hours.
- pH monitoring – 24-hour ambulatory monitoring uses a pH-sensitive probe positioned in the lower oesophagus and is used to identify acid reflux episodes (pH < 4). Catheter and implantable sensors are available; both are insensitive to alkali. Although only 5–10% of recorded acid reflux episodes are perceived by the patient, pH is a valuable means of relating episodes of acid reflux with patient’s symptoms.
- Impedance uses a catheter to measure the resistance to flow of ‘alternating current’ in the contents of the oesophagus. Combined with pH it allows assessment of both acid and alkaline reflux which is useful if pain does not respond to a proton-pump inhibitor (PPI).
- Radiolabelled technetium (see p. 245) is used in some centres.

Acid and alkali infusion into the oesophagus (Bernstein test) to reproduce the pain is obsolete.

The ‘Proton Pump Inhibitor Test’ – an empirical trial of a treatment dose of PPI to observe the effect on heartburn or ‘non-cardiac chest pain’ – is practical and widely used. It has an 80% sensitivity and 74% specificity. It should not be used in patients with dysphagia until cancer has been excluded.

Gastro-oesophageal reflux disease (GORD)

Pathophysiology (Fig. 6.6)
Small amounts of gastro-oesophageal reflux are normal. The lower oesophageal sphincter (LOS) in the distal oesophagus is in a state of tonic contraction and relaxes transiently to allow the passage of a food bolus (see p. 248). Sphincter pressure also increases in response to rises in intra-abdominal and intragastric pressures.

Other antireflux mechanisms involve the intra-abdominal segment of the oesophagus which acts as a flap valve. In addition, the mucosal rosette formed by folds of the gastric mucosa and the contraction of the crural diaphragm at the LOS acting like a pinchcock, prevent acid reflux. A large hiatus hernia can impair this mechanism. The oesophagus is also normally rapidly ‘cleared’ of refluxate by secondary peristalsis, gravity and salivary bicarbonate.

The clinical features of reflux occur when the antireflux mechanisms fail, allowing acidic gastric contents to make prolonged contact with the lower oesophageal mucosa. The sphincter relaxes transiently independently of a swallow (Transient Lower oEsophageal Sphincter Relaxation, TLESR) after meals and this is the cause of almost all reflux in normals and about two-thirds in GORD patients.

Oesophageal mucosal defence mechanisms
- Surface. Mucus and the unstirred water layer trap bicarbonate. This mechanism is a weak buffering mechanism compared to that in the stomach and duodenum.
- Epithelium. The apical cell membranes and the junctional complexes between cells act to limit diffusion of $\text{H}^+\text{ into the cells. In oesophagitis, the junctional complexes are damaged leading to increased $\text{H}^+$ diffusion and cellular damage.}$
- Postepithelium. Bicarbonate normally buffers acid in the cells and intracellular spaces. Hydrogen ions impair the growth and replication of damaged cells.
Sensory mechanisms. Acid stimulates primary sensory neurones in the oesophagus by activating the vanilloid receptor-1 (VR1). This can initiate inflammation and release of proinflammatory substances from the tissue and produce pain. Pain can also be due to contraction of longitudinal oesophageal muscle.

Clinical features
Heartburn is the major feature. Factors associated with GORD are shown in Table 6.4.

The burning is aggravated by bending, stooping or lying down which promote acid exposure, and may be relieved by oral antacids. The patient complains of pain on drinking hot liquids or alcohol.

The correlation between heartburn and oesophagitis is poor. Some patients have mild oesophagitis but severe heartburn; others have severe oesophagitis without symptoms, and may present with a haematemesis or iron deficiency anaemia from chronic blood loss. Psychosocial factors are often determinants of symptom severity. Many patients erroneously ascribe their symptoms to their hiatus hernia (Box 6.1) but the symptoms are due to reflux.

Differentiation of cardiac and oesophageal pain can be difficult; 20% of cases admitted to a coronary care unit have GORD (Box 6.2). In addition to the clinical features, a trial of a PPI is always worthwhile and if symptoms persist, ambulatory pH and impedence monitoring should be performed.

Regurgitation of food and acid into the mouth occurs, particularly on bending or lying flat. Aspiration pneumonia is unusual without an accompanying stricture, but cough and asthma can occur and respond slowly (1–4 months) to PPI.

Diagnosis and investigations
The clinical diagnosis can usually be made without investigation. Unless there are alarm signs, especially dysphagia (see p. 241), patients under the age of 45 years can safely be treated initially without investigations. If investigation is required, there are two aims:

- Assess oesophagitis and hiatus hernia by endoscopy. If there is oesophagitis (Fig. 6.7) or Barrett’s oesophagus (see p. 252), reflux is confirmed.
- Document reflux by intraluminal monitoring (Fig. 6.8). 24-hour intraluminal pH monitoring or impedence combined with manometry is helpful if the PPI test is negative and should always be performed to confirm reflux before surgery. Excessive reflux is defined as a

Box 6.1 Hiatus hernia

Sliding hiatus hernia
The oesophageal-gastro junction and part of the stomach ‘slides’ through the hiatus so that it lies above the diaphragm.

- Present in 30% of people over 50 years
- Produces no symptoms – any symptoms are due to reflux

Rolling or para-oesophageal hernia
Part of the fundus of the stomach prolapses through the hiatus alongside the oesophagus.

- The lower oesophageal sphincter remains below the diaphragm and remains competent
- Occasionally severe pain occurs due to volvulus or strangulation

Box 6.2 Features of the pain of gastro-oesophageal reflux and cardiac ischaemia

Reflex pain: burning, worse on bending, stooping or lying down
- Seldom radiates to the arms
- Worse with hot drinks or alcohol
- Relieved by antacids

Cardiac ischaemic pain:
- Gripping or crushing
- Radiates to neck or left arm
- Worse with exercise
- Accompanied by dyspnoea

Fig. 6.7 Oesophagitis seen on endoscopy.

Fig. 6.8 24-hour intraluminal pH monitoring. Five reflux episodes (pH < 4) occurred, but only three gave symptoms (arrows).
pH < 4 for more than 4% of the time. There should also be a good correlation between reflux (pH < 4.0) and symptoms. It is also helpful to assess oesophageal dysmotility as a potential cause of the symptoms.

**Treatment**

Approximately half of patients with reflux symptoms in primary care can be treated successfully with simple antacids, loss of weight and raising the head of the bed at night. Precipitating factors should be avoided, with dietary measures, reduction in alcohol consumption and cessation of smoking. These measures are simple to say and difficult to carry out, but useful in mild disease in compliant patients. 

_Helicobacter pylori_ eradication in GORD has little effect on the symptoms but is usually advised (see p. 261).

**Drugs**

_Alginate-containing antacids_ (10 mL three times daily) are the most frequently used agents for GORD. They form a gel or ‘foam raft’ with gastric contents to reduce reflux. Available over the counter, they are often used by the patient before consultation. Common proprietary antacids contain sodium which may exacerbate fluid retention; aluminium hydroxide has less sodium than magnesium trisilicate. Magnesium-containing antacids tend to cause diarrhoea whilst aluminium-containing compounds cause constipation.

_The dopamine antagonist prokinetic agents_ metoclopramide and domperidone are occasionally helpful as they enhance peristalsis and speed gastric emptying.

_H₂-receptor antagonists_ (e.g. cimetidine, ranitidine, famotidine and nizatidine) are frequently used for acid suppression if antacids fail as they can often be obtained over the counter.

_Proton pump inhibitors_ (PPIs: omeprazole, rabeprazole, lanseoprazole, pantoprazole, esomeprazole) inhibit gastric hydrogen/potassium-ATPase. PPIs reduce gastric acid secretion by up to 90% and are the drugs of choice for all but mild cases. Most patients with GORD will respond well but this is only 20–30% of patients presenting with heartburn. Patients with severe symptoms may need twice-daily PPIs and prolonged treatment, often for years. Once oesophageal sensitivity has normalized, a lower dose, e.g. omeprazole 10 mg, may be sufficient for maintenance. The patients who do not respond to a PPI are sometimes described as having non-erosive reflux disease (NERD) (Fig. 6.9), when the endoscopy is normal. These patients are usually female and often the symptoms are functional, although a small group have a hypersensitive oesophagus, giving discomfort with only slight changes in pH.

**Surgery**

Surgery should never be performed for a hiatus hernia alone. The best predictors of a good surgical result are typical reflux symptoms with documented acid reflux which correlates with symptoms and responds to a PPI. With such highly selected cases in experienced hands, the laparoscopic Nissen fundoplication has over a 90% satisfaction rate at 5 years, and recently available 10-year data show satisfaction rates remain high at 88%. Current surgical techniques return the oesophagogastric junction to the abdominal cavity, mobilize the gastric fundus, close the diaphragmatic crura snugly and involve a short tension-free fundoplication. Oesophageal stricture and erosive oesophagitis can be treated successfully.

**Fig. 6.9** Outcome of patients with reflux symptoms.

‘pH₇’ meets standard criteria for excessive acid reflux on intraluminal testing; pH₅, does not meet standard criteria for excessive acid reflux; Sh₁, symptom index; TLESR, transient lower oesophageal sphincter relaxation; HH, hiatus hernia; PPI, proton pump inhibitor.

_Indications for operation_ are not clear cut but include intolerance to medication, the desire for freedom from medication, the expense of therapy and the concern of long-term side-effects. The most common cause of mechanical fundoplication failure is recurrent hiatus hernia.

Patients with oesophageal dysmotility unrelated to acid reflux, patients who do not respond to PPIs and those with underlying functional bowel disease should not have surgery.

**Complications**

_Peptic stricture_

Peptic stricture usually occurs in patients over the age of 60. The symptoms are those of intermittent dysphagia for solids which worsen gradually over a long period. Mild cases may respond to PPI alone. More severe cases need endoscopic dilatation and long-term PPI therapy. Surgery is required if medical treatment fails.

_Barrett’s oesophagus_ (Fig. 6.10)

Barrett’s oesophagus is a condition in which part of the normal oesophageal squamous epithelium is replaced by metaplastic columnar mucosa to form a segment of ‘columnar-lined oesophagus’ (CLO). It is a complication of severe gastro-oesophageal reflux disease due to severe LOS hypotension and there is almost always a hiatus hernia. The diagnosis is made by endoscopy showing proximal displacement
of the squamocolumnar mucosal junction and biopsies demonstrating intestinal metaplasia. It may be seen as a continual sheet, or finger-like projections extending upwards from the squamocolumnar junction or as islands of columnar mucosa interspersed in areas of residual squamous mucosa. Recent guidelines suggest recording the length of circumferential CLO (C measurement) as well as the maximum length (M measurement) to aid assessment of progression or regression.

Central obesity increases the risk of Barrett’s by 4.3 times. Long segment (>3 cm) and short segment (<3 cm) Barrett’s is found respectively in 5% and 15% of patients, undergoing endoscopy for reflux symptoms. It is also often found incidentally in endoscoped patients without reflux symptoms. Barrett’s is commonest in middle-aged men. The major concern is that 0.5–1.0% of Barrett’s patients develop oesophageal adenocarcinoma per year. Barrett’s increases the chance of developing adenocarcinoma 30- to 50-fold. Progression of Barrett’s to cancer occurs through increasingly worse grades of dysplasia. The dysplasia is patchy, and biopsies from all four quadrants (every 2 cm) of the Barrett’s segment are recommended, as well as biopsies from macroscopically abnormal areas. High-grade dysplasia (HGD) can be hard to differentiate from early adenocarcinoma and there is a high risk of progression. Indeed, 30–40% of patients with HGD have cancer in the resected specimen. Chromoendoscopy (the topical application of stains or pigments via the endoscope) magnification and narrow band imaging may aid the diagnosis of intestinal metaplasia, dysplasia and carcinoma.

Screening and surveillance in Barrett’s oesophagus. There is little consensus about screening or surveillance, though many have strong opinions. Screening does not identify those at risk for cancer (40% of patients with oesophageal adenocarcinoma (OA) have no history of reflux symptoms); survival for mainly elderly patients with Barrett’s oesophagus is not significantly different from that for control subjects in the general population; no study has shown that surveillance is reliable in detecting curable dysplasia, as interval cancers occur during surveillance schemes; and treatment of the dysplasia has not been shown to prolong survival and/or improve quality of life, specifically by preventing oesophageal cancer. The estimated cost varies between $24700 and $98000 per life-year saved.

A consensus would be that patients without dysplasia do not require surveillance. Low-grade dysplasia requires extensive rebiopsy after 8–12 weeks of a PPI, rebiopsy 6 monthly if persistent and then 2–3 yearly if negative for dysplasia. For high-grade dysplasia – see treatment.

Treatment of Barrett’s oesophagus. There is no evidence that treatment with PPIs or antireflux surgery leads to Barrett’s regression, but symptomatic response does not correlate well with abolition of reflux. Ablation of high grade dysplastic Barrett’s is under evaluation using photodynamic therapy, laser, endoscopic mucosal resection, argon plasma coagulation and wide-field diathermy, particularly in patients ineligible for surgery, but there is currently little long-term evidence of benefit. Because of the low rate of progression to cancer, ablation of non-dysplastic CLO seems unlikely to be of benefit.

FURTHER READING

MOTILITY DISORDERS

Achalasia
Achalasia is characterized by oesophageal aperistalsis and impaired relaxation of the lower oesophageal sphincter.

Clinical features
Achalasia incidence is 1:100000 equally in males and females. It occurs at all ages but is rare in childhood. Patients usually have a long history of intermittent dysphagia, characteristically for both liquids and solids from the onset. Regurgitation of food from the dilated oesophagus occurs, particularly at night, and aspiration pneumonia is a complication. Spontaneous chest pain occurs, said to be due to oesophageal ‘spasm’. Dysphagia may be mild and accepted by the patient as normal. The pain may be misdiagnosed as cardiac. Weight loss is usually not marked.

Pathogenesis
The aetiology is unknown. Autoimmune, neurodegenerative and viral aetiologies have been implicated. A similar clinical picture is seen in chronic Chagas’ disease (American trypanosomiasis, p. 158) where there is damage to the neural plexus of the gut.

Histopathology shows inflammation of the myenteric plexus of the oesophagus with reduction of ganglion cell numbers. Cholinergic innervation appears to be preserved. Reduction in nitric oxide synthase-containing neurons has been shown by immunohistochemical staining. Pharmacologic studies in patients with achalasia support the selective loss of inhibitory, nitricergic neurones. Genetically engineered animals with targeted disruption of the gene encoding for the neuronal form of nitric oxide synthase and pharmacologic administration of NO donors substantiate the role of nitricergic denervation in achalasia. Thus the relaxation of the sphincter is impaired in the absence of nitric oxide. Some patients have autoantibodies to a dopamine-carrying protein on the surface of the cells in the myenteric plexus. Degenerative lesions are also found in the vagus. The differential diagnosis of achalasia world-wide includes genetic syndromes, infectious diseases, neoplasms and chronic inflammatory conditions.

Investigations
- Chest X-ray shows a dilated oesophagus, sometimes with a fluid level seen behind the heart. The fundal gas shadow is absent.
Barium swallow shows lack of peristalsis and often synchronous contractions in the body of the oesophagus, sometimes with dilatation. The lower end shows a ‘swan neck deformity’ due to failure of the sphincter to relax (Fig. 6.11).

Oesophagoscopy is performed to exclude a carcinoma at the lower end of the oesophagus which can produce a similar X-ray appearance. When there is marked dilatation, a 24-hour liquid-only diet and a washout prior to endoscopy is useful to remove food debris. In true achalasia the endoscope passes through the lower oesophageal sphincter with little resistance.

CT scan excludes distal oesophageal cancer.

Manometry shows aperistalsis of the oesophagus and failure of relaxation of the lower oesophageal sphincter (Fig. 6.5).

Treatment
All current forms of treatment for achalasia are palliative. Drug therapy rarely produces satisfactory or durable relief; nifedipine (20 mg sublingually) or sildenafil can be tried initially.

The treatment of choice is endoscopic dilatation of the LOS using a hydrostatic balloon under X-ray control. This weakens the sphincter and is successful initially in 80% of cases. About 50% of patients require a second or third dilatation in the first 5 years. There is a low but significant risk of perforation. Intrasphincteric injection of botulinum toxin A produces satisfactory initial results but the effects wear off within months. Further injections can be given. It is safer and simpler than dilatation, so may be valuable in patients at risk of death if a perforation occurs. Neither pneumatic dilatation nor botulinum toxin work as well in younger patients.

If these measures fail, surgical division of the LOS (cardiomyotomy, or Heller’s operation) is performed.

Reflex oesophagitis complicates all procedures and the aperistalsis of the oesophagus remains.

Complications
There is a slight increase in the incidence of squamous carcinoma of the oesophagus in both treated and untreated cases (7% after 25 years).

Systemic sclerosis (see also p. 545)
The oesophagus is involved in almost all patients with this disease. Diminished peristalsis and oesophageal clearance, detected manometrically (Fig. 6.5) or by barium swallow, is due to replacement of the smooth muscle by fibrous tissue. LOS pressure is decreased, allowing reflux with consequent mucosal damage. Strictures may develop. Initially there are no symptoms, but dysphagia and heartburn occur as the oesophagus becomes more severely involved. Similar motility abnormalities may be found in other connective tissue disorders, particularly if Raynaud’s phenomenon is present. Treatment is as for reflux (see p. 252) and benign stricture.

Diffuse oesophageal spasm
This is a severe form of oesophageal dysmotility that can sometimes produce retrosternal chest pain and dysphagia. It can accompany GORD. Swallowing is accompanied by bizarre and marked contractions of the oesophagus without normal peristalsis (Fig. 6.5). On barium swallow the appearance may be that of a ‘corkscrew’ oesophagus. However, asymptomatic oesophageal ‘dysmotility’ is not infrequent, particularly in patients over the age of 60 years.

A variant of diffuse oesophageal spasm is the ‘nutcracker’ oesophagus, which is characterized by very high-amplitude peristalsis (pressures > 200 mmHg) within the oesophagus. Chest pain is commoner than dysphagia.

Treatment
True oesophageal spasm producing severe symptoms is uncommon and treatment is often difficult. PPIs may be successful if reflux is a factor. Antispasmodics, nitrates or calcium-channel blockers – such as sublingual nifedipine 10 mg three times daily – may be tried. Occasionally, balloon dilatation or even longitudinal oesophageal myotomy is necessary.

Miscellaneous motility disorders
Abnormalities of motility that occasionally produce dysphagia are found in the elderly, in diabetes mellitus, myotonic dystrophy, oculopharyngeal muscular dystrophy and myasthenia gravis, as well as neurological disorders involving the brainstem.

Oesophageal diverticulum
Diverticula occur:
- immediately above the upper oesophageal sphincter (pharyngeal pouch – Zenker’s diverticulum) (see p. 1084).
near the middle of the oesophagus (trcation diverticulum due to inflammation, or associated with diffuse oesophageal spasm or mediastinal fibrosis)
- just above the lower oesophageal sphincter (epiphrenic diverticulum – associated with achalasia).

Usually detected incidentally on a barium swallow performed for other reasons, these are often asymptomatic. Dysphagia and regurgitation can occur with a pharyngeal pouch (see p. 1084).

**Rings and webs**

An oesophageal web is a thin, membranous tissue flap covered with squamous epithelium. Most acquired webs are located anteriorly in the postcricoid region of the cervical oesophagus and are well seen on barium swallow. They may produce dysphagia. In the Plummer–Vinson syndrome (or Paterson–Brown–Kelly syndrome) a web is associated with chronic iron deficiency anaemia, glossitis and angular stomatitis. This rare syndrome affects mainly women and its aetiology is not understood. The web may be difficult to see at endoscopy and may be ruptured unintentionally by the passage of the endoscope. Dilatation of the web is rarely necessary. Iron is given for the iron deficiency.

**Cricopharyngeal dysfunction**

There is poor relaxation of the cricopharyngeal muscle during swallowing so that a prominent indentation or ‘bar’ is seen on a barium swallow. It occurs in the elderly. Dysphagia is treated with dilatation but surgical myotomy may be necessary.

**Lower oesophageal rings**

Lower oesophageal rings are of two types:

1. **Mucosal (Schatzki’s ring, also called B ring)** (Fig. 6.12), which is located at the squamocolumnar mucosal junction; it is common, and is associated with characteristic history of intermittent bolus obstruction. Barium swallow with a distended oesophagus shows the abnormality which may be difficult to see at endoscopy.
2. **Muscular (A ring)**, which is located proximal to the mucosal ring; it is uncommon, covered by squamous epithelium and may cause dysphagia.

*Treatment* for these rings is usually with reassurance and dietary advice, but dilatation is occasionally necessary. After a single dilatation, 68% of patients with Schatzki’s rings are symptom free at 1 year, 35% remain symptom free after 2 years, but only 11% are symptom free at 3 years. Many also respond to oral PPI, either alone or with dilatation.

**Benign oesophageal stricture** (Fig. 6.13)

Peptic stricture secondary to reflux is the most common cause of benign strictures (for treatment, see p. 252). They also occur after the ingestion of corrosives, after radiotherapy, after sclerosis of varices, and following prolonged nasogastric intubation. Dysphagia is usually treated by endoscopic dilatation. Surgery is sometimes required.

**Oesophageal infections**

Infection is a cause of painful swallowing and is seen particularly in immunosuppressed (e.g. on chemotherapy) and debilitated patients and patients with AIDS. Infection can occur with:

- *Candida*
- *herpes simplex*
- *cytomegalovirus*.

It is occasionally difficult to distinguish between these either on barium swallow or oesophagoscopy, as only widespread ulceration is seen. In candidiasis the characteristic white plaques are frequently found; oral candidiasis is not always present. The diagnosis of *Candida* infection can be confirmed by examining a direct smear taken at endoscopy, but often infections are mixed and cultures and biopsies must be performed.

**Treatment**

Most patients on large doses of immunosuppressive agents are treated prophylactically with nystatin or amphotericin. Other antifungal or antiviral treatment is given appropriately (see Ch. 4).

**Mallory–Weiss syndrome**

This is described on page 269.

**Eosinophilic oesophagitis**

Eosinophils can be seen in the oesophageal mucosa (which is usually devoid of eosinophils microscopically) due to a variety of causes such as eosinophilic (or allergic) oesophagitis and GORD.

*Eosinophilic oesophagitis* is being increasingly recognized but its pathogenesis is unknown. There may be a personal or family history of allergic disorders. Food allergy is thought to be a pathogenic factor.

Patients present with a long history of dysphagia, food impaction, ‘heartburn’ and oesophageal pain. Usually the patient is male, white, and with an average age at diagnosis of 35, but it also occurs in children.

Typical endoscopic abnormalities include mucosal furrowing, loss of vascular pattern due to a thickened mucosa, plaques of eosinophilic surface exudate and prominent circular folds (Fig. 6.14), but the oesophagus may appear macroscopically normal. Reflux oesophagitis and Schatzki’s rings may co-exist. Endoscopic forceps biopsies (> 6) should be taken from upper, mid and lower oesophagus for histology with eosinophil counts.

The eosinophilic infiltration of the oesophagus due to reflux disease can be excluded by rebiopsy after a 6-week course of full dose PPI.

*Treatment* is with topical (swallowing inhaled steroid preparations, e.g. fluticasone, with inhalers without spacers) or systemic steroids. Children may respond dramatically to elimination diets but relapse when a normal diet is resumed. The response in adults is less certain. Dilatation is sometimes necessary but a high risk of perforation is reported.

**Oesophageal perforation or rupture**

*Oesophageal perforation* most commonly occurs at the time of endoscopic dilatation and, rarely, following insertion of a
nasogastric tube. Patients with malignant, corrosive or post-radiotherapy strictures are more likely to suffer perforation than those with a benign peptic stricture.

Management usually involves placement of an oesophageal stent (see p. 257), which dilates the (usually malignant) stricture and seals the hole. A water-soluble contrast X-ray is performed after 2–3 days to check the perforation has sealed.

‘Spontaneous’ oesophageal rupture occurs with violent vomiting (Boerhaave’s syndrome), producing severe chest pain and collapse in typical cases. Diagnosis can be difficult because classic symptoms are absent in about a third of cases and delays in presentation for medical care are common. It may follow alcohol ingestion. A chest X-ray shows a hydro pneumothorax. The diagnosis is made with a water-soluble contrast swallow or on CT. The mortality rate is approximately 35%, making it the most lethal perforation of the GI tract. The best outcomes are associated with early diagnosis and definitive surgical management within 12 hours of rupture. If intervention is delayed longer than 24 hours, the mortality rate (even after surgery) rises to above 50% and to nearly 90% after 48 hours.

### OESOPHAGEAL TUMOURS

#### Cancer of the oesophagus

This is the sixth most common cancer world-wide. Squamous tumours occurring in the middle third account for 40% of tumours, and in the upper third, 15%. Adenocarcinomas occur in the lower third of the oesophagus and at the cardia and represent approximately 45%. Primary small cell cancer is extremely rare.

#### Epidemiology and aetiological factors

**Squamous cell carcinoma (SCC)**

The geographic variation in incidence is greater than for any other carcinoma – often in regions very close to one another. It is common in Ethiopia, China, South and east Africa and in the Caspian regions of Iran. By contrast, north, middle and west Africa have low rates (www.cancerresearchuk.org).

In the UK the incidence is 5–10 per 100,000 and represents 2.2% of all malignant disease. The incidence of SCC is decreasing, in contrast to adenocarcinoma. SCC of the oesophagus is more common in men (2:1). Risk factors are shown in Table 6.5.

Diet rich in fibre, carotenoids, folate, vitamin C and non-starchy vegetables probably decrease the risk of oesophageal cancer whereas diets high in saturated fat and cholesterol and refined cereals have been associated with an increased risk. Red and processed meat intake have been associated with an increased risk of both oesophageal SCC and adenocarcinoma. Conversely, fish and white meat consumption have been inversely associated with risk of oesophageal SCC in case-control studies from Italy, Switzerland and Uruguay.

**Adenocarcinoma**

These tumours primarily arise in columnar-lined epithelium in the lower oesophagus (see also Barrett’s oesophagus, p. 252). The incidence of this tumour is increasing in western industrialized countries – by three- to fivelfold over the last 40 years in Europe and the USA. Incidence rates in the year 2000 were: Great Britain (5.0–8.7/100,000), Australia (4.8/100,000) and the Netherlands (4.4/100,000), followed by the US (3.7/100,000). Extension of an adenocarcinoma of the gastric cardia into the oesophagus can present with the same symptoms. Previous reflux symptoms increase the risk up to eightfold and the risk is proportional to their severity.

#### Clinical features

Carcinoma of the oesophagus occurs mainly in those aged 60–70 years. Dysphagia is progressive and unrelenting. Initially there is difficulty in swallowing solids, but typically dysphagia for liquids follows within weeks. Impaction of food causes pain, but more persistent pain implies infiltration of adjacent structures.

The lesion may be ulcerative, proliferative or scirrhouus, extending variably around the wall of the oesophagus to produce a stricture. Direct invasion of the surrounding structures and metastases to lymph nodes are commoner than disseminated metastases. Weight loss, due to the dysphagia as well as to anorexia, is frequent. Oesophageal obstruction eventually causes difficulty in swallowing saliva, and coughing and aspiration into the lungs is common.

Weight loss, anorexia and lymphadenopathy are the commonest physical signs.

#### Investigation

**Diagnostic**

- **Endoscopy** provides histological or cytological proof of the carcinoma; 90% of oesophageal carcinomas can be confirmed with this technique.
- **Barium swallow** can be useful where the differential diagnosis of dysphagia includes a motility disorder such as achalasia (Fig. 6.15a).

**Staging**

The TNM staging system is used (see p. 456). Tumour invasion of the wall of the oesophagus (T), presence of tumour in lymph nodes (N) or metastases (M) are combined into stage categories.

*Tylosis is a rare autosomal dominant condition with hyperkeratosis of the palms and soles.*
CT scan of the thorax and upper abdomen shows the volume of the tumour, local invasion, peritumoral and coeliac lymph node involvement and metastases in the lung and elsewhere. MRI is equivalent to CT in local staging but not as good for pulmonary metastases.

Endoscopic ultrasound has an accuracy rate of nearly 90% for assessing depth of tumour and infiltration and 80% for staging lymph node involvement. It is useful if CT does not show a lesion already too advanced for surgery. A fine needle aspiration (FNA) of lymph nodes improves staging accuracy.

Laparoscopy is useful if the tumour is at the cardia, to look for peritoneal and node metastases.

Positron emission tomography (PET) after fluorodeoxyglucose is used principally to confirm distant metastases suspected on CT.

Treatment
This depends on the age and performance status of the patient and the stage of the disease. Five-year survival with stage 1 is 80% (T1/T2, N0, M0), stage 2 is 30%, stage 3 is 18% and stage 4 is 4%. Seventy per cent of patients present with stage 3 or greater disease, so that overall survival is 27% at 1 year and around 10% at 5 years. Management should be undertaken by multidisciplinary teams.

Surgery provides the best chance of a cure and should be used only when imaging (see above) has shown that the tumour has not infiltrated outside the oesophageal wall (Stage 1). Surgery in this group shows an 80% survival rate if the postoperative pathology confirms the staging. The patients must be carefully evaluated preoperatively, particularly with regard to performance status (see p. 456) and surgery undertaken in designated units.

Chemoradiation. Pre-operative (‘neo-adjuvant’) chemoradiation therapy may benefit patients with stage 2b and 3 disease. Prolongation of survival has been shown in some studies.

Palliative therapy is often the only realistic possibility. Dilatation is only of short-term benefit. Insertion of an expanding metal stent allows liquids and soft foods to be eaten. Brachytherapy (see p. 465) prolongs luminal patency after stenting. Endoscopic laser destruction, or alcohol injections can be useful in proliferative tumours for relieving the dysphagia but repeated treatments are necessary.

Photodynamic therapy (PDT) can be useful. Chemoradiation is sometimes given, but evidence of benefit is poor.

Nutritional support, as well as support for the patient and their family, is vital in this distressing condition.

Other oesophageal tumours
Most other tumours are rare. Gastrointestinal stromal tumours (see p. 266) are found usually by chance. Ten per cent cause dysphagia or bleeding. Surgical removal is performed for symptomatic lesions or those over 3 cm which are more likely to harbour malignancy. Small benign tumours are relatively common and often do not require treatment.

Kaposi’s sarcoma is found in the oesophagus as well as the mouth (see p. 204) and hypopharynx in patients with AIDS.
The stomach and duodenum

Structure
The stomach consists of a small area immediately distal to the esophagus (the cardia), the upper region (the fundus, under the left diaphragm), the mid-region or body, and the antrum, which extends to the pylorus (Fig. 6.6).

The smooth muscle of the wall of the stomach has three layers – outer longitudinal, inner circular and innermost oblique layers. There are two sphincters, the gastro-oesophageal sphincter and the pyloric sphincter. The latter is largely made up of a thickening of the circular muscle layer and controls the exit of gastric contents into the duodenum.

The duodenum has outer longitudinal and inner smooth muscle layers. It is C-shaped and the pancreas sits in the concavity. It terminates at the duodenojejunal flexure where it joins the jejunum.

- The mucosal lining of the stomach can stretch in size with feeding. The greater curvature of the undistended stomach has thick folds or rugae. The mucosa of the upper two-thirds of the stomach contains parietal cells that secrete hydrochloric acid, and chief cells that secrete pepsinogen (which initiates proteolysis). There is often a colour change at the junction between the body and the antrum of the stomach that can be seen macroscopically, and confirmed by measuring surface pH.

- The antral mucosa secretes bicarbonate and contains mucus-secreting cells and G cells, which secrete gastrin. There are two major forms of gastrin, G17 and G34, depending on the number of amino-acid residues. G17 is the major form found in the antrum. Somatostatin is also produced by specialized antral cells (D cells).

- Mucus-secreting cells are present throughout the stomach and secrete mucus and bicarbonate. The mucus is made of glycoproteins called mucins.

- The ‘mucosal barrier’, made up of the plasma membranes of mucosal cells and the mucus layer, protects the gastric epithelium from damage by acid and, for example, alcohol, aspirin, NSAIDs and bile salts. Prostaglandins stimulate secretion of mucus, and their synthesis is inhibited by aspirin and NSAIDs, which inhibit cyclo-oxygenase (see Fig. 14.32).

- The duodenal mucosa has villi like the rest of the small bowel, and also contains Brunner’s glands that secrete alkaline mucus. This, along with the pancreatic and biliary secretions, helps to neutralize the acid secretion from the stomach when it reaches the duodenum.

Function
Factors controlling acid secretion are shown in Figure 6.16. Acid is not essential for digestion but does prevent some food-borne infections. Acid secretion is under neural and hormonal control. Both stimulate acid secretion through the direct action of histamine on the parietal cell. Acetylcholine and gastrin also release histamine via the enterochromaffin cells. Somatostatin inhibits both histamine and gastrin release and therefore acid secretion.

Other major gastric functions are:
- reservoir for food
- emulsification of fat and mixing of gastric contents
- secretion of intrinsic factor
- absorption (of only minimal importance).

Gastric emptying depends on many factors. There are osmoreceptors in the duodenal mucosa that control gastric emptying by local reflexes and the release of gut hormones. In particular, intraduodenal fat delays gastric emptying by negative feedback through duodenal receptors.

Helicobacter pylori infection
H. pylori is a slow-growing spiral Gram-negative flagellate urease-producing bacterium (Fig. 6.17) which plays a major role in gastritis and peptic ulcer disease. Its complete genomic sequence is known. It colonizes the mucous layer in the gastric antrum but is found in the duodenum only in areas of gastric metaplasia. H. pylori is found in greatest numbers under the mucous layer in gastric pits, where it adheres specifically to gastric epithelial cells. It is protected from gastric acid by the juxtapapillomucosal mucous layer which traps bicarbonate secreted by antral cells, and ammonia produced by bacterial urease.

Epidemiology of Helicobacter infection
The prevalence of H. pylori is high in developing countries (80–90% of the population), and much lower (20–50%) in developed countries. Infection rates are highest in lower income groups. Infection is usually acquired in childhood; although the exact route is uncertain, it may be faecal-oral or oral-oral, either by kissing or ingestion of contaminated vomit. Once acquired, the infection persists for life unless treated. The incidence increases with age, probably due to acquisition in childhood when hygiene was poorer (cohort effect) and not due to infection in adult life which is probably far less than 1% per year in developed countries.

Pathogenesis of Helicobacter infection
The pathogenetic mechanisms are not fully understood. H. pylori adheres by BabA adhesin to Lewis antigen expressed on the surface of gastric mucosal cells and causes gastritis in all infected subjects. Ulcers are commonest when the infecting strain expresses CagA (cytotoxic-associated protein) and VacA (vacuolating toxin) genes. CagA is a marker for a section of the bacterial DNA that contains genes responsible for a secretion system (Cag pathogenicity island, Pa) which injects CagA product into epithelial cells via a
Fig. 6.16 (a) Control of acid secretion.
(b) Mechanisms involved in acid secretion.

- Histamine stimulates G₄ via the H₂ receptors and acts via cyclic AMP.
- Prostaglandin E₂ activates the G₄ protein and INHIBITS acid secretion.
- Acetylcholine (ACh) acts via the vagus M₂ receptors.
- ACh also acts via the ECL cell.
- Gastrin acts via the gastrin receptor, increasing the intracellular free calcium, and also via the ECL cell stimulating histamine.

G₄ and Gₛ stimulating and inhibiting G-proteins; ECL, enterochromaffin cells.

Fig. 6.17 Helicobacter pylori. (a) Organisms (arrowed) are shown on the gastric mucosa (cresyl fast violet (modified Giemsa) stain). Courtesy of Dr Alan Phillips, Department of Paediatric Gastroenterology, Royal Free Hospital. (b) Scanning electron microscopy, showing the spiral-shaped bacterium.

phisms leading to increased levels of IL-1 are associated with atrophic gastritis and cancer.

Results of infection

- Antral gastritis
- Peptic ulcers (duodenal and gastric)
- Gastric cancer.

Antral gastritis is the usual effect of H. pylori infection. It is usually asymptomatic, although occasionally patients without ulcers claim relief of dyspeptic symptoms after Helicobacter eradication. Antral gastritis causes hypergastrinaemia due to gastrin release from antral G cells. The subsequent increase in acid output is usually asymptomatic.

Duodenal ulcer (DU) (see Fig. 6.19a). H. pylori is causally associated with DU disease because in patients with DU:

- 95% are infected with H. pylori in the antrum (antral gastritis).
- Cure of the infection heals the ulcer and stops duodenal ulcer recurrence.

The precise mechanism of duodenal ulceration is unclear, as only 15% of patients infected with H. pylori (50–60% of the adult population world-wide) develop duodenal ulcers. Factors that have been implicated include:

- Increased acid secretion because of:
  - increased parietal cell mass
  - increased gastrin secretion.
- Smoking impairing mucosal healing.
- Virulence factors such as Vac A (vacuolating toxin) and CagA (cytotoxic-associated protein) as well as urease and adherence factors (see above).
- Decreased inhibition of acid secretion; H. pylori-induced gastritis reduces somatostatin production in the antrum with loss of the negative feedback on gastrin secretion.
- Genetic susceptibility: duodenal ulcers are more common in patients who have blood group O and are non-secretors of blood group substances in saliva.
- Duodenal bicarbonate secretion is decreased by H. pylori inflammation and the damage and repair leads to gastric metaplasia which H. pylori colonizes, causing local release of cytokines and further damage.
**Gastric ulcer (GU)** (see Fig. 6.19b). Gastric ulcers are associated with a gastritis affecting the body as well as the antrum of the stomach (pangangritis) causing parietal cell loss and reduced acid production. The ulcers are thought to occur because of reduction of gastric mucosal resistance due to cytokine production by the infection or perhaps to alterations in gastric mucus.

**Epidemiology of peptic ulcer disease**
Duodenal ulcers affect 10–15% of the adult population and are two to three times more common than gastric ulcers. Ulcer rates are declining rapidly for younger men and increasing for older individuals, particularly women. Both DUs and GUs are common in the elderly. There is considerable geographical variation, with peptic ulcer disease being more prevalent in developing countries related to the high *H. pylori* infection.

**Pathology of peptic ulcer disease**
A *peptic ulcer* consists of a break in the superficial epithelial cells penetrating down to the muscularis mucosa; there is a fibrous base and an increase in inflammatory cells. *Erosions*, by contrast, are superficial breaks in the mucosa alone. Most DUs are found in the duodenal cap; the surrounding mucosa appears inflamed, haemorrhagic or friable (duodenitis). GUs are most commonly seen on the lesser curve near the incisura, but can be found in any part of the stomach. Peptic ulcers are seen without *H. pylori*, e.g. in patients on NSAIDs and in Zollinger–Ellison syndrome (see p. 385).

**Clinical features of peptic ulcer disease**
The characteristic feature of peptic ulcer is burning epigastric pain. It has been shown that if a patient points with a single finger to the epigastrium as the site of the pain this is strongly suggestive of peptic ulcer disease. The relationship of the pain to food is variable and on the whole not helpful in diagnosis. The pain of a DU classically occurs at night (as well as during the day) and is worse when the patient is hungry, but this is not reliable. The pain of both gastric and duodenal ulcers may be relieved by antacids.

Nausea may accompany the pain; vomiting is infrequent but often relieves pain. Anorexia and weight loss may occur, particularly with GUs. Persistent and severe pain suggests complications such as penetration into other organs. Back pain suggests a penetrating posterior ulcer. Severe ulceration can occasionally be symptomless, as many who present with acute ulcer bleeding or perforation have no preceding ulcer symptoms.

Untreated, the symptoms of a DU relapse and remit spontaneously. The natural history is for the disease to remit over many years due to the onset of atrophic gastritis and a decrease in acid secretion. Examination is usually unhelpful; epigastric tenderness is quite common in non-ulcer dyspepsia.

**Diagnosis of Helicobacter pylori infection**

**Non-invasive methods**

- **Serological tests** detect IgG antibodies and are reasonably sensitive (90%) and specific (83%). They have been used in diagnosis and in epidemiological studies. IgG titres may take up to 1 year to fall by 50% after eradication therapy and therefore are not useful for confirming eradication or the presence of a current infection. Antibodies can also be found in the saliva, but tests are not as sensitive or specific as serology.

  - **13-C-Urea breath test** (Fig. 6.18). This is a quick and reliable test for *H. pylori* and can be used as a screening test. The measurement of $^{13}\text{CO}_2$ in the breath after ingestion of $^{13}\text{C}$ urea requires a mass spectrometer. The test is very sensitive (97%) and specific (96%). This test is suitable for testing for eradication of the organism, but may be falsely negative if patients are taking PPIs at the time. A rapid release tablet which produces a result in 15 mins is becoming available.

  - **Stool antigen test**. A specific immunoassay using monoclonal antibodies for the qualitative detection of *H. pylori* antigen is widely available. The overall sensitivity is 97.6% with a specificity of 96%. It is useful in the diagnosis of *H. pylori* infection and for monitoring efficacy of eradication therapy. (Patients should be off PPIs for 1 week but can continue with H$_2$ blockers.)

**Invasive (endoscopy)**

- **Biopsy urease test**. Gastric biopsies are added to a substrate containing urea and phenol red. If *H. pylori* are present, the urease enzyme that they produce splits the urea to release ammonia which raises the pH of the solution and causes a rapid colour change (yellow to red). The test may be falsely negative if patients are taking PPIs or antibiotics at the time.

- **Culture**. Biopsies obtained can be cultured on a special medium, and in vitro sensitivities to antibiotics can be tested.

- **Histology**. *H. pylori* can be detected histologically on routine (Giemsa) stained sections of gastric mucosa obtained at endoscopy.

**Investigation of suspected peptic ulcer disease**

- **Patients under 55 years of age** with typical symptoms of peptic ulcer disease who are *H. pylori* positive can start eradication therapy without investigation.
Confirmation of the diagnosis and exclusion of cancer is required in older patients.

Endoscopy is the preferred investigation (Fig. 6.19). All GUs must be biopsied.

Endoscopy is required in all patients with ‘alarm symptoms’ (see p. 241).

**Eradication therapy**

Current recommendations are that all patients with duodenal and gastric ulcers should have *H. pylori* eradication therapy. Many patients have incidental *H. pylori* infection with no gastric or duodenal ulcer. Whether all such patients should have eradication therapy is controversial (see Functional dyspepsia, p. 311). However, eradication therapy is advised in the hope that symptoms will be reduced and because of the link between *H. pylori* and gastric cancer.

The increase in the prevalence of GORD and adenocarcinoma of the lower oesophagus in the last few years is currently unexplained, but has been postulated to be linked to eradication of *H. pylori*. This seems unlikely but is not disproven.

Standard eradication therapies are successful in approximately 90% of patients.

Reinfection is very uncommon (1%) in developed countries. In developing countries reinfection is more common, compliance with treatment may be poor and metronidazole resistance is high (>50%) (as it is frequently used for parasitic infections) so failure of eradication is common.

There are many regimens for eradication, but all must take into account that:

- good compliance is essential
- there is a high incidence of resistance to metronidazole, particularly in some populations
- oral metronidazole has frequent side-effects
- bismuth chelate is unpleasant to take, even as tablets.

Metronidazole, clarithromycin, amoxicillin, tetracycline and bismuth are the most widely used agents. Resistance to amoxicillin (1–2%) and tetracycline (<1%) is low except in countries where they are available without prescription where resistance may exceed 50%. Quinolones such as ciprofloxacin, furazolidone and rifabutin are also used when standard regimens have failed (‘rescue therapy’). Bismuth suppresses *H. pylori* effectively. None of these drugs is effective alone; eradication regimens therefore usually comprise two antibiotics given with powerful acid suppression in the form of a PPI, all given for 7 days.

Example regimes are:

- omeprazole 20 mg + clarithromycin 500 mg and amoxicillin 1 g – all twice daily

In some regimens, *H₂*-receptor antagonists, e.g. ranitidine or ranitidine bismuth citrate, are included instead of a PPI. Bismuth chelate is not usually given in initial regimens because of the more complex dosing regimen and side effects. In eradication failures bismuth chelate (120 mg 4× daily), metronidazole (400 mg 3× daily), tetracycline (500 mg 4× daily) and a PPI 20–40 mg 2× daily) for 14 days is used. Sequential courses of therapy are being used in areas where resistance is high.

Prolonged therapy with a PPI after a course of PPI-based 7-day triple therapy is not necessary for ulcer healing in most *H. pylori*-infected patients. The effectiveness of treatment for uncomplicated duodenal ulcer should be assessed symptomatically. If symptoms persist, breath or stool testing should be performed to check eradication.

Patients with a risk of bleeding or those with complications, i.e. haemorrhage or perforation, should always have a $^{13}$C urea breath test or stool test for *H. pylori* 6 weeks after the end of treatment to be sure eradication is successful. Long-term PPIs may be necessary if a rebleed would be likely to be fatal.

**General measures**

Stopping smoking should be strongly encouraged as smoking slows mucosal healing.

Patients with gastric ulcers should be routinely endoscoped at 6 weeks to exclude a malignant tumour by confirming healing with biopsy if necessary.

**Complications of peptic ulcer**

**Haemorrhage**

See page 267.

**Perforation** (Box 6.3; see also p. 316).

The frequency of perforation of peptic ulceration is decreases.
ing, partly attributable to medical therapy. DU perforate more commonly than GUUs, usually into the peritoneal cavity; perforation into the lesser sac also occurs. Detailed management of perforation is described on page 316. Surgery is usually performed to close the perforation and drain the abdomen. Conservative management using nasogastric suction, intravenous fluids and antibiotics is occasionally used in elderly and very sick patients.

**Gastric outlet obstruction**

The obstruction may be prepyloric, pyloric or duodenal. The obstruction occurs either because of an active ulcer with surrounding oedema or because the healing of an ulcer has been followed by scarring. However, obstruction due to peptic ulcer disease and gastric malignancy are now uncommon; Crohn’s disease or external compression from a pancreatic carcinoma are more common causes. Adult hypertrophic pyloric stenosis is a rare cause.

The stomach becomes full of gastric juice and ingested fluid and food, giving rise to the main symptom of vomiting, usually without pain as the characteristic ulcer pain has abated owing to healing.

Vomiting is infrequent, projectile, large in volume, and the vomitus contains particles of previous meals. On examination of the abdomen there may be a succussion splash. The diagnosis is made by endoscopy but can be suspected by the nature of the vomiting; by contrast, psychogenic vomiting is frequent, small volume and usually noisy.

Severe or persistent vomiting causes loss of acid from the stomach and a metabolic alkalosis (see p. 678). Vomiting will often settle with intravenous fluid and electrolyte replacement, gastric drainage via a nasogastric tube and potent acid suppression therapy. Endoscopic dilatation of the pyloric region is useful and, overall, 70% of patients can be managed without surgery.

**Surgical treatment and its long-term consequences**

Once the mainstay of treatment, surgery is now used in peptic ulcer disease only for complications including:

- recurrent uncontrolled haemorrhage: the bleeding vessel is ligated
- perforation, which is oversewn.

No other procedure, such as gastrectomy or vagotomy, is required.

In the past, two types of operation were performed:

- **Partial gastrectomy.**
- **Vagotomy.** Initially this was a truncal vagotomy and required a gastric drainage procedure such as pyloroplasty or gastro-jejunostomy. In later years this was usually highly selective vagotomy or proximal gastric vagotomy, in which only the nerves supplying the parietal cells were transected, and therefore no drainage of the stomach was required.

**Long-term complications** of surgery which are still seen occasionally include:

- **Recurrent ulcer.** If this occurs, check for *H. pylori*, rule out Zollinger–Ellison syndrome (see p. 385).
- **Dumping.** This term describes a number of upper abdominal symptoms (e.g. nausea and distension associated with sweating, faintness and palpitations) that occur in patients following gastrectomy or gastroenterostomy. It is due to ‘dumping’ of food into the jejunum, causing rapid fluid shifts from plasma to dilute the high osmotic load with reduction of blood volume. The symptoms are usually mild and patients adapt to them. It is rare for it to be a long-term problem, and if so, the symptoms usually have a functional element. Hypoglycaemia can also occur.

- Diarrhoea was chiefly seen after vagotomy. Recurrent severe episodes occurred in about 1% of patients. Antidiarrhoeals are the usual treatment.
- **Nutritional complications:** in the long-term almost any gastric surgery, but particularly gastrectomy, may be followed by:
  - iron deficiency, due to poor absorption
  - folate deficiency, usually due to poor intake
  - vitamin B₁₂ deficiency, due to intrinsic factor deficiency
  - weight loss, usually due to reduced intake.

**Other *H. pylori*-associated diseases**

- **Gastric adenocarcinoma.** The incidence of distal (but not proximal) gastric cancer parallels that of *H. pylori* infection in countries with a high incidence of gastric cancer. Serological studies show that people infected with *H. pylori* have a higher incidence of distal gastric carcinoma (see p. 264).
- **Gastric B cell lymphoma.** Over 70% of patients with gastric B cell lymphomas (mucosal-associated lymphoid tissue – MALT) have *H. pylori*. *H. pylori* gastritis has been shown to contain the clonal B cell that eventually gives rise to the MALT lymphoma (see p. 266).

### GASTROPATHY AND GASTRITIS

‘Gastritis’ indicates inflammation associated with mucosal injury (although the term is often used loosely by endoscopists to describe ‘redness’), and ‘gastropathy’ indicates epithelial cell damage and regeneration without inflammation. Several classifications of gastritis (e.g. Sydney classification) have been proposed but are controversial due to lack of correlation, for example between endoscopic and histological findings. *H. pylori* infection is the commonest cause of gastritis (80%). Autoimmune gastritis is seen in 5% while the remaining causes include viruses (e.g. cytomegalovirus and herpes simplex), duodenogastric reflux and specific causes, e.g. Crohn’s.

Gastropathy is usually caused by irritants (drugs, NSAIDs and alcohol), bile reflux, hypovolaemia and chronic congestion. Acute erosive/haemorrhagic gastropathy can also be seen after severe stress (stress ulcers) and secondary to burns (Curling ulcers), trauma, shock, renal failure or in portal hypertension (called portal gastropathy). The underlying mechanism for these ulcers is unknown but may be related to an alteration in mucosal blood flow.

**NSAIDs, Helicobacter and ulcers**

Aspirin and other NSAIDs deplete mucosal prostaglandins by inhibiting the cyclo-oxygenase (COX) pathway, which leads to mucosal damage. Cyclo-oxygenase occurs in two main
forms: COX-1, the constitutive enzyme, and COX-2, inducible by cytokine stimulation in areas of inflammation. NSAIDs more specific for COX-2 are available and these drugs have less effect on the COX-1 enzyme in the gastric mucosa. They still produce gastric mucosal damage but less than with other conventional NSAIDs.

Fifty per cent of patients taking regular NSAIDs will develop gastric mucosal damage and approximately 30% will have ulcers on endoscopy. Only a small proportion of patients have symptoms (about 5%) and only 1–2% have a major problem, i.e. GI bleed. Because of the large number of patients on NSAIDs including low-dose aspirin for vascular prophylaxis, this is a significant problem, particularly in the elderly.

_H. pylori_ and NSAIDs are independent and synergistic risk factors for the development of ulcers. In a meta-analysis, the odds ratio (OR) for the incidence of peptic ulcer was 61.1 in patients infected with _H. pylori_ and also taking NSAIDs, compared with uninfected controls not taking NSAIDs.

Alcohol in high concentration also damages the gastric mucosal barrier and is associated with acute gastric mucosal erosions and subepithelial haemorrhage which can lead to upper GI bleeding.

**Treatment**

- Stop the ingestion of NSAIDs.
- A PPI should be given.
- _H. pylori_ eradication therapy if _H. pylori_ positive.

In many patients with severe arthritis, stopping NSAIDs may not be possible. Therefore use:

- An NSAID with low GI side-effects at lowest dose possible (see p. 518) or if there is no cardiovascular risk, a COX-2 NSAID can be used (see p. 518).
- Prophylactic cytoprotective therapy, e.g. PPI or misoprostol (a synthetic analogue of prostaglandin E1 – 800 µg/day) for all high-risk patients; i.e. over 65 years; those with a peptic ulcer history, particularly with complications, and patients on therapy with corticosteroids or anticoagulants. Double dose _H_2-receptor antagonists (H2RAs) and PPIs reduce the risk of endoscopic duodenal and gastric ulcers and are better tolerated than misoprostol, which causes diarrhoea.

**Autoimmune gastritis**

This affects the fundus and body of the stomach (pangastri-tis), leading to atrophic gastritis and loss of parietal cells with achlorhydria and intrinsic factor deficiency causing the clinical syndrome of ‘pernicious anaemia’. Serum autoantibodies to gastric parietal cells are common and non-specific: antibodies to intrinsic factor are rarer and more significant (see p. 399).

**Ménétrier’s disease**

This is a rare condition with characteristic giant gastric folds, mainly in the fundus and the body of the stomach. Histologically there is hyperplasia of the gastric pits, atrophy of glands and an overall increase of mucosal thickness. Hyperchlorhydria is usually present. The patient may complain of epigastric pain. Peripheral oedema may occur because of hypoalbuminaemia due to protein loss through the gastric mucosa. It is probably premalignant but the rarity of the condition makes this uncertain. Treatment is unclear; some patients have responded to _Helicobacter_ eradication and some improve spontaneously. Anti-secretory drugs are usually given. A few patients will require surgery.

**MANAGEMENT OF DYSEPSIA IN THE COMMUNITY**

Meal-related upper abdominal symptoms (commonly known by the unhelpful term ‘dyspepsia’) are very common. Over-the-counter antacids and _H_2-receptor antagonists (H2RAs) are available and are widely used.

A history suggestive of gastro-oesophageal reflux disease (GORD) should be treated with antacids, lifestyle measures, and H2RAs or PPIs if necessary. Treatment may be on-demand or continuous, and may need to be long-term.

In people under 45 years, gastric cancer or any pathology is very rare. Initial investigation with endoscopy is therefore not recommended. Blind _Helicobacter_ eradication or ‘test and treat’ strategies are both used; their effectiveness depends on the prevalence of _Helicobacter_ and local resistance patterns. Neither endoscopy nor ‘test and treat’ are cost effective. Further investigation may be necessary to reassure those _H. pylori_-negative subjects and those who remain symptomatic after successful _H. pylori_ eradication, though organic disease is uncommon.

Older people (over 45 years) with new-onset dyspepsia and patients with alarm symptoms are traditionally investigated with endoscopy to exclude cancer and ulcers. Much investigation in this group is driven by the fear of missing a treatable cancer, though functional dyspepsia is by far the commonest diagnosis.

_Treatments_ used for dyspepsia (often over-the-counter) include:

- _Antacids_ (see p. 252).
- _H_2-receptor antagonists. These have molecular structures that fit the _H_2-receptors on the parietal cells. They can produce up to 80% reduction in nocturnal acid production but are less effective by day. There is little difference between the several second-generation _H_2RAs such as ranitidine and famotidine, but they have fewer side-effects and cross-reactivity with other medication, e.g. warfarin.
- _Proton pump inhibitors_ (see p. 252) are very effective for reflux symptoms, ulcer pain and healing but do not cure ulcer disease alone. They are also used empirically in functional dyspepsia, despite their cost.

**GASTRIC TUMOURS**

**Adenocarcinoma**

Gastric cancer is currently the fourth most common cancer found world-wide and the second leading cause of cancer-related mortality. The incidence increases with age (peak incidence 50–70 years), and it is rare under the age of 30 years. The highest incidences of the disease are found in Eastern Asia, Eastern Europe and South America. The incidence in men is twice that in women and varies throughout the world, being high in Japan (M: 53/100 000, F: 21.3/100 000) and Chile and relatively low in the USA (M: 7/100 000, F:
2.9/100,000). In the UK carcinoma of the stomach (see Fig. 6.1) is the seventh commonest cancer (M: 14/100,000, F 6/100,000) and the eighth most common fatal cancer. Although the overall world-wide incidence of gastric carcinoma is falling even in Japan, probably due to reductions in incidence of *Helicobacter*, proximal gastric cancers are increasing in the West.

**Epidemiology and pathogenesis**

- There is a strong link between *H. pylori* infection and distal gastric cancer. *H. pylori* is recognized by the International Agency for Research in Cancer (IARC) as a Group 1 (definite) gastric carcinogen. *H. pylori* infection causes chronic gastritis which eventually leads to atrophic gastritis and premalignant intestinal metaplasia (Fig. 6.20). Much of the earlier epidemiological data (i.e. the increase of cancer in lower socio-economic groups) can be explained by the intrafamilial spread of *H. pylori*.
- **Dietary factors** may also be involved (as both initiators and promoters) and have separate roles in carcinogenesis. Diets high in salt probably increase the risk. Dietary nitrates can be converted into nitrosamines by bacteria at neutral pH, and nitrosamines are known to be carcinogenic in animals but the evidence in human carcinogenesis is limited. Nitrosamines are also present in the stomach of patients with achlorhydria, who have an increased cancer risk. Consumption of foods high in non-starchy vegetables, allium vegetables (e.g. garlic), fruits and low in salt protect against cancer.
- **Smoking tobacco** is associated with an increased incidence of stomach cancer.
- The commonest **genetic abnormality** is a loss of heterozygosity (LOH) of tumour suppressor genes such as p53 (in 70% of cancers as well as in pre-cancerous states) and the APC gene (in over a third of gastric cancers). These abnormalities are similar to those found in colorectal cancers. Some rare families with diffuse gastric cancer have been shown to have mutations in the E-cadherin gene (CDH-1). There is a higher incidence of gastric cancer in blood group A patients.

- **First-degree relatives** of patients with gastric cancer have two- to three-fold increased relative risk of developing the disease, but this may be environmental rather than inherited.
- **Pernicious anaemia** carries a small increased risk of gastric carcinoma due to the accompanying atrophic gastritis.
- There is an increased risk of gastric cancer after a partial gastrectomy (postoperative stomach) whether performed for a gastric or a duodenal ulcer, probably due to untreated *H. pylori* infection.

Benign gastric ulcers have not been shown to develop into gastric cancer. It can, however, be difficult to differentiate a benign ulcer from a malignant ulcer, as 10–15% of malignant ulcers can heal on medical treatment. Thus it was originally thought that gastric ulcers could become malignant.

**Screening**

Earlier diagnosis has been advocated in an attempt to improve the poor prognosis of gastric cancer. Screening is discussed on page 454. Although the incidence of gastric cancer is falling in Japan where aggressive screening by barium meal and endoscopy is pursued, there is no evidence that screening has had an effect on overall mortality. Similarly, early investigation of dyspepsia has had little effect on mortality, possibly because of the relatively low incidence of cancer.

**Early gastric cancer** (Fig. 6.21)

Early gastric cancer is defined as a carcinoma that is confined to the mucosa or submucosa, regardless of the presence of lymph node metastases. It is associated with 5-year survival rates of approximately 90%, but many of these patients would have survived 5 years without treatment. In Japan, mass screening with mobile X-ray units has increased

---

**Fig. 6.20** Flow diagram showing the development of gastric cancer associated with *H. pylori* infection.

**Fig. 6.21** Early gastric cancer: (a) endoscopic view – showing subtle changes in mucosa; (b) same view following an ink spray.
the proportion of early gastric cancers (EGC) diagnosed. In a large series of patients with gastric cancer from the UK, only 0.7% were identified as having EGC. They are usually detected by chance as although EGC exists in western populations, endoscopists do not readily recognize it at present.

Pathology
There are two major types of gastric cancer:

- **Intestinal type**, with well-formed glandular structures. The tumours are polyloid or ulcerating lesions with heaped-up, rolled edges. Intestinal metaplasia is seen in the surrounding mucosa, often with *H. pylori*. This type is more likely to involve the distal stomach and occur in patients with atrophic gastritis. It has a strong environmental association.

- **Diffuse type**, with poorly cohesive cells that tend to infiltrate the gastric wall, may involve any part of the stomach, especially the cardia, and have a worse prognosis than the intestinal type. Unlike type 1 gastric cancers, type 2 cancers have similar frequencies in all geographic areas.

50% of gastric cancer in western countries now occurs in the proximal stomach.

Clinical features

Symptoms
Fifty per cent of patients with EGC discovered at screening have no symptoms. Most patients with carcinoma of the stomach have advanced disease at the time of presentation. The most common symptom of advanced disease is epigastric pain, indistinguishable from the pain of peptic ulcer disease, it may be relieved by food and antacids. The pain can vary in intensity, but may be constant and severe, and there may also be nausea, anorexia and weight loss. Vomiting is frequent and can be severe if the tumour encroaches on the pylorus. Dysphagia can occur with tumours involving the fundus. Gross haematemesis is unusual, but anaemia from occult blood loss is frequent. No pattern of symptoms is suggestive of early gastric cancer.

Widely spreading submucosal gastric cancer causes diffuse thickening and rigidity of the stomach wall and is called ‘linitis plastica’.

Patients can present at a late stage with malignant ascites or jaundice due to liver involvement. Metastases also occur in bone, brain and lung, producing appropriate symptoms.

Signs

Weight loss is often the dominant feature. Nearly 50% of patients have a palpable epigastric mass with abdominal tenderness. A palpable lymph node is sometimes found in the supraclavicular fossa (Virchow’s node, usually on the left side) and metastases are present in up to one-third of patients at presentation. This cancer is the most frequently associated with dermatomyositis (see p. 547) and acanthosis nigricans.

Diagnosis

- **Gastroscopy** (Fig. 6.22). Gastroscopy is usually performed so that biopsies can be taken for histological assessment and to exclude lymphoma. Positive biopsies can be obtained in almost all cases of obvious carcinoma, but a negative biopsy does not necessarily rule out the diagnosis. For this reason, 8–10 biopsies should be taken from suspicious lesions. Superficial brushings for cytology further improve the diagnostic rate.

- **Full blood count** and liver biochemistry.

- **Barium meal**. Although used as a screening test in Japan, this has largely been replaced by gastroscopy. A good quality double-contrast barium meal has a diagnostic accuracy of up to 90%. The carcinoma is usually seen as a filling defect or an irregular ulcer with rolled edges. With a diffuse (linitis plastica) infiltrating cancer, the X-ray may show a narrowed and rigid stomach.

Staging

- **CT scan** of the chest and abdomen: CT with a gastric water load can demonstrate gastric wall thickening, lymphadenopathy and lung and liver secondaries, but has limited ability to determine the depth of local tumour invasion.

- **Transabdominal ultrasound** can demonstrate masses, gastric wall thickening, lymphadenopathy and liver secondaries.

- **Endoscopic ultrasound** is useful for local staging to demonstrate the depth of penetration of the cancer through the gastric wall and extension into local lymph nodes. It complements CT and ultrasound but is only relevant in the absence of metastatic disease.

- **Laparoscopy** is useful in patients being considered for surgery to exclude serosal disease.

- **PET and CT/PET** can be helpful in further delineation of the cancer.

The TNM classification is used (see p. 456). The tumour grade (T) indicates depth of tumour invasion, N denotes the presence or absence of lymph nodes, M indicates presence or absence of metastases. TNM classification is then combined into stage categories 0–4. At presentation, two-thirds of patients are at stage 3 or 4, i.e. advanced disease (Table 6.6). The histological grade of the tumour also determines survival.

**Treatment**

Early non-ulcerated mucosal lesions can be removed endoscopically, but suitable lesions are rare outside Japan.

**Surgery** remains the most effective form of treatment if the patient is operable. Careful selection has reduced the numbers undergoing surgery and has improved the overall surgical 5-year survival rates to around 30%. Five-year survival rates in ‘curative’ operations are as high as 50%. Surgery and combined chemo-radiotherapy and treatment of advanced disease is described on page 490. Peri-operative chemotherapy with epirubicin, cisplatin and infusional 5-fluorouracil (ECF) (see Table 9.10) has improved 5-year survival in operable gastric and lower oesophageal adenocarcinomas from 23% to 36%. An alternative regimen is oral epirubicin, oxalplatin and capcitabine. Despite the improved results, the overall survival rate for a patient with gastric carcinoma has not dramatically improved, with a maximum 10% 5-year survival rate overall. Palliative care with relief of pain and counselling are usually required.

**Gastrointestinal stromal tumours (GIST)**

GI stromal tumours (GISTs) are a subset of GI mesenchymal tumours of varying differentiation. They are usually asymptomatic and found by chance but they can occasionally ulcerate and bleed. There are 200–900 new cases each year in the UK. GISTs mostly affect people between 55 and 65.

These tumours used to be classified as GI leiomyomas, leiomyosarcomas, leiomyoblastomas or Schwannomas. Truly benign leiomyomas do occur, mainly in the oesophagus. GISTs are now recognized as a distinct group of mesenchymal tumours and comprise about 80% of GI mesenchymal tumours. They are of stromal origin, thought to share a common ancestry with the interstitial cells of Cajal. They have varying differentiation. Mutations occur in the cellular proto-oncogene KIT (which leads to activation of cell-surface expression of the tyrosine kinase KIT (CD 117)) in 80% and also in platelet-derived growth factor receptor alpha (PDGFRA) in up to 10% of patients.

**Treatment** is surgical as far as possible. These tumours generally grow slowly but may be malignant. Imatinib, a tyrosine kinase inhibitor (p. 464), is used for unresectable or metastatic disease, but some patients are resistant; sunitinib is an alternative.

**Primary gastric lymphoma**

Mucosa-associated lymphatic tissue lymphomas are indolent B cell marginal zone lymphomas primarily involving sites other than lymph nodes (gastrointestinal tract, thyroid, breast or skin). They constitute about 10% of all types of non-Hodgkin’s lymphoma (NHL).

**Presentation**

Most patients are diagnosed in their sixties with stage I or stage II disease outside the lymph nodes. Patients have stomach pain, ulcers or other localized symptoms, but rarely have systemic complaints such as fatigue or fever.

**Causes**

About 90% of cases are due to *H. pylori* infection. Chromosome abnormalities t(1;14)(p22;q32) and t(11;18)(q21;q21) have also been noted in this form of NHL.

**Gastric polyps**

Gastric polyps are found in about 1% of endoscopies, usually by chance. They rarely produce symptoms.

Endoscopic excision is the usual approach to diagnosis and treatment. Occasional large or multiple polyps may require surgery.

**Hyperplastic polyps** are by far the most common. Most are less than 2 cm. The polyps are rarely premalignant, but may be accompanied by premalignant atrophic gastritis.

**Adenomatous polyps** are usually solitary lesions in the antrum. Approximately 3% progress to gastric cancer, especially if greater than 2 cm in diameter, but they are not a common cause of gastric cancer (cf colorectal cancer).

**Cystic gland polyps** contain microcysts that are lined by fundic-type parietal and chief cells. They are located in the fundus and body of the stomach. They are found in otherwise normal subjects, but are especially common in familial polyposis syndromes and have no malignant potential.

**Inflammatory fibroid polyps** are benign spindle cell tumours infiltrated by eosinophils. Excision of these polyps is indicated because of their propensity to enlarge and cause obstruction.

**FURTHER READING**

ACUTE AND CHRONIC GASTROINTESTINAL BLEEDING

This section should be read in conjunction with the descriptions of the specific conditions mentioned.

Acute upper gastrointestinal bleeding

The cardinal features are haematemesis (the vomiting of blood) and melaena (the passage of black tarry stools; the black colour due to blood altered by passage through the gut). Melaena can occur with bleeding from any lesion proximal to the right colon. Following a bleed from the upper GI tract, unaltered blood can appear per rectum, but the bleeding must be massive and is almost always accompanied by shock. The passage of dark blood and clots without shock is always due to lower GI bleeding.

Aetiology (Fig. 6.23)

Peptic ulceration is the commonest cause of serious and life-threatening gastrointestinal bleeding. The relative incidence of causes depends on the patient population; overall the incidence has fallen. In the developing world haemorrhagic viral infections (see Table 4.22, p. 114) can cause significant gastrointestinal bleeding.

Drugs. Aspirin (even 75 mg a day) and other NSAIDs can produce ulcers and erosions. These agents are also responsible for GI haemorrhage from both duodenal and gastric ulcers, particularly in the elderly. They are available over the counter and patients may not be aware they are taking aspirin or an NSAID. Corticosteroids in the usual therapeutic doses probably have no influence on GI haemorrhage. Anticoagulants do not cause acute GI haemorrhage per se but bleeding from any cause is greater if the patient is anticoagulated.

Clinical approach to the patient

All cases with a recent (i.e. within 48 hours) significant GI bleed should be seen in hospital. In many, no immediate treatment is required as there has been only a small amount of blood loss. Approximately 85% of patients stop bleeding spontaneously within 48 hours.

Scoring systems have been developed to assess the risk of rebleeding or death (Rockall) and need for intervention (Blatchford) such as transfusion or endoscopic therapy.

Table 6.7 shows the Rockall score which is based on clinical and endoscopy findings. The Blatchford score uses the level of plasma urea, haemoglobin and clinical markers but not endoscopic findings.

The following factors affect the risk of rebleeding and death:

- age
- evidence of co-morbidity, e.g. cardiac failure, ischaemic heart disease, renal disease and malignant disease
- presence of the classical clinical features of shock (pallor, cold peripheries, tachycardia and low blood pressure)
- endoscopic diagnosis
- ulcer with active bleeding or endoscopic stigmata of recent bleeding
- clinical signs of chronic liver disease.

Bleeding associated with liver disease is often severe and recurrent if it is from varices. Splenomegaly suggests portal hypertension but its absence does not rule out oesophageal varices. Liver failure can develop.

Immediate management

This is shown in Emergency Box 6.1. In addition, stop NSAIDs, aspirin and warfarin if patients are taking them.

Many hospitals have multidisciplinary specialist teams with agreed protocols and these should be followed carefully. Patients should be managed in high-dependency beds. Oxygen should be given by face mask and the patient should be kept nil by mouth until endoscopy has been performed.

Patients with large bleeds and clinical signs of shock require urgent resuscitation. Details of the management of shock are given in Figure 15.20.

Blood volume

The major principle is to rapidly restore the blood volume to normal. This can be best achieved by transfusion of red cell concentrates via one or more large-bore intravenous
Management of acute gastrointestinal bleeding

- History and examination. Note co-morbidity
- Monitor the pulse and blood pressure half-hourly
- Take blood for haemoglobin, urea, electrolytes, liver biochemistry, coagulation screen, group and crossmatching (2 units initially)
- Establish intravenous access – 2 large bore i.v. cannulae; central line if brisk bleed
- Give blood transfusion/colloid if necessary. Indications for blood transfusion are:
  (a) SHOCK (pallor, cold nose, systolic BP below 100 mmHg, pulse > 100 b.p.m.)
  (b) haemoglobin < 10 g/dL in patients with recent or active bleeding
- Oxygen therapy
- Urgent endoscopy in shocked patients/liver disease
- Continue to monitor pulse and BP
- Re-endoscopy for continued bleeding/hypovolaemia
- Surgery if bleeding persists

diately as haemodilution has not taken place. However, if the Hb is less than 10 g/dL and the patient has either bled recently or is actively bleeding, transfusion is usually necessary. In most patients the bleeding stops, albeit temporarily, so that further assessment can be made.

Endoscopy

Endoscopy will usually make a diagnosis and endoscopic therapy can be performed if needed. Endoscopy should be performed within 24 hours in patients with significant bleeds. Patients with Rockall scores of 0 or 1 may be candidates for immediate (see over) discharge and outpatient endoscopy the following day, depending on local policy.

After adequate resuscitation, urgent endoscopy should be performed in patients with shock, suspected varices or with continued bleeding. Endoscopy can detect the cause of the haemorrhage in 80% or more of cases. In patients with a peptic ulcer, if the stigmata of a recent bleed are seen (i.e. a spurting artery, active oozing, fresh or organized blood clot or black spots) the patient is more likely to rebleed. Calculation of the postendoscopy Rockall score gives an indication of the risk of rebleeding and death.

At first endoscopy:

- Varices should be treated, usually with banding.
- Stenting for varices is a recent innovation, not yet widely available – see page 350 for management of varices.
- Bleeding ulcers and those with stigmata of recent bleeding should be treated with two haemostatic methods, usually injection with epinephrine (adrenaline) and thermal coagulation (with heater probe, bipolar cannulae; plasma expanders or 0.9% saline is given until the blood becomes available (see p. 906).

Transfusion must be monitored to avoid overload leading to heart failure. The pulse rate and venous pressure are the best guides to adequacy of transfusion. A central venous pressure line is inserted for patients with organ failure who require blood transfusion, and in patients with severe hypotension.

Haemoglobin levels are generally a poor indicator of the need to transfuse because anaemia does not develop imme-
probe, laser or argon plasma coagulation) or endoscopic clipping because dual therapy is clearly more effective than monotherapy in reducing rebleeding.

- Antral biopsies should be taken to look for H. pylori. A positive biopsy urease test is valid, but a negative test is not reliable. If the urease test is negative, gastric histology should always be performed.

The above procedures reduce the incidence of rebleeding, although they do not significantly improve mortality.

**Drug therapy**

After diagnosis at endoscopy, intravenous omeprazole 80 mg followed by infusion 8 mg/h for 72 hours should be given to all ulcer patients as it reduces rebleeding rates and the need for surgery. PPI therapy has no effect on mortality in studies in the western world, but there is a positive effect in Oriental studies. H2-receptor antagonists are of no value.

**Uncontrolled or repeat bleeding**

Endoscopy should be repeated to assess the bleeding site and to treat, if possible. Surgery is necessary if bleeding is persistent and/or uncontrollable and should aim primarily to control the haemorrhage.

**Discharge policy**

The patient’s age, diagnosis on endoscopy, co-morbidity and the presence or absence of shock and the availability of support in the community should be taken into consideration. In general, all patients who are haemodynamically stable and have no stigmata of recent haemorrhage on endoscopy (Rockall Score pre-endoscopy 0, post-endoscopy ≤ 1) can be discharged from hospital within 24 hours. All shocked patients and patients with co-morbidity need inpatient observation.

**Specific conditions**

**Chronic peptic ulcer.** Eradication of H. pylori is started as soon as possible (see p. 261). A PPI is continued for 4 weeks to ensure ulcer healing. Eradication of H. pylori should always be checked in a patient who has bled and long-term acid suppression given if HP eradication is not possible. If bleeding is not controlled, surgery with ligation of the bleeding vessel is performed to control haemorrhage.

**Gastric carcinoma.** Most of these patients do not have large bleeds but surgery is occasionally necessary for uncontrolled or repeat bleeding. Usually surgery can be delayed until the patient has been fully evaluated (see p. 265). Oozing from gastric cancer is very difficult to control endoscopically.

**Oesophageal varices.** These are discussed on page 348.

**Mallory–Weiss tear.** This is a linear mucosal tear occurring at the oesophagogastric junction and produced by a sudden increase in intra-abdominal pressure. It often occurs after a bout of coughing or retching and is classically seen after alcoholic ‘dry heaves’. There may, however, be no antecedent history of retching. Most bleeds are minor and discharge is usual within 24 hours. The haemorrhage may be large but most patients stop spontaneously. Early endoscopy confirms diagnosis and allows therapy if necessary. Surgery with over-sewing of the tear is rarely needed.

**Bleeding after percutaneous coronary intervention (PCI).** This occurs in approximately 2% of patients undergoing PCI (who are on antiplatelet therapy), and has a high mortality of 5–10%. Urgent endoscopy should be performed with appropriate therapy for, for example, an ulcer. A proton pump inhibitor should be given intravenously. Management is difficult as cessation of antiplatelet therapy has a high risk of acute stent thrombosis and also an associated high mortality. Using a risk assessment score (e.g. Rockall, p. 268), a reasonable approach is to stop all antiplatelet therapy in high risk patients but continue in low risk ones. These patients should be under the combined care of a cardiologist and a gastroenterologist.

**Prognosis**

The mortality from gastrointestinal haemorrhage has not changed from 5–12% over the years, despite many changes in management, mainly because of a demographic shift to more elderly patients with co-morbidity. The lowest mortality rates are achieved in dedicated medical/surgical GI units. Early therapeutic endoscopy has not so far reduced the mortality, although rebleeding episodes are reduced.

**Acute lower gastrointestinal bleeding**

Massive bleeding from the lower GI tract is rare and usually due to diverticular disease or ischaemic colitis. Common causes of small bleeds are haemorrhoids and anal fissures. The causes of lower GI bleeding are shown in Figure 6.24.

**Management**

Most acute lower GI bleeds start and stop spontaneously. The few patients who continue bleeding and are haemodynamically unstable need resuscitation using the same principles as for upper GI bleeding (see p. 267). Surgery is rarely required.

A diagnosis is made using the history, examination including rectal examination and the following investigations as appropriate:

- proctoscopy (e.g. anorectal disease, particularly haemorrhoids)

**Fig. 6.24 Causes of lower gastrointestinal bleeding.**

The sites shown are illustrative – many of the lesions can be seen in other parts of the colon.
flexible sigmoidoscopy or colonoscopy (e.g. inflammatory bowel disease, cancer, ischaemic colitis, diverticular disease, angiodysplasia)

- angiography – vascular abnormality (e.g. angiodysplasia). The yield of angiography is low, so it is a test of last resort.

Isolated episodes of rectal bleeding in the young (<45 years) usually only require rectal examination and flexible sigmoidoscopy because the probability of a significant proximal lesion is very low unless there is a strong family history of colorectal cancer at a young age. Individual lesions are treated as appropriate.

**Chronic gastrointestinal bleeding**

Patients with chronic bleeding usually present with iron-deficiency anaemia (see Ch. 8).

Chronic blood loss producing iron deficiency anaemia in all men, and all women after the menopause, is always due to bleeding from the GI tract. The primary concern is to exclude cancer, particularly of the stomach or right colon, and coeliac disease. Occult blood tests are unhelpful (Box 6.4).

**Diagnosis**

Chronic blood loss can occur with any lesion of the GI tract that produces acute bleeding (Figs 6.23 and 6.24). However, oesophageal varices usually bleed obviously and rarely present as chronic blood loss. Although uncommon in developed countries, hookworm is the most common world-wide cause of chronic GI blood loss.

History and examination may indicate the most likely site of the bleeding, but if no clue is available it is usual to investigate both the upper and lower GI tract endoscopically at the same session ("top and tail").

Upper gastrointestinal endoscopy is usually performed first. Duodenal biopsies should always be taken to exclude coeliac disease which is a recognized cause of iron deficiency. Colonoscopy follows and any lesion should be biopsied or removed, though it is not safe to assume that colonic polyps are the cause of chronic blood loss. Unprepared CT scanning is a reasonable test to look for colon cancer in frail patients, and CT colonography can be used on the rare occasions colonoscopy fails to reach the caecum.

If gastroscopy, colonoscopy and duodenal biopsy have not revealed the cause, investigation of the small bowel is probably only justified if the anaemia is transfusion-dependent. The diagnostic yield of small bowel follow-through in this situation is very low. Video capsule endoscopy is the diagnostic investigation of choice if endoscopy fails to reveal the cause, but has no therapeutic ability. Push enteroscopy can examine part of the jejunum and new techniques of balloon-assisted enteroscopy can examine the whole small bowel though the procedure is time consuming. Thermal therapy can also be applied, e.g. to vascular lesions in the small bowel.

If these investigations fail to show the cause, coeliac axis and mesenteric angiography may be performed, although the yield is low. Occasionally, intravenous technetium-labelled colloid may be used to demonstrate a potential bleeding site in a Meckel’s diverticulum.

**Treatment**

The cause of the bleeding should be treated, if found. Oral iron is given to treat anaemia (see p. 396). Some patients will require maintenance with regular transfusion as a last resort.

**THE SMALL INTESTINE**

**Structure**

The small intestine extends from the duodenum to the ileocaecal valve. It is approximately 6 m in length, and 300 m² in surface area. The upper 40% is the duodenum and jejunum, the remainder is the ileum. Its surface area is enormously increased by circumferential mucosal folds that have on them multiple finger-like projections called villi. On the villi the surface area is further increased by microvilli on the luminal side of the epithelial cells (enterocytes) (Fig. 6.25).

Each villus consists of a core containing blood vessels, lacteals (lymphatics) and cells (e.g. plasma cells and lymphocytes). The lamina propria contains plasma cells, lymphocytes, macrophages, eosinophils and mast cells. The crypts of Lieberkühn are the spaces between the bases of the villi.

Enterocytes are formed at the bottom of the crypts and migrate toward the tops of the villi, where they are shed. This

---

**Box 6.4 Measurement of faecal occult blood**

This is frequently performed unnecessarily. It is only of value in:

- Premenopausal women – if a history of menorrhagia is uncertain and the cause of iron deficiency is unclear
- Mass population screening for large bowel malignancy

**Advantages:** cheap and easy to perform

**Disadvantages:** high false-positive rate, leading to unnecessary investigations

**Fig. 6.25 Structure of the small intestine.**
process takes 3–4 days. On its luminal side, the enterocyte is covered by microvilli and a gelatinous layer called the glyccalyx. Intraepithelial lymphocytes lie between the enterocytes. Scattered throughout the gut are peptide-secreting cells. Most of the blood supply to the small intestine is via branches of the superior mesenteric artery. The terminal branches are end arteries – there are no local anastomotic connections.

**Enteric nervous system (ENS)**

This controls the functioning of the small bowel; it is an independent system that coordinates absorption, secretion, blood flow and motility. It is estimated to contain 10⁸ neurons (as many as the spinal cord) contained in two major ganglionated plexuses; the myenteric plexus between the muscular layers of the intestinal wall, and the submucosal plexuses associated with the mucosa. The ENS communicates with the central nervous system via autonomic afferent and efferent pathways but can operate autonomously.

Coordination of small intestinal function involves a complex and poorly understood interplay between many neuroactive mediators and their receptors, ion channels, GI hormones, nitric oxide and other transmitters. For example, 5HT acts via numerous receptors, some of which also have their own subtypes. Tetrodotoxin (TTX) sensitive and TTX resistant sodium channels and acid sensitive ion channels are differentially expressed in different enterocytes. Acetylcholine, adrenaline, ATP, vasoactive intestinal peptide (VIP) and other hormones and opioids have been shown to have actions in the small bowel, but the exact role for each is far from being understood.

**Gut motility**

The contractile patterns of the small intestinal muscular layers are primarily determined by the enteric nervous system. The CNS and gut hormones also have a modulatory role on motility. The interstitial cells of Cajal which lie within the smooth muscle appear to govern rhythmic contractions.

**During fasting**, a distally migrating sequence of motor events termed the migrating motor complex (MMC) occurs in a cyclical fashion. The MMC consists of a period of motor quiescence (phase I) followed by a period of irregular contractile activity (phase II), culminating in a short (5–10 min) burst of regular phasic contractions (phase III). Each MMC cycle lasts for approximately 90 minutes. In the duodenum, phase III is associated with increased gastric, pancreatic and biliary secretions. The role of the MMC is unclear, but the strong phase III contractions propel secretions, residual food and desquamated cells toward the colon. It is named the ‘intestinal housekeeper’.

**After a meal**, the MMC pattern is disrupted and replaced by irregular contractions. This seemingly chaotic pattern lasts typically for 2–5 hours after feeding, depending on the size and nutrient content of the meal. The irregular contractions of the fed pattern have a mixing function, moving intraluminal contents to and fro, aiding the digestive process.

**Neuroendocrine peptide production**

The hormone-producing cells of the gut are scattered diffusely throughout its length and also occur in the pancreas. The cells that synthesize hormones are derived from neural ectoderm and are known as APUD (amine precursor uptake and decarboxylation) cells. Many of these hormones have very similar structures. Although they can be detected by radioimmunoassay in the circulation, their action is often local.

Gut hormones play a part in the regulation and integration of the functions of the small bowel and other metabolic activities. Their actions are complex and interacting, both with each other and with the ENS (Table 6.8).

**Physiology**

In the small bowel digestion and absorption of nutrients and ions takes place, as does the regulation of fluid absorption and secretion. The epithelial cells of the small bowel form a physical barrier that is selectively permeable to ions, small molecules and macromolecules. Digestive enzymes such as proteases and disaccharidases are produced by intestinal cells and expressed on the surface of microvilli; others such as lipases produced by the pancreas are associated with the glycocalyx. Some nutrients are absorbed most actively in specific parts of the small intestine; iron and folate in the duodenum and jejenum, vitamin B₁₂ and bile salts in the terminal ileum where they have specific receptors.

**General principles of absorption**

**Simple diffusion**

This process is non-specific, requires no carrier molecule or energy and takes place if there is a concentration gradient from the intestinal lumen (high concentration) to the bloodstream (low concentration). Vitamin B₁₂ can be absorbed from the jejunum by this means.

**Facilitated diffusion**

Absorption takes place down a concentration gradient, but a membrane carrier protein is involved, conferring specificity on the process. Fructose is an example.

**Active transport**

Absorption occurs via a specific ‘carrier’ protein, powered by cellular energy, and thus a substance can be transported against a concentration gradient. Many carrier proteins are powered by ion gradients across the enterocyte wall. For example, glucose crosses the enterocyte microvillus membrane from the lumen into the cell against a concentration gradient by using a co-transporter carrier molecule. This is the sodium/glucose co-transporter, SGLT1 (Fig. 6.26). The process is powered by the energy derived from the flow of Na⁺ ions from a high concentration outside the cell to a low concentration inside. The sodium gradient across the cell wall is maintained by a separate ATP-consuming Na⁺/K⁺ exchanger in the basolateral membrane. Glucose leaves the cell on the serosal side by facilitated diffusion via a sodium-independent carrier (GLUT-2) in the basolateral membrane.

Another active transport mechanism operates for Na⁺ absorption in the ileum using an Na⁺/H⁺ exchange mechanism powered by the outwardly directed gradient of H⁺ across the cell membrane.

**Absorption of nutrients in the small intestine**

**Carbohydrate**

Dietary carbohydrate consists mainly of starch, some sucrose and a small amount of lactose. Starch is a polysaccharide made up of numerous glucose units. Its hydrolysis begins in the mouth by salivary amylase, though the majority
Enhances microvillous monosaccharides of intestinal absorption. As lactose, the monosaccharides are transported across the intestine by maltose and maltotriose, together with sucrose and lactose, are hydrolysed on the microvillus membrane by their appropriate oligo- and disaccharidases to form the monosaccharides glucose, galactose and fructose. These monosaccharides are transported across the enterocytes into the blood (Fig. 6.26).

**Protein**

Dietary protein is digested by pancreatic proteolytic enzymes to amino acids and peptides prior to absorption. These...
enzymes are secreted by the pancreas as pro-enzymes and transformed to active forms in the lumen by an enzymatic cascade initiated by enterokinase (EK). Protein in the duodenal lumen stimulates the release of EK from duodenal cells. EK activates trypsinogen to trypsin, and this in turn activates the other pro-enzymes, chymotrypsin and elastase.

These enzymes break down protein into oligopeptides. Some di- and tri-peptides are absorbed intact by carrier-mediated processes, while the remainder are broken down into free amino acids by peptidases on the microvillus membranes of the enterocytes, prior to absorption into the cell by a variety of amino acid and peptide carrier systems.

**Fat** (Fig. 6.27)

Dietary fat consists mainly of triglycerides with some cholesterol and fat-soluble vitamins. Fat is emulsified by mechanical action in the stomach. Bile containing the amphipathic detergents bile acids and phospholipids enters the duodenum following gall bladder contraction. They act to solubilize fat and promote hydrolysis of triglycerides in the duodenum by pancreatic lipase to yield fatty acids and monoglycerides. Bile acids, phospholipids and the products of fat digestion cluster together with their hydrophilic ends on the outside to form aggregations called mixed micelles. Trapped in the centre of the micelles are the hydrophobic monoglycerides, fatty acids and cholesterol. At the cell membrane the lipid contents of the micelles are absorbed, while the bile salts remain in the lumen. Inside the cell the monoglycerides and fatty acids are re-esterified to triglycerides. The triglycerides

**Fig. 6.26** Solute (glucose, galactose, fructose) transport across the apical membrane (glucose and galactose are transported via the sodium/glucose cotransporter – SGLT1). Fructose is transported by the facilitative transporter GLUT-5 across the apical and basolateral membranes. Water absorption is mainly cellular but paracellular absorption also occurs. The tight junction is a network of strands and is a dynamic structure. The sodium/potassium-ATPase pump is located in the basolateral membrane.

**Fig. 6.27** (a) The pathophysiology of fat absorption. (b) Diagram showing the formation of mixed micelles.
and other fat soluble molecules (e.g. cholesterol, phospholipids) are then incorporated into chylomicrons to be transported into the lymph.

By contrast, another mechanism exists for medium-chain triglycerides (MCT; fatty acids of chain length 6–12) which are transported via the portal vein with a small amount of long-chain fatty acid. Patients with pancreatic exocrine or bile salt insufficiency can therefore supplement their fat absorption with MCT.

Bile salts are not absorbed in the jejunum, so that the intraluminal concentration in the upper gut is high. They pass down the intestine to be absorbed in the terminal ileum and are transported back to the liver. This enterohepatic circulation prevents excess loss of bile salts (see p. 323).

The pathophysiology of fat absorption is shown in Figure 6.27. Interference with absorption can occur at all stages, as indicated, giving rise to steatorrhoea (>17 mmol or 6 g of faecal fat per day).

**Water and electrolytes**

Large amounts of water and electrolytes, partly dietary, but mainly from intestinal secretions, are absorbed coupled with absorption of monosaccharides, amino acids and bicarbonate in the upper jejunum. Water and electrolytes are also absorbed paracellularly (between the enterocytes) down electrochemical and osmotic gradients. Additional water and electrolytes are absorbed in the ileum and colon, where active sodium transport is not coupled to solute absorption. Secretion of fluid and electrolytes occur together to maintain the normal functioning of the gut. Secretory diarrhoea (see p. 306) can occur because of defects in intestinal secretory mechanisms.

**Water-soluble vitamins, essential metals and trace elements**

These are all absorbed in the small intestine. Vitamin B12 (see p. 399) and bile salts are absorbed by specific transport mechanisms in the terminal ileum; malabsorption of both these substances often occurs following ileal resection.

**Calcium absorption**

Calcium absorption is discussed on page 558.

**Iron absorption**

Iron absorption is discussed on page 393.

**Response of the small bowel to antigens and pathogens**

The small bowel has a number of mechanisms to prevent colonization and invasion by pathogens while simultaneously preventing inappropriate responses to foreign antigens or the indigenous bacterial population. At the same time commensal bacteria maintain the integrity of the small bowel and play a major role in host physiology.

**Mechanisms**

**Physical defence**

- The mucus layer
- Continuous shedding of surface epithelial cells
- The physical movement of the luminal contents
- Colonization resistance – the ability of the indigenous microbiota to outcompete pathogens for a survival niche in the gut.

**Innate chemical defence**

- Enzymes such as lysozyme and phospholipase A2 secreted by Paneth cells at the base of the crypts help ensure an infection-free environment in the gut, even in the presence of commensal bacteria.
- Antimicrobial peptides are secreted from enterocytes and Paneth cells in response to pathogenic bacteria. These include defensins, which are 15–20 amino acid peptides with potent activity against a broad range of pathogens including Gram-positive and Gram-negative bacteria, fungi and viruses. Other peptides that contribute to the defence against organisms include the antibacterial cathelicidin, BPI (Bactericidal Permeability-
inducing protein), antimicrobial lectins, and β-Resistin-like molecule (RELMB) which appears to have anthelmintic effects.

- **Trefoil peptides** are a family of small proteins secreted by goblet cells. They consist of a three-loop structure with intra-chain disulphide bonds which makes the molecules highly resistant to digestion. Their actions include stabilization of mucus, promotion of cell migration over injured areas, and promotion of repair. Three trefoil factors (TFF) are found in humans (TFF1, TFF2 and TFF3) all of which have been implicated in the response to gastrointestinal injury in experimental models. Their molecular mode of action is not yet known.

**Innate immunological defence**

- **Humoral. IgA** is the principal mucosal antibody. IgA mediates mucosal immunity by agglutinating and neutralizing pathogens in the lumen and preventing colonization of the epithelial surface (Fig. 6.28). Seventy to ninety per cent of the 10^15 IgA-producing cells per metre of human small bowel are IgA plasma cells. IgA is secreted from immunocytes in the lamina propria as dimers joined by a protein called the ‘Joining chain’ (J-chain); in this form it is known as polymeric IgA (plgA). This plgA is internalized by endocytosis at the basolateral membrane of enterocytes expressing the polymeric IgA Receptor (plgAR), which is the receptor for J-chain. It crosses the cell as a complex of plgA/plgAR and is secreted onto the mucosal surface of the enterocyte as a complex of plgA with a fragment of plgAR (secretory component, SC). This molecule is known as secretory IgA (sIgA).

- **B cell sensitization.** Antigens from the lumen of the bowel are transported by M (microfold) and dendritic cells in the specialized (follicle associated epithelium (FAE)). This covers Peyer’s patches in the ‘dome’ region which contain abundant virgin B cells, helper T cells and antigen-presenting cells. Activated B cells then produce IgA locally and are programmed to home back to the lamina propria. They travel through mesenteric lymph nodes and then via the thoracic duct to the blood and back to the small bowel and other mucosal surfaces (such as the airways) where they undergo terminal differentiation into plasma cells. Homing back to the gut is facilitated by the αβ7-integrin on gut-derived lymphocytes binding to MAdCAM-1, uniquely expressed on blood vessels in the gut.

**Cellular defence** Host defence is also provided by T lymphocytes that initiate, activate and regulate adaptive immune responses. Intestinal T lymphocytes occur principally in three major compartments:

1. Organized gut-associated lymphoid tissue (GALT) such as Peyer’s patches where mucosal T cell responses are generated, and after which cells leave the organized lymphoid tissue and home back to the mucosa.
2. The lamina propria, containing mostly CD4 cells.
3. The surface epithelium where these lymphocytes are known as intraepithelial lymphocytes (IELs) and are mostly CD8 cells.

T cells are sensitized to antigen in the Peyer’s patch lymphoid tissue in a similar fashion to B cells, pass through mesenteric lymph nodes into the thoracic duct and into the circulation, homing back to the small bowel to end up in the lamina propria or the epithelium. It is probable that IELs are cytotoxic cells, capable of killing virally or bacterially infected epithelial cells. CD4 cells in the lamina propria of healthy individuals are highly activated cells, probably protecting against low-grade infections, since loss of these cells, as in HIV infection, leads to colonization of the gut by protozoa such as cryptosporidia.

**Commensal bacteria**

The relationship between the hundred thousand billion microbes in the human gut and the host are only beginning to be appreciated. Germ-free mice have essentially no mucosal immune system showing that the abundant and activated immune system seen in healthy individuals is driven by the flora, without adverse effects. Bacteria also release chemical signals such as LPS and lipoteichoic acid that are recognized by Toll-like receptors (TLRs) (see p. 59) present on a variety of intestinal cells, priming repair processes and enhancing the ability of the epithelium to respond to injury. Thus, genetically engineered animals with absent TLR signalling pathways develop exaggerated responses to intestinal injury.

**Oral tolerance**

The immune system must guard against pathogens and toxins while avoiding an excessive response to the multiplicity of food antigens and commensal bacteria. The mechanisms by which tolerance occurs are undoubtedly multiple, including maintaining barrier function to prevent excess antigen uptake, active inhibition via regulatory T cells, and dendritic cells which promote tolerogenic rather than immunogenic T cell responses. All of these are likely to play a role in diseases such as coeliac disease, caused by an excessive T cell response to gluten, or Crohn’s disease, where tolerance to the indigenous bacterial population is defective.

**Presenting features of small bowel disease**

Regardless of the cause, the common presenting features of small bowel disease are:

- **Diarrhoea.** Although a common feature of small bowel disease, 10–20% of patients will have no diarrhoea or any other gastrointestinal symptoms. *Steatorrhoea* occurs when the stool fat is > 17 mmol/day (or 6 g/day). The stools are pale, bulky, offensive, float (because of their increased air content), leave a fatty film on the water in the pan and are difficult to flush away.

- **Abdominal pain** and discomfort. Abdominal distension can cause discomfort and flatulence. The pain has no specific character or periodicity and is not usually severe.

- **Weight loss.** Weight loss is largely due to the anorexia that invariably accompanies small bowel disease. The calorie deficit due to malabsorption is small relative to the reduction in intake.

- **Nutritional deficiencies.** Deficiencies of iron, B12, folate or all of these, leading to anaemia, are the only common deficiencies. Occasionally malabsorption of other vitamins or minerals occurs, causing bruising (vitamin K deficiency), tetany (calcium deficiency), osteomalacia (vitamin D deficiency), or stomatitis, sore tongue and
aphthous ulceration (multiple vitamin deficiencies). Ankle oedema due to hypoproteinaemia is due to low intake and intestinal loss of albumin (protein-losing enteropathy).

*Physical signs* are few and non-specific. If present, they are usually associated with anaemia and the nutritional deficiencies described above.

Abdominal examination is often normal, but sometimes distension and, rarely, hepatomegaly or an abdominal mass are found. Gross weight loss, oedema and muscle wasting is seen only in severe cases. A neuropathy, not always due to B₁₂ deficiency, can be present.

**Investigation of small bowel disease** (Fig. 6.29)
The emphasis in the investigation of malabsorption is on the structural features of the underlying disorder, rather than on the documentation of malabsorption itself.

**Blood tests**
- **Full blood count and film.** Anaemia can be microcytic, macrocytic or normocytic and the blood film may be dimorphic. Other abnormal cells (e.g. Howell-Jolly bodies, p. 423) may be seen in splenic atrophy associated with coeliac disease.
- *If the MCV is low,* serum ferritin and the serum soluble transferrin receptor should be measured to differentiate iron deficiency from anaemia of chronic disorder (see p. 397).
- *If the MCV is high,* serum B₁₂, and serum and red cell folate should be measured.
- However, with mixed deficiencies, the MCV may be normal. The red cell folate is a good indicator of the presence of small bowel disease. It is frequently low in both coeliac disease and Crohn’s disease, which are the two most common causes of small bowel disease in developed countries.
- **Serum albumin** gives some indication of the nutritional status and the presence of intestinal protein loss. Always check urine protein loss to ensure that albumin is not being lost from the kidneys.
- **Low serum calcium** and raised alkaline phosphatase may indicate the presence of osteomalacia due to vitamin D deficiency.
- **Immunological tests.** Measurement of serum antibodies to endomysium and tissue transglutaminase are useful for the diagnosis of coeliac disease.
- **HLA testing** is useful in coeliac disease.

**Small bowel anatomy**
- **Small bowel follow-through** (see p. 245). This detects gross anatomical defects such as diverticula, strictures and Crohn’s disease. Dilatation of the bowel and a changed fold pattern may suggest malabsorption but these are non-specific findings. Gross dilatation is seen in myopathic pseudo-obstruction.

*Fig. 6.29* Flow diagram for investigation of patients with suspected small bowel disease. EMA, endomysial antibody; tTG, tissue transglutaminase.
Small bowel biopsy. This is used to assess the microanatomy of the small bowel mucosa. Biopsies are usually obtained via an endoscope passed into the duodenum and should be well-orientated for correct evaluation. The histological appearances are described in the sections on individual diseases. A smear of the jejunal juice or a mucosal impression should also be made when *Giardia intestinalis* is suspected.

CT scanning is used to look for small bowel wall thickening, diverticula and for extraintestinal features such as abscesses (e.g. in Crohn’s disease).

MRI enteroclysis, which does not involve radiation, is also used to assess and monitor changes in small bowel anatomy.

**Tests of absorption**

These are required only in complicated cases.

**Fat malabsorption.** The confirmation of the presence of steatorrhoea is only occasionally necessary. Three-day faecal fat analysis, triglyceride breath tests and serum β-carotene are now rarely performed. In rare cases when it is essential to confirm steatorrhoea, Sudan III staining of a faecal sample can be used.

**Lactose tolerance test.** Testing is of little use in adults because lactose intolerance is rarely a clinical problem; patients who are upset by milk usually avoid it. Formal testing involves giving an oral dose of 50 g of lactose and serial measurement of blood glucose over 2 hours (N.B. 500 mL of milk contain 20 g of lactose). There is a high incidence of lactase deficiency in many parts of the world (e.g. the Mediterranean countries, and parts of Africa and Asia).

**Other tests**

**Hydrogen breath test.** This is frequently used as a screening test to measure transit time and to detect small bowel bacterial overgrowth. Bacteria are present in the oral cavity so the mouth should be rinsed out with an antiseptic mouthwash beforehand. The appearance of a breath hydrogen peak after oral lactulose is used to estimate mouth to caecum transit time. An earlier rise in the breath hydrogen after lactulose indicates bacterial breakdown in the small intestine. This test is simple to perform and it does not involve radioisotopes. However, interpretation is often difficult with a low sensitivity and specificity.

**14C-glycocolic acid breath test.** Some bacteria can deconjugate an orally administered 14C labelled bile salt, releasing 14C-glycine, which is metabolized and appears in the breath as 14CO2. This test has largely been replaced by the hydrogen breath test.

**Direct intubation.** Aspiration of intestinal juices can detect bacterial contamination, but it is seldom used. Bacterial counts are performed on aerobic and anaerobic cultures. Chromatography of bile salts can be performed on the aspirate to detect evidence of deconjugation.

**Tests for pancreatic insufficiency** are used in the differential diagnosis of steatorrhoea.

**Other blood tests.** Serum immunoglobulins are measured to exclude immune deficiencies. Gut peptides (e.g. VIP) are measured in high-volume secretory diarrhoea, and chromogranins A and B are raised in endocrine tumours.

**Tests for protein-losing enteropathy (PLE)** (see p. 282). These tests are rarely required unless a low serum albumin is a major clinical feature.

**Measurement of α1-antitrypsin clearance** does not require an isotope (see p. 376). α1-antitrypsin is a large molecule (>50000 daltons), which is resistant to proteolysis. Simultaneous measurements of serum and stool concentration (24-hour collection) are made.

**Bile salt loss.** This can be demonstrated by giving oral 75Se-homocholyl taurine (SeHCAT – a synthetic taurine conjugate) and measuring the retention of the bile acid by whole-body counting at 7 days.

---

**MALABSORPTION**

In many small bowel diseases, malabsorption of specific substances occurs, but these deficiencies do not usually dominate the clinical picture. An example is Crohn’s disease, in which malabsorption of vitamin B12 can be demonstrated, but this is not usually the major problem; diarrhoea and general ill-health are the major features.

The major disorders of the small intestine that cause malabsorption are shown in Table 6.9.

**Coeliac disease (gluten-sensitive enteropathy)**

Coeliac disease (CD) is a condition in which there is inflammation of the mucosa of the upper small bowel that improves when gluten is withdrawn from the diet and relapses when gluten is reintroduced. Up to 1% of many populations are affected, though most have clinically silent disease.

**Aetiology**

Gluten is the entire protein content of the cereals wheat, barley and rye. Prolamins (gliadin from wheat, hordeins from barley, secalins from rye) are damaging factors. These proteins are resistant to digestion by pepsin and chymotrypsin because of their high glutamine and proline content and remain in the intestinal lumen triggering immune responses.

**Immunology.** Gliadin peptides pass through the epithelium and are deaminated by tissue transglutaminase which increases their immunogenicity. Gliadin peptides then bind to antigen-presenting cells which interact with CD4+ T cells in the lamina propria via HLA class II molecules DQ2 or DQ8. These T cells produce pro-inflammatory cytokines, particularly interferon γ. CD4+ T cells also interact with B cells to produce endomysial and tissue transglutaminase antibodies. Gliadin peptides also cause release of interleukin 15 from enterocytes, activating intraepithelial lymphocytes with a natural killer cell marker. This inflammatory cascade releases metalloproteinases and other mediators that contribute to

the villous atrophy and crypt hyperplasia which are typical of the disease.

The mucosa of the proximal small bowel is predominantly affected, the mucosal damage decreasing in severity towards the ileum as gluten is digested into smaller ‘non-toxic’ fragments.

**Inheritance.** There is an increased incidence of CD within families but the exact mode of inheritance is unknown; 10–15% of first-degree relatives will have the condition, although it may be asymptomatic. The concordance rate in identical twins is about 70%.

HLA-DQ2 (DQA1*0501, DQB1*0201) and HLA-DQ8 (DQA1*0301, DQB1*0302) are associated with CD. Over 90% of patients will have HLA-DQ2, compared with 20–30% of the general population. Studies in twins and siblings indicate that HLA genes are responsible for less than 50% of the genetic cause of the disease. Many unaffected people also carry these genes, so other factors must also be involved.

Non-HLA genes may also contribute to coeliac disease, e.g. chromosome regions 19p13.1, 11q, 5q31-33 and 6q21-22. The CD28/CTLA4/IL5 gene cluster has also shown linkage with coeliac disease.

**Environmental factors.** Breast-feeding and the age of introduction of gluten into the diet was thought to be significant but this remains controversial.

Rotavirus infection in infancy also increases the risk, and adenovirus-12 which has sequence homology with α-gliadin has been suspected as a causative agent.

**Clinical features**

Coeliac disease can present at any age. In infancy it sometimes appears after weaning onto gluten-containing foods. The peak period for diagnosis in adults is in the fifth decade, with a female preponderance. Many patients are asymptomatic (silent) and come to attention because of routine blood tests, e.g. a raised MCV, or iron deficiency in pregnancy. The symptoms are very variable and often non-specific, e.g. tiredness and malaise often associated with anaemia.

GI symptoms may be absent. Diarrhoea or steatorrhoea, abdominal discomfort, bloating or pain and weight loss suggest more severe disease. Mouth ulcers and angular stomatitis are frequent and can be intermittent. Infertility and neuropsychiatric symptoms of anxiety and depression occur.

Rare complications include tetany, osteomalacia, or gross malnutrition with peripheral oedema. Neurological symptoms such as paraesthesia, ataxia (due to cerebellar calcification), muscle weakness or a polyneuropathy occur; the prognosis for these symptoms is variable. There is an increased incidence of atopy and autoimmune disease, including thyroid disease, type 1 diabetes and Sjögren’s syndrome. Other associated diseases include inflammatory bowel disease, primary biliary cirrhosis, chronic liver disease, interstitial lung disease and epilepsy. IgA deficiency is more common than in the general population. Long-term problems include osteoporosis which occurs even in patients on long-term gluten-free diets.

**Physical signs** are usually few and non-specific and are related to anaemia and malnutrition.

**Diagnosis**

Small bowel biopsy is the standard for diagnosis, and is essential because treatment involves a life-long diet that is both expensive and socially limiting. Because the disease is sometimes patchy and it can be difficult to orientate endoscopic biopsies for histological section, four to six forceps biopsies should be taken from the second part of the duodenum. Endoscopic signs including absence of mucosal folds, mosaic pattern of the surface and scalloping of mucosal folds are often present; however, their absence is not conclusive because they are markers of relatively severe disease. Biopsies should always be taken if CD is a possibility.

**Histology** (Fig. 6.30). Histological changes are of variable severity and, though characteristic, are not specific. Villous atrophy can be caused by many other conditions, but CD is the commonest cause of subtotal villous atrophy. The villous architecture is almost normal in mild cases, but there are abnormal numbers of intraepithelial lymphocytes. In severe cases there is an absence of villi, with flattening of the mucosal surface.

Histological examination shows crypt hyperplasia with chronic inflammatory cells in the lamina propria, and villous atrophy. The enterocytes become cuboidal with an increase in the number of intraepithelial lymphocytes. In the lamina propria there is an increase in lymphocytes and plasma cells. The most severe histological change with mucosal atrophy and hypoplasia is seen in patients who do not respond to a gluten-free diet.

**Serology.** Persistent diarrhoea, folate or iron deficiency, a family history of CD and associated autoimmune disease are indications for serological testing.

The most sensitive tests are for endomysial and antitissue transglutaminase antibodies. The sensitivity of these tests is >90% though both are not always positive in the same subject. Titres of either correlate with the severity of mucosal damage so they can be used for dietary monitoring. Standard tests use IgA class antibodies. Selective IgA deficiency occurs in 2.5% of CD patients but only 0.25% of normals and renders these tests falsely negative. IgG-based tests should then be used.

**HLA typing.** HLA-DQ2 is present in 90–95% of CD patients and HLA-DQ8 in about 8%, i.e. most of the rest. The absence of both alleles has a high negative predictive value for coeliac disease. HLA typing is useful for ruling out the disease, for example in patients already on a gluten free diet.

**Other investigations**

**Haematology.** Mild or moderate anaemia is present in 50% of cases. Folate deficiency is common, often causing macrocytosis. B12 deficiency is rare. Iron deficiency due to malabsorption of iron and increased loss of desquamated cells is common. A blood film may therefore show microcytes and macrocytes as well as hypersegmented polymorphonuclear leucocytes and Howell–Jolly bodies (see p. 423) due to splenic atrophy.

**Biochemistry.** In severe cases, biochemical evidence of osteomalacia may be seen (low calcium and high phosphate) and hypoalbuminaemia.

**Radiology.** A small bowel follow-through may show dilatation of the small bowel with slow transit. Folds become thicker and in severe disease total effacement is seen. Radiology is now mainly used when a complication, e.g. lymphoma, is suspected.

**Bone densitometry (DXA) should be performed on all patients because of the risk of osteoporosis.**
Wireless capsule endoscopy (see p. 246) is used to look for gut abnormalities when a complication is suspected.

Absorption tests are often abnormal (see p. 277) but are seldom performed because they are not crucial to the diagnosis.

Treatment and management

Replacement minerals and vitamins, e.g., iron, folic acid, calcium, vitamin D, may be needed initially to replace body stores.

Treatment is with a gluten-free diet for life. Dietary elimination of wheat, barley, and rye usually produces a clinical improvement within days or weeks. Morphological improvement often takes months, especially in adults. Oats are tolerated by most coeliacs, but must not be contaminated with flour during their production. Meat, dairy products, fruits, and vegetables are naturally gluten-free and are all safe.

Gluten-free products can be expensive, unless subsidised by national health services. Patient support organizations such as The Coeliac Society are valuable as information sources and for advice about diet, recipes, and gluten-free processed foods. Despite advice, many patients do not keep to a strict diet but maintain good health. The long-term effects of this low gluten intake are uncertain but osteoporosis can occur even in treated cases.

The usual cause for failure to respond to the diet is poor compliance. Dietary adherence can be monitored by serial tests for endomysial antibody (EMA) and tissue transglutaminase (tTG). If clinical progress is suboptimal then a repeat intestinal biopsy should be taken. If the diagnosis is equivocal a gluten challenge, i.e., reintroduction of gluten with evidence of jejunal morphological change, confirms the diagnosis.

Patients should have pneumococcal vaccinations (because of splenic atrophy) once every 5 years (see p. 423).

Complications

A few patients do not improve on a strict diet and are said to have unresponsive coeliac disease. Often no cause is found, but enteropathy-associated T cell lymphoma (EATCL), ulcerative jejunitis or carcinoma are sometimes responsible. The incidence of EATCL (see p. 264) and small bowel adenocarcinoma is increased in coeliac disease.

Ulcerative jejunitis presents with fever, abdominal pain, perforation and bleeding. Diagnosis for these conditions is with barium studies but laparotomy with full-thickness biopsies is often required. Steroids and immunosuppressive agents, e.g., azathioprine, are used.

Carcinoma of the oesophagus as well as extra-gastrointestinal cancers are also increased in incidence. Malignancy seems to be unrelated to the duration of the disease but the incidence is reduced by a gluten-free diet.

Dermatitis herpetiformis (see also p. 1256)

This is an uncommon blistering subepidermal eruption of the skin associated with a gluten-sensitive enteropathy. Rarely
there may be gross malabsorption, but usually the jejunal morphological abnormalities are not as severe as in coeliac disease. The inheritance and immunological abnormalities are the same as for coeliac disease. The skin condition responds to dapsona but a gluten-free diet improves both the enteropathy and the skin lesion.

**Tropical sprue**

This is a condition presenting with chronic diarrhoea and malabsorption that occurs in residents or visitors to affected tropical areas. The disease is endemic in most of Asia, some Caribbean islands, Puerto Rico and parts of South America. Epidemics occur, lasting up to 2 years, and in some areas repeated epidemics occur at varying intervals of up to 10 years.

The term tropical sprue is reserved for severe malabsorption (of two or more substances) accompanied by diarrhoea and malnutrition. Malabsorption of a mild degree, sometimes following an enteric infection, is quite common in the tropics; it is usually asymptomatic and is sometimes called tropical malabsorption.

**Aetiology**

The aetiology is unknown, but is likely to be infective because the disease occurs in epidemics and patients improve on antibiotics. A number of agents have been suggested but none has been unequivocally shown to be responsible. Different agents could be involved in different parts of the world.

**Clinical features**

These vary in intensity and consist of diarrhoea, anorexia, abdominal distension and weight loss. The onset is sometimes acute and occurs either a few days or many years after being in the tropics. Epidemics can break out in villages, affecting thousands of people at the same time. The onset can also be insidious, with chronic diarrhoea and evidence of nutritional deficiency. The clinical features of tropical sprue vary in different parts of the world, particularly as different criteria are used for diagnosis.

**Diagnosis**

Acute infective causes of diarrhoea must be excluded (see p. 307), particularly *Giardia*, which can produce a syndrome very similar to tropical sprue. Malabsorption should be demonstrated, particularly of fat and B₁₂. The jejunal mucosa is abnormal, showing some villous atrophy (partial villous atrophy). In most cases the lesion is less severe than that found in coeliac disease, although it affects the whole small bowel. Mild mucosal changes can be seen in asymptomatic individuals in the tropics.

**Treatment and prognosis**

Many patients improve when they leave the sprue area and take folic acid (5 mg daily). Most patients also require an antibiotic to ensure a complete recovery (usually tetracycline 1 g daily for up to 6 months).

Severely ill patients require resuscitation with fluids and electrolytes for dehydration, and nutritional deficiencies should be corrected. Vitamin B₁₂ (1000 µg) is also given to all acute cases.

The prognosis is excellent. Mortality is usually associated with water and electrolyte depletion, particularly in epidemics.

**Bacterial overgrowth**

The gut contains many resident bacteria in the terminal ileum and colon. Anaerobic bacteria, e.g. *Bacteroides*, bifidobacteria, are 100–1000 times more abundant than aerobic (facultative anaerobes), e.g. *Escherichia*, *Enterobacter*, *Enterococcus*. This gut microflora has major functions including metabolic, e.g. fermentation of non-digestible dietary residues into short chain fatty acids as an energy source in the colon.

The microflora which influences epithelial cell proliferation, is involved in the development and maintenance of the immune system and protects the gut mucosa from colonization by pathogenic bacteria. Bacteria also initiate vitamin K production.

The upper part of the small intestine is almost sterile, containing only a few organisms derived from the mouth. Gastric acid kills some ingested organisms and intestinal motility keeps bacterial counts in the jejunum low. The normal terminal ileum contains faecal-type organisms, mainly *Escherichia coli* and anaerobes, and the colon has abundant bacteria.

**Bacterial overgrowth is normally found associated with a structural abnormality of the small intestine such as a stricture or diverticulum, although it can occur occasionally in the elderly without.** *E. coli* and/or *Bacteroides*, both in concentrations greater than 10⁸/mL, are found as part of a mixed flora. These bacteria are capable of deconjugating and dehydroxylation bile salts, so that unconjugated and dehydroxylated bile salts can be detected in small bowel aspirates.

The clinical features of overgrowth are chiefly diarrhoea and steatorrhoea. There may also be symptoms due to the underlying small bowel pathology. Steatorrhoea (see p. 275) occurs because of conjugated bile salt deficiency. Some bacteria can metabolize vitamin B₁₂ and interfere with its binding to intrinsic factor, leading to mild B₁₂ deficiency (see p. 399) rarely severe enough to produce a neurological deficit. Some bacteria produce folic acid giving a high serum folate. Bacterial overgrowth has only minimal effects on the absorption of other substances. Confirmation of bacterial overgrowth is with the hydrogen breath test (see p. 277); aspiration studies are not routinely performed.

**Treatment**

If possible, the underlying lesion should be corrected (e.g. a stricture should be resected). Where this is not possible, rotating courses of antibiotics are necessary, such as metronidazole, a tetracycline or ciprofloxacin. The response to antibiotics is unpredictable.

**Intestinal resection**

Small intestinal resection is usually well tolerated, but massive resection leaving less than 1 m of small bowel in continuity is followed by the short-bowel syndrome. The effects of resection depend on the amount and location of the resection and the presence or absence of the colon. Resection of the jejunum is better tolerated than ileal resection, where there is less adaptation, probably due to low levels of glucagon-like peptide 2 (GLP-2), which is a specific growth hormone for the enterocyte.

**Ileal resection**

The ileum is the site of specific mechanisms for the absorption of bile salts and vitamin B₁₂. Relatively small resections
lead to malabsorption of these substances. Removal of the ileocaecal valve increases the incidence of diarrhoea (Fig. 6.31).

The following occur after ileal resection:

- **Bile-salt induced diarrhoea:** bile salts and fatty acids enter the colon and cause malabsorption of water and electrolytes (see p. 307).
- **Steatorrhoea and gallstone formation:** increased bile salt synthesis can compensate for loss of approximately one-third of the bile salts in the faeces. Greater loss than this results in decreased micelle formation and steatorrhoea, and lithogenic bile and gallstone formation.
- **Oxaluria and oxalate stones:** bile salts in the colon cause increased oxalate absorption with oxaluria leading to urinary stone formation.
- **B<sub>12</sub> deficiency:** low serum B<sub>12</sub>, macrocytosis and other effects of B<sub>12</sub> deficiency.

Investigations include a small bowel follow-through, measurement of B<sub>12</sub>, bile salt retention (SeHCAT test) and occasionally fat absorption (see p. 277). A hydrogen breath test may show rapid transit (see p. 277). Many patients require B<sub>12</sub> replacement and some need a low-fat diet if there is steatorrhoea. Diarrhoea is often improved by colestyramine which binds bile salts and reduces the level of diarrhoeogenic bile salts in the colon.

**Jejunal resection**

The ileum can compensate for loss of jejunal absorptive function. Jejunal resection may lead to gastric hypersecretion with high gastric levels; the exact mechanism of this is unclear. Structural and functional intestinal adaptation take place over the course of a year, with an increase in the absorption per unit length of bowel.

**Massive intestinal resection**

**(short-bowel syndrome)**

This most often occurs following resection for Crohn’s disease, mesenteric vessel occlusion (see p. 283), radiation enteritis (see p. 282) or trauma. There are two common situations:

**Shortened small intestine ending at a terminal small bowel stoma**

The major problem is of sodium and fluid depletion and the majority of patients with 100 cm or less of jejunum remaining will require parenteral supplements of fluid and electrolytes, often with nutrients. Sodium losses can be minimized by increasing salt intake, restricting clear fluids between meals and administering oral glucose-electrolyte mixture with a sodium concentration 90 mmol/L. Jejunal transit time can be increased and stomal effluent loss of fluids and electrolytes reduced by treatment with the somatostatin analogue octreotide, and to a much lesser extent, with loperamide, codeine phosphate or co-phenotrope. There is no benefit from a low-fat diet, but fat assimilation can be increased on treatment with colestyramine and synthetic bile acids.

**Shortened small intestine in continuity with colon**

Only a small proportion of these patients require parenteral supplementation of fluid, electrolytes and nutrients because of the absorptive capacity of the colon for fluid and electrolytes. Unabsorbed fat results in impairment of colonic fluid and electrolyte absorption so patients should be on a low-fat diet. A high carbohydrate intake is advised as unabsorbed carbohydrate is metabolized anaerobically to short-chain fatty acids (SCFAs) which are absorbed; they also stimulate fluid and electrolyte absorption in the colon and act as an energy source (1.6 kcal/g). Patients are often treated with colestyramine to reduce diarrhoea and colonic oxalate absorption.

**Whipple’s disease**

Whipple’s disease is a rare infectious bacterial disease caused by *Tropheryma whippelii*. About 1000 cases have been described; 87% are males, usually white and middle-aged. It usually presents with arthritis and arthralgia, progressing over years to weight loss and diarrhoea with abdominal pain, systemic symptoms of fever and weight loss. Peripheral lymphadenopathy and involvement of the heart, lung, joints and brain may occur, simulating many neurological conditions. 15% of patients have atypical symptoms.

Blood tests may show features of chronic inflammation and malabsorption. Endoscopy typically shows pale, shaggy duodenal mucosa with eroded, red, friable patches.

**Diagnosis** is made by small bowel biopsy. Periodic acid–Schiff (PAS)-positive macrophages are present but are non-specific. On electron microscopy, the characteristic trilaminar cell wall of *T. whippelii* can be seen within macrophages. *T. whippelii* antibodies can be identified by immunohistochemistry. A confirmatory PCR-based assay is available.

**Treatment** is with antibiotics which cross the blood–brain barrier, such as 160 mg trimethoprim and 800 mg sulphamethoxazole (co-trimoxazole) daily for 1 year. This is often preceded by a 2-week course of streptomycin and penicillin.
or ceftriaxone. Treatment periods of less than a year are associated with relapse in about 40%.

Radiation enteritis

Radiation of more than 40 Gy will damage the intestine. The chronic effects of radiation are muscle fibre atrophy, ulcerative changes due to ischaemia, and obstruction due to radiation-induced fibrotic strictures.

Pelvic irradiation is frequently used for gynaecological and urinary tract malignancies, so the ileum and rectum are the areas most often involved.

At the time of the irradiation, there may be nausea, vomiting, diarrhoea and abdominal pain, usually improving within 6 weeks of completion of therapy.

Chronic radiation enteritis is diagnosed if symptoms persist for 3 months or more. The prevalence is more than 15%. Abdominal pain due to obstruction is the main symptom. Malabsorption can be due to bacterial overgrowth in dilated segments and mucosal damage.

Many patients suffer from increased bowel frequency. Treatment is symptomatic, although often unsuccessful in chronic radiation enteritis. Surgery should be avoided if possible, being reserved for obstruction or perforation.

Acute radiation damage to the rectum produces a radiation proctitis with diarrhoea and tenesmus, with or without blood. Local steroids sometimes help initially. When the acute phase heals, mucosal telangiectases form and may cause persistent bleeding. They can be treated with argon plasma coagulation or, under a light anaesthetic, by packing the rectum with a formalin-soaked swab for 2 minutes, both of which destroy the telangiectases.

Parasite infestation

Giardia intestinalis (see p. 161) not only produces diarrhoea but can produce malabsorption with steatorrhea. Minor changes are seen in the jejunal mucosa and the organism can be found in the jejunal fluid or mucosa.

Cryptosporidiosis (see p. 162) can also produce malabsorption.

Patients with HIV infection are particularly prone to parasitic infestation (see Table 6.24).

Other causes of malabsorption

- Drugs that bind bile salts (e.g. colestyramine) and some antibiotics (e.g. neomycin) produce steatorrhea.
- Orlistat (see p. 232) is used in obesity to reduce fat absorption by inhibiting gastric and pancreatic lipase causing diarrhoea and steatorrhea.
- Thyrotoxicosis: diarrhoea, rarely with steatorrhea, occurs in thyrotoxicosis owing to increased gastric emptying and increased motility.
- Zollinger–Ellison syndrome.
- Intestinal lymphangiectasia produces diarrhoea and rarely steatorrhea (see p. 283).
- Lymphoma that has infiltrated the small bowel mucosa causes malabsorption.
- Diabetes mellitus: diarrhoea, malabsorption and steatorrhea may occur, sometimes due to bacterial overgrowth from autonomic neuropathy causing small bowel stasis.

- Hypogammaglobulinaemia, which is seen in a number of conditions including lymphoid nodular hyperplasia, causes steatorrhea due either to an abnormal jejunal mucosa or to secondary infestation with Giardia intestinalis.

MISCELLANEOUS INTESTINAL DISEASES

Protein-losing enteropathy

Protein-losing enteropathy refers to intestinal conditions causing protein loss, usually manifest by hypoalbuminaemia. The causes are protein, including Crohn’s disease, tumours, Ménetrier’s disease, coeliac disease and lymphatic disorders (e.g. lymphangiectasia).

Usually protein-losing enteropathy forms a minor part of the generalized disorder, but occasionally hepatic synthesis of albumin cannot compensate for the protein loss, and peripheral oedema dominates the clinical picture. The investigations are described on page 277 and treatment is that of the underlying disorder.

Meckel’s diverticulum

This is the most common congenital abnormality of the GI tract, affecting 2–3% of the population. The diverticulum projects from the wall of the ileum approximately 60 cm from the ileocaecal valve. It is usually symptomless, but 50% contain gastric mucosa that secretes hydrochloric acid. Peptic ulcers can occur and may bleed (see p. 267) or perforate.

Acute inflammation of the diverticulum also occurs and is indistinguishable clinically from acute appendicitis. Obstruction from an associated band rarely occurs.

Treatment is surgical removal, often laparoscopically.

Tuberculosis (see also p. 863)

Tuberculosis (TB) can affect the intestine as well as the peritoneum (see p. 318). In developed countries, most patients are from ethnic minority groups, or are immunocompromised due to HIV or drugs. Intestinal tuberculosis is due to reactivation of primary disease caused by Mycobacterium tuberculosis. Bovine TB occurs in areas where milk is unpasteurized and is rare in western countries.

Clinical features are abdominal pain, weight loss, anaemia, fever with night sweats, obstruction, right iliac fossa pain or a palpable mass. The ileocaecal area is most commonly affected, but the colon, and rarely other parts of the gastrointestinal tract, can be involved. One-third of patients present acutely with intestinal obstruction or generalized peritonitis. 50% have X-ray evidence of pulmonary tuberculosis.

Diagnosis

TB must be differentiated from Crohn’s disease and should always be a differential diagnosis in Asian immigrants in developed countries. A caecal carcinoma can present with similar symptoms.

- A small bowel follow-through will show transverse ulceration, diffuse narrowing of the bowel with shortening of the caecal pole.
Ultrasound or CT shows additional mesenteric thickening and lymph node enlargement.

Histology and culture of tissue is desirable, but it is not always possible. Specimens can be obtained by colonoscopy or laparoscopy but laparotomy is required in some cases.

**Treatment**

Drug treatment is similar to that for pulmonary TB – rifampicin, isoniazid and pyrazinamide (see p. 866) – but treatment should last 1 year. Treatment should be started if there is a high degree of suspicion.

**Amyloid** (see also p. 1078)

In systemic amyloidosis there is usually diffuse involvement that may affect any part of the GI tract. Occasionally amyloid deposits occur as polyoid lesions. The symptoms depend on the site of involvement; amyloidosis in the small intestine gives rise to diarrhoea.

**Rheumatic autoimmune disorders**

*Systemic sclerosis* (see p. 545) most commonly affects the oesophagus (see p. 250), although the small bowel and colon are often found to be involved if the appropriate radiological studies are performed. Frequently there are no symptoms of this involvement, but diarrhoea and steatorrhoea can occur. This is usually due to bacterial overgrowth of the small bowel as a result of reduced motility, dilatation and the presence of diverticula.

In *rheumatoid arthritis* (see p. 523) and systemic lupus erythematosus (see p. 541), gastrointestinal symptoms may occur, but rarely predominate.

**Intestinal ischaemia**

Intestinal ischaemia results from occlusion of arterial inflow, occlusion of venous outflow or failure of perfusion; these factors may act alone or in combination and usually occur in the elderly. Ischaemia can be due to:

- **Arterial inflow occlusion:**
  - atheroma
  - thrombosis
  - embolus (cardiac arrhythmia) including cholesterol emboli (see p. 609)
  - aortic disease (occluding ostia of mesenteric vessels)
  - vasculitis (see p. 548), thromboangiitis and Takayasu’s syndrome (see p. 809)
  - neoplasia (occlusion of vessels – rare).

- **Venous outflow occlusion.** Occurs in 5–15% of cases and usually in sick patients with circulatory failure.

- **Infarction without occlusion.** Approximately one-third of patients dying with acute ischaemic necrosis of the small intestine have no demonstrable occlusion of a major vessel. Reduced cardiac output, hypotension and shock are the main causes of reduced intestinal blood flow leading to non-occlusive infarction.

**Acute small intestinal ischaemia**

Patients present with sudden abdominal pain and vomiting. An embolus from the heart in a patient with atrial fibrillation is the commonest cause, usually occluding the superior mesenteric artery. The abdomen is usually distended and tender, and bowel sounds are absent. The patient is hypotensive and ill. Surgery is necessary to resect the gangrenous bowel. Mortality is high (up to 90%) and is related to coexisting disease, the development of multiorgan failure (MOF) (see p. 909) and massive fluid and electrolyte losses in the postoperative period. Survivors may go on to develop nutritionally inadequate short-bowel syndrome (see p. 281).

**Ischaemic colitis**

See page 297.

**Chronic small intestinal ischaemia**

This is due to atheromatous occlusion or cholesterol emboli of the mesenteric vessels, particularly in the elderly. Such an occlusion does not always produce clinical effects because of the collateral circulation. The characteristic symptom is abdominal pain occurring after food. This may be followed by acute mesenteric vascular occlusion. Loud bruits may be heard but, as these are heard in normal subjects, they are of doubtful significance. The diagnosis is made using angiography. The term ‘coeliac axis compression syndrome’ has been used in young patients with chronic abdominal pain, bruits and minor angiographic changes. It is not an organic syndrome, but results from the false correlation of pain and bruits.

**Eosinophilic gastroenteritis**

In this condition of unknown aetiology there is eosinophilic infiltration and oedema of any part of the gastrointestinal mucosa. The gastric antrum and proximal small intestine are usually involved either as a localized lesion (eosinophilic granuloma) or diffusely with sheets of eosinophils seen in the serosal and submucosal layers. There is an association with asthma, eczema and urticaria.

The condition occurs mainly in the third decade. The clinical presentation depends on the site of gut involvement. Abdominal pain, nausea and vomiting and upper GI bleeding occur. Peripheral eosinophilia occurs in only 20% of patients. Endoscopic biopsy is useful for making the diagnosis histologically. Radiology may demonstrate mass lesions.

Treatment is with steroids for the widespread infiltration, particularly if peripheral eosinophilia is present.

In some adults the condition appears to be allergic (allergic gastroenteritis) and is associated with peripheral eosinophilia and high levels of plasma and tissue IgE. Eosinophilic oesophagitis is described on page 255, but its relationship to eosinophilic gastritis is unclear.

**Intestinal lymphangiectasia**

Dilatation of the lymphatics may be primary or secondary to lymphatic obstruction, such as occurs in malignancy or constrictive pericarditis. Hypoproteinaemia with ankle oedema is the main feature. The rare primary form may be detected incidentally as dilated lacteals on a jejunal biopsy or it can produce steatorrhoea of varying degrees. Serum immunoglobulin levels are reduced, with low circulating lymphocytes. Treatment is with a low-fat diet, MCT and fat-soluble vitamin supplements as required. Octreotide has a dramatic effect in a few primary cases, although the mechanism of action is unknown.
Abetalipoproteinaemia

This is rare and is due to a failure of apo B-100 synthesis in the liver and apo B-48 in the intestinal cell, so that chylomicrons are not formed. This leads to fat accumulation in the intestinal cells, giving a characteristic histological appearance to the jejunal mucosa. Clinical features include acanthocytosis (spiky red cells owing to membrane abnormalities), a form of retinitis pigmentosa, and mental and neurological abnormalities. The latter can be prevented by vitamin E injections.

TUMOURS OF THE SMALL INTESTINE

The small intestine is relatively resistant to the development of neoplasia and only 3–6% of all GI tumours and fewer than 1% of all malignant lesions occur here. The reason for the rarity of tumours is unknown. Explanations include the fluidity and relative sterility of small bowel contents and the rapid transit time, reducing the time of exposure to potential carcinogens. It is also possible that the high population of lymphoid tissue and secretion of IgA in the small intestine protect against malignancy.

Adenocarcinoma of the small intestine is rare and found most frequently in the duodenum (in the periampullary region) and in the jejunum. It is the most common tumour of the small intestine, accounting for up to 50% of primary tumours.

Lymphomas are most frequently found in the ileum. These are of the non-Hodgkin’s type and must be distinguished from peripheral or nodal lymphomas involving the gut secondarily.

In developed countries, the most common type of lymphoma is the B cell type arising from MALT (see p. 262). These lymphomas tend to be annular or polypoid masses in the distal or terminal ileum, whereas most T cell lymphomas are ulcerated plaques or strictures in the proximal small bowel.

A tumour similar to Burkitt’s lymphoma also occurs and commonly affects the terminal ileum of children in North Africa and the Middle East.

Predisposing factors for adenocarcinoma and lymphoma

Coeliac disease

There is an increased incidence of lymphoma of the T cell type and adenocarcinoma of the small bowel, as well as an unexplained increase in all malignancies both in the GI tract and elsewhere. The reason for the local development of malignancy is unknown. It is now accepted that coeliac disease is a premalignant condition, but there is no association with the length of the symptoms. Treatment with a gluten-free diet reduces the risk of both lymphoma and carcinoma.

Crohn’s disease

There is a small increase in the incidence of adenocarcinoma of the small bowel in Crohn’s disease.

Immunoproliferative small intestinal disease (IPSID)

IPSID is a B cell disorder in which there is proliferation of plasma cells in the lamina propria of the upper small bowel producing truncated monoclonal heavy chains, without associated light chains. The α heavy chains are found in the gut mucosa on immunofluorescence and can also be detected in the serum. It occurs usually in countries surrounding the Mediterranean, but it has also been found in other developing countries in South America and the Far East. IPSID predominantly affects people in lower socio-economic groups in areas with poor hygiene and a high incidence of bacterial and parasitic infection of the gut. IPSID presents as a malabsorptive syndrome associated with diffuse lymphoid infiltration of the small bowel and neighbouring lymph nodes, progressing in some cases to a lymphoma. The condition has also been documented in the developed world.

Clinically, patients present with abdominal pain, diarrhoea, anorexia, weight loss and symptoms of anaemia. There may be a palpable mass, and a small bowel follow-through may detect a mass lesion. Endoscopic biopsy is useful where lesions are within reach. Ultrasonic and CT may show bowel wall thickening and the involvement of lymph nodes, which is common with lymphoma. Wireless capsule endoscopy can be used where obstruction by the capsule is not likely, but cannot deliver histology.

Treatment of small intestinal tumours

Adenocarcinoma. Most patients are treated surgically with a segmental resection. The overall 5-year survival rate is 20–35%; this varies with the histological grade and the presence or absence of lymph node involvement. Radiotherapy and chemotherapy are used in addition.

IPSID. If there is no evidence of lymphoma, antibiotics, e.g. tetracycline, should be tried initially. In the presence of lymphoma, combination chemotherapy is used; in one series the 3- to 5-year survival rate was 58%.

Lymphoma. Most patients require surgery and radiotherapy with chemotherapy for more extensive disease. The prognosis varies with the type. The 5-year survival rate for T cell lymphomas is 25%, but is better for B cell lymphomas, varying from 50% to 75%, depending on the grade of lymphoma.

Carcinoid tumours

These originate from the enterochromaffin cells (APUD cells) of the intestine. They make up 10% of all small bowel neoplasms, the most common sites being in the appendix, terminal ileum and the rectum. It is often difficult to be certain histologically whether a particular tumour is benign or malignant. Ten per cent of carcinoid tumours in the appendix present as acute appendicitis, secondary to obstruction. Surgical resection of the tumour is usually performed.

Most carcinoids do not secrete hormones or vasoactive compounds, and may present with liver enlargement due to metastases.

Carcinoid syndrome occurs in only 5% of patients with carcinoid tumours and only when there are liver metastases. Patients complain of spontaneous or induced bluish-red flushing, predominantly on the face and neck, sometimes leading to permanent changes with telangiectases.

Gastrointestinal symptoms consist of abdominal pain and recurrent watery diarrhoea. Cardiac abnormalities are found in 50% of patients and consist of pulmonary stenosis or tricuspid incompetence. Examination of the abdomen reveals
hapatomegaly. The tumours secrete a variety of biologically active amines and peptides, including serotonin (5-hydroxytryptamine – 5-HT), bradykinin, histamine, tachykinins and prostaglandins. The diarrhoea and cardiac complications are probably caused by 5-HT itself, but the cutaneous flushing is thought to be produced by one of the kinins, such as bradykinin. This is known to cause vasodilatation, bronchospasm and increased intestinal motility.

**Diagnosis and treatment**

- **Ultrasound examination** confirms the presence of liver secondary deposits.
- **Urine** shows a high concentration of 5-hydroxyindoleacetic acid (5-HIAA) which is the major metabolite of 5-HT.

*Treatment* is with octreotide and lanreotide; both are octapeptide somatostatin analogues that inhibit the release of many gut hormones. They alleviate the flushing and diarrhoea and can control a carcinoid crisis. Octreotide is given subcutaneously in doses up to 200 μg three times daily initially; a depot preparation 30 mg every 4 weeks can then be used. Lanreotide 30 mg is given every 7–10 days, or as a gel 60 mg every 28 days. Long-acting octreotide also sometimes inhibits tumour growth and, since its introduction, other therapy has become usually unnecessary. Interferon and other chemotherapeutic regimens occasionally reduce tumour growth, but have not been shown to increase survival.

Most patients survive for 5–10 years after diagnosis.

**Peutz–Jeghers syndrome**

This consists of mucocutaneous pigmentation (circumoral (95% of patients), hands (70%) and feet (60%)) and gastrointestinal polyps. It has an autosomal dominant inheritance. The gene STK11 (also known as LKB1) responsible for Peutz–Jeghers codes for a serine protein kinase and can be used for genetic analysis. The brown buccal pigment is characteristic of the condition. The polyps, which are hamartomas, can occur anywhere in the GI tract but are most frequent in the small bowel. They may bleed or cause small bowel obstruction or intussusception (50% of patients).

Treatment is by endoscopic polypectomy. Balloon enteroscopy may be necessary to reach all the small bowel polyps. Bowel resection should be avoided if possible, but may be necessary in patients presenting with gangrenous bowel due to intussusception. Follow-up is with yearly pan-endoscopy. There is an increased incidence of GI cancers. Non-GI cancers also occur with increased frequency, so yearly screening for uterine, ovarian and cervical cancer should start in the teens, and breast and testicular screening by the age of 20.

**Other tumours**

Adenomas, lipomas and stromal tumours (see p. 266) are rarely found and are usually asymptomatic and picked up incidentally. They occasionally present with iron deficiency anaemia. In familial adenomatous polyposis (FAP) (p. 301) duodenal adenomas form in one-third of patients and may progress to adenocarcinoma. This is the commonest cause of death in FAP patients who have been treated by prophylactic colectomy.

---

**INFLAMMATORY BOWEL DISEASE (IBD)**

Two major forms of non-specific inflammatory bowel disease are recognized: Crohn’s disease (CD), which can affect any part of the GI tract, and ulcerative colitis (UC), which affects only the large bowel.

There is overlap between these two conditions in their clinical features, histological and radiological abnormalities; in 10% of cases of colitis a definitive diagnosis of either UC or CD is not possible. Currently it is necessary to distinguish between these two conditions because of certain differences in their management. It is possible that these conditions represent two aspects of the same disease.

Three additional forms of inflammatory bowel disease are also recognized, namely microscopic ulcerative, microscopic lymphocytic and microscopic collagenous colitis (see p. 294).

**Epidemiology**

The incidence of CD varies from country to country but is approximately 4–10 per 100 000 annually, with a prevalence of 27–106 per 100 000. The incidence of UC is stable at 6–15 per 100 000 annually, with a prevalence of 80–150 per 100 000.

Although both conditions have a world-wide distribution, the highest incidence rates and prevalence have been reported from northern Europe, the UK and North America. Both race and ethnic origin affect the incidence and prevalence of CD and UC. Thus in North America prevalence rates of CD are lower in Hispanic and Asian people (4.1, 5.6 per 100 000 respectively) compared to white individuals (43.6 per 100 000). Jewish people are more prone to inflammatory bowel disease than any other ethnic group. Prevalence rates also change after migration (e.g. higher rates in Chinese people living in Hong Kong compared with mainland China).

Crohn’s disease is slightly more common in females (M:F = 1:1.2) and occurs at a younger age (mean 26 years) than UC (M:F = 1.2:1; mean 34 years).

**Aetio-pathogenesis**

Although the aetiology of IBD is unknown, it is becoming clear that IBD represents the outcome of three essential interactive co-factors: genetic susceptibility, the environment and host immune response (Fig. 6.32), with the environmental factors representing both the local microenvironment (enteric microflora) and also the nutritional environment.
Familial. A positive family history is the largest independent risk factor for the disease. Thus up to 1 in 5 patients with CD and 1 in 6 patients with UC will have a first-degree relative with the disease.

Genetic. There is increased concordance for the disease (CD more than UC) in monozygotic twins in comparison with dizygotic twins who demonstrated familial aggregation. UC and CD are polygenic diseases. There is no single locus but susceptibility loci have been identified on chromosomes 16 (IBD1), 12, 6, 14, 5, 19, 1, 16 (IBD8) and 3, and these have been renamed IBD1–9 respectively. Significant loci have also been found on chromosome 13q and in Jewish families on 1p and 3q. Linkage mutations have been found on Card 15 (NOD2), the underlying gene on chromosome 16 (IBD1), and also genes underlying the IBD5 and IBD3 loci. The Card 15 (NOD2) gene is associated with CD in white populations, and has been associated with strictureing small bowel CD. Recent SNP (single nucleotide polymorphism) scans have identified a locus for UC and CD at ECM1 (extracellular matrix protein 1). Several other risk loci for both diseases have been found on IL23R, IL12B, NKK2-3 and MST1. The autophagy genes ATG16L1 and IRGM, which control an intracellular degradation process (along with CARD15), are specific for CD.

Apart from susceptibility, HLA genes on chromosome 6 also appear to have a role in modifying the disease. Thus the DRB1*0103 allele, which is uncommon, is linked to a particularly aggressive course of UC and the need for surgery, as well as with colonic CD. DRB1*0103 and MICA*010 are associated with perianal disease and DRB1*0701 with ileal CD. For the extraintestinal disease complications and HLA links see page 287.

Environmental factors. Good domestic hygiene has been shown to be a risk factor for CD but not for UC. Thus poor and large families living in crowded conditions with no tap or hot water and consuming contaminated food have a lower risk of developing CD.

H. pylori sero-prevalence is high in developing countries but low in patients with CD. A ‘clean’ environment may not expose the intestinal immune system to pathogenic or non-pathogenic microorganisms, particularly helminth parasites, and therefore be ‘untrained’ to confront minor infections. Helminth infections are associated with a type 2 helper T cell response (Th2), which would counterbalance the type-1 helper T cell response (Th1) that is characteristic of CD. If such a mechanism is operative, it would explain why there is a frequent association of a recent intestinal infection with the first presentation and subsequent flare-ups of CD.

Lifestyle. Breast feeding may provide protection against inflammatory bowel disease developing in offspring. Breast feeding per se does not contribute to disease exacerbation.

- Nutritional factors. Many foods and food components have been suggested to play a role in the aetiopathogenesis of IBD (e.g. high sugar and fat intake) but unfortunately the results of numerous studies have been equivocal.
- Smoking. Patients with CD are more likely to be smokers, and smoking has been shown to exacerbate CD. By contrast, there is an increased risk of UC in non- or ex-smokers and nicotine has been shown to be an effective treatment of UC.
- Adverse life events and psychological factors such as chronic stress and depression seem to increase relapses in patients with quiescent disease.

Appendicectomy is ‘protective’ for the development of UC, particularly if performed for appendicitis or for mesenteric lymphadenitis before the age of 20. It also influences the clinical course of UC, with a lower incidence of colectomy and need for immunosuppressive therapy. By contrast, appendicectomy may increase the risk of development of CD and may result in more aggressive disease.

Intestinal microbiota. The gut is colonized by 10 times more bacterial organisms than there are host cells, there being 300–400 distinct bacterial species. Evidence supports a hypothesis that IBD is characterized by an overaggressive immune response to luminal bacterial antigens and other products, occurring against a background of genetic susceptibility (see above).

- Bacterial flora. There is an alteration in the bacterial flora, with an increase in anaerobic bacteria in CD and an increase in aerobic bacteria in UC.
- Bacterial antigens. Bacteria may exert their pro-inflammatory influence by producing toll-like receptor ligands such as peptidoglycan-polysaccharides (PG-PS), lipopolysaccharides (LPS), which interact in the normal intestine with surface toll-like receptors (TLR). The disruption in TLR signalling could prevent the mucosa withstands bacterial insult.
- Intestinal mucosal invasion. The intestinal wall in IBD patients is contaminated by adherent and invading bacteria. Recently it has been shown that there is increased E. coli adherence to the ileal-epithelial cells in CD. This occurs via E. coli’s type 1 pilus to a protein called carcinoma embryonic antigen-related cell adhesion molecule 6 (CEACAM 6). The latter may become a marker for inflammation.
- Defective chemical barrier or intestinal defensins (see p. 274). Evidence suggests a decrease in human α
impaired mucosal barrier function may explain the presence of unusual and potentially pathogenic bacteria, e.g. Mycobacterium paratuberculosis (MAP), Listeria and mucosal adherent E. coli. Their presence does not necessarily imply causation of the disease. However, MAP has recently been found in the blood of patients with CD and further studies are awaited.

- Butyrate. Sulphate-producing bacteria increase luminal levels of hydrogen sulphide (H₂S), which leads to a reduction of butyrate oxidation in colonic mucosa, producing an energy-deficient state and leading to mucosal inflammation. H₂S and methanethiol may produce the malodorous flatus that some patients complain of prior to a flare-up.

■ Pathogenesis. IBD results from a defective mucosal immune system producing an inappropriate response to luminal antigens, such as bacteria which enter the intestine via a leaky epithelium. Bacterial ligands interact with toll-like receptors expressed on the epithelial cell membrane via co-stimulatory molecules which enable the epithelial cells to act as antigen presenting cells to myeloid dendritic cells. There then follows a stimulation of naïve Th 0 cells into effector T cells (Th1 (IL-12, INFγ), Th2 (IL-5) and Th17 (IL-17)), which predominate over the regulatory T cells (T reg).

The pro-inflammatory cytokines released by these activated T cells stimulate macrophages to secret tumour necrosis factor α (TNF-α), IL-1 and IL-6 in large quantities.

Macrophages are also stimulated by plasmacytoid dendritic cells via natural killer cells which themselves can cause direct cytotoxic effects on cells and secrete inflammatory cytokines.

These mechanisms all result in leucocytes leaving the circulation to enter the tissue and release chemokines (lymphokines, arachidonic acid metabolites, neuropeptides and free oxygen radicals), all of which lead to tissue damage and also attract more inflammatory cells like a vicious circle.

Pathology

- Crohn’s disease is a chronic inflammatory condition that may affect any part of the gastrointestinal tract from the mouth to the anus but has a particular tendency to affect the terminal ileum and ascending colon (ileocolonic disease). The disease can involve one small area of the gut such as the terminal ileum, or multiple areas with relatively normal bowel in between (skip lesions). It may also involve the whole of the colon (total colitis) sometimes without small bowel involvement.

- Ulcerative colitis can affect the rectum alone (proctitis), can extend proximally to involve the sigmoid and descending colon (left-sided colitis), or may involve the whole colon (total colitis). In a few of these patients there is also inflammation of the distal terminal ileum (backwash ileitis).

Macroscopic changes

In Crohn’s disease the involved small bowel is usually thickened and narrowed. There are deep ulcers and fissures in the mucosa, producing a cobblestone appearance. Fistulae and abscesses may be seen in the colon. An early feature is aphtoid ulceration, usually seen at colonoscopy (Fig. 6.33); later, larger and deeper ulcers appear in a patchy distribution, again producing a cobblestone appearance.

In ulcerative colitis the mucosa looks reddened, inflamed and bleeds easily. In severe disease there is extensive ulceration with the adjacent mucosa appearing as inflammatory polyps.

In fulminant colonic disease of either type, most of the mucosa is lost, leaving a few islands of oedematous mucosa (mucosal islands), and toxic dilatation occurs. On healing, the mucosa can return to normal, although there is usually some residual glandular distortion.

Microscopic changes

In Crohn’s disease the inflammation extends through all layers (transmural) of the bowel, whereas in UC a superficial inflammation is seen. In CD there is an increase in chronic inflammatory cells and lymphoid hyperplasia, and in 50–60% of patients granulomas are present. These granulomas are non-caseating epithelioid cell aggregates with Langhans’ giant cells.

In ulcerative colitis the mucosa shows a chronic inflammatory cell infiltrate in the lamina propria. Crypt abscesses and goblet cell depletion are also seen.

The differentiation between these two diseases can usually be made not only on the basis of clinical and radiological data but also on the histological differences seen in the rectal and colonic mucosa obtained by biopsy (Table 6.10).

It is occasionally not possible to distinguish between the two disorders, particularly if biopsies are obtained in the acute phase, and such patients are considered to have an indeterminate inflammatory colitis. Serological testing may be of value in differentiating the two conditions (see p. 289).

Extragastrointestinal manifestations

These occur with both diseases. Joint complications are commonest, and the peripheral arthropathies are classified as type 1 (pauci-articular) and type 2 (polyarticular).

Type 1 attacks are acute, self-limiting (<10 weeks) and occur with IBD relapses; they are associated with other extraintestinal manifestations of IBD activity.

Type 2 arthropathy lasts longer (months to years), is independent of IBD activity and usually associated with uveitis.

The incidence of joint and other extragastrointestinal manifestations is shown in Table 6.11. There is an association of HLA DRB1*0103 with pauci-articular large joint arthritits in UC and CD and small joint symmetrical arthritis with HLA-B44. HLA B27 is associated with sacroilitis.

The clinical features are very variable and depend partly on the region of the bowel that is affected. The disease may present insidiously or acutely. The abdominal pain can be colicky, suggesting obstruction, but it usually has no special characteristics and sometimes in colonic disease only minimal discomfort is present. Diarrhoea is present in 80% of all cases and in colonic disease it usually contains blood, making it difficult to differentiate from UC. Steatorrhoea can be present in small bowel disease. Diarrhoea can also be due to bile acid malabsorption occurring as a consequence of the effects of old and presently inactive disease rather than to active disease.

Crohn’s disease can present as an emergency with acute right iliac fossa pain mimicking appendicitis. If laparotomy is undertaken, an oedematous reddened terminal ileum is found. There are other causes of an acute ileitis (e.g. infections such as *Yersinia*).

Up to 30% of patients presenting with acute ileitis turn out eventually to have CD. Crohn’s disease can be complicated by anal and perianal disease and this is the presenting feature in 25% of cases, often preceding colonic and small intestinal symptoms by many years (Table 6.12).

Enteric fistulae, e.g. to bladder or vagina, occur in 20–40% of cases, equally divided between internal and external fistulae; the latter usually occurring after surgery.

### Examination

Physical signs are few, apart from loss of weight and general ill-health. Aphthous ulceration of the mouth is often seen. Abdominal examination is often normal although tenderness and/or a right iliac fossa mass are occasionally found. The mass is due either to inflamed loops of bowel that are matted together or to an abscess. The anus should always be examined to look for oedematous anal tags, fissures or perianal abscesses.

Extragastrointestinal features of inflammatory bowel disease should be looked for (see Table 6.11).

Sigmoidoscopy should always be performed in patients with suspected CD. With small bowel involvement the rectum may appear normal, but a biopsy must be taken as non-specific histological changes can sometimes be found in the mucosa. Even with extensive colonic CD the rectum may be spared and be relatively normal, but patchy involvement with an oedematous haemorrhagic mucosa can be present.

### Investigations

**Blood tests**

- *Anaemia* is common and is usually the normocytic, normochromic anaemia of chronic disease. Deficiency of iron and/or folate also occurs. Despite terminal ileal

### Differential diagnosis

All causes of diarrhoea should be excluded (see Table 6.22) and stool cultures should always be performed. Crohn’s disease should be considered in all patients with evidence of malabsorption, e.g. megaloblastic anaemia, or malnourishment, as well as in children with small stature. Ileocolonic tuberculosis (see p. 282) is common in developing countries, e.g. India, which makes a diagnosis of CD difficult. Microscopy and culture for TB of any available tissue is essential in these countries. A therapeutic trial of antituberculosis therapy may be required.

Lymphomas can occasionally involve the ileum and caecum.

### Crohn’s disease

**Clinical features**

The major symptoms are diarrhoea, abdominal pain and weight loss. Constitutional symptoms of malaise, lethargy, anorexia, nausea, vomiting and low-grade fever may be present and in 15% of these patients there are no gastrointestinal symptoms. Despite the recurrent nature of this condition, many patients remain well and have an almost normal lifestyle. However, patients with extensive disease often have frequent recurrences, necessitating multiple hospital admissions.

#### Table 6.12 Anal and perianal complications of Crohn’s disease

- Fissure in ano (multiple and indolent)
- Haemorrhoids
- Skin tags
- Perianal abscess
- Ischiorectal abscess
- Fistula in ano (may be multiple)
- Anorectal fistulae
involvement in CD, megaloblastic anaemia due to B₁₂ deficiency is unusual, although serum B₁₂ levels can be below the normal range.

- Raised ESR and CRP and a raised white cell count.
- Hypoaalbuminaemia is present in severe disease.
- Liver biochemistry may be abnormal.
- Blood cultures are required if septicaemia is suspected.
- Serological tests. Saccharomyces cerevisiae antibody is usually present while pANCA antibody is negative. The reverse is true in UC but the clinical value of these tests is limited.

**Stool cultures**
These should always be performed on presentation if diarrhoea is present.

**Radiology and imaging**
A barium follow-through examination or CT scan with oral contrast should always be performed in patients suspected of having CD. The findings include an asymmetrical alteration in the mucosal pattern with deep ulceration, and areas of narrowing or stricturing. Although commonly confined to the terminal ileum (Fig. 6.34), other areas of the small bowel can be involved and skip lesions with normal bowel are seen between affected sites.

Imaging of the small bowel may also be performed by magnetic resonance enteroclysis.

**Colonoscopy** is performed if colonic involvement is suspected except in patients presenting with severe acute disease. The findings vary from mild patchy superficial (apthoid) ulceration to more widespread larger and deeper ulcers producing a cobblestone appearance (see Fig. 6.33).

In patients presenting acutely with colonic symptoms, plain abdominal X-ray, ultrasound or CT is used to outline the colon as for UC (see p. 291).

**High-resolution ultrasound** and CT scanning are both helpful techniques in defining thickness of the bowel wall and mesentery as well as intra-abdominal and para-intestinal abscesses.

**Endoanal ultrasound and MRI** are used to evaluate perianal disease.

**Radionuclide scans** with gallium-labelled polymorphs or indium- or technetium-labelled leucocytes are used in some centres to identify small intestinal and colonic disease and to localize extraintestinal abscesses.

**Disease activity**
This can be assessed using simple parameters such as Hb, white cell count, inflammatory markers (raised ESR, CRP and platelet count) and serum albumin. Formal clinical activity indices (e.g. CD activity index) are used in research studies. Calprotectin is a calcium-binding protein and accounts for 60% of cytosolic protein of neutrophils. Faecal calprotectin has the potential as a simple cheap non-invasive marker of disease activity in IBD and may be of value in predicting response to and failure of treatment.

**Medical management of Crohn’s disease**

(Box 6.5)
The aim of management is to induce and then maintain a remission. Patients with mild symptoms may require only symptomatic treatment. Cigarette smoking should be stopped. Diarrhoea can be controlled with loperamide, codeine phosphate or co-phenotrope. Diarrhoea in longstanding inactive disease may be due to bile acid malabsorption (see p. 307) and should be treated with colestyramine. Anaemia, if due to vitamin B₁₂, folic acid or iron deficiency, should be treated with the appropriate haematinics. Anaemia in more active disease is usually normochromic and normocytic (anaemia of chronic disease, p. 399) and will usually improve as the patient gets better. Occasionally erythropoetin is required (see p. 632). Patients with active (moderate/severe) attacks may have to be admitted to hospital. Patients with moderate to severe total Crohn’s colitis are treated as for UC (see p. 292).

**Induction of remission**
Glucocorticosteroids are commonly used to induce remission in moderate and severe attacks of CD (oral prednisolone 30–60 mg/day). In patients with ileocaecal, but not colonic, CD, slow-release formulations of budesonide are as efficacious as oral prednisolone. Budesonide has high topical potency and because of its extensive hepatic inactivation has low systemic availability, which induces less suppression of endogenous cortisol and reduces frequency and intensity of steroidal side-effects. Overall remission/response rates vary from 60% to 90% depending on type, site and extent of disease.

**Enteral nutrition** is an underutilized means of inducing remission in moderate and severe attacks of CD, and efficacy is independent of nutritional status. If enteral diets with a low fat (1.3% of total calories) and a low linoleic acid content are administered as the sole source of nutrition for 28 days, rates of induction of remission are similar to those obtained with steroids. Relapse rates are high, however, particularly in those with colonic involvement.

In unresponsive patients, remission is sometimes induced and maintained by raising the dose of azathioprine to levels that make patients leucopenic.
Maintenance of remission
Flare ups commonly occur after steroid dosages are tapered and/or enteral nutrition stopped, and alternative treatment strategies have to be introduced. For example, steroid dosage may have to be temporarily increased, to re-induce remission. Remission in patients with Crohn’s colitis, but not in those with small intestinal involvement, can be treated with aminosalicylates. Remission in other patients can be maintained with azathioprine (AZA, 2.5 mg/kg/day), 6-mercaptopurine (6MP, 1.5 mg/kg/day), methotrexate (25 mg i.m./week) and mycophenolate mofetil (1 g/day) (Box 6.5). These drugs have steroid sparing properties. Long-term treatment with these drugs is necessary as the rate of relapse on discontinuation is high (70%).

AZA is the most widely used drug to maintain remission. Careful early monitoring is required as hypersensitivity reactions can occur. The key enzyme involved in AZA and 6MP metabolism is thiopurine methyl transferase (TPMT). This enzyme has a significant genetic variation and deficiencies can result in high circulating levels of drugs with increased risk of bone marrow depression. Assays of TPMT activity are now available and should be performed before treatment. TPMT deficiency is not the only cause of bone marrow depression so 3-monthly blood counts should be performed on all patients.

In patients in whom remissions cannot be induced or maintained with corticosteroid/immunosuppressive therapy, treatment with a biological agent will be indicated.

Biological agents
Infliximab, a chimeric anti-TNF-α monoclonal antibody, is the most widely used biological agent. Successful at inducing remission in corticosteroid/immunosuppressive resistant patients, remission can be maintained (5 mg/kg i.v. weeks 0, 2, 6, and 8-weekly until week 46). Further courses of treatment can be given to reinduce and maintain a remission. Up to 60% of patients will form antibodies against infliximab which can shorten duration of response and predispose to an infusion reaction. Formation of antibodies against infliximab can be reduced by prior treatment with AZA and incidence of infusion reactions reduced by prior i.v. infusion of 200 mg hydrocortisone. Other adverse effects include opportunistic infections. The incidence of neoplasms and lymphoma is not increased on treatment.

Two other TNF-α antibody inhibitors have now been widely used.
Adalimumab is a fully human anti-TNF monoclonal antibody that is administered subcutaneously and is effective in patients who have failed to respond to infliximab as well as those who have not received it.
Cetirizumab pegol is a pegylated Fab’ fragment of humanized anti TNF-α monoclonal antibody. It can also be administered subcutaneously and short-term and longer-term efficacy has been demonstrated.

New anti TNF-α antibody therapies include CDP571, etanercept and oncept. Box 6.6 summarizes some of the other novel biological agents that are being trialled for the treatment of CD.

Surgical management of Crohn’s disease
Approximately 80% of patients will require an operation at some time during the course of their disease. Nevertheless, surgery should be avoided if possible and only minimal resections undertaken, as recurrence (15% per year) is almost inevitable. Patients undergoing their second surgery for CD should be treated with AZA or 6MP to reduce the chance of recurrence. The evidence base is not strong enough to support this recommendation for patients undergoing their first surgery. The indications for surgery are:

- failure of medical therapy, with acute or chronic symptoms producing ill-health
- complications (e.g. toxic dilatation, obstruction, perforation, abscesses, enterocutaneous fistula)
- failure to grow in children despite medical treatment.

In patients with small bowel disease, some strictures can be widened (stricturoplasty), whereas others require resection and end-to-end anastomosis.

When colonic CD involves the entire colon and the rectum is spared or minimally involved a subtotal colectomy and ileorectal anastomosis may be performed. An eventual recurrence rate of 60–70% in the ileum, rectum or both is to be expected; however, two-thirds of these patients retain a functional rectum for 10 years. If the whole colon and rectum are involved a panproctocolectomy with an end ileostomy is the standard operation. In this operation the colon and rectum are removed and the ileum is brought out through an opening in the right iliac fossa and attached to the skin. The patient wears an ileostomy bag, which is stuck on to the skin over the ileostomy spout. The bag needs to be emptied once or twice daily, so this is compatible with a near-normal lifestyle. Stoma care therapists are readily available with help and advice. CD patients are not suitable for a pouch operation (see p. 292) as recurrence in the pouch is high.

Problems associated with ileostomies include:

- mechanical problems
- dehydration, particularly in hot climates
- psychosexual problems
- infertility in men (due to rectal surgery)
- recurrence of CD.

Ulcerative colitis
Clinical features
The major symptom in UC is diarrhoea with blood and mucus, sometimes accompanied by lower abdominal dis-
comfort. General features include malaise, lethargy and anorexia with weight loss. Aphthous ulceration in the mouth is seen. The disease can be mild, moderate or severe, and in most patients runs a course of remissions and exacerbations. Ten per cent of patients have persistent chronic symptoms, while some patients may have only a single attack.

When the disease is confined to the rectum (proctitis), blood mixed with the stool, urgency and tenesmus are common. There are normally few constitutional symptoms, but patients are nevertheless greatly inconvenienced by the frequency of defecation.

In an acute attack of UC, patients have bloody diarrhoea, passing up to 10–20 liquid stools per day. Diarrhoea also occurs at night, with urgency and incontinence that is severely disabling for the patient. Occasionally blood and mucus alone are passed.

**Severe attack.** The definition of a severe attack is given in Table 6.13. The patient is often very ill and needs urgent treatment in hospital.

**Toxic megacolon** is a serious complication. The plain abdominal X-ray shows a dilated thin-walled colon with a diameter of >6 cm; it is gas filled and contains mucosal islands (Fig. 6.35). It is a particularly dangerous stage of advanced disease with impending perforation and a high mortality (15–25%). Urgent surgery is required in all patients in whom toxic dilatation has not resolved within 48 hours with intensive therapy as above. The differential diagnosis includes an infectious colitis, e.g. *C. difficile* and CMV, particularly in patients with HIV infections.

**Examination**

In general there are no specific signs in UC. The abdomen may be slightly distended or tender to palpation. The anus is usually normal. Rectal examination will show the presence of blood. Rigid sigmoidoscopy is usually abnormal, showing an inflamed, bleeding, friable mucosa. Very occasionally rectal sparing occurs, in which case sigmoidoscopy will be normal.

**Investigations**

**Blood tests**

- In moderate to severe attacks an iron deficiency anaemia is commonly present and the white cell and platelet counts are raised.
- The ESR and CRP are often raised; liver biochemistry may be abnormal, with hypoalbuminaemia occurring in severe disease.
- pANCA may be positive. This is contrary to CD, where pANCA is usually negative (see p. 289).

**Stool cultures**

These should always be performed to exclude infective causes of colitis.

**Imaging**

A plain abdominal X-ray with an abdominal ultrasound are the key investigations in moderate to severe attacks. The extent of disease can be judged by the air distribution in the colon and the presence of colonic dilatation can be noted. Thickening of the colonic wall can be detected on ultrasound as can the degree of hyperaemia in the colonic wall, present in severe disease. The presence of free fluid within the abdominal cavity can also be assessed.

**Colonoscopy**

A colonoscopy should not be performed in severe attacks of disease for fear of perforation. In more longstanding and chronic disease it is useful in defining extent and activity of disease, and excluding the onset of dysplasia and carcinoma in patients with longstanding disease (see p. 293) of 10 years’ duration or more.

**Radionuclide scans**

These can be used to assess colonic inflammation (see p. 245).

**Medical management of ulcerative colitis (UC)**

Wherever possible, patients with UC and CD should be managed in patient-focused inflammatory bowel disease clinics. All patients with UC should be treated with an aminosalicylate. The active moiety of these drugs is 5-aminosalicylic acid (5-ASA). 5-ASA is absorbed in the small intestine (and may be nephrotoxic), so the design of the various aminosalicylate preparations is based on the binding of 5-ASA by an azo bond to sulfapyridine.

(sulfasalazine), 4-aminobenzoyl-β-alanine (balsalazide) or to 5-ASA itself (olsalazine), coating with a pH-sensitive polymer (Asacol) or packaging of 5-ASA in microspheres (Pentasa).

The azo bonds are broken down by colonic bacteria to release 5-ASA within the colon. The pH-dependent forms are designed to release 5-ASA in the terminal ileum. Luminal pH profiles in patients with inflammatory bowel disease are abnormal and in some patients capsules of 5-ASA coated with pH-sensitive polymer may pass through into the faeces intact. 5-ASA is released from microspheres throughout the small intestine and colon. The mode of action of 5-ASA in inflammatory bowel disease is unknown, but the aminosalicylates have been shown to be effective in inducing remission in mild to moderately active disease and maintaining remission in all forms of disease. Sulfasalazine is being used less frequently because of its wider side-effect profile from the sulphonamide component.

**Proctitis**

Oral aminosalicylates plus a local rectal steroid preparation (10% hydrocortisone foam; prednisolone 20 mg enemas or foam) are the first-line treatment. Mesalazine enemas and budesonide enemas can be tried. Some cases of proctitis can be ‘resistant’ to treatment. In these, oral corticosteroids alone or in combination with azathioprine are used and in rare cases short-chain fatty acid enemas may help.

**Left-sided proctocolitis**

Oral aminosalicylates plus local rectal steroid preparations may be effective but in moderate to severe attacks oral prednisolone will be required. If patients do not respond within 2 weeks they should be admitted to hospital.

**Total colitis (moderate to severe attacks)**

(Table 6.13)

Patients should be admitted to hospital and treated initially with hydrocortisone 100 mg i.v. 6-hourly with oral aminosalicylates. Full investigations (see above) should be performed initially and full supportive therapy administered (i.v. fluids, nutritional support via the enteral (not parenteral) route if required).

Patients who have been previously admitted within 2–3 years with moderate to severe attacks of total colitis can be started on azathioprine if not already on this treatment, as it takes time to work. The clinical status of patients should subsequently be monitored (fever, tachycardia, abdominal signs) and daily FBC, ESR, CRP, electrolytes and urea, tests of liver function, including serum albumin, straight abdominal X-ray and stool weights should be performed. Success or failure of medical treatment of a severe attack of UC must be judged by an experienced gastroenterologist.

A persistent fever, tachycardia, falling Hb, rising white cell count, falling potassium, falling albumin and persistently raised stool weights (>500 g/day) with loose blood-stained stool are all signs that the patient is not responding to treatment and that surgery may be indicated.

A concept of rescue therapy to avoid colectomy has now been developed for patients with poor prognostic signs and a CRP > 45 mg/L after 3 days of i.v. hydrocortisone. They should be treated, in addition to hydrocortisone, with either i.v. cyclosporin 2 mg/kg/day or possibly TNF-α antibody therapy. Other rescue agents under consideration include visilizumab and leucocytapheresis (selective removal of white cells from blood and re-infusion of red cells and leukocyte-poor plasma). Delaying colectomy in very sick patients can increase mortality.

In patients responding to i.v. hydrocortisone treatment, oral prednisolone therapy should be substituted and doses slowly tailed off (5–10 mg weekly). Maintenance of remission is with aminosalicylates. In patients in whom it is not possible to reduce the dose of prednisolone without flare-up, azathioprine is used.

**Surgical management of ulcerative colitis**

While the treatment of UC remains primarily medical, surgery continues to have a central role because it may be life-saving, is curative and eliminates the long-term risk of cancer. The main indication for surgery is for a severe attack which fails to respond to medical therapy. Other indications are listed in Box 6.7.

In acute disease, subtotal colectomy with end ileostomy and preservation of the rectum is the operation of choice. At a later date a number of surgical options are available. These include proctectomy with a permanent ileostomy. To avoid a permanent ileostomy, ileorectal anastomosis can be performed; annual biopsies of the rectal mucosa must be carried out to detect dysplasia, a histological change that precedes the development of a rectal stump carcinoma. With an ileo-anal anastomosis (Fig. 6.36), a pouch of ileum is formed that acts as a reservoir. The pouch is anastomosed to the anus at the dentate line following endoanal excision of the mucosa of the distal rectum and anal canal. Continence is usually achieved. A third of patients, however, will experience ‘pouchitis’ in which there is inflammation of the pouch.

![Fig. 6.36 An ileo-anal pouch for ulcerative colitis.](image-url)
mucosa with clinical symptoms of diarrhoea, bleeding, fever and at times exacerbation of extracolonic manifestations (Fig. 6.37). The incidence of pouchitis is twice as high in patients with primary sclerosing cholangitis. Two-thirds of pouchitis cases will recur either as acute relapsing or chronic unremitting forms. Treatment is not always satisfactory and includes topical and oral 5-ASA, corticosteroids, metronidazole and ciprofloxacin. Probiotics (four strains of lactobacillus, three strains of bifidobacterium and one of streptococcus) have been shown to prevent the onset of pouchitis and to maintain remission in pouchitis patients. Probiotics have also been used as maintenance therapy in UC (Box 6.8). Finally, short-chain fatty acid enemas and alicaforsen (a selective inhibitor of intercellular adhesion molecule 1, ICAM-1, expression) enemas have shown promise in the treatment of pouchitis.

Course and prognosis
A third of patients with distal inflammatory proctitis due to UC will develop more proximal disease, with 5–10% developing total colitis. A third of patients with UC will have a single attack and the others will have a relapsing course. A third of patients with UC will undergo colectomy within 20 years of diagnosis.

Cancer in inflammatory bowel disease
Patients with UC and Crohn’s colitis have an increased incidence of developing colon cancer and patients with CD of the small intestine a small increase in incidence of small bowel carcinoma. The following screening strategies are suggested, although evidence for some is lacking. A screening colonoscopy with multiple biopsies should be done every 2 years in patients with total UC and Crohn’s colitis of 10 years’ standing and annually after 20 years. Patients with left-sided UC and those with less than total Crohn’s colitis should have a screening colonoscopy at 15 years and biannually thereafter. Patients with UC and primary sclerosing cholangitis are particularly at risk of developing colon cancer and should have a yearly screening colonoscopy.

Pregnancy and inflammatory bowel disease
Women with inactive IBD have normal fertility. Fertility, however, may be reduced in those with active disease, and patients with active disease are twice as likely to suffer spontaneous abortion than those with inactive disease.

The rate of relapse of UC in pregnant patients is similar to non-pregnant patients and is often due to inappropriate discontinuation of maintenance therapy. The risk of a flare up in the puerperal period is enhanced in patients who have a flare up in the first trimester. Patients with CD like those with UC do not have an increased risk of flare up during pregnancy. Relapse (if it does occur) is, however, more likely during the first trimester.

Aminosalicylates, steroids and azathioprine are safe at the time of conception and during pregnancy. The sulphasalazine moiety of sulfasalazine impairs spermatogenesis, so the partners of women trying to conceive should be treated with an alternative aminosalicylate. There is no good evidence that male patients with IBD should stop either AZA or 6MP.

Mortality in inflammatory bowel disease
Population-based studies demonstrate a mortality in UC similar to that in the general population. The two exceptions are patients with severe colitis who have a slightly higher mortality in the first year after diagnosis and patients aged

---

**Box 6.8 Probiotic use in inflammatory bowel disease**

Probiotics are live microorganisms which when ingested can modify the composition of enteric microflora. Commonly used probiotics are lactobacilli, bifidobacteria, non-pathogenic *E. coli*.

**Rationale for use**
- Germ-free animals are susceptible to gastrointestinal infections and inflammation
- Pseudomembranous colitis due to *C. difficile* follows antibiotic therapy
- In vitro isolates of normal bacteria inhibit growth of pathogenic bacteria
- Regulatory signals between bacterial flora and intestinal epithelial cells maintain mucosal integrity

**Use**
- Pouchitis (see p. 292) – probiotics can prevent onset and maintain a remission, possibly by increasing tissue levels of IL-10 and reducing TH-1 cytokine production as well as normalizing colonic bacterial function
- May be useful in maintaining remissions in ulcerative colitis

---

**Fig. 6.37** Pouchitis. Fibreoptic sigmoidoscopic appearances. (a) Mild changes. (b) Severe haemorrhagic ulceration.
over 60 at the time of diagnosis. Although currently it is unclear whether there is a slightly higher overall mortality in patients with CD or not, those with extensive jejunal and ileal disease and those with gastric and duodenal disease have been shown to have a higher relative mortality.

**Microscopic inflammatory colitis**

Patients with this group of disorders present with chronic or fluctuating watery diarrhoea. Although the macroscopic features on colonoscopy are normal, the histopathological findings on biopsy are abnormal. There are three distinct forms of microscopic inflammatory colitis:

- **Microscopic ulcerative colitis.** There is a chronic inflammatory cell infiltrate in the lamina propria, with deformed crypt architecture, and goblet cell depletion with or without crypt abscesses. Treatment is as for UC; many patients respond to treatment with aminosalicylates alone.

- **Microscopic lymphocytic colitis.** There is surface epithelial injury, prominent lymphocytic infiltration in the surface epithelium and increased lamina propria mononuclear cells. It affects males and females equally and is associated with a high prevalence of antibiotic use.

- **Microscopic collagenous colitis.** There is a thickened subepithelial collagen layer (>10 µm) adjacent to the basal membrane with increased infiltration of the lamina propria with lymphocytes and plasma cells and surface epithelial cell damage. It is predominantly a disorder of middle-aged or elderly females, and is associated with a variety of autoimmune disorders (arthritis, thyroid disease, CREST syndrome (see p. 546) and primary biliary cirrhosis). The prevalence of collagenous colitis has been shown to be 15.7/10^5 population with an annual incidence of 1.8/10^5 population. There are a number of reports linking drugs to the development of collagenous colitis, e.g. NSAIDs, simvastatin, H2-receptor antagonists. The incidence of both microscopic lymphocytic and collagenous colitis is increased in patients with coeliac disease and this must be excluded in these patients.

There are no controlled clinical trials of treatment in microscopic lymphocytic or collagenous colitis. Treatment is usually with aminosalicylates, budesonide, bismuth-containing preparations (tripotassium dicitratobismuthate, Pepto-Bismol), prednisolone and azathioprine in that order. A small number of patients with microscopic lymphocytic and collagenous colitis have co-existing bile acid malabsorption and as such can respond to colestyramine. In general, patients with microscopic collagenous colitis are easier to treat than those with the lymphocytic form of the disease.

---

**THE COLON AND RECTUM**

**Structure**

The large intestine starts at the caecum, on the posterior medial wall of which is the appendix. The colon is made up of ascending, transverse, descending and sigmoid parts, which join the rectum at the rectosigmoid junction.

The muscle wall consists of an inner circular layer and an outer longitudinal layer. The outer layer is incomplete, coming together to form the taenia coli, which produce the haustral pattern seen in the normal colon.

The mucosa of the colon is lined with epithelial cells with crypts but no villi, so that the surface is flat. The mucosa is full of goblet cells. A variety of cells, mainly lymphocytes and macrophages, are found in the lamina propria.

The blood supply to the colon is from the superior and inferior mesenteric vessels. Generally there are good anastomotic channels, but the caecum and splenic flexure are areas where ischaemia can occur. The colon is innervated mainly by the enteric nervous system with input from the parasympathetic and sympathetic pathways. Spinal afferent neurones from the dorsal root ganglia innervate the entire colon.

The rectum is about 12 cm long. Its interior is divided by three crescentic circular muscles producing shelf-like folds. These are the rectal valves that can be seen at sigmoidoscopy. The anal canal has an internal and an external sphincter.

**Physiology of the colon**

The main roles of the colon are the absorption of water and electrolytes (Table 6.14) and the propulsion of contents from the caecum to the anorectal region. Approximately 1.5–2 L of fluid pass the ileocaecal valve each day. Absorption is stimulated by short-chain fatty acids which are produced predominantly in the right colon by the anaerobic metabolism of dietary fibre by bacterial polysaccharidase enzyme systems. Colonic contents are mixed, aiding absorption by non-propagative segmenting muscular contractions. High-amplitude propagative colonic contractions cause propulsion. Peristalsis is induced by the release of serotonin (5-HT) from neuroendocrine cells in response to luminal distension.
Serotonin activates the HT₄ receptors, which in turn results in the activation of sensory (calcitonin gene-related peptide (CGRP)) neurones. Normal colonic transit time is 24–48 hours with normal stool weights of up to 250 g/day.

**Physiology of defecation**

The role of the rectum and anus in defecation is complex. The rectum is normally empty. Stool is propelled into the rectum by propagated colonic contractions. Sensation of fullness, a desire to defecate and urgency to defecate are experienced with increasing volumes of rectal content (threshold 100 mL). The sensations are associated with rectal contraction and a relaxation of the internal anal sphincter, both of which serve to push the stool down into the proximal anal canal. This increases the defecatory urge, which can only be suppressed by vigorous contraction of the external sphincter and puborectalis. If conditions are appropriate for defecation the subject sits or squats, contracts the diaphragm and abdominal muscles and relaxes the pelvic floor muscles, including the puborectalis, and the anal sphincter muscles with the result that stool is expelled.

**CONSTIPATION**

‘Constipation’ is a very common symptom, particularly in women and the elderly. It is often more of a perception than a real entity. A consensus definition used in research (The Rome III criteria) defines constipation as having two or more of the following for at least 12 weeks: infrequent passage of stools (<3/week), straining > 25% of time, passage of hard stools, incomplete evacuation and sensation of anorectal blockage. According to these definitions ‘constipation’ affects more than 1 in 5 of the population.

Many symptoms are attributed by patients to constipation and include headaches, malaise, nausea and a bad taste in the mouth. Other symptoms include abdominal bloating and/or discomfort (undistinguishable from the irritable bowel syndrome) as well as local and perianal pain. The causes of constipation are shown in Table 6.15.

**Assessment of constipation**

This relies on the history. When there has been a recent change in bowel habit in association with other symptoms (e.g. rectal bleeding) a barium enema or colonoscopy is indicated. A barium enema should always be preceded by a rectal examination and rigid sigmoidoscopy to exclude ano-rectal lesions that can otherwise be missed. By these means, gastrointestinal causes such as colorectal cancer and narrowed segments due to diverticular disease (Table 6.15) can be excluded.

Constipation can be classified into three broad categories but there is much overlap:

- normal transit through the colon (59%)
- defecatory disorders (25%)
- slow transit (13%).

Defecatory disorders with slow transit can occur together (3%).

**Normal-transit constipation**

In normal-transit constipation, stool traverses the colon at a normal rate, the stool frequency is normal and yet patients believe they are constipated. This is likely to be due to perceived difficulties of evacuation or the passage of hard stools. Patients may complain of abdominal pain or bloating.

Normal-transit constipation can be distinguished from slow-transit constipation by undertaking marker studies of colonic transit. Capsules containing 20 radio-opaque shapes are swallowed on days 1, 2 and 3 and an abdominal X-ray

obtained 120 hours after ingestion of the first capsule. Each capsule contains shapes of different configuration and the presence of more than 4 shapes from the first capsule, 6 from the second and 12 from the third denotes moderate to severe slow transit (Fig. 6.38).

**Slow-transit constipation**

Slow-transit constipation occurs predominantly in young women who have infrequent bowel movements (usually less than once a week). The condition often starts at puberty and the symptoms are usually an infrequent urge to defecate, bloating, abdominal pain and discomfort, which can make the condition difficult to distinguish from constipation-predominant irritable bowel syndrome. Some patients with severe slow-transit constipation have delayed emptying of the proximal colon and others a failure of ‘meal-stimulated’ colonic motility. Histopathological abnormalities have been demonstrated in the colons of some patients with severe slow-transit constipation, and some patients have coexisting disorders of small intestinal motility, consistent with a diagnosis of chronic idiopathic intestinal pseudo-obstruction (see p. 317).

**Defecatory disorders**

A ‘paradoxical’ contraction rather than the normal relaxation of the puborectalis and external anal sphincter and associated muscles during straining may prevent evacuation (pelvic floor dyssynergia, anismus). These are mainly due to dysfunction of the anal sphincter and pelvic floor. An anterior rectocele is a common problem where there is a weakness of the rectovaginal septum, resulting in protuberance of the anterior wall of the rectum with trapping of stool if the diameter is >3 cm. In some patients the mucosa of the anterior rectal wall prolapses downwards during straining (see p. 300) impeding the passage of stool, whilst in others there may be a higher mucosal intussusception.

In some patients the rectum can become unduly sensitive to the presence of small volumes of stool, resulting in the urge to pass frequent amounts of small-volume stool and the sensation of incomplete evacuation.

The defecatory disorders can often be characterized by performing evacuation proctography (Fig. 6.39) and tests of anorectal physiology.

**Treatment**

Any underlying cause should be treated. In patients with normal and slow-transit constipation the main focus should be directed to increasing the fibre content of the diet in conjunction with increasing fluid intake. Fibre intake should be increased by dietary means rather than by prescribing commercially available fibre sources in order to avoid substrate inducibility of colonic bacterial polysaccharidase enzyme systems which can lead in turn to excessive flatus production. These patients should therefore be referred to a dietician.

The use of laxatives should be restricted to severe cases. Types of laxatives available are listed in Box 6.9. Osmotic laxatives act by increasing colonic inflow of fluid and electrolytes; this acts not only to soften the stool but to stimulate colonic contractility. Magnesium sulphate 5–10 g dissolved in a glass of hot water should be taken before breakfast; it works in 2–4 hours. The polyethylene glycols (Macrogols) have the advantage over the synthetic disaccharide lactulose in that they are not fermented anaerobically in the colon to gas which can distend the colon to cause pain. The osmotic laxatives are preferred to the stimulatory laxatives, which act by stimulating colonic contractility and by causing intestinal secretion. The use of irritant suppositories can be helpful in some patients with defecatory disorders. The use of enemas should be restricted to the management of elderly, infirm and immobile patients and those with neurological disorders.

Patients with defecatory disorders should be referred to a specialist centre as surgery may be indicated, for example, for anterior rectocele or internal anal mucosal intussusception. Anterior mucosal prolapse can be treated by injection, and those with pelvic floor dyssynergia (anismus) can benefit from biofeedback therapy.
Box 6.9 Laxatives and enemas

**Bulking-forming laxatives**
- Dietary fibre
- Wheat bran
- Methylcellulose
- Muco-laginous gums – sterculia
- Muco-laginous seeds and seed coats, e.g. ispaghula husk

**Stimulant laxatives (stimulate motility and intestinal secretion)**
- Phenolphthalein
- Bisacodyl
- Anthraquinones – senna and dantron (only for the terminally ill)
- Docusate sodium
- Methylated trexone (for opioid induced constipation)
- Lubiprostone

**Osmotic laxatives**
- Magnesium sulphate
- Lactulose
- Macrogols

**Suppositories**
- Bisacodyl
- Glycerol

**Enemas**
- Arachis oil
- Docusate sodium
- Hypertonic phosphate
- Sodium citrate

---

**MISCELLANEOUS COLONIC CONDITIONS**

**Megacolon**

The term ‘megacolon’ is used to describe a number of congenital and acquired conditions in which the colon is dilated. In many instances it is secondary to chronic constipation and in some parts of the world Chagas’ disease is a common cause.

All young patients with megacolon should have Hirschsprung’s disease excluded. In this disease, which presents in the first years of life, an aganglionic segment of the rectum (megarectum) gives rise to constipation and subacute obstruction. Occasionally Hirschsprung’s disease affecting only a short segment of the rectum can be missed in childhood. A preliminary rectal biopsy is performed and stained with special stains for ganglion cells in the submucosal plexus. In doubtful cases full-thickness biopsy, under anaesthesia, should be obtained. A frozen section is stained for acetylcholinesterase, which is elevated in Hirschsprung’s disease. Manometric studies show failure of relaxation of the internal sphincter, which is diagnostic of Hirschsprung’s disease. This disease can be successfully treated surgically.

Treatment of other causes of a megacolon is similar to that of slow-transit constipation, but saline washouts and manual removal of faeces are sometimes required.

**Faecal incontinence**

Seven per cent of the healthy population over the age of 65 experience incontinence at least weekly. Incontinence occurs when the intrarectal pressure exceeds the intra-anal pressure and is classified as minor (inability to control flatus or liquid stool, causing soiling) or major (frequent and inadvertent evacuation of stool of normal consistency). The common causes of incontinence are shown in Table 6.16. Obstetric injury is a common cause and sphincter defects have been found in up to 30% of primiparous women. A faecal incontinence rate of over 25% has been described and this gets more severe with increasing age. Endoanal ultrasonography with enhancing per vaginal views is the investigation of choice in the assessment of anal sphincter damage (Fig. 6.40). Neurophysiological investigation of pudendal nerve function, anal sensation and anal sphincter function may be required to elicit the cause of the problem. In the future, static and dynamic pelvic MRI may become the investigation of choice in faecal incontinence.

Initial management of minor incontinence is bowel habit regulation. Loperamide is the most potent antidiarrhoeal agent which also increases internal sphincter tone.

Biofeedback is effective in some patients with faecal incontinence associated with impaired function of the puborectalis muscle and the external anal sphincter. Sacral spinal nerve stimulation has been shown to be effective in the treatment of patients with a functionally deficient but morphologically intact external anal sphincter.

Surgery may be required for anal sphincter trauma and should be carried out in specialist centres.

**Ischaemic disease of the colon (ischaemic colitis)**

Occlusion of branches of the superior mesenteric artery (SMA) or inferior mesenteric artery (IMA), often in the older age group, commonly presents with sudden onset of abdom-
inal pain and the passage of bright red blood per rectum, with or without diarrhoea. There may be signs of shock and evidence of underlying cardiovascular disease. The majority of cases affect the splenic flexure and left colon. This condition has also been described in women taking the contraceptive pill and in patients with thrombophilia (see p. 442) and small- or medium-vessel vasculitis (see p. 550).

On examination the abdomen is distended and tender. A straight abdominal X-ray often shows thumb-printing (a characteristic sign of ischaemic disease) at the site of the splenic flexure.

The differential diagnosis is of other causes of acute colitis. A rigid sigmoidoscopy (normal mucosal appearances often with presence of blood) and a gentle instant enema is preferred to colonoscopy (to avoid perforation) in cases where the diagnosis is in doubt. A barium enema should be performed when the patient has fully recovered, to exclude the formation of a stricture at the site of disease. Patients without evidence of underlying cardiovascular disease should be screened for thrombophilia and vasculitis.

Treatment
Most patients settle on symptomatic treatment. A few develop gangrene and perforation and require urgent surgery.

Pneumatosis cystoides intestinalis
This is a rare condition in which multiple gas-filled cysts are found in the submucosa of the intestine, chiefly the colon. The cause is unknown but some cases are associated with chronic obstructive pulmonary disease. Patients are usually asymptomatic, but abdominal pain and diarrhoea do occur and occasionally the cysts rupture to produce a pneumoperitoneum. This condition is diagnosed on X-ray of the abdomen, barium enema or sigmoidoscopy when cysts are seen.

Treatment is often unnecessary but continuous oxygen therapy will help to disperse the largely nitrogen-containing cysts. Metronidazole may help.

**DIVERTICULAR DISEASE**

Diverticula are frequently found in the colon and occur in 50% of patients over the age of 50 years. They are most frequent in the sigmoid, but can be present over the whole colon.

The term diverticulosis indicates the presence of diverticula; diverticulitis implies that these diverticula are inflamed. It is perhaps better to use the more general term diverticular disease, as it is often difficult to be sure whether the diverticula are inflamed. The precise mechanism of diverticular formation is not known. There is thickening of the muscle layer and, because of high intraluminal pressures, pouches of mucosa extrude through the muscular wall through weakened areas near blood vessels to form diverticula. An alternative explanation is cholinergic denervation with increasing age which leads to hypersensitivity and increased uncoordinated muscular contraction. Diverticular disease seems to be related to the low-fibre diet eaten in developed countries.

Diverticulitis occurs when faeces obstruct the neck of the diverticulum causing stagnation and allowing bacteria to multiply and produce inflammation. This can then lead to bowel perforation (peridiverticulitis), abscess formation, fistulae into adjacent organs, or even generalized peritonitis.

**Clinical features and management**

Diverticular disease is asymptomatic in 95% of cases and is usually discovered incidentally on a barium enema examination. No treatment other than dietary advice is required in those patients. In symptomatic patients intermittent left iliac fossa pain or discomfort and an erratic bowel habit commonly occur. In severe disease luminal narrowing can occur in the sigmoid colon, giving rise to severer pain and constipation. In the absence of clinical signs of acute diverticulitis a colonoscopy or ‘virtual colonoscopy’ (see p. 244) is the investigation of choice. Barium enema (Fig. 6.41) combined with flexible sigmoidoscopy is also used. Technically it is sometimes difficult to obtain adequate views of the sigmoid region in diverticular disease and if this is the case a fibreoptic sigmoidoscopy may be required. Treatment of uncomplicated symptomatic disease is with a well-balanced (soluble and insoluble) fibre diet (20 g/day) with smooth muscle relaxants if required.

**Acute diverticulitis**

This most commonly affects diverticula in the sigmoid colon. It presents with severe pain in the left iliac fossa, often accompanied by fever and constipation. These symptoms and signs are similar to appendicitis but on the left side. On examination the patient is often febrile with a tachycardia. Abdominal examination shows tenderness, guarding and rigidity on the left side of the abdomen. A palpable tender mass is sometimes felt in the left iliac fossa.

**Investigations**

- **Blood tests.** A polymorphonuclear leucocytosis is often present. The ESR and CRP are raised.
- **Spiral CT of the lower abdomen** (Fig. 6.42) will show colonic wall thickening, diverticula and often pericolic collections and abscesses. There is usually a streaky increased density extending into the immediate pericolic fat with thickening of the pelvic fascial planes. These...
Diverticular disease.
(a) Double-contrast enema showing diverticula (arrows). The barium is black on these films. (b) Diverticula (arrows) seen on colonoscopy.

Fig. 6.41

Fig. 6.42 Spiral CT of lower abdomen, showing acute diverticulitis (arrow). The bowel wall is thickened and there is loss of clarity of the pericolic fat. A narrow segment of bowel is seen to the left of the diseased segment.

findings are diagnostic of acute diverticulitis (95% sensitivity and specificity) and differ from those of malignant disease. Sigmoidoscopy and colonoscopy are not performed during an acute attack.

Ultrasound examination is often more readily available and is cheaper. It can demonstrate thickened bowel and large pericolic collections, but is less sensitive than CT.

Treatment
Acute attacks can be treated on an outpatient basis using a cephalosporin and metronidazole. Patients who are more ill will require admission for bowel rest, intravenous fluids and i.v. antibiotic therapy (e.g. gentamicin, or a cephalosporin) and metronidazole.

Complications of diverticular disease
- Perforation, which usually, but not always, occurs in association with acute diverticulitis, can lead to formation of a paracolic or pelvic abscess or generalized peritonitis. Surgery may be required.
- Fistula formation into the bladder, causing dysuria or pneumaturia, or into the vagina, causing discharge.
- Intestinal obstruction (see p. 316) usually after repeated episodes of acute diverticulitis.
- Bleeding, which is sometimes massive. In most cases the bleeding stops and the cause of the bleeding can be established by colonoscopy and sometimes angiography. In rare cases emergency segmental colectomy is required.
- Mucosal inflammation in areas of diverticula occurs, giving the appearance of a segmental colitis at endoscopy.

ANORECTAL DISORDERS

Pruritus ani
Pruritus ani, or an itchy bottom, is common. Perianal excoriation results from scratching. Usually the condition results from seepage from haemorrhoids or overactivity of sweat glands. Treatment consists of salt baths, keeping the area dry with powder; the use of all creams should be avoided. Secondary causes include threadworm (Enterobius vermicularis) infestation, fungal infections (e.g. candidiasis) and perianal eczema, which should be treated appropriately.

Haemorrhoids
Haemorrhoids (primary, internal, second degree, prolapsing, third degree prolapsed) usually cause rectal bleeding, discomfort and pruritus ani. Patients may notice red blood on their toilet paper and blood on the outside of their stools. They are the most common cause of rectal bleeding (Fig. 6.24). Diagnosis is made by inspection, rectal examination and proctoscopy. If symptoms are minor no treatment is required; depending on severity of symptoms, treatment is with injection of sclerosant, rubber band ligation or surgery.

FURTHER READING
An anal fissure is a tear in the sensitive skin-lined lower anal canal distal to the dentate line which produces pain on defecation. It can be an isolated primary problem in young to middle-aged adults or occur in association with Crohn’s disease or ulcerative colitis, in which case perianal abscesses and anal fistulae can complicate the fissure. Diagnosis can usually be made on the history alone and the fissures can be seen usually posteriorly. Rectal examination is often not possible because of pain and sphincter spasm. The spasms not only cause pain but impair wound healing. In severe cases proctoscopy and sigmoidoscopy should be performed under anaesthesia to exclude other anorectal disease. Initial treatment is with local anaesthetic gel and stool softeners. Use of 0.4% glyceryl trinitrate and 2% diltiazem ointments are of benefit. Botulinum toxin is used in chronic fissures but lateral subcutaneous internal sphincterotomy is the best treatment for severe cases.

Fistula in ano
Subcutaneous, low and high anal fistulae are the commonest types (Fig. 6.43). Anorectal fistulae are rarer forms. The fistulae usually present as abscesses and heal after the abscess is incised. In other cases a small discharging sinus may be noted by the patient. Endoanal ultrasonography, magnetic resonance and/or examination under anaesthetic is usually required to define the primary and any secondary tracks and detect any associated disease. Management is usually surgical with approximately 90% of fistulae being laid open or excised.

Anrectal abscesses
Anorectal abscesses are a common cause of admission to hospital. They are two to three times commoner in men, particularly in men who have sex with men and who indulge in penetrative anal sex. They may be the first manifestation of Crohn’s disease, ulcerative colitis and tuberculosis. Perianal and ischiorectal abscess, the commonest forms, present with painful, tender swellings and discharge. Examination under anaesthetic, MRI and endoanal ultrasound are used for evaluation. Treatment is with surgical incision and drainage with antibiotics.

Rectal prolapse, intussusception and solitary rectal ulcer syndrome (SRUS)
All these conditions are thought to be related, with rectal prolapse being the unifying pathology. Some patients with SRUS do not have prolapse but strain excessively and ulcerate the anterior rectal wall, which is forced into the anus during futile straining efforts.

Rectal prolapse starts as an intussusception of the upper rectum which passes into the lower part of the viscus, and progression results in its protrusion through the anal canal to emerge as an external prolapse. Constipation and chronic straining are the likely causes. In addition, the presence of an intussuscepting rectum will mimic presence of stool in the rectum and lead to straining efforts to evacuate the prolapse. In some patients repeated straining leads to traumatic ulceration of the mucosa and formation of SRUS. Patients commonly present with slight bleeding and mucus on defecation, tenesmus and sensation of anal obstruction.

SRUS is commonly on the anterior wall of the rectum within 13 cm of the anal verge and this is sometimes difficult to distinguish from cancer and Crohn’s disease during endoscopic examination. SRUS has typical histological features of non-specific inflammatory changes with bands of smooth muscle extending into the lamina propria.

Asymptomatic SRUS should not be treated. Symptomatic patients should be advised to stop straining and measures taken to soften the stool. If rectal prolapse can be demonstrated during defecation, this should be repaired; in severe cases surgical treatment by resection rectopexy may be indicated. Surgical treatment for complete rectal prolapse is also required.

**COLONIC TUMOURS**

**Colon polyps and polyposis syndromes**

A colonic polyp is an abnormal growth of tissue projecting from the mucous membrane of the colon. They may be millimetres to several centimetres in diameter and may be single or multiple, pedunculated, sessile or ‘flat’ (Fig. 6.44a,b,c).

Many histological types of polyps are found in the colon (Table 6.17). Adenomas are the precursor lesions in most cases of colon cancer.

**Classification of colorectal polyps** (Table 6.17)

**Neoplastic polyps**

*Sporadic adenomas* An adenoma is a benign tumour of columnar cells or glandular tissue. They may have tubular, tubulovillous or villous morphology. The vast majority of adenomas are not inherited and are termed ‘sporadic’. Although many sporadic adenomas do not become malignant in the patient’s lifetime, they have a tendency to progress to cancer via increasing grades of dysplasia due to progressive accumulation of genetic changes. Factors favouring malignant transformation in colorectal polyps and the relationship between adenoma size and likelihood of cancer are shown in Box 6.10.

The progression from benign polyp to cancer is shown in Figure 6.45 on page 303.

The likelihood of an adenoma being present increases with age; they are rare before the age of 30 years. By the age of 60–70, 5% of asymptomatic subjects will have a polyp of 1 cm or more, or cancer with no symptoms, and up to

</table>

50% will have at least one small <1 cm adenoma. Removal of polyps at colonoscopy and subsequent surveillance reduces the risk of development of colon cancer by approximately 80%. It is thought that the remaining 20% are either newly formed, or missed, or difficult to detect, e.g. a flat adenoma. Techniques such as chromoscopy using dye spray or narrow band imaging are now being used to assist in their detection (flat adenomas account for approximately 12% of all adenomas).

Polyps in the rectum and sigmoid often present with rectal bleeding. More proximal lesions rarely produce symptoms and most are diagnosed on barium enema, CT colography or on colonoscopy performed for screening for other reasons. Large villous adenomas can present with profuse diarrhoea with mucus and hypokalaemia.

Once a polyp has been found it is almost always possible to remove it endoscopically. Guidelines (British Society of Gastroenterology (BSG) 2002) recommend a repeat colonoscopy:

- at 5 years if 1 or 2 adenomas <1 cm are found,
- at 3 years if there are 3–4 small adenomas or at least one >1 cm, and
- at 1 year if there are 5 or more small adenomas or there are 3 or more, at least one of which is >1 cm.

If any doubt exists about the completeness of excision of any polyp then an earlier repeat examination is suggested.

**Inherited polyposis syndromes**

About 5% of colorectal cancers have a well-defined single gene basis.

**Familial adenomatous polyposis** (FAP) is an autosomal dominant condition arising from germline mutations of the APC gene located on chromosome 5q21-q22. More than 825 different mutations have been identified. Penetration is virtually 100%. It is characterized by the presence of hundreds to thousands of colorectal adenomas and duodenal adenomas. The mean age of adenoma development is 16 years; the average age for developing colorectal cancer is 39 years. Tracing and screening of relatives is essential, usually after 12 years of age, and affected individuals should be offered a prophylactic colectomy, often before the age of 20. Surgical options include colectomy and ileorectal anastomosis which requires life-long surveillance of the rectal stump, or a restorative proctocolectomy or pouch procedure with complete removal of rectal mucosa.

Cystic gland polyps, predominantly in the proximal stomach, and duodenal adenomas are frequently found in FAP, as well as other extraintestinal lesions such as osteomas, epidermoid cysts and desmoid tumours. The duodenal adenomas may progress to cancer and are the commonest cause of death in colectomized patients with FAP. Congenital hypertrophy of the retinal pigment epithelium (CHRPE) occurs in many families with FAP. Other cancers in FAP include thyroid, pancreatic and hepatoblastomas.

APC gene mutations can be found in about 80% of families with FAP. Once the mutation has been identified in an index case, other family members can be tested for the mutation and screening can then be directed at mutation carriers. If a mutation cannot be found in a known FAP case, all family members should undergo clinical screening with regular colonoscopy.

**Attenuated FAP** may be missed as it presents later (44 years average age) and has fewer polyps (<100), which tend to occur more on the right side of the colon than on the left. It may be indistinguishable from sporadic cases but the gene mutation is in the APC germ line.

![Fig. 6.44](a) Colonic appearance of (a) a sessile flat polyp with Indigo carmine; (b) colon after resection of a sessile polyp; (c) a large pedunculated polyp.
MYH-associated polyposis. MYH (MUT Y Homolog) -associated polyposis is an autosomal recessive inherited syndrome of multiple colorectal adenomas and cancer. MYH is a base-excision-repair gene that corrects oxidative DNA damage. MYH-AP may account for 7–8% of families with the FAP phenotype in whom APC mutations cannot be found. Subjects with multiple adenomas or an FAP phenotype without APC mutations and with a family history compatible with a recessive pattern of inheritance should be tested for MYH-AP.

Hereditary non-polyposis colon cancer (HNPCC: Lynch syndrome). HNPCC is called ‘non-polyposis’ to distinguish it from FAP, though polyps are formed in the colon and may progress rapidly to colon cancer. It affects 1:5000 people, causing 3–10% of colorectal cancer cases.

The disease is caused by a mutation in one of the DNA mismatch repair genes, usually hMSH2 or hMLH1 but others (hMSH6, PMS1 and PMS2) are involved. Mismatch repair genes are responsible for maintaining the stability of DNA during replication. Inheritance is autosomal dominant. The defect in function of the mismatch repair mechanism causes naturally occurring highly repeated short DNA sequences known as microsatellites to be shorter or longer than normal, a phenomenon called microsatellite instability (MSI).

Onset of cancer is earlier than in sporadic cases, at age 40–50 or younger. Tumours have a predilection for the right colon, in contrast to sporadic cases. In contrast to FAP, the lifetime risk of colon cancer (penetration of the gene) in mutation carriers is 70–80%. Other cancers are also more common in HNPCC: stomach, small intestine, bladder, skin, brain and hepatobiliary system. Female patients are at risk for endometrial and ovarian cancer.

The diagnosis is made from the family history of colon cancer at a young age and the presence of associated cancers in the family. These are formalized in the various editions of the Amsterdam and the Bethesda criteria (Table 6.18).

Turcot’s syndrome consists of FAP or hereditary non-polyposis colon cancer with brain tumours.

Gardner’s syndrome has in addition to FAP desmoid tumours, osteomas of the skull and other lesions.

Non-neoplastic polyps

Hamartomatous polyps are commonly large and stalked. The inherited syndromes show autosomal dominant inheritance and include:

- Juvenile polyps which occur mainly in children and teenagers and are found mainly in the colon and histologically show mucus retention cysts. Most are sporadic, but a syndrome of juvenile polyposis is defined as: >3–5 juvenile colonic polyps, juvenile polyps throughout the Gl tract, or any number of polyps with a family history. It is an autosomal dominant condition and the relevant gene has been identified (Table 6.17). The polyps are a cause of bleeding and intussusception in the first decade of life. There is also an increased risk of colonic cancer (relative risk (RR) of 34), and surveillance and removal of polyps must be undertaken.

- Peutz–Jeghers syndrome which is considered on page 285.

- PTEN hamartoma-tumour syndrome (PHTS) which includes Cowden syndrome, Bannayan–Riley–Ruvalcaba syndrome and all syndromes caused by germline PTEN mutations. Cowden (multiple hamartoma) syndrome is associated with characteristic skin stigmata and intestinal polyps regarded as hamartomas but with a mixture of cell types. These patients have an increased risk of various extraintestinal malignancies (thyroid, breast, uterine and ovarian). These syndromes are uncommon and together account for <1% of colon cancer cases.

Hyperplastic (metaplastic) polyps. These are frequently found in the rectum and sigmoid colon. These pale, sessile mucosal nodules usually measure <5 mm and are normally without significant malignant potential. However, metaplastic polyposis is defined as the presence of more than 10 colonic metaplastic polyps, some of which are large. These phenotypes are rare but appear to exhibit an increased risk of colon cancer.

Colorectal carcinoma

Colorectal cancer (CRC) is the third most common cancer world-wide and the second most common cause of cancer death in the UK.

Each year over 30000 new cases are diagnosed in England and Wales (68% colon, 32% rectal cancer) and it is registered as the cause of death in about half this number. The prevalence rate per 100000 (at all ages) is 53.5 for men and 36.7 for women. The incidence increases with age; the average age at diagnosis is 60–65 years. Approximately 20% of patients in the UK have distant metastases at diagnosis. The disease is much more common in westernized countries than in Asia or Africa.

Factors related to risk of colorectal cancer are shown in Table 6.19.

Genetics of colorectal cancer

Most colorectal cancers develop as a result of a stepwise progression from normal mucosa to adenoma to invasive
cancer. This progression is controlled by the accumulation of abnormalities in a number of critical growth-regulating genes. These include *APC* mutation and loss, *K-ras* mutation, *Smad2/4* loss, and *TP53* mutation and loss, and altered DNA methylation with progression to carcinoma. CDK 8 has recently been found to regulate gene expression in the proliferation of colorectal cancer, and it also regulates the WNT/β-catenin signalling pathway involved in many colon cancers. Microsatellite instability (MSI) and chromosomal instability (CIN) are frequently detected in colon cancers. A third group, MACS (Microsatellite And Chromosomal Stable) is also recognized. MSI has been described (see under HNPPC, p. 302). CIN indicates loss of heterozygosity (LOH) in a number of cancer-related genes, though the underlying mechanisms are not well understood. About 15% of sporadic colorectal cancers show MSI and 50% exhibit LOH.

**Cancer families**

A family history of CRC confers an increased risk to relatives. Family history is, next to age, the most common risk factor for CRC. FAP (Fig. 6.46) is the best-recognized syndrome predisposing to colorectal cancer but represents less than 1% of all colorectal cancers. Hereditary non-polyposis colorectal cancer (HNPPC) accounts for 3–10% of familial cancer (see p. 302).

Additionally, some colon cancers arise, at least in part, from an inherited predisposition, so-called familial risk (Table 6.20). Estimates of their frequency range from 10% to 30% of all CRC but the genes involved have yet to be identified. The risk of CRC can be estimated from a family history matched with empirical risk tables so that appropriate advice regarding screening can be offered.

Most colorectal cancers are, however, sporadic and occur in individuals without a strong family history. Their distribution is shown in Figure 6.47.

**Pathology**

CRC, which is usually a polypoid mass with ulceration, spreads by direct infiltration through the bowel wall. It involves lymphatics and blood vessels with subsequent spread, most commonly to the liver and lung. Synchronous...
Biopsy of the tumour is mandatory, usually at endoscopy.

- **Double-contrast barium enema** can visualize the large bowel but is now being superseded by CT colonography.
- **Endoanal ultrasound and pelvic MRI** are used for staging rectal cancer.
- **Chest, abdominal and pelvic CT scanning** to evaluate tumour size, local spread and liver and lung metastases.
- **PET scanning** is useful for detecting occult metastases and for evaluation of suspicious lesions found on CT or MR.
- **MR** is also useful for evaluating suspicious lesions found on CT or US, especially in the liver.
- **Serum carcinoembryonic antigen (CEA)** is of little use for primary diagnosis, but may be useful for follow-up; rising levels suggest recurrence. It should not be performed as a screening test.
- **Faecal occult blood tests** have been used for mass screening but are of no value in hospital or general practice.

### Treatment

Treatment should be undertaken by multidisciplinary teams working in specialist units. About 80% of patients with colorectal cancer undergo surgery, though fewer than half of these survive more than 5 years. The operative procedure depends on the cancer site. Long-term survival relates to the stage of the primary tumour and the presence of metastatic disease (Table 6.21). There has been a gradual move from using Dukes’ classification to using the TNM classification system (see p. 456). Long-term survival is only likely when the cancer is completely removed by surgery with adequate clearance margins and regional lymph node clearance.

- **Total mesorectal excision (TME)** is used to carefully remove the entire package of mesorectal tissue surrounding the cancer. A low rectal anastomosis is then performed. Abdomino-perineal excision which requires a permanent colostomy is reserved for very low tumours within 5 cm of the anal margin. TME combined with preoperative radiotherapy reduces local recurrence rates in rectal cancer to around 8% and improves survival. Pre- or postoperative chemotherapy reduces local recurrence rates but had no effect on survival in a recent study.
- **Colon cancer. A segmental resection** and restorative anastomosis with removal of the draining lymph nodes as far as the root of the mesentery is used for cancer elsewhere in the colon. Surgery in patients with obstruction carries greater morbidity and mortality. Where technically possible, preoperative decompression by endoscopic stenting with a mesh-metal stent relieves obstruction so surgery can be elective rather than emergency, and is probably associated with a decrease in morbidity and mortality.
- **Local transanal surgery** is very occasionally used for early superficial rectal cancers.
- **Surgical or ablative treatment of liver and lung metastases** prolongs life where treatment is technically feasible and the patient is fit enough to undergo the treatment.
- **Radiotherapy** is not helpful for colonic cancers proximal to the rectum because of difficulties delivering a

</table>

A sufficient dose to the tumour without excess toxicity to adjacent structures, particularly the small bowel.

- **Adjuvant postoperative chemotherapy** improves disease-free survival and overall survival in stage III (Dukes’ C) colon cancer (see p. 490). Those with Duke’s B tumours with advanced features such as vascular invasion may also benefit.

Treatment of advanced colorectal cancer is discussed on page 490.

**Follow-up**

All patients who have surgery should have a total colonoscopy performed before surgery to look for additional lesions. If total colonoscopy cannot be achieved before surgery, a second ‘clearance’ colonoscopy within 6 months of surgery is essential. Patients with stage II or III disease should be followed up with regular colonoscopy and CEA measurements; rising levels of CEA suggest recurrence. CT scanning to detect operable liver metastases should be performed for up to 5 years post surgery.

**Prevention and screening**

- **Diet.** A low-fat, high-fibre diet for the prevention of sporadic colorectal cancer and endoscopic screening is recommended for at-risk patients with a strong family history and for inherited syndromes (e.g. FAP, HNPCC).
- **NSAIDs or aspirin** may play a role in prevention.
- **Faecal occult blood (FOB) tests** have been studied as a screening test for colorectal cancer. Several large randomized studies have demonstrated a reduction in cancer-related mortality of 15–33%. The disadvantage of screening with FOB is its relatively low sensitivity, which means many negative colonoscopies. In FOB screen-positive patients in the UK National Bowel Cancer Screening Programme (NHSC BCS), about 10% have cancer, 40% have adenomas and the colon is normal in 50%.
- **Colonoscopy** is the gold-standard technique for the examination of the colon and rectum and is the investigation of choice for high-risk patients. Universal screening strategies have been recommended in the USA, but the shortage of skilled endoscopists, the expense, the need for full bowel preparation and the small risk of perforation make colonoscopy impractical as a population screening tool at present.

- **CT colonography** (‘virtual colonoscopy’) (see Fig. 6.3) is being increasingly used.
- Genetic testing and stool DNA tests also contribute to screening programmes.

**FURTHER READING**

**DIARRHOEA**

Diarrhoea is a common clinical problem and there is no uniformly accepted definition of diarrhoea. Organic causes (stool weights > 250 g per day) have to be distinguished from ‘functional causes’, and is the first step in the assessment of the history. Sudden onset of bowel frequency associated with crampy abdominal pains, and a fever will point to an infective cause; bowel frequency with loose blood-stained stools to an inflammatory basis; and the passage of pale offensive stools that float, often accompanied by loss of appetite and weight loss, to steatorrhoea. Nocturnal bowel frequency and urgency usually point to an organic cause. Passage of frequent small-volume stools (often formed) points to a functional cause (see Functional gastrointestinal disorders, p. 309).

**Mechanisms**

**Osmotic diarrhoea**

The gut mucosa acts as a semi-permeable membrane and fluid enters the bowel if there are large quantities of non-absorbed hypertonic substances in the lumen. This occurs because:
the patient has ingested a non-absorbable substance
(e.g. a purgative such as magnesium sulphate or
magnesium-containing antacid)

- the patient has generalized malabsorption so that high
concentrations of solute (e.g. glucose) remain in the
lumen

- the patient has a specific absorptive defect (e.g.
disaccharidase deficiency or glucose–galactose
malabsorption).

The volume of diarrhoea produced by these mechanisms is
reduced by the absorption of fluid by the ileum and colon.
The diarrhoea stops when the patient stops eating or the
malabsorptive substance is discontinued.

**Secretory diarrhoea**

In this disorder, there is both active intestinal secretion
of fluid and electrolytes as well as decreased absorption. The
mechanism of intestinal secretion is shown in Figure 6.49a.

Common causes of secretory diarrhoea are:

- enterotoxins (e.g. cholera, *E. coli* – thermostable or
thermolabile toxin, *C. difficile*)

- hormones (e.g. vasoactive intestinal peptide in the
Verner–Morrison syndrome, p. 385)

- bile salts (in the colon) following ileal resection

- fatty acids (in the colon) following ileal resection

- some laxatives (e.g. docusate sodium).

---

**Fig. 6.49** Mechanisms of diarrhoea.

(a) Small intestinal secretion of water and electrolytes.

- **Cholera toxin** binds to its receptor
(monosialoganglioside G1) via fimbria
(toxin co-regulated pilus) on its β
subunit. This activates the αs subunit (of
the Gs protein), which in turn
dissociates and activates cyclic AMP
(cAMP). The increase in cAMP activates
intermediates (e.g. protein kinase and
Ca2+) which then act on the apical
membrane causing CI– secretion (with
water) and inhibition of Na+ and CI–
absorption.

- **E. coli**. Heat-labile *E. coli* enterotoxin
shares a receptor with cholera toxin.
Heat-stable (HS) *E. coli* toxin binds to
its own receptor and activates
guanylate cyclase (cGMP), producing
the same effect on secretion.

- **C. difficile** activates the protein kinases
via Ca2+/calmodulin (Ca2+/CM),

- **Zona occludens toxin**. This toxin is the
product of the ZOT gene, which is the
gene required for the CTX gene which
encodes for cholera toxin. It has
enterotoxid activity, producing
secretion.

Cholera and *E. coli* cause these
effects without invasion of the cell.
Gs G protein consisting of subunits α,
β, γ, i, inhibitory; s, stimulatory; ATP,
adenoine trisphosphate; GTP,
guanosine trisphosphate; GMP,
guanosine monophosphate; GC,
guanylyl cyclase; PKC, protein kinase C; VIP,
vasoactive intestinal polypeptide.

(b) Colonic mucosal cell. This
demonstrates one of the mechanisms by
which an invasive pathogen (e.g. *Shigella*)
acts. Following penetration, the pathogens
generate cytotoxins which lead to
mucosal ulceration and cell death.
Inflammatory diarrhoea (mucosal destruction)

Diarrhoea occurs because of damage to the intestinal mucosal cell so that there is a loss of fluid and blood (Fig. 6.49b). In addition, there is defective absorption of fluid and electrolytes. Common causes are infective conditions (e.g. dysentery due to Shigella), and inflammatory conditions (e.g. ulcerative colitis and Crohn’s disease).

Abnormal motility

Diabetic, post-vagotomy and hyperthyroid diarrhoea are all due to abnormal motility of the upper gut. In many of these cases the volume and weight of the stool is not all that high, but frequency of defecation occurs; this therefore may not be true diarrhoea.

Causes of diarrhoea are shown in Table 6.22. It should be noted that the irritable bowel syndrome, colorectal cancer, diverticular disease and faecal impaction with overflow in the elderly do not cause ‘true’ organic diarrhoea (i.e. >250 g/day), even though the patients may complain of diarrhoea.

Factitious diarrhoea (4%)

Purging abuse

Dilutional diarrhoea

World-wide, infection and infestation are a major problem and these are discussed under the causative organisms in Chapter 4.

Acute diarrhoea (excluding cholera, discussed on p. 143)

Diarrhoea of sudden onset is very common, often short-lived and requires no investigation or treatment. This type of diarrhoea is seen after dietary indiscretions, but diarrhoea due to viral agents also lasts 24–48 hours (see p. 113). The causes of other infective diarrhoeas are shown on page 129.

Travellers’ diarrhoea, which affects people travelling outside their own countries, particularly to developing countries, usually lasts 2–5 days; it is discussed on page 131. Clinical features associated with the acute diarrhoeas include fever, abdominal pain and vomiting. If the diarrhoea is particularly severe, dehydration can be a problem; the very young and very old are at special risk from this. Investigations are necessary if the diarrhoea has lasted more than 1 week. Stools (up to three) should be sent immediately to the laboratory for culture and examination for ova, cysts and parasites. If the diagnosis has still not been made, a sigmoidoscopy and rectal biopsy should be performed and imaging should be considered.

Oral fluid and electrolyte replacement is often necessary. Special oral rehydration solutions (e.g. sodium chloride and glucose powder) are available for use in severe episodes of diarrhoea, particularly in infants. Antidiarrhoeal drugs are thought to impair the clearance of any pathogen from the bowel but may be necessary for short-term relief (e.g. codeine phosphate 30 mg four times daily, or loperamide 2 mg three times daily). Antibiotics are sometimes given (see p. 132) depending on the organism.

Chronic diarrhoea

This always needs investigation. All patients should have a sigmoidoscopy and rectal biopsy. The flow diagram in Figure 6.50 is illustrative; whether the large or the small bowel is investigated first will depend on the clinical story of, for example, bloody diarrhoea or steatorrhoea. The investigations and treatment are described in detail under the individual diseases.

When difficulties exist in distinguishing between functional and organic causes of diarrhoea, hospital admission for a formal 72-hour assessment of stool weights is helpful and will also assist in the diagnosis of factitious causes of diarrhoea.

Antibiotic-associated diarrhoea (pseudomembranous colitis) (see p. 131)

Pseudomembranous colitis may develop following the use of any antibiotic. Diarrhoea occurs in the first few days after taking the antibiotic or even up to 6 weeks after stopping the drug. The causative agent is *Clostridium difficile* (see p. 131).

Bile acid malabsorption

Bile acid malabsorption is an underdiagnosed cause of chronic diarrhoea and many patients with this disorder are assumed to have irritable bowel syndrome. Bile acid diarrhoea occurs when the terminal ileum fails to reabsorb bile
acids. Bile acids (particularly the dihydroxy bile acids – deoxycholate and chenodeoxycholate) when present in increased concentrations in the colon lead to diarrhea by reducing absorption of water and electrolytes and, at higher concentrations, inducing secretion as well as increasing colonic motility. A variety of causes of bile acid malabsorption are recognized (Table 6.23).

Bile acid malabsorption should be considered not only in patients with chronic diarrhea of unknown cause but also in patients with diarrhea and associated disease who are not responding to standard therapy (e.g. patients with terminal ileal Crohn’s disease, microscopic inflammatory colitis).

Diagnosis is made using the SeHCAT test in which a radiolabelled bile acid analogue is administered and percentage retention at 7 days calculated (<19% retention abnormal). Treatment is with cholestyramine, a resin which binds and inactivates the action of bile acids in the colon. The best results of treatment are obtained in patients with a SeHCAT retention of <5%.

Factitious diarrhoea

Factitious diarrhoea accounts for up to 4% of new patients with diarrhoea attending gastroenterology clinics.

Purgative abuse

This is most commonly seen in females who surreptitiously take high-dose purgatives and are often extensively investigated for chronic diarrhoea. The diarrhoea is usually of high volume (>1 L daily) and patients may have a low serum potassium. Sigmoidoscopy may show pigmented mucosa, a condition known as melanosis coli. Histologically the rectal biopsy shows pigment-laden macrophages in patients taking...
Causes is unclear. To of population in the Shigella shows gastrointestinal 6.24 purgative raised Lymphoma symptomatic. an anthraquinone purgative (e.g. senna). Melanosis coli is also seen in people regularly taking purgatives in normal doses.

In advanced cases a barium enema may show a dilated colon and loss of hastral pattern.

Phenolphthalein laxatives can be detected by pouring an alkali (e.g. sodium hydroxide) on the stools, which then turn pink; a magnesium-containing purgative will give a high faecal magnesium content. Anthraquinones can also be measured in the urine. If the diagnosis is suspected, a locker or bed search (while the patient is out of the ward) is occasionally necessary. Management is difficult as most patients deny purgative ingestion. Purgative abuse often occurs in association with eating disorders and all patients needs psychiatric help. It is sometimes safer not to confront the patient with their diagnosis.

Dilutional diarrhoea

In this condition raised stool weights occur as a consequence of patients deliberately diluting their stool with urine or tap water. The diagnosis is made by measuring stool osmolality and electrolyte concentrations in order to calculate the faecal osmolar gap. Measurement of stool creatinine content is helpful in excluding dilution of stools with urine, and early admission to hospital for formal assessment of stool weights may avoid unnecessary invasive investigations being carried out.

Diarrhoea in patients with HIV infection

Chronic diarrhoea is a common symptom in HIV infection, but HIV’s role in the pathogenesis of diarrhoea is unclear. Cryptosporidium (see p. 142) is the pathogen most commonly isolated. Isospora belli and microsporidia have also been found.

The cause of the diarrhoea is often not found and treatment is symptomatic. Table 6.24 shows the conditions affecting the gastrointestinal tract in patients with AIDS.

There is a large group of gastrointestinal disorders that are termed ‘functional’ because symptoms occur in the absence of any demonstrable abnormalities in the digestion and absorption of nutrients, fluid and electrolytes and no structural abnormality can be identified in the gastrointestinal tract.

Table 6.25 lists some of the symptoms that are suggestive of a functional gastrointestinal disorder. Modern classification systems are based on the premise that for each disorder there is a symptom cluster that ‘breeds true’ across clinical and population groups. There is inevitably overlap, with some symptoms being common to more than one disorder.

Table 6.26 lists the common functional gastrointestinal disorders as defined by Rome III criteria. These conditions are extremely common world-wide, making up to 80% of patients seen in the gastroenterology clinic.

FUNCTIONAL GASTROINTESTINAL DISORDERS
Pathophysiology and brain–gut interactions
People with functional gastrointestinal disorders (FGID) are characterized by having a greater gastrointestinal motility response to life events than normal subjects. There is, however, a poor association between measured gastrointestinal motility changes and symptoms in many of the FGIDs. Patients with FGID have been shown to have abnormalities in visceral sensation and have a lower pain threshold when tested with balloon distension (visceral hyperalgesia). Visceral hyperalgesivity possibly relates to:

- altered receptor sensitivity at the viscus itself
- increased excitability of the spinal cord dorsal horn neurones
- altered central modulation of sensations.

Symptoms are likely to be generated as a consequence of disturbed gastrointestinal motility that leads to distension with visceral hyperalgesia accentuating the pain. In a group of patients who developed IBS symptoms following severe acute enteric infection, inflammatory changes were demonstrated in the enteric mucosa with serotonin-producing enteroendocrine cell hyperplasia, the excessive release of serotonin being thought by some to contribute to symptom development.

The brain–gut axis describes a combination of intestinal motor, sensory and CNS activities (Fig. 6.51). Thus extrinsic (e.g. vision, smell) and intrinsic (e.g. emotion, thought) information can affect gastrointestinal sensation because of the neural connections from higher centres. Conversely, viscerotropic events can affect central pain perception, mood and behaviour.

Psychological stress can exacerbate gastrointestinal symptoms, and psychological disturbances are more common in patients with FGIDs. These disturbances alter attitude to illness, promote healthcare seeking, and often lead to a poor clinical outcome. They have psychosocial consequences with poor quality of life at home and work. Early in life, genetic and environmental influences (e.g. family attitudes towards bowel training, verbal or sexual abuse, exposure to an infection) may affect psychosocial development (susceptibility to life stress, psychological state, coping skills, development of social support) or the development of gut dysfunction (abnormal motility or visceral hypersensitivity).

FGID should be regarded as a dysregulation of brain–gut function.

FUNCTIONAL OESOPHAGEAL DISORDERS
The criteria for diagnosis rest mainly on compatible symptoms. However, pathological gastro-oesophageal reflux and other causes may need full investigation, particularly in the elderly with a short history.

Globus
This presents as:

- Persistent or intermittent sensation of a lump or foreign body in the throat.
- Occurrence of the sensation between meals.
- The absence of dysphagia and pain on swallowing (odynophagia).

Treatment is with explanation and reassurance and a trial of antireflux therapy. Antidepressants may be tried.

Functional chest pain, of presumed oesophageal origin
This is characterized by episodes of mainly midline chest pain, not burning in nature, that are potentially of oesophageal origin and which occur in the absence of a cardiological cause, gastro-oesophageal reflux and achalasia.

More than half of patients will respond to high-dose acid-suppression therapy in the first week; some will respond to nitrates and calcium-channel blockers.

A history of psychiatric disorder is found in more than 60% of patients and antidepressant therapy, e.g. amitripty-
line or the selective serotonin reuptake inhibitor citalopram, have been shown to be effective.

**FUNCTIONAL GASTRODUODENAL DISORDERS**

**Functional dyspepsia**
This is the second most common functional gastrointestinal disorder (after irritable bowel syndrome). Patients can present with a spectrum of symptoms including upper abdominal pain/discomfort, fullness, early satiety, bloating and nausea.

These patients have no structural abnormality as an explanation for their symptoms.

**Functional dyspepsia subgroups**

Two subgroups based on the predominant (or most bothersome) single symptoms are suggested:

- **Epigastric pain syndrome** with pain centred in the upper abdomen as the predominant (most bothersome) symptom.
- **Postprandial distress syndrome** with an unpleasant or troublesome non-painful sensation (discomfort) centred in the upper abdomen being the predominant symptom. This sensation may be associated with upper abdominal fullness, early satiety, bloating and nausea.

There is considerable overlap between these two groups.

**Investigations**

Many young patients (<50) require no investigation. Older patients or those with alarm symptoms require endoscopy. Gastroscopy often shows gastritis but whether this is the cause of the symptoms is doubtful.

**Treatment**

The range of therapies prescribed for functional dyspepsia reflects the uncertain pathogenesis and the lack of satisfactory treatment options. Management is further confounded by high placebo response rates (20–60%). A proportion of patients will respond satisfactorily to reassurance, explanations and lifestyle changes. Proton pump inhibitors and prokinetic agents may be used for patients with epigastric pain syndrome and postprandial distress syndrome respectively. Reducing intake of fat, coffee, alcohol and cigarette smoking may help.

*H. pylori* eradication therapy has been shown to be effective in some patients with functional dyspepsia.

**Aerophagia**

Aerophagia refers to a repetitive pattern of swallowing or ingesting air and belching. It is usually an unconscious act unrelated to meals. Usually no investigation is required. Explanation that the symptoms are due to swallowed air and reassurance are necessary, as is treatment of associated psychiatric disease.

**Functional vomiting**

Functional vomiting is a rare condition in clinical practice, although chronic nausea is a frequent accompaniment in all functional gastrointestinal disorders. Clinically functional vomiting is characterized by:

- frequent episodes of vomiting, occurring on at least 1 day a week
- absence of criteria for an eating disorder, rumination or major psychiatric disease
- absence of self-induced and medication-induced vomiting
- absence of abnormalities in the gut or central nervous system and metabolic disease to explain the recurrent vomiting.

Investigation is often not required but always exclude non-GI disorders (see Table 6.1).

Treatment is with anti-nausea drugs and antidepressants; behavioural therapy and psychotherapy are helpful. Dietary changes occasionally help.

**FUNCTIONAL BOWEL DISORDERS**

**Irritable bowel syndrome (IBS)**

IBS is the commonest FGID. In western populations, up to one in five people report symptoms consistent with IBS. Only approximately 50% will consult their doctors and of these up to 30% will be referred by their GP to a hospital specialist. Up to 40% of all patients seen in specialist gastroenterology clinics will have IBS. Estimates in the UK put the annual cost of IBS to healthcare resources as £45.6 billion; in the US the cost is higher at $8 billion. In the UK approximately a quarter of IBS patients lose time off work for periods ranging from 7 to 13 days each year.

The factors that determine whether an IBS sufferer in the community seeks medical advice include the demonstration that consulters have higher illness attitude scores and higher anxiety and depression scores than non-consulters. Consulters perceive that their symptoms are severer than non-consulters, and consulting behaviour may be determined by the number of presenting symptoms. Female consulters outnumber male consulters by a factor of 2–3. Reasons for this include the fact that anxiety and depression scores are higher in women than in men and the gut may be more sensitive to various stimuli in women. It is likely that men and women perceive internal events in the abdomen differently.
and that women may be more focused on these events. Food and eating are of more special psychological significance for women, as evidenced by a much higher incidence of eating disorders in women. The whole pelvic region carries a more specific significance for women, being associated not only with defecation, urination and sexuality but additionally with menstruation, pregnancy and childbirth. Finally, women in western society in general seem more willing than men to seek medical attention for a whole variety of disorders.

**IBS – a multisystem disorder**

IBS patients suffer from a number of non-intestinal symptoms (Table 6.27). The non-intestinal symptoms of IBS can be more intrusive than the classical features of IBS. IBS coexists with chronic fatigue syndrome (see p. 1192), fibromyalgia (see p. 516) and temporomandibular joint dysfunction.

The biopsychosocial conceptualization of the pathogenesis and clinical expression of FGIDs (Fig. 6.51) is particularly relevant to IBS and Box 6.11 lists some common factors that have been shown to trigger IBS symptoms. Infectious diarrhoea precedes the onset of IBS symptoms in 7–30% of patients. Whether this is a factor for all patients or just a small subgroup remains controversial. Risk factors in these patients have been shown to include female gender, severity and duration of diarrhoea, pre-existing life events and high hypochondriacal anxiety and neurotic scores at the time of the initial illness. Symptoms of anxiety and depression are more common in IBS patients and stress or adverse life events often precede the onset of chronic bowel symptoms.

**Diagnostic criteria (Rome III 2006)**

These criteria state that in the preceding 3 months there should be at least 3 days per month of recurrent abdominal pain or discomfort associated with two or more of the following:

1. improvement with defecation
2. onset associated with a change in frequency of stool
3. onset associated with a change in form (appearance) of stool.

These are useful for comparative studies. Subgroups of IBS patients can be identified according to the criteria listed in Table 6.28.

The decision as to whether to investigate and if so what choice of investigations is required should be based on clinical judgement. Pointers to the need for thorough investigation are the presence of the above symptoms in association with rectal bleeding, nocturnal pain, fever and weight loss and a clinical suspicion of organic diarrhoea (stool wt > 250 g/day).

**Treatment**

Current strategies for treatment of IBS are based on the biopsychosocial conceptualization of IBS (Fig. 6.51) with targeting of central and end-organ therapies (Box 6.12). End-organ and central approaches to treatment should not be mutually exclusive and can be used in sequence and in combinations. The initial promise of the emerging receptor active drugs (HT$_3$ receptor antagonists for diarrhoea-predominant IBS, HT$_2$ receptor agonists for constipation-predominant IBS) have not been realized as to date the new drugs have either not received regulatory approval or have been voluntarily withdrawn by the manufacturers. Kappa opioid agonists for use in patients in whom visceral hyperalgesia plays a predominant role in the pathogenesis of their symptoms may still become available.

**Probiotics and prebiotics**

Probiotics are live or attenuated bacteria or bacterial products that confer a significant health benefit to the host. Two recent studies have shown a beneficial effect of *Bifidobacterium infantis* 35624 on IBS symptoms and in one the symptomatic response was associated with normalization of the ratio of an anti-inflammatory to a proinflammatory cytokine suggesting an immune modulating role for this organism in IBS.

Problems with quality control and formulation of probiotics are currently restricting the clinical availability of some probiotics.

Prebiotics are non-digestible food supplements that are fermented by host bacteria thereby altering the microbiota of

the host often by stimulating the growth of healthy bacteria. A trans-galacto oligosaccharide prebiotic has now been shown to be bifidobacteria enhancing in IBS patients and to alleviate symptoms. This group of compounds may have considerable potential as therapeutic agents in IBS.

### Pain/gas/bloat syndrome/midgut dysmotility

There exist a group of patients with functional bowel disease whose abdominal pain and other clinical features are likely to occur as a consequence of disordered motility and visceral sensation that predominantly affects the small intestine or midgut. The symptom-based diagnostic criteria are abdominal pain, often exacerbated by eating and not relieved by opening the bowels and not associated with the passage of more frequent or looser stools than normal and not associated with constipation. Other symptoms include abdominal distension (bloating). Abdominal distension that is not restricted to the upper abdomen occurs, as well as postprandial fullness, nausea and, on occasions, anorexia and weight loss.

Some patients with pain/gas/bloat syndrome have particularly severe and chronic symptoms, that may also be nocturnal. A subgroup of these have been shown to have manometric features consistent with a diagnosis of chronic idiopathic intestinal pseudo-obstruction (CIIP), and specifically of an enteric neuropathy. Full-thickness small intestinal biopsies have confirmed the diagnosis in some patients, while in others a deficiency of α actin staining in the inner circular layer of smooth muscle has been demonstrated. More appropriately these patients should be considered to have a gastrointestinal neuromuscular disorder (GINMD) of the gut. About 10% of these patients are subsequently found to have an underlying autoimmune overlap disorder (see p. 548).

**Treatment** of patients with pain/gas/bloat syndrome is not easy; and in some, pain can be chronic and severe. Narcotics should always be avoided. Central and end-organ targeted treatment approaches should be combined, e.g. selective serotonin reuptake inhibitor paroxetine combined with a prokinetic agent domperidone or smooth muscle relaxant, e.g. mebeverine. Treatment of patients with neuromuscular disorders of the gut requires a multidisciplinary approach, with emphasis on management of pain, psychological state and nutrition. Patients with underlying autoimmune inflammatory mixed connective tissue disorders may benefit from primary treatment of these.

### Functional diarrhoea

In this form of functional bowel disease, symptoms occur in the absence of abdominal pain and commonly are:

- The passage of several stools in rapid succession usually first thing in the morning. No further bowel action may occur that day or defecation only after meals.
- The first stool of the day is usually formed, the later ones mushy, looser or watery.
- Urgency of defecation.
- Anxiety, uncertainty about bowel function with restriction of movement (e.g. travelling).
- Exhaustion after the ‘morning rush’.

Chronic diarrhoea without pain is caused by many diseases indistinguishable by history from functional diarrhoea. Features atypical for a functional disorder (e.g. large-volume stools, rectal bleeding, nutritional deficiency and weight loss) call for more extensive studies of intestinal structure and function. In cases where it proves difficult to distinguish between functional and organic causes of diarrhoea, patients should be admitted to hospital for a formal 3-day analysis of stool weights and faecal fat estimation, and a purgative screen together with stool osmolality and creatinine contents to exclude factitious causes of diarrhoea (see p. 308). Outpatient analysis of stool weights is unreliable as brain–gut dyssynchrony may result in increased stool weights in the normal home environment.

Treatment of functional diarrhoea is with loperamide often combined with a tricyclic antidepressant prescribed at night (e.g. clomipramine 10–30 mg).
THE ACUTE ABDOMEN

This section deals with the acute abdominal conditions that cause the patient to be hospitalized within a few hours of the onset of pain (Table 6.29). The diagnosis when made quickly reduces morbidity and mortality. Although a specific diagnosis should be attempted, the immediate problem in management is to decide whether an ‘acute abdomen’ exists and whether surgery is required.

**History**

This should include previous operations, any gynaecological problems and whether any concurrent medical condition is present.

**Pain**

The onset, site, type and subsequent course of the pain should be determined as accurately as possible. In general, the pain of an acute abdomen can either be constant (usually owing to inflammation) or colicky because of a blocked ‘tube’. The inflammatory nature of a constant pain will be supported by a raised temperature, tachycardia and/or a raised white cell count. If these are normal, then other causes (e.g. musculoskeletal, aortic aneurysm) or rare causes (e.g. porphyria) should be considered. Colicky pain can be due to an obstruction of the gut, biliary system, urogenital system or the uterus. These will probably initially require conservative management along with analgesics. If a colicky pain becomes a constant pain, then inflammation of the organ may have supervened (e.g. strangulated hernia, ascending cholangitis or salpingitis).

A sudden onset of pain suggests:

- a perforation (e.g. of a duodenal ulcer)
- a rupture (e.g. of an aneurysm)
- torsion (e.g. of an ovarian cyst)
- acute pancreatitis.

**Back pain suggests:**

- pancreatitis
- rupture of an aortic aneurysm
- renal tract disease.

Inflammatory conditions (e.g. appendicitis) produce a more gradual onset of pain. With peritonitis the pain is continuous and may be made worse by movement.

**Vomiting**

Vomiting may accompany any acute abdominal pain but, if persistent, it suggests an obstructive lesion of the gut. The character of the vomit should be asked – does it contain blood, bile or small bowel contents?

**Other symptoms**

Any change in bowel habit or of urinary frequency should be documented and, in females, a gynaecological history should be taken.

**Physical examination**

The general condition of the person should be noted. Does the patient look ill? Is he or she shocked? Large volumes of fluid may be lost from the vascular compartment into the peritoneal cavity or into the lumen of the bowel, giving rise to hypovolaemia, i.e. a pale cold skin, a weak rapid pulse and hypotension.

**The abdomen**

- **Inspection.** Look for the presence of scars, distension or masses.
- **Palpation.** The abdomen should be examined gently for sites of tenderness and the presence or absence of guarding. Guarding is involuntary spasm of the abdominal wall and it indicates peritonitis. This can be localized to one area or it may be generalized, involving the whole abdomen.
- **Bowel sounds.** Increased high-pitch tinkling bowel sounds indicate fluid obstruction; this occurs because of fluid movement within the large dilated bowel lumen. Absent bowel sounds suggest peritoneal involvement. In an obstructed patient, absent bowel sounds suggest strangulation, ischaemia or ileus. It is essential that the hernial orifices be examined if intestinal obstruction is suspected.

**Vaginal and rectal examination**

Vaginal examination can be very helpful, particularly in diagnosing gynaecological causes of an acute abdomen (e.g. a ruptured ectopic pregnancy). Rectal examination is less helpful as localized tenderness may be due to any cause; it may show blood on the finger stall.

**Sigmoidoscopy**

If diarrhoea is present, sigmoidoscopy is indicated to aid exclusion of infective, inflammatory and ischaemic causes of acute pain. A specimen of stool should be taken for stool culture for bacterial pathogens (e.g. *Campylobacter, Salmonella, Shigella*) when diarrhoea is present – stool should also be tested for *Clostridium difficile* toxin if antibiotic therapy or hospital precedes onset of diarrhoea and acute abdominal pain (see p. 131).

**Other observations**
- **Mouth.** The tongue is furred in some cases and a fetor is present.
- **Temperature.** Fever is more common in acute inflammatory processes.
- **Urine.** Examine for:
  - blood – suggests urinary tract infection or renal colic
  - glucose and ketones – ketoacidosis can present with acute pain
  - protein and white cells – to exclude acute pyelonephritis.
- **Think of medical causes (Table 6.30).**

**Investigations**
- **Blood count.** A raised white cell count occurs in inflammatory conditions.
- **Serum amylase.** High levels (more than five times normal) indicate acute pancreatitis. Raised levels below this can occur in any acute abdomen and should not be considered diagnostic of pancreatitis.
- **Serum electrolytes.** These are not particularly helpful for diagnosis but useful for general evaluation of the patient.
- **Pregnancy.** A urine dipstick is used with women of child-bearing age.
- **X-rays.** A chest X-ray is useful to detect air under the diaphragm owing to a perforation. Dilated loops of bowel or fluid levels are suggestive of obstruction (erect and supine abdominal X-ray).
- **Ultrasound.** This is useful in the diagnosis of acute cholangitis, cholecystitis and aortic aneurysm, and in expert hands is reliable in the diagnosis of acute appendicitis. Gynaecological and other pelvic causes of pain can be detected.

- **CT scan.** Spiral CT is the most accurate investigation in most acute emergencies. It should be used more often to avoid unnecessary laparotomies.
- **Laparoscopy.** This has gained increasing importance as a diagnostic tool prior to proceeding with surgery, particularly in men and women over the age of 50 years. In addition, therapeutic manoeuvres, such as appendicectomy, can be performed.

**Acute appendicitis**

This is the most common surgical emergency. It affects all age groups. Appendicitis should always be considered in the differential diagnosis if the appendix has not been removed.

Acute appendicitis mostly occurs when the lumen of the appendix becomes obstructed with a faecolith; however, in some cases there is only generalized acute inflammation. If the appendix is not removed at this stage, gangrene occurs with perforation, leading to a localized abscess or to generalized peritonitis.

**Clinical features and management**

Most patients present with abdominal pain; in many it starts vaguely in the centre of the abdomen, becoming localized to the right iliac fossa in the first few hours. Nausea, vomiting, anorexia and occasional diarrhoea can occur.

Examination of the abdomen usually reveals tenderness in the right iliac fossa, with guarding due to the localized peritonitis. There may be a tender mass in the right iliac fossa. Although raised white cell counts, ESR and CRP are helpful, other laboratory tests can be unhelpful. An ultrasound scan can detect an inflamed appendix and can also indicate an appendix mass or other localized lesion. CT is highly sensitive and specific, and reduces the incidence of removing the ‘normal’ appendix. With the use of these investigations the incidence of ‘normal’ appendix histology has fallen to 15–20%.

**Differential diagnosis**
- Non-specific mesenteric lymphadenitis – may mimic appendicitis.
- Acute terminal ileitis due to Crohn’s disease or *Yersinia* infection.
- Gynaecological causes.
- Inflamed Meckel’s diverticulum.
- Functional bowel disease.

**Treatment**

The appendix is removed by open surgery or laparoscopically. If an appendix mass is present, the patient is usually treated conservatively with intravenous fluids and antibiotics. The pain subsides over a few days and the mass usually disappears over a few weeks. Interval appendicectomy is recommended at a later date to prevent further acute episodes.

**Gynaecological causes**

*Ruptured ectopic pregnancy.* The fallopian tube is the commonest extraterine site of implantation. Delayed diagnosis is the major cause of morbidity. Most patients will present

</table>
with recurrent low abdominal pain associated with vaginal bleeding. Diagnosis is usually made with abdominal and transvaginal ultrasound. Most patients can be managed by laparoscopic salpingostomy or salpingectomy.

**Ovarian:**
- Rupture of ‘functional’ ovarian cysts in the middle of the cycle (Mittelschmerz).
- Torsion or rupture of ovarian cysts.

**Acute salpingitis.** Most cases are associated with sexually transmitted infection. Patients commonly present with bilateral low abdominal pain, a fever and vaginal discharge. In the Fitz-Hugh–Curtis syndrome the Chlamydia infection tracks up the right paracolic gutter to cause a perihepatitis. Patients can present with acute right hypochondrial pain, fever and mildly abnormal liver biochemistry.

**Acute peritonitis**

**Localized peritonitis**

There is virtually always some degree of localized peritonitis with all acute inflammatory conditions of the gastrointestinal tract (e.g. acute appendicitis, acute cholecystitis). Pain and tenderness are largely features of this localized peritonitis. The treatment is for the underlying disease.

**Generalized peritonitis**

This is a serious condition resulting from irritation of the peritoneum owing to infection (e.g. perforated appendix), or from chemical irritation due to leakage of intestinal contents (e.g. perforated ulcer). In the latter case, superadded infection gradually occurs; *E. coli* and *Bacteroides* are the most common organisms.

The peritoneal cavity becomes acutely inflamed, with production of an inflammatory exudate that spreads throughout the peritoneum, leading to intestinal dilatation and paralytic ileus.

**Clinical features and management**

In perforation, the onset is sudden with acute severe abdominal pain, followed by general collapse and shock. The patient may improve temporarily, only to become worse later as generalized toxoaemia occurs.

When the peritonitis is secondary to inflammatory disease, the onset is less rapid with the initial features being those of the underlying disease.

Investigations should always include an erect chest. X-ray is used to detect free air under the diaphragm, and a serum amylase to diagnose acute pancreatitis, which is treated conservatively. Imaging with ultrasound and/or CT should always be performed for diagnosis.

Peritonitis is treated surgically after adequate resuscitation with the re-establishment of a good urinary output. This includes insertion of a nasogastric tube, intravenous fluids and antibiotics. Surgery has a twofold objective:
- peritoneal lavage of the abdominal cavity
- specific treatment of the underlying condition.

**Complications**

Any delay in treatment of peritonitis produces more profound toxoaemia and septicaemia which may lead to development of multiorgan failure (see p. 909). Local abscess formation can occur and should be suspected if a patient continues to remain unwell postoperatively with a swinging fever, high white cell count and continuing pain. Abscesses are commonly pelvic or subphrenic and can be localized and drained using ultrasound and CT scanning techniques.

**Intestinal obstruction**

Most intestinal obstruction is due to a mechanical block. Sometimes the bowel does not function, leading to a paralytic ileus. This occurs temporarily after most abdominal operations and with peritonitis. Some causes of intestinal obstruction are shown in Table 6.31.

Obstruction of the bowel leads to bowel distension above the block, with increased secretion of fluid into the distended bowel. Bacterial contamination occurs in the distended stagnant bowel. In strangulation the blood supply is impeded, leading to gangrene, perforation and peritonitis unless urgent treatment of the condition is undertaken.

**Clinical features**

The patient complains of abdominal colic, vomiting and constipation without passage of wind. In upper gut obstruction the vomiting is profuse but in lower gut obstruction it may be absent.

Examination of the abdomen reveals distension with increased bowel sounds. Marked tenderness suggests strangulation, and urgent surgery is necessary. Examination of the hernial orifices and rectum must be performed. X-ray of the abdomen reveals distended loops of bowel proximal to the obstruction. Fluid levels are seen in small bowel obstruction on an erect film. In large bowel obstruction, the caecum and ascending colon are distended. An instant water-soluble gastrografin enema without air insufflation may help to demonstrate the site of the obstruction. CT can localize the lesion accurately and is the investigation of choice.

**Management**

Initial management is by resuscitation with intravenous fluids (mainly isotonic saline with potassium) and decompression. Many cases will settle on conservative management, but an increasing temperature, raised pulse rate, increasing pain and a rising white cell count require urgent scanning and possible exploratory laparotomy.

Laparotomy with removal of the obstruction will be necessary in some cases of small bowel obstruction. If the bowel is gangrenous owing to strangulation, gut resection will be required. A few patients (e.g. those with Crohn’s disease) may have recurrent episodes of incomplete intestinal obstruct-

</table>
tion that can be managed conservatively. In large bowel obstruction due to malignancy, colorectal stents are being used, followed by elective surgery. In critically ill patients, a defunctioning colostomy may be required. Volvulus of the sigmoid colon can be managed by the passage of a flexible sigmoidoscope or a rectal tube to un-kink the bowel, but recurrent volvulus may require sigmoid resection.

**Acute colonic pseudo-obstruction**

It is now recognized that a clinical picture mimicking mechanical obstruction may develop in patients who do not have a mechanical cause. In more than 80% of cases it complicates other clinical conditions, for example:

- intra-abdominal trauma, pelvic spinal and femoral fractures
- postoperatively (abdominal, pelvic, cardiothoracic, orthopaedic, neurological)
- intra-abdominal sepsis
- pneumonia
- metabolic (e.g. electrolyte disturbances, malnutrition, diabetes mellitus, Parkinson’s disease)
- drugs – opiates (particularly after orthopaedic surgery), antidepressants, antiparkinsonian drugs.

Patients present with rapid and progressive abdominal distension and pain. X-ray shows a gas-filled large bowel. Management is of the underlying problem (e.g. withdraw opiate analgesia) together with a trial of i.v. neostigmine therapy (Box 6.13). Patients should be monitored carefully and consideration should be given to surgery if the diameter of the caecum exceeds 14 cm.

**Small intestinal pseudo-obstruction** is a rare chronic condition that can occur in association with systemic sclerosis, systemic lupus erythematosus (SLE), Sjögren’s syndrome, thyroid disease, amyloidosis and paraneoplastic syndromes. Primary myopathic and neuropathic forms also exist, with the former sometimes being familial. There are other patients with clinical and manometric features of small intestinal pseudo-obstruction who have normal full-thickness biopsies of smooth muscle but α-actin deficiency in the inner circular layer of the smooth muscle. Myopathic forms can present with attacks of non-mechanical obstruction and/or functional small intestinal failure with dilated non-propulsive intestines and coexisting bacterial overgrowth. These patients are managed in specialist centres with facilities to manage home total parenteral nutrition (TPN). The other patients, including those with enteric neuropathies, often present with a long history of abdominal pain and other intractable midgut symptoms. Many have extraintestinal symptoms, and a multidisciplinary approach to management is required, including, in a number, access to facilities to provide needle catheter jejunostomy enteral feeding as well as home TPN.

### THE PERITONEUM

The peritoneal cavity is a closed sac lined by mesothelial cells, which produce surfactant that acts as a lubricant within the peritoneal cavity. The cavity contains less than 100 mL of serous fluid containing less than 30 g/L of protein.

The mesothelial cells lining the diaphragm have gaps that allow communication between the peritoneum and the diaphragmatic lymphatics. Approximately one-third of fluid drains through these lymphatics, the remainder through the parietal peritoneum. These mechanisms allow particulate matter to be removed rapidly from the peritoneal cavity.

Complement activation is an early defence mechanism followed rapidly by upregulation of the peritoneal mesothelial cells and migration of polymorphonuclear neutrophils and macrophages into the peritoneum.

Mast cells release potent mediators of inflammation and interact with T cells to generate an immune response.

The peritoneal-associated lymphoid tissue includes the omental milky spots, the lymphocytes within the peritoneal cavity and the draining lymph nodes. B cells with a unique CD5+ are common. This defence system plays a major role in localizing peritoneal infection. Some conditions that can affect the peritoneum are shown in Table 6.32.

**Peritonitis** can be acute or chronic, as seen in tuberculosis. Most cases of infective peritonitis are secondary to gastrointestinal disease, but it occurs occasionally without intra-abdominal sepsis in ascites due to liver disease. Very rarely, fungal and parasitic infections can also cause primary peritonitis (e.g. amebiasis, candidiasis). Peritonitis is discussed further on page 316.

The peritoneum can be involved by secondary malignant deposits, and the most common cause of ascites in a young to middle-aged woman is an ovarian carcinoma.

A **subphrenic abscess** is usually secondary to infection in the abdomen and is characterized by fever, malaise, pain in the right or left hypochondrium and shoulder-tip pain. An erect chest X-ray shows gas under the diaphragm, impaired movement of the diaphragm on screening and a pleural effusion. Ultrasound is usually diagnostic. Percutaneous catheter

**Box 6.13 Treatment of acute colonic pseudo-obstruction**

- Neostigmine 2.0 mg i.v. over 3–5 min in presence of doctor with ECG monitor
- 0.3–1 mg atropine if symptomatically bradycardic. Nurse the patient supine for 60 min
- Monitor abdominal circumference and the diameter of the caecum, ascending, transverse and descending colon on straight abdominal X-ray

---

**FURTHER READING**

drainage inserted under CT or ultrasound guidance and antibiotics is highly successful therapy.

Ascites is associated with all diseases of the peritoneum. The fluid that collects is an exudate with a high protein content. It is also seen in liver disease. The mechanism, causes and investigation of ascites are discussed on page 351.

Retroperitoneal fibrosis (periaortitis)

This is a rare condition in which there is a marked fibrosis over the posterior abdominal wall and retroperitoneum. It is described on p. 616.

Tuberculous peritonitis

This is the second most common form of abdominal TB. Three subgroups can be identified: wet, dry and fibrous.

- In patients with the wet type, ascitic fluid should be examined for protein concentration (>20 g/L) and tubercle bacilli (rarely found).
- In the dry form, patients present with subacute intestinal obstruction which is due to tuberculous small bowel adhesions.
- In the fibrous form, patients present with abdominal pain, distension and ill-defined irregular tender abdominal masses.

The diagnosis of peritoneal TB can be supported by findings on ultrasound or CT screening (mesenteric thickening and lymph node enlargement). A histological diagnosis is not always required before instituting treatment. In some patients careful laparoscopy (to avoid perforation) may have to be performed, and rarely laparotomy.

Treatment

Drug treatment is similar to that for pulmonary TB (see p. 866) and should be supervised by chest physicians who have experience in dealing with contacts.

In many countries alcohol is the major cause of liver disease, followed by hepatitis C virus infection. Hepatitis B virus is still a significant factor but widespread vaccination will reduce its prevalence. Health education and the improvement in public health should help to stop the spread of viral infections.

**THE LIVER**

**STRUCTURE OF THE LIVER AND BILIARY SYSTEM**

**The liver**

The liver is the largest internal organ in the body (1.2–1.5 kg) and is situated in the right hypochondrium. Functionally, it is divided into right and left lobes by the middle hepatic vein. The right lobe is larger and contains the caudate and quadrate lobes. The liver is further subdivided into a total of eight segments (Fig. 7.1) by divisions of the right, middle and left hepatic veins. Each segment receives its own portal pedicle, permitting individual segment resection at surgery.

The blood supply to the liver constitutes 25% of the resting cardiac output and is via two main vessels:
The hepatic artery, which is a branch of the coeliac axis, supplies 25% of the total blood flow. Autoregulation of blood flow by the hepatic artery ensures a constant total liver blood flow.

The portal vein drains most of the gastrointestinal tract and the spleen. It supplies 75% of the blood flow. The normal portal pressure is 5–8 mmHg; flow increases after meals.

Both vessels enter the liver via the hilum (porta hepatitis). The blood from these vessels is distributed to the segments and passes into the sinusoids via the portal tracts.

Blood leaves the sinusoids, entering branches of the hepatic vein which join into three main branches before entering the inferior vena cava.

The caudate lobe is an autonomous segment as it receives an independent blood supply from the portal vein and hepatic artery, and its hepatic vein drains directly into the inferior vena cava.

Lymph, formed mainly in the perisinusoidal space, is collected in lymphatics which are present in the portal tracts. These small lymphatics enter larger vessels which eventually drain into the hepatic ducts.

The acinus is the functional unit of the liver. This consists of parenchyma supplied by the smallest portal tracts containing portal vein radicles, hepatic arterioles and bile ductules (Fig. 7.2). The hepatocytes near this triad (zone 1) are well supplied with oxygenated blood and are more resistant to damage than the cells nearer the terminal hepatic (central) veins (zone 3).

The sinusoids lack a basement membrane and are loosely surrounded by specialist fenestrated endothelial cells and Kupffer cells (phagocytic cells). Sinusoids are separated by plates of liver cells (hepatocytes). The subendothelial space that lies between the sinusoids and hepatocytes is the space of Disse, which contains a matrix of basement membrane constituents and stellate cells. (See Fig. 7.22.)

Stellate cells store retinoids in their resting state and contain the intermediate filament, desmin. When activated (to myofibroblasts) they are contractile and probably regulate sinusoidal blood flow. Endothelin and nitric oxide play a major role in modulating stellate cell contractility. Stellate cells, after activation, produce extracellular matrix components, including collagen (see p. 345).

**The biliary system**

Bile canaliculi form a network between the hepatocytes. These join to form thin bile ductules near the portal tract, which in turn enter the bile ducts in the portal tracts. These then combine to form the right and left hepatic ducts that leave each liver lobe. The hepatic ducts join at the porta hepatitis to form the common hepatic duct. The cystic duct connects the gall bladder to the lower end of the common hepatic duct. The gall bladder lies under the right lobe of the liver and stores and concentrates hepatic bile; it has a capacity of approximately 50 mL. The common bile duct is formed by the combination of the cystic and hepatic ducts and is approximately 8 mm in diameter, narrowing at its distal end to pass into the duodenum. The common bile duct and pancreatic duct open into the second part of the duodenum through a common channel at the ampulla of Vater. The lower end of the common bile duct contains the muscular sphincter of Oddi, which contracts rhythmically and prevents bile from entering the duodenum in the fasting state.

**FUNCTIONS OF THE LIVER**

**Protein metabolism** (see also p. 209)

**Synthesis and storage**

The liver is the principal site of synthesis of all circulating proteins apart from γ-globulins, which are produced in the reticuloendothelial system. The liver receives amino acids...
from the intestine and muscles and, by controlling the rate of gluconeogenesis and transamination, regulates levels in the plasma. Plasma contains 60–80 g/L of protein, mainly in the form of albumin, globulin and fibrinogen.

Albumin has a half-life of 16–24 days, and 10–12 g are synthesized daily. Its main functions are first to maintain the intravascular oncotic (colloid osmotic) pressure, and second to transport water-insoluble substances such as bilirubin, hormones, fatty acids and drugs. Reduced synthesis of albumin over prolonged periods produces hypoalbuminaemia and is seen in chronic liver disease and malnutrition. Hypoalbuminaemia is also found in hypercatabolic states (e.g. trauma with sepsis) and in diseases where there is an excessive loss (e.g. nephrotic syndrome, protein-losing enteropathy).

Transport or carrier proteins such as transferrin and caeruloplasmin, acute-phase and other proteins (e.g. α1-antitrypsin and α-fetoprotein) are also produced in the liver.

The liver also synthesizes all factors involved in coagulation (apart from one-third of factor VIII) – that is, fibrinogen, prothrombin, factors V, VII, IX, X and XII, proteins C and S and antithrombin (see Ch. 8) as well as components of the complement system. The liver stores large amounts of vitamins, particularly A, D and B12, and lesser amounts of others (vitamin K and folate), and also minerals – iron in ferritin and haemosiderin and copper.

**Degradation (nitrogen excretion)**

Amino acids are degraded by transamination and oxidative deamination to produce ammonia, which is then converted to urea and excreted by the kidneys. This is a major pathway for the elimination of nitrogenous waste. Failure of this process occurs in severe liver disease.

**Carbohydrate metabolism**

Glucose homeostasis and the maintenance of the blood sugar is a major function of the liver. It stores approximately 80 g of glycogen. In the immediate fasting state, blood glucose is maintained either by glucose released from the breakdown of glycogen (glycogenolysis) or by newly synthesized glucose (gluconeogenesis). Sources for gluconeogenesis are lactate, pyruvate, amino acids from muscles (mainly alanine and glutamine) and glycerol from lipolysis of fat stores. In prolonged starvation, ketone bodies and fatty acids are used as alternative sources of fuel as the body tissues adapt to a lower glucose requirement (see Ch. 5).

**Lipid metabolism**

Fats are insoluble in water and are transported in the plasma as protein–lipid complexes (lipoproteins). These are discussed in detail on page 1061.

The liver has a major role in the metabolism of lipoproteins. It synthesizes very-low-density lipoproteins (VLDLs) and high-density lipoproteins (HDLs). HDLs are the substrate for lecithin–cholesterol acyltransferase (LCAT), which catalyses the conversion of free cholesterol to cholesterol ester (see below). Hepatic lipase removes triglyceride from intermediate-density lipoproteins (IDLs) to produce low-density lipoproteins (LDLs) which are degraded by the liver after uptake by specific cell-surface receptors (see Fig. 19.19).

Triglycerides are mainly of dietary origin but are also formed in the liver from circulating free fatty acids (FFAs) and glycerol and incorporated into VLDLs. Oxidation or de novo synthesis of FFA occurs in the liver, depending on the availability of dietary fat.

Cholesterol may be of dietary origin but most is synthesized from acetyl-CoA mainly in the liver, intestine, adrenal cortex and skin. It occurs either as free cholesterol or is esterified with fatty acids; this reaction is catalysed by LCAT. This enzyme is reduced in severe liver disease, increasing the ratio of free cholesterol to ester, which alters membrane structures. One result of this is the red cell abnormalities (e.g. target cells) seen in chronic liver disease. Phospholipids (e.g. lecithin) are synthesized in the liver. The complex interrelationships between protein, carbohydrate and fat metabolism are shown in Figure 7.3.

**Formation of bile**

**Bile secretion and bile acid metabolism**

Bile consists of water, electrolytes, bile acids, cholesterol, phospholipids and conjugated bilirubin. Two processes are involved in bile secretion across the canalicular membrane of the hepatocyte – a bile salt-dependent and a bile salt-independent process – each contributing about 230 mL per day. The remainder of the bile (about 150 mL daily) is produced by the epithelial cells of the bile ductules.

Bile formation requires firstly the uptake of bile acids and other organic and inorganic ions across the basolateral (sinusoidal) membranes by multiple transport proteins (sodium taurocholate co-transporting polypeptide (NTCP) and sodium independent organic anion transporting polypeptide 2 (OATP2), Fig. 7.4). This process is driven by Na’/K’-ATPase in the basolateral membrane. Intracellular transport across the hepatocyte is partly through microtubules and partly by cytosol transport proteins.

Bile acids are also synthesized in hepatocytes from cholesterol. The rate-limiting step in their production is that catalysed mainly by cholesterol-7α-hydroxylase and the P450 enzymes (CYP7A1 and CYP8B1).
The bile acid receptor, farnesol X, blocks bile acid formation from cholesterol and also regulates the transport proteins (NTCP, OATP2) that increase bile acid uptake by the liver. The canalicular membrane contains additional transporters, mainly ATPase-dependent, which carry molecules into the biliary canaliculi against a concentration gradient. These canalicular multispecific organic anion transporters (multidrug-resistance protein 2 (MRP2)), multidrug resistance protein (MDR3) and the bile salt excretry pump (BSEP) mediate transport of a broad range of compounds including bilirubin diglucuronide, glucuronidated and sulphated bile acids and other organic anions. Na⁺ and water follow the passage of bile salts into the biliary canaliculus by diffusion across the tight junction between hepatocytes (a bile salt-dependent process). In the bile salt-independent process water flow is due to other osmotically active solutes such as glutathione and bicarbonate.

Secretion of a bicarbonate-rich solution is stimulated mainly by secretin and is inhibited by somatostatin. In this process several membrane proteins are involved, including the Cl⁻/HCO₃⁻ exchanger and the cystic fibrosis transmembrane conductance regulator which controls Cl⁻ secretion, as well as water channels (aquaporins) in cholangiocyte membranes.

The bile acids are excreted into the bile and then pass via the common bile duct into the duodenum. The two primary bile acids – cholic acid and chenodeoxycholic acid (Fig. 7.4) – are conjugated with glycine or taurine (in a ratio of 3:1 in humans) and this process increases their solubility. Intestinal bacteria convert these acids into secondary bile acids, deoxycholic and lithocholic acid. Figure 7.5 shows the enterohepatic circulation of bile acids.

The average total bile flow is approximately 600 mL per day. In the faeces the bile acid fraction is approximately 600 mL per day. In the faeces the bile acid fraction is approximately 600 mL per day. The mucosa of the gall bladder absorbs 80–90% of the water and electrolytes, but is impermeable to bile acids and cholesterol. Following a meal, cholecystokinin is secreted by the I cells of the duodenal mucosa and stimulates contraction of the gall bladder and relaxation of the sphincter of Oddi, so that bile enters the duodenum. An adequate bile flow is dependent on bile salts being returned to the liver by the enterohepatic circulation.

Bile acids act as detergents; their main function is lipid solubilization. Bile acid molecules have both a hydrophilic and a hydrophobic end. In aqueous solutions they aggregate to form micelles, with their hydrophobic (lipid-soluble) ends in the centre. Micelles are expanded by cholesterol and phospholipids (mainly lecithin), forming mixed micelles.
Hormone and drug inactivation

The liver catabolizes hormones such as insulin, glucagon, oestrogens, growth hormone, glucocorticoids and parathyroid hormone. It is also the prime target organ for many hormones (e.g. insulin). It is the major site for the metabolism of drugs (see p. 365) and alcohol (see p. 238). Fat-soluble drugs are converted to water-soluble substances that facilitate their excretion in the bile or urine. Cholecalciferol is converted to 25-hydroxycholecalciferol.

Immunological function

The reticuloendothelial system of the liver contains many immunologically active cells. The liver acts as a ‘sieve’ for the bacterial and other antigens carried to it via the portal tract from the gastrointestinal tract. These antigens are phagocytosed and degraded by Kupffer cells, which are macrophages attached to the endothelium. Kupffer cells have specific membrane receptors for ligands and are activated by several factors, such as infection. They secrete interleukins, tumour necrosis factor (TNF), collagenase and lysosomal hydrolases. Antigens are degraded without the production of antibody, as there is very little lymphoid tissue. They are thus prevented from reaching other antibody-producing sites in the body and thereby prevent generalized adverse immunological reactions. The reticuloendothelial system plays a role in tissue repair, T and B lymphocyte interaction, and cytotoxic activity in disease processes. Following stimulation by, for example, endotoxin, the Kupffer cells release IL-6, IL-8 and TNF-α. These cytokines stimulate the sinusoidal cells, stellate cells and natural killer cells to release proinflammatory cytokines. The stimulated hepatocytes themselves express adhesion molecules and release IL-8, which is a potent neutrophil chemoattractant. Homing of mucosal lymphocytes (enterohepatic circulation) has been proposed. These exogenous leucocytes again release more cytokines – all damaging the function of the hepatocyte, including hepatocellular bile formation which leads to cholestasis. Cytokines also stimulate hepatic apoptosis.

Investigations

Investigative tests can be divided into:

- **Blood tests**
  - (a) Liver ‘function’ tests:
    - (i) serum albumin and bilirubin
    - (ii) prothrombin time
  - (b) Liver biochemistry:
    - (i) serum aspartate and alanine aminotransferases – reflecting hepatocellular damage
    - (ii) serum alkaline phosphatase, γ-glutamyl transpeptidase – reflecting cholestasis
    - (iii) total protein
  - (c) Viral markers
  - (d) Additional blood investigations; haematological, biochemical, immunological, markers of liver fibrosis and genetic analysis.

- **Urine tests** – for bilirubin and urobilinogen
- **Imaging techniques** – to define gross anatomy
- **Liver biopsy** – for histology.
Most routine ‘liver function tests’ sent to the laboratory will be processed by an automated multichannel analyser to produce serum levels of bilirubin, aminotransferases, alkaline phosphatase, \( \gamma \)-glutamyl transpeptidase (\( \gamma \)-GT) and total proteins. These routine tests are markers of liver damage, but not actual tests of ‘function’ per se. Subsequent investigations are often based on these tests.

**Blood tests**

Useful blood tests for certain liver diseases are shown in Table 7.1.

**Liver function tests**

**Serum albumin**

This is a marker of synthetic function and is a valuable guide to the severity of chronic liver disease. A falling serum albumin in liver disease is a bad prognostic sign. In acute liver disease initial albumin levels may be normal.

**Prothrombin time (PT)**

This is also a marker of synthetic function. Because of its short half-life, it is a sensitive indicator of both acute and chronic liver disease. Vitamin K deficiency should be excluded as the cause of a prolonged PT by giving an intravenous bolus (10 mg) of vitamin K. Vitamin K deficiency commonly occurs in biliary obstruction, as the low intestinal concentration of bile salts results in poor absorption of vitamin K.

Prothrombin times vary in different laboratories depending upon the thromboplastin used in the assay. The International Normalized Ratio (INR) is therefore used in many countries (see p. 434) but does not eliminate variation across laboratories.

**Liver biochemistry**

**Bilirubin**

In the serum, bilirubin is normally almost all unconjugated. In liver disease, increased serum bilirubin is usually accompanied by other abnormalities in liver biochemistry. Determination of whether the bilirubin is conjugated or unconjugated is only necessary in congenital disorders of bilirubin metabolism (see below) or to exclude haemolysis.

**Aminotransferases**

These enzymes (often referred to as transaminases) are present in hepatocytes and leak into the blood with liver cell damage. Two enzymes are measured:

- **Aspartate aminotransferase** (AST) is primarily a mitochondrial enzyme (80%; 20% in cytoplasm) and is also present in heart, muscle, kidney and brain. High levels are seen in hepatic necrosis, myocardial infarction, muscle injury and congestive cardiac failure.
- **Alanine aminotransferase** (ALT) is a cytosol enzyme, more specific to the liver so that a rise only occurs with liver disease.

**Alkaline phosphatase (ALP)**

This is present in the canalicular and sinusoidal membranes of the liver, but is also present in many other tissues, such as bone, intestine and placenta. If necessary, its origin can be determined by electrophoretic separation of isoenzymes or bone-specific monoclonal antibodies. Alternatively, if there is also an abnormality of, for example, the \( \gamma \)-GT, the ALP can be presumed to come from the liver.

Serum ALP is raised in cholestasis from any cause, whether intrahepatic or extrahepatic disease. The synthesis of ALP is increased and this increase is detected in the blood. In cholestatic jaundice, levels may be four to six times the normal limit. Raised levels may also occur in conditions with infiltration of the liver (e.g. metastases) and in cirrhosis, frequently in the absence of jaundice. The highest serum levels due to liver disease (> 1000 IU/L) are seen with hepatic metastases and primary biliary cirrhosis.

\( \gamma \)-Glutamyl transpeptidase

This is a microsomal enzyme that is present in many tissues as well as the liver. Its activity can be induced by such drugs as phenytoin and by alcohol. If the ALP is normal, a raised serum \( \gamma \)-GT is a good guide to alcohol intake and can be used as a screening test (see p. 1212). Mild elevation of the \( \gamma \)-GT is common even with a small alcohol consumption and does not necessarily indicate liver disease if the other liver biochemical tests are normal. In cholestasis the \( \gamma \)-GT rises in parallel with the ALP as it has a similar pathway of excretion. This is also true of the 5-nucleotidase, another microsomal enzyme that can be measured in blood.

**Total proteins**

This measurement, in itself, is of little value. Serum albumin is discussed above. The globulin fraction consists of many proteins that can be separated on electrophoresis. A raised globulin fraction, seen in liver disease, is usually due to increased circulating immunoglobulins and is polyclonal (see below).
Viral markers
Viruses are a major cause of liver disease. Virological studies have a key role in diagnosis; markers are available for most common viruses that cause hepatitis.

Additional blood investigations
Haematological
A full blood count is always performed. Anaemia may be present. The red cells are often macrocytic and can have abnormal shapes – target cells and spur cells – owing to membrane abnormalities. Vitamin $B_12$ levels are normal or high, while folate levels are often low owing to poor dietary intake. Other changes are caused by the following:

- Bleeding produces a hypochromic, microcytic picture.
- Alcohol causes macrocytosis, sometimes with leucopenia and thrombocytopenia.
- Hypersplenism results in pancytopenia.
- Cholestasis can often produce abnormal-shaped cells and also deficiency of vitamin K.
- Haemolysis accompanies acute liver failure and jaundice.
- Aplastic anaemia is present in up to 2% of patients with acute viral hepatitis.
- A raised serum ferritin with transferrin saturation (>60%) is seen in hereditary haemochromatosis.

Biochemical
- $a_1$-Antitrypsin. A deficiency of this enzyme can produce cirrhosis.
- $a_2$-Fetoprotein. This is normally produced by the fetal liver. Its reappearance in increasing and high concentrations in the adult indicates hepatocellular carcinoma. Increased concentrations in pregnancy in the blood and amniotic fluid suggest neural tube defects of the fetus. Blood levels are also slightly raised with regenerative liver tissue in patients with hepatitis, chronic liver disease and also in teratomas.
- Serum and urinary copper and serum caeruloplasmin – for Wilson’s disease (see p. 357).

Immunological tests
Serum immunoglobulins
Increased $\gamma$-globulins are thought to be due to reduced phagocytosis by sinusoidal and Kupffer cells of the antigens absorbed from the gut. These antigens then stimulate antibody production in the spleen, lymph nodes and lymphoid and plasma cell infiltrate in the portal tracts. In primary biliary cirrhosis, the predominant serum immunoglobulin that is raised is IgM, while in autoimmune hepatitis it is IgG.

Serum autoantibodies
- Anti-mitochondrial antibody (AMA) is found in the serum in over 95% of patients with primary biliary cirrhosis (p. 355). Many different AMA subtypes have been described, depending on their antigen specificity. AMA is demonstrated by an immunofluorescent technique and is neither organ- nor species-specific. Some subtypes are occasionally found in autoimmune hepatitis and other autoimmune diseases.
- Nucleic, smooth muscle (actin), liver/kidney microsomal antibodies can be found in the serum in high titre in patients with autoimmune hepatitis. These antibodies can be found in the serum in other autoimmune conditions and other liver diseases.
- Anti-nuclear cytoplasmic antibodies (ANCA) are present in primary sclerosing cholangitis.

Markers of liver fibrosis
Fibrosis plays a key role in the outcome of certain chronic liver diseases, particularly non-alcoholic fatty liver disease (NAFLD) and chronic hepatitis C disease. Blood tests are being used to decrease the reliance on liver biopsy as the definitive way of detecting fibrosis.

- Fibrotest/fibrosure tests measure $\alpha_1$-macroglobulin, $\alpha_2$-haptoglobin, $\gamma$-globulin, apoprotein A1, $\gamma$-GT and total bilirubin. These results are formulated to determine a fibrosis index. The index is sensitive and specific (>90%) for the absence of fibrosis, and has 80% sensitivity and specificity for severe fibrosis.

- Markers of matrix deposition include procollagen I and III peptide and Type IV collagen. Markers of matrix degradation, e.g. matrix metalloproteinase (MMP) 2, 3, 9, and tissue inhibitors of metalloproteinases (TIMPS), e.g. TIMP1 and 2 are also being used as markers of fibrosis.

Genetic analysis
These tests are performed routinely for haemochromatosis ($HFE$ gene) and $\alpha_1$-antitrypsin deficiency. Markers are also available for Wilson’s disease (see p. 357).

Urine tests
Dipstick tests are available for bilirubin and urobilinogen. Bilirubinuria is due to the presence of conjugated (soluble) bilirubin. It is found in the jaundiced patient with hepatobiliary disease; its absence implies that the jaundice is due to increased unconjugated bilirubin. Urobilinogen in the urine is, in practice, of little value but suggests haemolysis or hepatic dysfunction of any cause.

Imaging techniques
Ultrasound examination
This is a non-invasive, safe and relatively cheap technique. It involves the analysis of the reflected ultrasound beam detected by a probe moved across the abdomen. The normal liver appears as a relatively homogeneous structure. The gall bladder, common bile duct, pancreas, portal vein and other structures in the abdomen can be visualized. Abdominal ultrasound is useful in:

- a jaundiced patient (p. 329)
- hepatomegaly/splenomegaly
- the detection of gallstones (Fig. 7.6)
- focal liver disease – lesions >1 cm
- general parenchymal liver disease
- assessing portal and hepatic vein patency
- lymph node enlargement.

Other abdominal masses can be delineated and biopsies obtained under ultrasonic guidance. Colour Doppler ultrasound will demonstrate the vascularity of a lesion and the direction of blood flow in the portal and hepatic veins. Ultrasound contrast agents, most of which are based on the pro-
Using vibration intravenous and imaging. A through Stiffness be detected ultrasound with multiple nodules, which ultrasound, characterization small, correlates of liver, low in amplitude as aspiration of is after immediately allows potent-
classical contrast-enhanced spiral CT. more amplitude can be increased within the liver, the velocity of which correlates directly with hepatic stiffness. Stiffness (measured in kPa) increases with increasing liver fibrosis (sensitivity and specificity 80–95% compared to liver biopsy). It cannot be used in the presence of ascites and morbid obesity.

**Endoscopic ultrasound (EUS)**

In this technique, a small high-frequency ultrasound probe is mounted on the tip of an endoscope and placed by direct vision into the duodenum. The close proximity of the probe to the pancreas and biliary tree permits high-resolution ultrasound imaging. It allows accurate staging of small, potentially operable, pancreatic tumours and offers a less invasive method for bile duct imaging. It has a high accuracy in detection of small neuroendocrine tumours of the pancreas. EUS-guided fine-needle aspiration of tumours provides cytological/histological tissue for confirmation of malignancy. EUS is also used to place transmural tubes to drain pancreatic and peripancreatic fluid collections.

**Computed tomography (CT) examination**

This technique is complementary to ultrasound, which is usually performed first. It provides excellent visualization of the liver, pancreas, spleen, lymph nodes and lesions in the porta hepatis but involves a high radiation dose. CT allows assessment of the size, shape and density of the liver and can characterize focal lesions in terms of their vascularity. CT is more sensitive in detecting calcification than plain X-rays. Ultrasound is usually more valuable for lesions in the bile duct and gall bladder. CT has advantages in obese subjects.

Spiral CT involves rapid acquisition of a volume of data during or immediately after intravenous contrast injection using multiple detectors. Data can thus be acquired in both arterial and portal venous phases of enhancement, enabling more precise characterization of a lesion and its vascular supply (Fig. 7.7). Retrospective analysis of data allows mul-

---

**Fig. 7.6** Gall bladder ultrasound with multiple echogenic gallstones causing well-defined acoustic shadowing. 1, gall bladder; 2, gallstones; 3, echogenic shadow.

**Fig. 7.7** Use of contrast-enhanced spiral CT. There is an irregular mass (arrow) in the posterior aspect of the right lobe of the liver which is only well seen on the early arterial phase enhanced scan (b).
Magnetic resonance imaging (MRI)
(see also p. 1120)
MRI produces cross-sectional images in any plane within the body and does not involve radiation. Diffuse liver disease alters the T1 and T2 characteristics, and MRI is probably the most sensitive investigation of focal liver disease. Other fat-suppression modes such as STIR allow good differentiation between haemangiomas and other lesions. Contrast agents such as intravenous gadolinium allow further characterization of lesions, are suitable for those with iodine allergy, and provide angiography and venography of the splanchic circulation. This has superseded direct arteriography.

Magnetic resonance cholangiopancreatography (MRCP)
This technique involves the manipulation of a volume of data acquired by MRI. A heavily T2-weighted sequence enhances visualization of the ‘water-filled’ bile ducts and pancreatic ducts to produce high-quality images of ductal anatomy. This non-invasive technique is replacing diagnostic (but not therapeutic) ERCP (see below).

Plain X-rays of the abdomen
These are rarely requested but may show:

- gallstones – 10% contain enough calcium to be seen
- air in the biliary tree owing to its recent instrumentation, surgery or to a fistula between the intestine and the gall bladder
- pancreatic calcification
- rarely, calcification of the gall bladder (porcelain gall bladder).

Radionuclide imaging – scintiscanning
In a technetium-99m (99mTc) colloid scan, the colloid is injected intravenously to be taken up by the reticuloendothelial cells of the liver and spleen. In chronic liver disease there is poor uptake in the liver and most of the colloid is taken up in the spleen and bone marrow. Ultrasound has largely replaced this technique.

In a 99mTc-IODIDA scan, technetium-labelled iododiethyl IODA is taken up by the hepatocytes and excreted rapidly into the biliary system. Its main uses are in the diagnosis of:

- acute cholecystitis
- jaundice due to either biliary atresia or hepatitis in the neonatal period.

Endoscopy
Upper GI endoscopy is used for the diagnosis and treatment of varices, for the detection of portal hypertensive gastropathy, and for associated lesions such as peptic ulcers. Colonoscopy may show portal hypertensive colopathy.

Endoscopic retrograde cholangiopancreatography (ERCP)
This technique is used to outline the biliary and pancreatic ducts. It involves the passage of an endoscope into the second part of the duodenum and cannulation of the ampulla. Contrast is injected into both systems and the patient is screened radiologically. Contrast medium with a low iodine content of 1.5 mg/mL is used for the common bile duct so that gallstones are not obscured; a higher iodine content of 2.8 mg/mL is used for the pancreatic duct. In addition, other diagnostic and therapeutic procedures can be carried out:

- Common bile duct stones can be removed after a diathermy cut to the sphincter has been performed to facilitate their withdrawal. Sphincterotomy has a serious morbidity rate of 3–5%: acute pancreatitis is the commonest, severe haemorrhage is rare. There is an overall mortality of 0.4%.
- The biliary system can be drained by passing a tube (stent) through an obstruction, or placement of a nasobiliary drain.
- Brachytherapy can be administered after placement at ERCP for therapy of cholangiocarcinoma.

The complication rate in diagnostic ERCP is 2–3%.

A raised serum amylase is often seen and pancreatitis is the most common complication. Cholangitis with or without septicaemia is also seen, and broad-spectrum antibiotics (e.g. 500 mg ciprofloxacin ×2) should be given prophylactically to all patients with suspected biliary obstruction, or a history of cholangitis.

Percutaneous transhepatic cholangiography (PTC)
Under a local anaesthetic, a fine flexible needle is passed into the liver. Contrast is injected slowly until a biliary radicle is identified and then further contrast is injected to outline the whole of the biliary tree. In patients with dilated ducts, the success rate is near 100%. ERCP is the preferred first investigation because therapy (e.g. stone removal) can be undertaken at the same time.

In difficult cases the two techniques are sometimes combined, PTC showing the biliary anatomy above the obstruction, with ERCP showing the more distal anatomy. If an obstruction in the bile ducts is seen, a bypass stent can sometimes be inserted, draining either externally or, for long-term use, internally. Contraindications are as for liver biopsy (see below). The main complications are bleeding and cholangitis with septicaemia, and prophylactic antibiotics should be given as for ERCP.

Angiography
This is performed by selective catheterization of the coeliac axis and hepatic artery. It detects the abnormal vasculature of hepatic tumours, but spiral CT and magnetic resonance angiography (MRA) have replaced this in many cases. The portal vein can be demonstrated with increased definition using subtraction techniques, and splenoportography (by direct splenic puncture) is rarely performed. In digital vascular imaging (DVI), contrast given intravenously or intra-arterially can be detected in the portal system using computerized subtraction analysis. Hepatic venous cannulation allows abnormal hepatic veins to be diagnosed in patients with Budd–Chiari syndrome and also serves as an indirect measurement of portal pressure. There is a 1:1 relationship of occluded (by balloon) hepatic venous pressure with portal pressure in patients with alcoholic or viral-related cirrhosis. The height of portal pressure has been shown to have prognostic value for survival and a reduced portal...
pressure 20% from baseline values has been associated with protection from rebleeding. Retrograde CO₂ portography is used when there is doubt about portal vein patency and can be combined with transjugular biopsy and hepatic venous pressure measurement.

**Liver biopsy** (see Practical Box 7.1)

Histological examination of the liver is valuable in the differential diagnosis of diffuse or localized parenchymal disease. Liver biopsy can be performed on a day-case or overnight-stay basis. The indications and contraindications are shown in Table 7.2. The mortality rate is less than 0.02% when performed by experienced operators.

---

**Practical Box 7.1 Needle biopsy of the liver**

This should be performed only by experienced doctors and with sterile precautions. Patient consent must be obtained following explanation of the procedure.

- The patient’s coagulation status (prothrombin time, platelets) is checked.
- The patient’s blood group is checked and serum saved for crossmatching.
- The patient lies on his back at the edge of the couch.
- The liver margins are delineated using percussion. Alternatively ultrasound examination can be used to confirm liver margins and position of the gall bladder.
- Local anaesthetic is injected at the point of maximum dullness in the mid-axillary line through the intercostal space during expiration. Anaesthetic (1% lidocaine, approximately 5 ml) should be injected down to the liver capsule.
- A tiny cut is made in the skin with a scalpel blade.
- A special needle (Menghini, Trucut or Surecut) is used to obtain the biopsy whilst the patient holds his breath in expiration.
- The biopsy is laid on filter paper and placed in 10% formalin. If a culture of the biopsy is required it should be placed in a sterile pot.
- The patient should be observed, with pulse and blood pressure measurements taken regularly for at least 6 h.

**Liver biopsy** guided by ultrasound or CT is also performed particularly when specific lesions need to be biopsied. Laparoscopy with guided liver biopsy is performed through a small incision in the abdominal wall under local anaesthesia (general anaesthesia is preferred in some centres). A transjugular approach is used when liver histology is essential for management but coagulation abnormalities or ascites prevent the percutaneous approach.

Most complications of liver biopsy occur within 24 hours (usually in the first 2 hours). They are often minor and include abdominal or shoulder pain which settles with analgesics. Minor intraperitoneal bleeding can occur, but this settles spontaneously. Rare complications include major intraperitoneal bleeding, haemothorax and pleurisy, biliary peritonitis, haemobilia and transient septicaemia. Haemobilia produces biliary colic, jaundice and melaena within 3 days of the biopsy.

---

**SYMPTOMS OF LIVER DISEASE**

**Acute liver disease**

This may be asymptomatic and anicteric. Symptomatic disease, which is often viral, produces generalized symptoms of malaise, anorexia and fever. Jaundice may appear as the illness progresses.

**Chronic liver disease**

Patients may be asymptomatic or complain of non-specific symptoms, particularly fatigue. Specific symptoms include:

- right hypochondrial pain due to liver distension
- abdominal distension due to ascites
- ankle swelling due to fluid retention
- haematemesis and melaena from gastrointestinal haemorrhage
- pruritus due to cholestasis – this is often an early symptom of primary biliary cirrhosis
- breast swelling (gynaecomastia), loss of libido and amenorrhoea due to endocrine dysfunction
- confusion and drowsiness due to neuropsychiatric complications (portosystemic encephalopathy).

---

**SIGNS OF LIVER DISEASE**

**Acute liver disease**

There may be few signs apart from jaundice and an enlarged liver. Jaundice is a yellow coloration of the skin and mucous membranes and is best seen in the conjunctiva and sclerae. In the cholestatic phase of the illness, pale stools and dark urine are present. Spider naevi and liver palms usually indicate chronic disease but they can occur in severe acute disease.

**Chronic liver disease**

The physical signs are shown in Figure 7.8. However, it is possible for the physical examination to be normal in patients with advanced chronic liver disease.

**The skin**

The chest and upper body may show spider naevi. These are telangiectases that consist of a central arteriole with radiating...
Jaundice

Jaundice (icterus) is detectable clinically when the serum bilirubin is greater than 50 µmol/L (3 mg/dL). The usual division of jaundice into prehepatic, hepatocellular and obstructive (cholestatic) is an oversimplification as in hepatocellular jaundice there is invariably cholestasis, and the clinical problem is whether the cholestasis is intrahepatic or extrahepatic. Jaundice will therefore be considered under the following headings:

- **Haemolytic jaundice** – increased bilirubin load for the liver cells
- **Congenital hyperbilirubinaemias** – defects in conjugation
- **Cholestatic jaundice**, including hepatocellular (parenchymal) liver disease and large duct obstruction.

### Haemolytic jaundice

The increased breakdown of red cells (see p. 403) leads to an increase in production of bilirubin. The resulting jaundice is usually mild (serum bilirubin of 68–102 µmol/L or 4–6 mg/dL) as normal liver function can easily handle the increased bilirubin derived from excess haemolysis. Unconjugated bilirubin is not water-soluble and therefore will not pass into the urine; hence the term ‘acholuric jaundice’. Urinary urobilinogen is increased.

The causes of haemolytic jaundice are those of haemolytic anaemia (p. 405). The clinical features depend on the cause; anaemia, jaundice, splenomegaly, gallstones and leg ulcers may be seen.

Investigations show features of haemolysis (p. 403). The level of unconjugated bilirubin is raised but the serum ALP, transferases and albumin are normal. Serum haptoglobulins are low. The differential diagnosis is from other forms of jaundice.

### Congenital hyperbilirubinaemias (non-haemolytic)

#### Unconjugated

**Gilbert’s syndrome**

This is the most common familial hyperbilirubinaemia and affects 2–7% of the population. It is asymptomatic and is usually detected as an incidental finding of a slightly raised bilirubin (17–102 µmol/L or 1–6 mg/dL) on a routine check. All the other liver biochemistry is normal and no signs of liver disease are seen. There is a family history of jaundice in 5–15% of patients. Hepatic glucuronidation is approximately 30% of normal, resulting in an increased proportion of bilirubin monoglucuronide in bile. Most patients have reduced levels of UDP-glucuronosyl transferase (UGT-1) activity, the enzyme that conjugates bilirubin with glucuronic acid. Mutations occur in the gene (HUG-Br1) encoding this enzyme, with an expanded nucleotide repeat consisting of two extra bases in the upstream S’ promoter element. This abnormality appears to be necessary for the syndrome, but is not in itself sufficient for the phenotypic expression of the syndrome.

The major importance of establishing this diagnosis is to inform the patient that this is not a serious disease and to prevent unnecessary investigations. The raised unconjugated bilirubin is diagnostic and rises on fasting and during a mild illness. The reticulocyte count is normal, excluding haemolysis, and no treatment is necessary.

**Crigler–Najjar syndrome**

This is very rare. Only patients with type II (autosomal dominant) with a decrease rather than absence (type I – autosomal recessive) of UDP-glucuronosyl transferase can survive into adult life. Mutation of the **HUG-Br1** gene for UDP-glucuronosyl transferase has been demonstrated in the coding region. Liver histology is normal. Transplantation is the only effective treatment.
**Conjugated**

Dubin-Johnson (autosomal recessive) and Rotor’s (possibly autosomal dominant) syndromes are due to defects in bilirubin handling in the liver. The prognosis is good in both. In the Dubin-Johnson syndrome there are mutations in both MRP2 (p. 322) transporter genes. The liver is black owing to melanin deposition.

**Benign recurrent intrahepatic cholestasis**

This is rare and presents in early adulthood. Recurrent attacks of acute cholestasis occur without progression to chronic liver disease. Jaundice, severe pruritus, steatorrhoea and weight loss develop. Serum \( \gamma \)-GT is normal. The gene has been mapped to the FIC1 locus, but the precise relation to cholestasis is unclear. It may be associated with intrahepatic cholestasis of pregnancy (p. 362).

**Progressive familial intrahepatic cholestasis syndromes**

This is a heterogeneous group of conditions defined by defective secretion of bile acids. They are autosomal recessive. In type 1, with cholestasis in infancy (previously known as Byler’s disease), \( \gamma \)-GT is normal. The gene is on the familial intrahepatic cholestasis-1 gene (FIC1) locus, but has been mapped to a region encoding P type ATPases (ATP8B1) on chromosome 18q21. Type 2 has been mapped to the bile salt export pump gene (BSEP). The protein is located in the canicular domain of the plasma membrane of the hepatocyte. The phenotypic expression frequently presents as a non-specific giant cell hepatitis progressing to cholestasis. Type 3 is due to the multidrug resistance protein 3-P-glycoprotein (MDR-3) gene mutation leading to deficient canalicular phosphatidylcholine transport and thus toxic bile acids causing liver damage. Liver transplantation is the only cure for these syndromes.

**Cholestatic jaundice (acquired)**

This can be divided into extrahepatic and intrahepatic cholestasis. The causes are shown in Figure 7.9.

- Extrahepatic cholestasis is due to large duct obstruction of bile flow at any point in the biliary tract distal to the bile canaliculi.
- Intrahepatic cholestasis occurs owing to failure of bile secretion. A number of cellular mechanisms in cholestasis have been described in animal models, including inhibition of the Na\(^+\)/K\(^+\)-ATPase in the basolateral membranes, decreased fluidity of the sinusoidal plasma membrane, disruption of the microfilaments responsible for canicular tone, and damage to the tight junctions. In addition, inflammatory change in ductular cells interferes with bile flow.

Clinically in both types there is jaundice with pale stools and dark urine, and the serum bilirubin is conjugated. However, intrahepatic and extrahepatic cholestatic jaundice must be differentiated as their clinical management is entirely different.

**Differential diagnosis of jaundice**

The history often gives a clue to the diagnosis. Certain causes of jaundice are more likely in particular categories of people. For example, a young person is more likely to have hepatitis, so questions should be asked about drug and alcohol use, and sexual behaviour. An elderly person with gross weight loss is more likely to have a carcinoma. All patients may complain of malaise. Abdominal pain occurs in patients with biliary obstruction by gallstones, and sometimes with an enlarged liver there is pain resulting from disension of the capsule.

Questions should be appropriate to the particular situation, and the following aspects of the history should be covered.

- **Country of origin.** The incidence of hepatitis B virus (HBV) infection is increased in many parts of the world (p. 335).
- **Duration of illness.** A history of jaundice with prolonged weight loss in an older patient suggests malignancy. A short history, particularly with a prodromal illness of malaise, suggests a hepatitis.
- **Recent outbreak of jaundice.** An outbreak in the community suggests hepatitis A virus (HAV).
- **Recent consumption of shellfish.** This suggests HAV infection.
- **Intravenous drug use, or recent injections or tattoos.** These all increase the chance of HBV and hepatitis C virus (HCV) infection.

---

**FURTHER READING**

Men having sex with men. This increases the chance of HBV infection.
Female prostitution. This increases the chance of HBV infection.
Blood transfusion or infusion of pooled blood products. Increased risk of HBV and HCV. In developed countries all donors are screened for HBV and HCV.
Alcohol consumption. A history of drinking habits should be taken, although many patients often understate their consumption.
Drugs taken (particularly in the previous 2–3 months). Many drugs cause jaundice (see p. 365).
Travel. Certain areas have an increased risk of HAV infection as well as hepatitis E (HEV) infection (this has a high mortality in pregnancy).
A recent anaesthetic. Halothane (named patient only in UK) and occasionally isoflurane, and the recently introduced sevoflurane may cause jaundice, particularly in those already sensitive to halogenated anaesthetics. The risk with desflurane appears remote.
Family history. Patients with, for example, Gilbert’s disease may have family members who get recurrent jaundice.
Recent surgery on the biliary tract or for carcinoma.
Environment. People engaged in recreational activities in rural areas, as well as farm and sewage workers, are at risk for leptospirosis and hepatitis E.
Fever or rigors. These are suggestive of cholangitis or possibly a liver abscess.

Clinical features
The signs of acute and chronic liver disease should be looked for (p. 329). Certain additional signs may be helpful:

Hepatomegaly. A smooth tender liver is seen in hepatitis and with extrahepatic obstruction, but a knobbly irregular liver suggests metastases. Causes of hepatomegaly are shown in Table 7.3.
Splenomegaly. This indicates portal hypertension in patients when signs of chronic liver disease are present. The spleen can also be ‘tipped’ occasionally in viral hepatitis.
Ascites. This is found in cirrhosis but can also be due to carcinoma (particularly ovarian) and many other causes (see Table 7.14).

A palpable gall bladder can suggest a carcinoma of the pancreas obstructing the bile duct. Generalized lymphadenopathy suggests a lymphoma.
Cold sores may suggest a herpes simplex virus hepatitis.

Investigations
Jaundice is not itself a diagnosis and the cause should always be sought. The two most useful tests are the viral markers for HAV, HBV and HCV (in high-risk groups), plus an ultrasound examination. Liver biochemistry confirms the jaundice and may help in the diagnosis.

An ultrasound examination should always be performed to exclude an extrahepatic obstruction, and to diagnose any features compatible with chronic liver disease except when hepatitis A is strongly suspected in a young patient. Ultrasound will demonstrate:

- the size of the bile ducts, which are dilated in extrahepatic obstruction (Fig. 7.10)
- the level of the obstruction

![Fig. 7.10](a) Liver ultrasound showing (a) dilated intrahepatic bile ducts (arrow), (b) common bile duct (arrow). The normal bile duct measures 6 mm at the porta hepatis.)
the cause of the obstruction in virtually all patients with
tumours and in 75% of patients with gallstones.

The pathological diagnosis of any mass lesion can be made
by fine-needle aspiration cytology (sensitivity approximately
60%) or by needle biopsy using a spring-loaded device
(sensitivity approximately 90%)

A flow diagram for the general investigation of the jaun-
diced patient is shown in Figure 7.11.

Liver biochemistry

In hepatitis, the serum AST or ALT tends to be high in
the disease with only a small rise in the serum ALP. Con-
versely, in extrahepatic obstruction the ALP is high with
a smaller rise in aminotransferases. These findings cannot,
however, be relied on alone to make a diagnosis in an indi-
vidual case. The prothrombin time (PT) is often prolonged in
long-standing liver disease, and the serum albumin is also
low.

Haematological tests

In haemolytic jaundice the bilirubin is raised and the other
liver biochemistry is normal. A raised white cell count may
indicate infection (e.g. cholangitis). A leucopenia often occurs
in viral hepatitis, while abnormal mononuclear cells suggest
infectious mononucleosis and a Monospot test should be
performed.

Other blood tests

These include tests to exclude unusual causes of liver
disease (e.g. cytomegalovirus antibodies), autoimmune
antibodies, e.g. anti-mitochondrial antibodies (AMA) for the
diagnosis of primary biliary cirrhosis, and α-fetoprotein for a
hepatocellular carcinoma.

HEPATITIS

Acute parenchymal liver damage can be caused by many
agents (Fig. 7.12).

Chronic hepatitis is defined as any hepatitis lasting for 6
months or longer and is often classified according to the
aetiology (Table 7.4). Chronic viral hepatitis is the principal
cause of chronic liver disease, cirrhosis and hepatocellular
carcinoma world-wide.

**Acute hepatitis**

**Pathology**

Although some histological features are suggestive of the aetiological factor, most of the changes are essentially similar whatever the cause. Hepatocytes show degenerative changes (swelling, cytoplasmic granularity, vacuolation), undergo necrosis (becoming shrunken, eosinophilic Councilman bodies) and are rapidly removed. The distribution of these changes varies somewhat with the aetiopathological agent, but necrosis is usually maximal in zone 3. The extent of the damage is very variable between individuals affected by the same agent: at one end of the spectrum, single and small groups of hepatocytes die (spotty or focal necrosis), while at the other end there is multifocal necrosis involving a substantial part of the liver (massive necrosis) resulting in fulminant hepatic failure. Between these extremes there is limited confluent necrosis with collapse of the reticulin framework resulting in linking (bridging) between the central veins, the central veins and portal tracts, and between the portal tracts. The extent of the inflammatory infiltrate is also variable, but portal tracts and lobules are infiltrated mainly by lymphocytes. Other variable features include cholestasis in zone 3 and fatty change, the latter being prominent in hepatitis that is due to alcohol or certain drugs.

**Chronic hepatitis**

**Pathology**

Chronic inflammatory cell infiltrates comprising lymphocytes, plasma cells and sometimes lymphoid follicles are usually present in the portal tracts. The amount of inflammation varies from mild to severe. In addition, there may be:
- loss of definition of the portal/periportal limiting plate – interface hepatitis (damage is due to apoptosis rather than necrosis)
- lobular change, focal lytic necrosis, apoptosis and focal inflammation
- confluent necrosis
- fibrosis which may be mild, bridging (across portal tracts) or severe cirrhosis.

The overall severity of the hepatitis is judged by the degree of the hepatitis and inflammation (grading) and the severity of the fibrosis or cirrhosis (staging) using various scoring systems. For example, the Knodell Scoring System (histological activity index) uses the sum of four factors (periportal or bridging necrosis, intralobular degeneration and focal necrosis, portal inflammation and fibrosis). The Ishak score stages fibrosis from 0 (none) to 6 (cirrhosis). Scoring systems are useful for drug trials and for assessing progression of disease but have limitations.

**VIRAL HEPATITIS**

The differing features of the common forms of viral hepatitis are summarized in Table 7.5.

**HEPATITIS A**

**Epidemiology**

Hepatitis A is the most common type of viral hepatitis occurring world-wide, often in epidemics. The disease is commonly seen in the autumn and affects children and young adults. Spread of infection is mainly by the faeco-oral route and arises from the ingestion of contaminated food or water (e.g. shellfish). Overcrowding and poor sanitation facilitate spread. There is no carrier state. In the UK it is a notifiable disease.

**Hepatitis A virus (HAV)**

HAV is a picornavirus, having the structure shown in Figure 7.13. It has a single serotype as only one epitope is immunodominant. It replicates in the liver, is excreted in bile and is then excreted in the faeces of infected persons for about 2 weeks before the onset of clinical illness and for up to 7 days after. The disease is maximally infectious just before the onset of jaundice. HAV particles can be demonstrated in the faeces by electron microscopy.

**Clinical features**

The viraemia causes the patient to feel unwell with non-specific symptoms that include nausea, anorexia and a distaste for cigarettes. Many recover at this stage and remain anicteric.

After 1 or 2 weeks some patients become jaundiced and symptoms often improve. Persistence of nausea, vomiting or any mental confusion warrants assessment in hospital. As the jaundice deepens, the urine becomes dark and the stools pale owing to intrahepatic cholestasis. The liver is moderately enlarged and the spleen is palpable in about 10% of patients. Occasionally, tender lymphadenopathy is seen, with a transient rash in some cases. Thereafter the jaundice lessens and in the majority of cases the illness is over within 3–6 weeks. Extrahepatic complications are rare but include arthritis, vasculitis, myocarditis and renal failure. A biphasic illness occasionally occurs, with the return of jaundice. Rarely the disease may be very severe with fulminant hepatitis, liver coma and death. The typical sequence of events after HAV exposure is shown in Figure 7.14.

**Investigations**

**Liver biochemistry**

**Prodromal stage:** the serum bilirubin is usually normal. However, there is bilirubinuria and increased urinary urobilinogen. A raised serum AST or ALT, which can sometimes be very high, precedes the jaundice.
Icteric stage: the serum bilirubin reflects the level of jaundice. Serum AST reaches a maximum 1–2 days after the appearance of jaundice, and may rise above 500 IU/L. Serum ALP is usually less than 300 IU/L.

After the jaundice has subsided, the aminotransferases may remain elevated for some weeks and occasionally for up to 6 months.

Haematological tests
There is leucopenia with a relative lymphocytosis. Very rarely there is a Coombs’-positive haemolytic anaemia or an associated aplastic anaemia. The prothrombin time (PT) is pro-
In severe cases. The erythrocyte sedimentation rate (ESR) is raised.

**Viral markers: antibodies to HAV**

IgG antibodies are common in the general population over the age of 50 years, but an anti-HAV IgM means an acute infection. In areas of high prevalence most children have antibodies by the age of 3 years following asymptomatic infection.

**Other tests**

Further tests are not necessary in the presence of an IgM antibody, but liver biochemistry must be followed to establish a return to normal levels.

**Differential diagnosis** is from all other causes of jaundice – but in particular from other types of viral and drug-induced hepatitis.

**Course and prognosis**

The prognosis is excellent, with most patients making a complete recovery. The mortality in young adults is 0.1% but it increases with age. Death is due to fulminant hepatic necrosis. During convalescence, 5–15% of patients may have relapse of the hepatitis but this settles spontaneously. Occasionally a more severe jaundice with cholestasis will run a prolonged course of 7–20 weeks and is called ‘cholestatic viral hepatitis’. There is no reason to stop alcohol consumption other than for the few weeks when the patient is ill. Patients may complain of debility for several months following resolution of the symptoms and biochemical parameters. This is known as the post-hepatitis syndrome; it is a functional illness. Treatment is by reassurance. HAV hepatitis never progresses to chronic liver disease.

**Treatment**

There is no specific treatment, and rest and dietary measures are unhelpful. Corticosteroids have no benefit. Admission to hospital is not usually necessary.

**Prevention and prophylaxis**

Control of hepatitis depends on good hygiene. The virus is resistant to chlorination but is killed by boiling water for 10 minutes.

**Active immunization**

A formaldehyde-inactivated HAV vaccine is given to people travelling frequently to endemic areas, patients with chronic liver disease, people with haemophilia, and workers in frequent contact with hepatitis cases (e.g. in residential institutions for patients with learning difficulties). Community outbreaks can be interrupted by vaccination. A single dose produces antibodies that persist for at least 1 year, with immunity lasting beyond 10 years. This obviates the need for a booster injection in healthy individuals. Universal vaccination has been suggested.

**Passive immunization**

Normal human immunoglobulin (0.02 mL/kg i.m.) is used if exposure to HAV is <2 weeks. HAV vaccine should also be given.

### HEPATITIS B

**Epidemiology**

The hepatitis B virus (HBV) is present world-wide with an estimated 360 million carriers. The UK and the USA have a low carrier rate (0.5–2%), but it rises to 10–20% in parts of Africa, the Middle and the Far East.

*Vertical transmission* from mother to child in utero, during parturition or soon after birth, is the usual means of transmission world-wide. This is related to the HBV replicative state of the mother (90% HbeAg+, 30% HbeAg–) and is uncommon in Africa where horizontal transmission (sib to sib) is common. HBV is not transmitted by breast feeding.

*Horizontal transmission* occurs particularly in children through minor abrasions or close contact with other children, and HBV can survive on household articles, e.g. toys, toothbrushes, for prolonged periods so transmission may be possible.

HBV spread also occurs by the intravenous route (e.g. by transfusion of infected blood or blood products, or by contaminated needles used by drug users, tattooists or acupuncturists), or by close personal contact, such as during sexual intercourse, particularly in men having sex with men (25% of cases in the USA). The virus can be found in semen and saliva.

**Hepatitis B virus (HBV)**

The complete infective virion or Dane particle is a 42 nm particle comprising an inner core or nucleocapsid (27 nm) surrounded by an outer envelope of surface protein (HBsAg). This surface coat is produced in excess by the infected hepatocytes and can exist separately from the whole virion in serum and body fluid as 22 nm particles or 22 nm tubules.

HBsAg contains a major ‘a’ antigenic determinant as well as several subtypes: ‘d’, ‘y’, ‘w’ and ‘r’. Combinations of these subdeterminants (e.g. ad, aw, ayw and ayr) are used to classify HBV genotypes A–H, of which the main types are type A (35%), B (22%), C (31%) and D (10%). There is a strong correlation between genotypes and geographical areas. Genotype A is mainly seen in North West Europe, North America and Central Africa; B in South East Asia (including China, Taiwan and Japan); genotype C in South East Asia; D in southern Europe, India and the Middle East; E in West Africa; F in South and Central America, in American Indians and in Polynesia; G in France and the USA; and H in Central and South America. These genotypes have a bearing on, for example, the time to HBeAg seroconversion (B < C), response to interferon treatment (A > B; C > D) and chronic liver disease (A < D).

The core or nucleocapsid is formed of core protein (HbcAg) containing incompletely double-stranded circular DNA and DNA polymerase/reverse transcriptase. One strand is almost a complete circle and contains overlapping genes that encode both structural proteins (pre-S, surface (S), core (C)) and replicative proteins (polymerase and X). The other strand is variable in length. DR1 and DR2 are direct repeats necessary for HBV synthesis during viral replication (Fig. 7.15).

HBeAg is a protein formed via specific self-cleavage of the pre-core/core gene product which is secreted separately by the cell.
Hepatitis B virus (HBV) genome. The viral DNA is partially double-stranded (red incomplete circle and blue circle). The long strand (blue) encodes seven proteins from four overlapping reading frames (S, surface (Pre-S<sub>1</sub>, Pre-S<sub>2</sub>, S); C, core (Pre-C, C); P, polymerase (P) and X gene (X)). EcoRI restriction enzyme-binding site is included as a reference point. DR, direct repeats.

**Hepatitis B mutants**

Mutations occur in the various reading frames of the HBV genome (see Fig. 7.15). These mutants can emerge in patients with chronic HBV infection (escape mutants) or can be acquired by infection.

HBsAg mutants are produced by alterations in the ‘a’ determinants of the HbsAg proteins with usually a substitution of glycine for arginine at position 145. This results in changes in the antibody binding domain and the usual tests for HBsAg may be affected.

A mutation in the pre-core region when a guanosine (G) to adenosine (A) change creates a stop codon (TAG) prevents the production of HBeAg, but the synthesis of HbcAg is unaffected. To detect infectivity, HBV-DNA must always be measured as no eAg will be present.

DNA polymerase mutants occur, particularly after lamivudine therapy.

**Pathogenesis**

Pre-S<sub>1</sub> and pre-S<sub>2</sub> regions are involved in attachment to an unknown receptor on the hepatocyte. After penetration into the cell, the virus loses its coat and the virus core is transported to the nucleus without processing. The transcription of HBV into mRNA takes place by the HBV DNA being converted into a closed circular form (Yc DNA), which acts as a template for RNA transcription.

Translation into HBV proteins (Table 7.6) as well as replication of the genome takes place in the endoplasmic reticulum; they are then packaged together and exported from the cell. There is an excess production of non-infected HbsAg particles which are extruded into the circulation.

The HBV is not directly cytopathic and the liver damage produced is by the cellular immune response of the host.

Cytotoxic T cells recognize the viral antigen via HLA class I molecules on the infected hepatocytes; Th1 responses (interleukin-2, gamma-interferon) are thought to be associated with the clearance of the virus and Th2 (interleukins 4, 5, 6, 10, 13) responses with the development of chronic infection and severity of the disease. Viral persistence in patients with a very poor cell-mediated response leads to a healthy inactive chronic HBV infective state. A better response, however, results in continuing hepatocellular damage with the development of chronic hepatitis.

Chronic HBV infection goes through a replicative and an integrated phase. In the replicative phase there is active viral replication with hepatic inflammation and the patient is highly infectious with HBeAg and HBV DNA positivity. At some stage the viral genome becomes integrated into the host DNA and the viral genes are then transcribed along with those of the host. At this stage, the level of HBV DNA in the serum is low and the patient is HBeAg negative and HBe antibody positive. The aminotransferases are now normal or only slightly elevated and liver histology shows little inflammation, often with cirrhosis. Hepatocellular carcinoma (HCC) develops in patients with this late-stage disease, but the mechanism is still unclear. The REVEAL Study (Risk Evaluation of Viral load Elevation and Associated Liver disease) showed that the risk of HCC was related to levels of HBV DNA rather than a raised aminotransferase (ALT). Integration of the viral DNA with the host-cell chromosomal DNA does appear to have a major role in carcinogenesis. There is evidence to implicate inactivation of p53-induced apoptosis by protein X (Table 7.6), allowing accumulation of abnormal cells and, eventually, carcinogenesis.

**Clinical features of acute hepatitis**

The sequence of events following acute HBV infection is shown in Figure 7.16. In many cases, however, the infection is subclinical. When HBV infection is acquired perinatally, an acute hepatitis usually does not occur as there is a high level of immunological tolerance and the virus persists in over 90%. If there is an acute clinical episode the virus is cleared in approximately 99% of patients as there is a good immune reaction. The clinical picture is the same as that found in HAV infection, although the illness may be more severe. In addition, a serum sickness-like immunological syndrome may be seen. This consists of rashes (e.g., urticaria or a maculopapular rash) and polyarthritis affecting small joints occurring in up to 25% of cases in the prodromal period. Fever is usual. Extrahepatic immune complex-mediated conditions such as an arteritis or glomerulonephritis are occasionally seen.

**Investigations**

These are generally the same as for hepatitis A.

**Specific tests.** The markers for HBV are shown in Table 7.7. HBsAg is looked for initially; if it is found, a full viral profile

is then performed. In acute infection, as HBsAg may be cleared rapidly, anti-HBc IgM is diagnostic. HBV DNA is the most sensitive index of viral replication. HBV DNA has been shown to persist (using polymerase chain reaction (PCR) techniques) even when the e antibody has developed.

**Fig. 7.16** Time course of the events and serological changes seen following infection with hepatitis B virus.

(a) Acute infection

**Antigens**

HBsAg appears in the blood from about 6 weeks to 3 months after an acute infection and then disappears.

**Antibodies**

Anti-HBs appears late and indicates immunity.

Anti-HBc is the first antibody to appear and high titres of IgM anti-HBc suggest an acute and continuing viral replication. It persists for many months. IgM anti-HBc may be the only serological indicator of recent HBV infection in a period when HBsAg has disappeared and anti-HBs is not detectable in the serum.

Anti-HBe appears after the anti-HBc and its appearance relates to a decreased infectivity, i.e. a low risk.

(b) Development of chronic hepatitis followed by seroconversion

HBsAg persists and indicates a chronic infection (or carrier state).

HBeAg persists and correlates with increased severity and infectivity and the development of chronic liver disease. When anti-HBe develops (seroconversion) the Ag disappears and there is a rise in ALT.

HBV DNA suggests continual viral replication. For mutants – see text.

**Fig. 7.17** Clinical course of hepatitis B infection acquired in adults.

**Course**

The majority of patients recover completely, fulminant hepatitis occurring in up to 1%. Some patients go on to develop chronic hepatitis (p. 338), cirrhosis (p. 345) and hepatocellular carcinoma (p. 363) or have inactive chronic HBV infection (Fig. 7.17). The outcome depends upon several factors, including the virulence of the virus and the immunocompetence and age of the patient. Some genetic factors, e.g. the presence of MHC class II genotype, may alter host defence to HBV. Complete eradication of HBV infection is probably rare.

**Treatment for acute hepatitis**

This is mainly symptomatic. Antiviral agents, e.g. lamivudine, have been used in very ill patients but there are no controlled data on their efficacy. However, patients should have their HBV markers monitored and many experts suggest that nucleoside analogues should be given for the persistent presence of HbeAg beyond 12 weeks.
Prevention and prophylaxis

Prevention depends on avoiding risk factors (see above). These include not sharing needles and having safe sex. Vertical transmission is discussed below. Infectivity is highest in those with the e antigen and/or HBV DNA in their blood. These patients should be counselled about their infection. In developing countries, blood and blood products are still a hazard. Standard safety precautions in laboratories and hospitals must be enforced strictly to avoid accidental needle punctures and contact with infected body fluids.

Passive and active immunization

Vaccination is universally available in most developed countries as well as countries with high endemicity. Groups at high risk are: all healthcare personnel; members of emergency and rescue teams; morticians and embalmers; children in high-risk areas; people with haemophilia; patients in some psychiatric units; patients with chronic kidney disease/on dialysis units; long-term travellers; homosexual and bisexual men and prostitutes; intravenous drug users. Routine vaccination is available in the USA.

Combined prophylaxis (i.e. vaccination and immunoglobulin) should be given to: staff with accidental needle-stick injury; all newborn babies of HBsAg-positive mothers; regular sexual partners of HBsAg-positive patients, who have been found to be HBV-negative.

For adults a dose of 500 IU of specific hepatitis B immunoglobulin (HBig) (200 IU to newborns) is given and the vaccine (i.m.) is given at another site.

Active immunization

This is with a recombinant yeast vaccine produced by insertion of a plasmid containing the gene of HBsAg into a yeast.

Dosage regimen. Three injections (at 0, 1 and 6 months) are given into the deltoid muscle; this gives short-term protection in over 90% of patients. People who are over 50 years of age or clinically ill and/or immunocompromised (including those with HIV infection or AIDS) have a poor antibody response; more frequent and larger doses are required. Antibody levels should be measured at 7–9 months after the initial dose in all at-risk groups. Antibody levels fall steadily after vaccination and booster doses may be required after approximately 3–5 years. It is not cost-effective to check antibody levels prior to active immunization. There are few side-effects from the vaccine; soreness at the site of injection may occur, with very occasionally a fever, rash or a ‘flu-like’ illness.

Chronic HBV infection

Inactive chronic HBV infection

Following an acute HBV infection, which may be subclinical, approximately 1–10% of patients will not clear the virus and will develop inactive chronic HBV infection. This occurs more readily with neonatal (90%) or childhood (20–50% below the age of 5 years) infection than when HBV is acquired in adult life (<10%) (see Fig. 7.17). There is a vast geographical variation in the incidence of inactive chronic hepatitis B. In the UK, patients are usually discovered incidentally on blood tests, such as when they are screened for donating blood for transfusion or when attending genital medicine or antenatal clinics. Patients with inactive chronic hepatitis have HBsAg in their serum and are HBeAg negative, HBe antibody positive with lower levels of HBV DNA in their serum. They have no evidence of active liver disease (normal or only slightly raised transaminases) and are not highly infective. Most remain HBsAg positive, but do not develop progressive liver disease, although some patients have episodes of reactive hepatitis. This develops when the immune balance changes and lymphocytes recognize infected hepatocytes causing hepatitis. There is an annual spontaneous clearance rate of HBsAg of 1–2%.

Active chronic HBV infection

These patients have raised serum aminotransferases with evidence of HBV replication; they have HBe antigen or HBV DNA in their serum. A liver biopsy shows chronic hepatitis.

Clinical features and investigations of active chronic hepatitis

Chronic hepatitis is more frequent in men and it is often not preceded by an acute attack. The condition may be asymptomatic or may present as a mild, slowly progressive hepatitis; 50% present with established chronic liver disease. Clinical relapses or ‘flares’ occur, sometimes associated with seroconversion (see below) of HBeAg to anti-HBe or vice versa.

Investigations show a moderate rise in aminotransferases and a slightly raised ALP. The serum bilirubin is often normal. HBsAg and HBV DNA are found in the serum, usually with HBe antigen, unless a mutant virus is involved (see p. 336).

Histologically, there is a full spectrum of changes from near normal with only a few lymphocytes and interface hepatitis to a full-blown cirrhosis. HBsAg may be seen as a ‘ground-glass’ appearance in the cytoplasm on haematoxylin and eosin staining, and this can be confirmed on orcein staining or more specifically with immunohistochemical staining. HBCag can also be demonstrated in hepatocytes by appropriate immunohistochemical staining.

Treatment for chronic hepatitis

- Patients positive for HBeAg. HBsAg and HBV DNA (>20000 IU/mL – for copies multiply by 5.6) with abnormal serum ALT (>2× normal) should be treated. Liver biopsy is not essential in this group.
- Patients with HBeAg and HBV DNA levels >20000 IU/L who have ALT values >2× normal, should not be treated because the efficacy of therapy is low. A liver biopsy may help as treatment is sometimes given if inflammation is marked.
- Patients who are negative for HBeAg with a HBV DNA level of >2000 should also be treated. Those with DNA levels >2000 should have a liver biopsy to help with the decision to treat or not.

The aim of treatment is the seroconversion of HBeAg (when present) and the reduction of HBV DNA to undetectable levels by PCR. In addition normalization of the serum ALT level and histological improvement in inflammation and fibrosis reflects a good response.
- Patients with compensated cirrhosis with HBV DNA >2000 IU/L should be treated and those with a DNA <2000 should only be treated if the ALT is high.
- Patients with decompensated cirrhosis can also be treated but liver transplantation may be required.
In patients in whom HBeAg disappears, remission is usually sustained for many years. The patient remains a carrier with HBsAg present, although some will eventually become HBsAg negative.

**Antiviral agents**

Interferon, lamivudine, adefovir, entecavir and tenofovir are the most commonly used drugs (p. 100). Response to therapy is judged by the HBV DNA level.

*Pegylated α-2a interferon* (180 μg once a week subcutaneously) gives response rates of 25–45% (depending on genotype – A and B respond best) after 12 months of treatment. Patients with concomitant HIV respond poorly and those with cirrhosis should not receive interferon.

*Side-effects* of treatment are many, with an acute flu-like illness occurring 6–8 hours after the first injection. This usually disappears after subsequent injections, but malaise, headaches and myalgia are common and depression, reversible hair loss and bone marrow depression and infection may occur. The platelet count should be monitored. These drug reactions occur in up to 30% of patients, and the dose may have to be lowered.

Overall, the response rate (i.e. disappearance of HbeAg) is 25–40%. The success rate depends on factors shown in Table 7.8.

In older patients HbeAg usually disappears (sometimes due to changes in the viral genome). Many such patients have inactive disease but some reactivate without regaining HbeAg (HbeAg negative disease). They respond poorly to interferon but can be treated with nucleoside and nucleotide analogues, i.e.:

- **Lamivudine** 100 mg/day given orally, is well tolerated. However, by 4 years, 80% develop viral resistance due to YMDD mutant (tyrosine (Y), methionine (M), aspartate (D)), which itself causes hepatitis. Lamivudine monotherapy is no longer recommended.

- **Entecavir** is more effective than lamivudine and reduces HBV DNA more quickly, and there is much less viral resistance. Serum HBV DNA becomes negative in 67% (HBeAg-positive patients) and 90% (HBeAg-negative patients) by 48 weeks.

- **Tenofovir** 300 mg per day is effective against lamivudine-resistant virus and, as monotherapy, has a similar potency to entecavir.

The duration of all treatment, and which combination of antivirals is optimal, is still being assessed.

### In general

Current treatment for HbeAg positive disease is with pegylated interferon or tenofovir or entecavir. Interferon should be given for 1 year. The oral antiviral agents should be used long term. HbeAg negative disease requires long-term (many years) oral therapy.

### Prognosis

The clinical course of hepatitis B is very variable and treatments have improved survival. Progression from the acute to the chronic phase depends on the age at which infection is acquired. Established cirrhosis is associated with a poor prognosis. Hepatocellular carcinoma is a frequent association and is one of the most common carcinomas in HBV-endemic areas such as the Far East. This incidence is being reduced by routine HBV vaccination of all children.

### HEPATITIS D

This is caused by the hepatitis D virus (HDV or delta virus) which is an incomplete RNA particle enclosed in a shell of HbsAg and belongs to the delta viridae family. It is unable to replicate on its own but is activated by the presence of HBV. It is particularly seen in intravenous drug users but can affect all risk groups for HBV infection. Hepatitis D viral infection can occur either as a co-infection with HBV or as a superinfection in an HBsAg-positive patient.

*Co-infection* of HDV and HBV is clinically indistinguishable from acute icteric HBV infection, but a biphasic rise of serum aminotransferases may be seen. *Diagnosis* is confirmed by finding serum IgM anti-HDV in the presence of IgM anti-HBc. IgM anti-delta appears at 1 week and disappears by 5–6 weeks (occasionally 12 weeks) when serum IgG anti-delta is seen. The HDV RNA is an early marker of infection. The infection may be transient but the clinical course is variable.

*Superinfection* results in an acute flare-up of previously quiescent chronic HBV infection. A rise in serum AST or ALT may be the only indication of infection. *Diagnosis* is by finding HDV RNA or serum IgM anti-HDV at the same time as IgG anti-HBc. Active HBV DNA synthesis is reduced by delta superinfection and patients are usually negative for HBeAg with low HBV DNA.

Fulminant hepatitis can follow both types of infection but is more common after co-infection. HDV RNA in the serum and liver can be measured and is found in acute and chronic HDV infection.

### Chronic D hepatitis

This is a relatively infrequent chronic hepatitis, but spontaneous resolution is rare. Between 60% and 70% of patients will develop cirrhosis, and more rapidly than with HBV infection alone. In 15% the disease is rapidly progressive with development of cirrhosis in only a few years. The diagnosis is made by finding anti-delta antibody in a patient with chronic liver disease who is HBsAg positive. It can be confirmed by finding HDV in the liver or HDV RNA in the serum by reverse transcription PCR. *Treatment* for patients with active liver disease (raised ALT levels and/or inflammation on biopsy) is with pegylated α-2a interferon for 12 months, but response is poor. Lamivudine and adefovir appear to be unhelpful; there are no large trials of HDV treatment so optimal therapy is not known.
HEPATITIS C

Epidemiology
The prevalence rate of infection in healthy blood donors is about 0.02% in Northern Europe, 1–3% in Southern Europe, possibly linked to intramuscular injections of vaccines or other medicines, and 6% in Africa, with rates as high as 19% in Egypt owing to parenteral antimony treatment for schistosomiasis. The virus is transmitted by blood and blood products and was common in people with haemophilia treated before screening of blood products was introduced. The incidence in intravenous drug users is high (50–60%). The low rate of hepatitis C (HCV) infection in high-risk groups—such as men who have sex with men, prostitutes and attendees at STI clinics—suggests a limited role for sexual transmission. Vertical transmission from healthy mother to child can occur, but is very rare. Other routes of community-acquired infection (e.g. close contact) are extremely rare. In 20% of cases the exact mode of transmission is unknown. An estimated 240 million people are infected with this virus worldwide.

Hepatitis C virus (HCV)
HCV is a single-stranded RNA virus of the Flaviviridae family. The RNA genome is approximately 10 Kb in length, encoding a polyprotein product consisting of structural (capsid and envelope) and non-structural viral proteins (Fig. 7.18). Comparisons of subgenomic regions, such as E1, NS4 or NS5, have allowed variants to be classified into six genotypes. Variability is distributed throughout the genome with the non-structural gene of different genotypes showing 30–50% nucleotide sequence disparity. Genotypes 1a and 1b account for 70% of cases in the USA and 50% in Europe. There is a rapid change in envelope proteins, making it difficult to develop a vaccine. Antigens from the nucleocapsid regions have been used to develop enzyme-linked immunosorbent assays (ELISA). The current assay, ELISA-3, incorporates antigens NS3, NS4 and NS5 regions.

Clinical features
Most acute infections are asymptomatic, with about 10% of patients having a mild flu-like illness with jaundice and a rise in serum aminotransferases. Most patients will not be diagnosed until they present, years later, with evidence of abnormal transference values at health checks or with chronic liver disease. Extrahepatic manifestations are seen, including arthritis, glomerulonephritis associated with cryoglobulinaemia, and porphyria cutanea tarda. There is a higher incidence of diabetes, and associations with lichen planus, sicca syndrome and non-Hodgkin’s lymphoma.

Fig. 7.18 Hepatitis C virus. Diagram showing a single-stranded RNA virus with viral proteins. C, core; NS, non-structural; E, envelope.

Diagnosis
This is frequently by exclusion in a high-risk individual with negative markers for HAV, HBV and other viruses. A drug cause for hepatitis should be excluded if possible. HCV RNA can be detected from 1 to 8 weeks after infection. Anti-HCV tests are usually positive 8 weeks from infection.

Treatment
Interferon has been used in acute cases to prevent chronic disease. Needle-stick injuries must be followed and treated early if there is evidence of HCV viraemia, usually re-tested for at 4 weeks.

Course
Eighty five to ninety per cent of asymptomatic patients develop chronic liver disease. A higher percentage of symptomatic patients ‘clear’ the virus with only 48–75% going on to chronic liver disease (p. 341). Cirrhosis develops in about 20–30% within 10–30 years and of these patients between 7% and 15% will develop hepatocellular carcinoma. The course is adversely affected by co-infection with HBV and/or HIV, and by alcohol consumption, which should be discouraged.

Chronic hepatitis C infection
Pathogenesis
As with hepatitis B infection, cytokines in the Th2 phenotypes are profibrotic and lead to the development of chronic infection. A dominant CD4 Th2 response with a weak CD8 gamma-interferon response may lead to rapid fibrosis. Th1 cytokines are antifibrotic and thus a dominant CD4 Th1 and CD8 cytolytic response may cause less fibrosis. Viral load and viral genotype do not affect rate of fibrosis; persistence of HCV infection has been shown to be associated with HLA-DRB1*0701 and DRB4*0101. Other factors also have an effect on the development of fibrosis, particularly male gender, high alcohol intake, a fatty liver and diabetes.

Clinical features
Patients with chronic hepatitis C infection are usually asymptomatic, the disease being discovered only following a routine biochemical test when mild elevations in the aminotransferases (usually ALT) are noticed (50%). The elevation in ALT may be minimal and fluctuating (Fig. 7.19) and some patients have a persistently normal ALT (25%), the disease being detected by checking HCV antibodies (e.g. in blood donors).

Severe chronic hepatitis (25%) and even cirrhosis can be present with only minimal elevation in aminotransferases, but progression is very uncommon in those with a persistently normal ALT. Fatigue is the commonest symptom with sometimes nausea, anorexia and weight loss, which do not correlate with disease activity.

Diagnosis
This is made by finding HCV antibody in the serum using third-generation ELISA-3 tests. HCV RNA should be assayed using quantitative HCV-RNA PCR. The viraemia is usually variable; less than 60 000 IU/mL signifies a greater likelihood of response to antiviral therapy.
The HCV genotype should be characterized in patients who are to be given treatment (see below).

Liver biopsy is indicated if treatment is being considered, especially for genotype 1 and 4. Non-invasive methods for the diagnosis of fibrosis such as serum markers and elastography (p. 326) can replace the need for biopsy in many cases and are useful in follow-up. The changes on liver biopsy are highly variable. Sometimes only minimal inflammation is detected, but in most cases the features of chronic hepatitis are present, as described (p. 333). The METAVIR scoring system grades the inflammation from 0 (none) to 4 (severe), and fibrosis 0 (none) to 4 (cirrhosis) and is used to guide therapy. Lymphoid follicles are often present in the portal tracts, and fatty change is frequently seen.

**Treatment** (Fig. 7.20)

Treatment is appropriate for patients with chronic hepatitis on liver histology who have HCV RNA in their serum and who have raised serum aminotransferases for more than 6 months. Patients with persistently normal aminotransferases are also treated if they have abnormal histology. The presence of cirrhosis is not a contraindication, but therapeutic responses are less likely. Patients with decompensated cirrhosis should be considered for transplantation. The aim of treatment is to eliminate the HCV RNA from the serum in order to:

- stop the progression of active liver disease
- prevent the development of hepatocellular carcinoma.

**Antiviral agents**

Current treatment is combination therapy with pegylated interferon, which is interferon with a polyethyleneeglycol tail (α2a 180 µg/week or α2b 1.5 µg/kg/week), and ribavirin (1000–1200 mg/day for genotype 1, 800 mg/day for genotype 2 or 3) in daily divided doses for 12 months for genotype 1, and 6 months for other genotypes. Efficacy is also determined by viral load, with HCV RNA <600 000 IU/L less likely to respond.

Side-effects of interferon are described on page 339. Ribavirin is usually well tolerated but side-effects include a dose-related haemolysis, pruritus and nasal congestion. Pregnancy should be avoided as ribavirin is teratogenic.

**Monitoring results.** An early virological response is defined as becoming HCV RNA negative or having at least a 2 log reduction in RNA following treatment in the first 12 weeks.

**Fig. 7.19** Time course of the events and serological changes seen following infection with hepatitis C virus.

**Fig. 7.20** Approach to a patient with hepatitis C. ALT, alanine aminotransferase; PCR, polymerase chain reaction. Adapted from Dhumeaux D, Marcellin P, Lerebours E. Treatment of hepatitis C. The 2002 French consensus. *Gut* 2003; 52 with permission from the BMJ Publishing Group.

This occurs in about 80% of patients tolerating full dosage. If this is not achieved, the patient is unlikely to respond and treatment should be stopped. If HCV RNA is undetectable at 4 weeks, treatment for patients with genotype 2 can be stopped at 12–16 weeks and for genotype 1 (if <600 000 IU/mL at baseline) at 6 months.

A sustained response is clearance of HCV RNA at 6 months after the end of therapy. It is a good surrogate marker for the resolution of the hepatitis. This is achieved in 40–50% of patients with genotypes 1 and 4 and 80% in genotype 2 or 3. In sustained responders relapse is unlikely and histological progression is halted. Best results are obtained in young patients with low HCV RNA levels and genotype 2 or 3. For non-responders and relapsers, longer duration of therapy is being assessed.

**HEPATITIS E**

Hepatitis E virus (HEV) is an RNA virus (Hepevirus) (Fig. 7.21) which causes a hepatitis clinically very similar to hepatitis A.
CAUSES OF LIVER INFECTIONS

Acute Hepatitis D due to Other Infectious Agents

Hepatitis D virus is an RNA virus that requires hepatitis B virus (HBV) for its replication. In the absence of HBV, it cannot cause infection. The symptoms of acute hepatitis D are similar to those of hepatitis B. The liver biopsy shows intranuclear inclusions and giant cells.

Yellow fever (see also p. 114). This viral infection is carried by the mosquito Aedes aegypti and can cause acute hepatic necrosis. There is no specific treatment.

Herpes simplex (see also p. 104). Very occasionally the herpes simplex virus causes a generalized acute infection, particularly in the immunosuppressed patient, and occasionally in pregnancy. Aminotransferases are usually massively elevated. Liver biopsy shows extensive necrosis. Aciclovir is used for treatment.

Toxoplasmosis (see also p. 160). This produces a clinical picture similar to that of infectious mononucleosis, with abnormal liver biochemistry, but the Paul–Bunnell test is negative.

FURTHER READING

Fulminating Hepatic Failure (FHF)

This is defined as severe hepatic failure in which encephalopathy develops in under 2 weeks in a patient with a previously normal liver (occasionally in some patients with previous liver damage; e.g. D virus superinfection in a previous carrier of HBsAg and in Wilson’s disease). Cases that evolve at a slower pace (2–12 weeks) are called subacute or subfulminating hepatic failure. FHF is a rare but often life-threatening syndrome that is due to acute hepatitis from many causes (Table 7.9). The causes vary throughout the world; most cases are due to viral hepatitis, but paracetamol overdose is commonly implicated in the UK (50% of cases). HCV does not cause FHF although exceptional cases have been reported from Japan.

Histologically there is multifocal necrosis involving a substantial part of the liver. Severe fatty change is seen in pregnancy (p. 364), Reye’s syndrome (p. 363) or following tetracycline administration intravenously.

Clinical features
Examination shows a jaundiced patient with a small liver and signs of hepatic encephalopathy. The mental state varies...

**Box 7.1** Transfer criteria to specialized units for patients with acute liver injury

- INR > 3.0
- Presence of hepatic encephalopathy
- Hypotension after resuscitation with fluid
- Metabolic acidosis
- Prothrombin time (seconds) > interval (hours) from overdose (paracetamol cases)

from slight drowsiness, confusion and disorientation (grades I and II) to unresponsive coma (grade IV) with convulsions. Fetor hepaticus is common, but ascerts and splenomegaly are rare. Fever, vomiting, hypotension and hypoglycaemia occur. Neurological examination shows spasticity and hyperreflexia; plantar responses remain flexor until late. Cerebral oedema develops in 80% of patients with FHF but is far less common with subacute failure and its consequences of intracranial hypertension and brain herniation are the most common causes of death. Other complications include bacterial and fungal infections, gastrointestinal bleeding, respiratory arrest, renal failure (hepatorenal syndrome and acute tubular necrosis) and pancreatitis.

**Investigations**

There is hyperbilirubinaemia, high serum aminotransferases and low levels of coagulation factors, including prothrombin and factor V. Aminotransferases are not useful indicators of the course of the disease as they tend to fall along with the albumin with progressive liver damage. An EEG is sometimes helpful in grading the encephalopathy. Ultrasound will define liver size and may indicate underlying liver pathology.

**Treatment**

There is no specific treatment, but patients should be managed in a specialized unit. Transfer criteria to such units are shown in Box 7.1. Supportive therapy as for hepatic encephalopathy is necessary (see p. 353). When signs of raised intracranial pressure (which is sometimes measured directly) are present, 20% mannitol (1 g/kg bodyweight!) should be infused intravenously; this dose may need to be repeated. Dexamethasone is of no value. Hypoglycaemia, hypokalaemia, hypomagnesaemia, hypophosphataemia and hypocalcaemia should be anticipated and corrected with 10% dextrose infusion (checked by 2-hourly Dextrostix testing), potassium, calcium, phosphate and magnesium. Coagulopathy is managed with intravenous vitamin K, platelets, blood or fresh frozen plasma. Haemorrhage may be a problem and patients are given a proton pump inhibitor (PPI) to prevent gastrointestinal bleeding. Prophylaxis against bacterial and fungal infection is routine, and suspected infection should be treated immediately with suitable antibiotics. Renal and respiratory failure should be treated as necessary. Liver transplantation has been a major advance for patients with FHF. It is difficult to judge the timing or the necessity for transplantation, but there are guidelines based on validated prognostic indices of survival (see below).

**Course and prognosis**

In mild cases (grades I and II encephalopathy with drowsiness and confusion), two-thirds of the patients will survive. The outcome of severe cases (grades III and IV encephalopathy with stupor or deep coma) is related to the aetiology. In special units, 70% of patients with paracetamol overdosage and grade IV coma survive, as do 30–40% patients with HAV or HBV hepatitis. Poor prognostic variables indicating a need to transplant the liver are shown in Box 7.2.

**AUTOIMMUNE HEPATITIS**

This condition occurs most frequently in women. In type I (see below) there is an association with other autoimmune diseases (e.g. pernicious anaemia, thyroiditis, coeliac disease and Coombs’-positive haemolytic anaemia), and 60% of cases are associated with HLA, DR3, DR52a loci, HLA-DRB1*0301 and HLA-DRB2*0401. In Asians, the condition is associated with HLA-DR4.

**Pathogenesis**

The cause is unknown. It is proposed, in a genetically predisposed person, that an environmental agent (perhaps a
virus) causes a sequence of T cell mediated events against liver antigens, producing a progressive necroinflammatory process which results in fibrosis and cirrhosis. In vitro observations have shown that there is a defect of suppressor (regulatory) T cells which may be primary or secondary. However, no clear mechanism causing the inflammation has been found.

Clinical features

There are two peaks in presentation. In the peri- and post-menopausal group, patients may be asymptomatic or present with fatigue, the disease being discovered by abnormalities in liver biochemistry or because of signs of chronic liver disease on routine examination. In the teens and early twenties the disease (often type II) presents as an acute hepatitis with jaundice and very high aminotransferases, which do not improve with time. This age group often has clinical features of cirrhosis with hepatosplenomegaly, cutaneous striae, acne, hirsuties, bruises and, sometimes, ascites. An ill patient can also have features of an autoimmune disease with a fever, migratory polyarthralgia, glomerulonephritis, pleurisy, pulmonary infiltration or lung fibrosis.

There are overlap syndromes with primary biliary cirrhosis and primary sclerosing cholangitis, existing concomitantly or developing consecutively.

Investigations

Liver biochemistry

The serum aminotransferases are high, with lesser elevations in the ALP and bilirubin. The serum γ-globulins are high, frequently twice normal, particularly the IgG. The biochemical pattern is similar in both types.

Haematology

A mild normochromic normocytic anaemia with thrombocytopenia and leucopenia is present, even before portal hypertension and splenomegaly. The prothrombin time is often high.

Autoantibodies

Two types of autoimmune hepatitis have been recognized:

- Type I with antibodies (titres >1:80)
  - (a) anti-nuclear (ANA)
  - (b) anti-smooth muscle (anti-actin)
  - (c) soluble liver antigen (anti SLA/LP) – 10–30% cases.
  - This occurs most frequently in girls and young women.
- Type II with antibodies: anti-liver/kidney microsomal (anti-LKM1). The main target is cytochrome P4502D6 (CYP2D6) on liver cell plasma membranes.
  - Approximately 13% of patients lack the above autoantibodies.

Liver biopsy

This shows the changes of chronic hepatitis described previously. The amount of interface hepatitis is variable, but tends to be high in untreated patients. Lymphoid follicles are less often seen than in hepatitis C, and plasma cell infiltration is frequent. Approximately one-third of patients have cirrhosis at presentation.

Treatment

Prednisolone 30 mg is given daily for 2 weeks, followed by a slow reduction and then a maintenance dose of 10–15 mg daily; azathioprine should be added, 1–2 mg/kg daily, as a steroid-sparing agent and in some patients as sole long-term maintenance therapy. Mycophenolate, ciclosporin and tacrolimus have been used in resistant cases.

Course and prognosis

Steroid and azathioprine therapy induce remission in over 80% of cases. Treatment is lifelong in most cases. Those with initial cirrhosis are more likely to relapse following treatment withdrawal and require indefinite therapy. Liver transplantation is performed if treatment fails, although the disease may recur. Hepatocellular carcinoma occurs less frequently than with viral-induced cirrhosis.

Drug-Induced Chronic Hepatitis

Several drugs can cause a CH which clinically bears many similarities to autoimmune hepatitis. Patients are often female, present with jaundice and hepatomegaly, have raised serum aminotransferases and globulin levels, and LE cells and anti-LKM1 antibodies may be detected. Improvement follows drug withdrawal but exacerbations can occur with drug re-introduction. Isoniazid, amiodarone and methotrexate can lead to chronic histological changes. With rare exceptions patients with pre-existing chronic liver disease are not more susceptible to drug injury.

Chronic alcoholic liver disease can occasionally have histological appearances more like a chronic hepatitis.

Chronic Hepatitis of Unknown Cause

As more and more people are having routine blood tests, mild elevations in the serum aminotransferases and γ-GT are found. Many of these patients have no symptoms and no evidence of liver disease clinically. All known aetiological agents should be excluded (see above), and tests carried out to exclude primary biliary cirrhosis, primary sclerosing cholangitis, Wilson’s disease, haemochromatosis and α1-antitrypsin deficiency. Risk factors for NASH should be evaluated.

Liver biopsy should be performed if the elevation in the aminotransferases continues for over a year, to confirm the presence of chronic hepatitis, but often non-specific changes are found.

Non-Alcoholic Fatty Liver Disease (NAFLD)

This is an increasingly recognized condition that can lead to cirrhosis in 1% and hepatocellular carcinoma. NAFLD is estimated to affect 3–6% of the population in the USA and of these, 1–3% have non-alcoholic steatohepatitis (NASH).

Histological changes are similar to those of alcohol-induced hepatic injury and range from simple fatty change to fat and inflammation (steatohepatitis, NASH) and fibrosis.
Oxidative stress injury and other factors lead to lipid peroxidation in the presence of fatty infiltration and inflammation results. Fibrosis then may occur which is enhanced by insulin resistance, which induces connective tissue growth factor. Risk factors for NAFLD are obesity, hypertension, type 2 diabetes and hyperlipidaemia, such that NAFLD is considered the liver component of the metabolic syndrome. Insulin resistance is universal.

Most patients are asymptomatic; hepatomegaly may be present. Mild increases in serum transferases and/or γ-GT (with ALT > AST) are frequently the sole abnormality in the liver biochemistry.

**Diagnosis** is by demonstration of a fatty liver, usually on ultrasound, with the exclusion of other causes of liver injury, e.g. alcohol. Liver biopsy allows staging of the disease but when this should be performed is unclear as there are no definitive guidelines. Most would biopsy if the ALT is persistently over twice normal.

**Elastography** (p. 326) is being used to evaluate the degree of fibrosis.

**Management.** Currently weight loss, strict control of hypertension, diabetes and lipid levels are the only treatments. Fatty liver on its own does not progress. Factors indicating progression are unknown, but diabetic patients are most at risk. Thiazolidinediones (p. 1038) which ameliorate insulin resistance, are being evaluated – histological improvement has been documented in short term studies. Liver transplantation is reserved for end-stage cirrhosis, but the condition may recur. Regular follow-up is indicated, particularly for patients with NASH.

**CIRRHOSIS**

Cirrhosis results from the necrosis of liver cells followed by fibrosis and nodule formation. The liver architecture is diffusely abnormal and this interferes with liver blood flow and function. This derangement produces the clinical features of portal hypertension and impaired liver cell function.

**Aetiology**

The causes of cirrhosis are shown in Table 7.10. Alcohol is now the most common cause in the West, but viral infection is the most common cause world-wide. With the identification of HCV, and recognition of non-alcoholic fatty liver disease (NAFLD), idiopathic (cryptogenic) cirrhosis is diagnosed infrequently. Young patients with cirrhosis must be investigated carefully as the cause may be treatable (e.g. Wilson’s disease).

**Pathogenesis**

Chronic injury to the liver results in inflammation, necrosis and, eventually, fibrosis (Fig. 7.22). Fibrosis is initiated by activation of the stellate cells (see p. 320). Kupffer cells, damaged hepatocytes and activated platelets are probably involved. Stellate cells are activated by many cytokines and their receptors, reactive oxygen intermediates and other paracrine and autocrine signals.

In the early stage of activation the stellate cells become swollen and lose retinoids with upregulation of receptors for proliferative and fibrogenic cytokines, such as platelet-derived growth factor (PDGF), and transforming growth factor β1 (TGF-β1). TGF-β1 is the most potent fibrogenic mediator identified so far. Inflammatory cells contribute to fibrosis via cytokine secretion.

In the space of Disse, the normal matrix is replaced by collagens, predominantly types 1 and 3, and fibronectin. Subendothelial fibrosis leads to loss of the endothelial fenestrations (ports), and this impairs liver function. Collagenases (matrix metalloproteinases, MMPs) are able to degrade this collagen but are inhibited by tissue inhibitors of metalloproteinases (TIMPs), which are increased in human liver fibrosis. There is accumulating evidence that in the early stages liver fibrosis is reversible, particularly when inflammation is reduced, e.g. by suppressing or eliminating viruses.

**Pathology**

The characteristic features of cirrhosis are regenerating nodules separated by fibrous septa and loss of the normal lobular architecture within the nodules (Fig. 7.23a). Two types of cirrhosis have been described which give clues to the underlying cause:

- **Micronodular cirrhosis.** Regenerating nodules are usually less than 3 mm in size and the liver is involved uniformly. This type is often caused by ongoing alcohol damage or biliary tract disease.
Macronodular cirrhosis. The nodules are of variable size and normal acini may be seen within the larger nodules. This type is often seen following chronic viral hepatitis. A mixed picture with small and large nodules is sometimes seen. Symptoms and signs are described on page 328.

**Investigations**

These are performed to assess the severity and type of liver disease.

**Severity**

- **Liver function.** Serum albumin and prothrombin time are the best indicators of liver function: the outlook is poor with an albumin level below 28 g/L. The prothrombin time is prolonged commensurate with the severity of the liver disease (Box 7.3).
- **Liver biochemistry.** This can be normal, depending on the severity of cirrhosis. In most cases there is at least a slight elevation in the serum ALP and serum aminotransferases. In decompensated cirrhosis all biochemistry is deranged.
- **Serum electrolytes.** A low sodium indicates severe liver disease due to a defect in free water clearance or to excess diuretic therapy.
- **Serum creatinine.** An elevated concentration >130 µmol/L is a marker of worse prognosis.

In addition, serum α-fetoprotein if >200 ng/mL is strongly suggestive of the presence of a hepatocellular carcinoma.

**Type**

This can be determined by:

- viral markers
- serum autoantibodies
- serum immunoglobulins
- iron indices and ferritin
- copper, caeruloplasmin (p. 357)
- α₁-antitrypsin (p. 358).

Serum copper and serum α₁-antitrypsin should always be measured in young cirrhatics. Total iron-binding capacity (TIBC) and ferritin should be measured to exclude hereditary haemochromatosis; genetic markers are also available (p. 356).

**Imaging**

- **Ultrasound examination.** This can demonstrate changes in size and shape of the liver. Fatty change and fibrosis produce a diffuse increased echogenicity. In established cirrhosis there may be marginal nodularity of the liver surface and distortion of the arterial vascular architecture. The patency of the portal and hepatic veins can be evaluated. It is useful in detecting hepatocellular carcinoma. **Elastography** is being used in diagnosis and follow-up to avoid liver biopsy (p. 326).
- **CT scan** (see p. 326). Figure 7.23b and c shows hepatosplenomegaly, and dilated collaterals are seen in chronic liver disease. Arterial phase-contrast-enhanced scans are useful in the detection of hepatocellular carcinoma.
- **Endoscopy** is performed for the detection and treatment of varices, and portal hypertensive

#### (b) Model of end-stage liver disease (MELD)

\[ 3.8 \times LN(\text{bilirubin in mg/dL}) + 9.6 \times LN(\text{creatinine in mg/dL}) + 11.2 \times LN(\text{INR}) + 6.4 \]

To convert:
- bilirubin from µmol/L to mg/dL divide by 17
- creatinine from µmol/L to mg/dL divide by 88.4
- LN, natural logarithm; INR, international normalized ratio. MELD scores (with no complications): 1-year survival 97% (score <10); 70% (score 30–40).

LIVER TRANSPLANTATION

This is an established treatment for a number of liver diseases. Shortage of donors is a major problem in all developed countries and in some, such as Japan, living related donors form the majority of transplant operations.

**Indications** include the following:

- **Acute liver disease.** Patients with fulminant hepatic failure of any cause, including acute viral hepatitis (p. 333), may be considered.

- **Chronic liver disease.** The indications for transplantation are usually for complications of cirrhosis, no longer responsive to therapy. Timing of the transplant depends on donor availability. All patients with end-stage (Child’s grade C) cirrhosis should be referred to a transplant centre and also those with debilitating symptoms. In addition specific extrahepatic complications of cirrhosis, even with preserved liver function, such as hepatopulmonary syndrome (shunting in the lung leading to hypoxia) and porto-pulmonary hypertension, can be reversed by liver transplantation.

- **Primary biliary cirrhosis.** Patients with this disease should be transplanted when their serum bilirubin is persistently >100 µmol/L or symptoms such as itching are intolerable.

- **Chronic hepatitis B if HBV DNA negative or levels falling under therapy.** Following transplantation, recurrence of hepatitis is prevented by hepatitis B immunoglobulin.
and nucleoside analogues in combination to prevent escape mutants (see p. 336).

- **Chronic hepatitis C** is the most common indication. Universal HCV reinfecion occurs with chronic hepatitis of varying severity and cirrhosis occurs in 10–20% at 5 years. Antiviral agents may delay this progression if sustained viral response occurs.
- **Autoimmune hepatitis.** In patients who have failed to respond to medical treatment or have major side-effects of corticosteroid therapy. It can recur.
- **Alcoholic liver disease.** Well-motivated patients who have stopped drinking without improving of liver disease are offered a transplant, with concomitant and frequent counselling before and after transplant.
- **Primary metabolic disorders.** Examples are Wilson’s disease, hereditary haemochromatosis and α1-antitrypsin deficiency.
- **Other conditions,** such as sclerosing cholangitis.

### Contraindications

Absolute contraindications include active sepsis outside the hepatobiliary tree, malignancy outside the liver, liver metastases (except neuroendocrine), and if the patient is not psychologically committed.

Relative contraindications are mainly anatomical considerations that would make surgery more difficult, such as extensive splanchnic venous thrombosis. With exceptions, patients aged 65 years or over are not usually transplanted. In hepatocellular carcinoma the recurrence rate is high unless there are fewer than three small (<3 cm) lesions, or a solitary nodule of <5 cm.

### Surgical procedure

Pretransplant work-up includes confirmation of the diagnosis, ultrasound and cross-sectional imaging, radiological demonstration of the hepatic arterial and biliary tree as well as assessment of cardiorespiratory and renal status. Because of the ethical and financial implications of this operation, regular psychosocial support is vital, and psychiatric counselling may be necessary in some cases.

The donor should be ABO compatible (but no HLA matching is necessary) and have no evidence of active sepsis, malignancy, HIV, HBV or HCV infection. Younger donors (<50 years) result in better graft function. The liver is cooled and stored on ice; its preservation time can be up to 20 hours. The recipient operation takes approximately 8 hours and may require a large blood transfusion, but sometimes none at all. Cadaveric donor livers may consist of whole graft, split grafts (for two recipients) or reduced grafts from non-heart-beating donors. Live donors may be healthy individuals or patients with, for example, familial amyloid polyneuropathy, whose livers can then be transplanted into others (domino transplant). Right lobe donors have a mortality between 1 in 200 and 1 in 400.

The operative mortality is low. Most postoperative deaths occur in the first 3 months. Sepsis and haemorrhage can be serious complications. Opportunistic infections are still a problem owing to immunosuppression. Various immunosuppressive agents have been used, but microemulsified ciclosporin, tacrolimus in combination with either azathioprine or mycophenolate mofetil, steroids and sirolimus are the most common. A pretransplant serum creatinine above 160 µmol/L (2 mg/dL) is the best predictor of post-transplant death.

### Rejection

**Acute or cellular rejection** is usually seen 5–10 days post-transplant; it can be asymptomatic or there may be a fever. Histologically, there is a pleomorphic portal infiltrate with prominent eosinophils, bile duct damage and endothelialitis of the blood vessels. This type of rejection responds to immunosuppressive therapy.

**Chronic ductopenic rejection** is seen from 6 weeks to 9 months post-transplant, with disappearing bile ducts (vanishing bile duct syndrome, VBDS) and an arteriopathy with narrowing and occlusion of the arteries. Early ductopenic rejection may rarely be reversed by immunosuppression, but often requires retransplantation.

**Graft-versus-host disease** is extremely rare.

### Prognosis

E elective liver transplantation in low-risk patients has a 90% 1-year survival. Five-year survivals are as high as 70–85% largely owing to the introduction of ciclosporin and tacrolimus. Patients require lifelong immunosuppression, although the doses can be reduced over time without significant problems.

### COMPLICATIONS AND EFFECTS OF CIRRHOSIS

These are shown in Table 7.12.

### Portal hypertension

The portal vein is formed by the union of the superior mesenteric and splenic veins. The pressure within it is normally 5–8 mmHg with only a small gradient across the liver to the hepatic vein in which blood is returned to the heart via the inferior vena cava. Portal hypertension can be classified according to the site of obstruction:

- **prehepatic** – due to blockage of the portal vein before the liver
- **intrahepatic** – due to distortion of the liver architecture, which can be presinusoidal (e.g. in schistosomiasis) or postsinusoidal (e.g. in cirrhosis)
- **posthepatic** – due to venous blockage outside the liver (rare).

As portal pressure rises above 10–12 mmHg, the compliant venous system dilates and collaterals occur within the systemic venous system. The main sites of the collaterals are at the gastro-oesophageal junction, the rectum, the left renal vein, the diaphragm, the retroperitoneum and the anterior abdominal wall via the umbilical vein.

The collaterals at the gastro-oesophageal junction (varices) are superficial in position and tend to rupture. Por-
tosystemic anastomoses at other sites seldom give rise to symptoms. Rectal varices are found frequently (30%) if care-
fully looked for and can be differentiated from haemorrhoids,
which are lower in the anal canal. The microvasculature of
the gut becomes congested giving rise to portal hypertensive
gastropathy and colopathy, in which there is persist-
ently and sometimes erosions, which can bleed.

**Pathophysiology**

Portal vascular resistance is increased in chronic liver
disease. During liver injury, stellate cells are activated and
transform into myofibroblasts. In these cells there is de novo
expression of the specific smooth muscle protein α-actin.
Under the influence of mediators, such as endothelin, nitric
oxide or prostaglandins, the contraction of these activated
cells contributes to abnormal blood flow patterns and
increased resistance to blood flow. In addition the balance
of fibrogenic and fibrolytic factors is shifted towards fibro-
genesis. This increased resistance leads to portal hyperten-
sion and opening of portosystemic anastomoses in both
precirrhotic and cirrhotic livers. Neoangiogenesis also occurs.
Patients with cirrhosis have a hyperdynamic circulation. This
is thought to be due to the release of mediators, such as
nitric oxide and glucagon, which leads to peripheral and
splanchnic vasodilatation. This effect is followed by plasma
volume expansion due to sodium retention (see the discus-
sion on ascites, p. 351), and this has a significant effect in
maintaining portal hypertension.

**Causes** (see Table 7.13)
The most common cause is cirrhosis. Other causes include
the following.

**Prehepatic causes**

Extrahepatic blockage is due to portal vein thrombosis. The
cause is often unidentified, but some cases are due to portal
vein occlusion secondary to congenital portal venous abnor-
malities or neonatal sepsis of the umbilical vein. Many are
due to inherited defects causing prothrombotic conditions,
e.g. factor V Leiden.

** Patients usually present with bleeding, often at a young
age. They have normal liver function and, because of this,
their prognosis following bleeding is excellent.
The portal vein blockage can be identified by ultrasound
with Doppler imaging; CT and MR angiography are also
used.

**Treatment is usually repeated endoscopic therapy or non-
selective beta-blockade. Splenectomy is only performed
if there is isolated splenic vein thrombosis. Anticoagulation
prevents further thrombosis, and does not increase the risk
of bleeding; it is used when there is a high risk of recurrent
thrombosis.**

**Intrahepatic causes**

Although cirrhosis is the most common intrahepatic cause of
portal hypertension, there are other causes:

- **Non-cirrhotic portal hypertension.** Patients present with
portal hypertension and variceal bleeding but without cirrhosis. Histologically, the liver shows mild portal tract
fibrosis. The aetiology is unknown, but arsenic, vinyl
chloride, antiretroviral therapy and other toxic agents
have been implicated. A similar disease is found
frequently in India. The liver lesion does not progress
and the prognosis is therefore good.

- **Schistosomiasis** with extensive 'pipe-stem' fibrosis is the
commonest cause, but is confined to endemic areas
such as Egypt and Brazil. However, often there may be
concomitant liver disease such as HCV infection.

- Other causes include congenital hepatic fibrosis,
nodal regenerative hyperplasia and partial nodular
transformation. The last two conditions are rare. They
share the common features of hyperplastic liver cell
growth in the form of nodules, but in contrast to
cirrhosis, fibrosis is typically absent. A wedge liver
biopsy is usually required to establish the diagnosis. In
none of these conditions are hormones implicated in
aetiology or progression.

**Posthepatic causes**

Prolonged severe heart failure with tricuspid incompetence
and constrictive pericarditis can both lead to portal hyperten-
sion. The Budd–Chiari syndrome is described on page 359.

**Clinical features**

Patients with portal hypertension are often asymptomatic and
the only clinical evidence of portal hypertension is sple
megaly. Clinical features of chronic liver disease are usually
present (see p. 326). Presenting features may include:

- haematemesis or melaena from rupture of
gastro-oesophageal varices or portal hypertensive
gastropathy
- ascites
- encephalopathy
- breathlessness due to porto-pulmonary hypertension or
hepatopulmonary syndrome (rare).

**Variceal haemorrhage**

Approximately 90% of patients with cirrhosis will develop
gastro-oesophageal varices, over 10 years, but only one-
third of these will bleed from them. Bleeding is likely to occur
with large varices, red signs on varices (diagnosed at endos-
copy) and in severe liver disease.

### Table 7.13 Causes of portal hypertension

| **Prehepatic** | Portal vein thrombosis |
| **Intrahepatic** |  |
| **Pre-sinusoidal** | Schistosomiasis |
| | Sarcoidosis |
| | Primary biliary cirrhosis |
| **Sinusoidal** | Cirrhosis (e.g. alcoholic) |
| | Partial nodular transformation |
| **Post-sinusoidal** | Veno-occlusive disease |
| | Budd–Chiari syndrome |
| **Posthepatic** | Right heart failure (rare) |
| | Constrictive pericarditis |
| | IVC obstruction |
Management of gastrointestinal haemorrhage due to oesophageal varices. TIPS, transjugular intrahepatic portosystemic shunt.

**Management**

Management can be divided into the active bleeding episode, the prevention of rebleeding, and prophylactic measures to prevent the first haemorrhage. Despite all the therapeutic techniques available, the prognosis depends on the severity of the underlying liver disease, with an overall mortality from variceal haemorrhage of 25%, reaching 50% in Child’s grade C.

**Initial management of acute variceal bleeding** (Fig. 7.24)

See also the discussion of the general management of gastrointestinal haemorrhage on page 267.

**Resuscitation**

- Assess the general condition of the patient – pulse and blood pressure.
- Insert an intravenous line and obtain blood for grouping and crossmatching, haemoglobin, PT/INR, urea, electrolytes, creatinine, liver biochemistry and blood cultures.
- Restore blood volume with plasma expanders or, if possible, blood transfusion. These measures are discussed in more detail in the treatment of shock (p. 904). Prompt correction of hypovolaemia is necessary in patients with cirrhosis as their baroreceptor reflexes are diminished.
- Ascitic tap.
- Monitor for alcohol withdrawal. Give thiamine i.v.
- Start prophylactic antibiotics – third generation cephalosporins, e.g. cefotaxime. These treat and prevent infection and early rebleeding and reduce mortality.

**Urgent endoscopy**

Endoscopy should be performed to confirm the diagnosis of varices (Fig. 7.25). It also excludes bleeding from other sites (e.g. gastric ulceration) or portal hypertensive (or congestive) gastropathy. The latter term is used for chronic gastric congestion, punctate erythema and gastric erosions. It is a source of bleeding but varices may or may not be present.

Propranolol (see below) is the best treatment for this gastropathy.

**Injection sclerotherapy or variceal banding**

The varices should be injected with a sclerosing agent that may arrest bleeding by producing vessel thrombosis. A needle is passed down the biopsy channel of the endoscope and a sclerosing agent is injected into the varices. Alternatively, the varices can be banded by mounting a band on the tip of the endoscope, sucking the varix just into the end of the scope and dislodging the band over the varix using a trip-wire mechanism (Fig. 7.25d).

Acute variceal sclerotherapy and banding are the treatment of choice; they arrest bleeding in 80% of cases and reduce early rebleeding. Between 15% and 20% of bleeding comes from gastric varices and here results of sclerotherapy and banding are poor. Injection of tissue glue is preferable.

**Other measures available**

**Vasoconstrictor therapy**

The main use of this is for emergency control of bleeding whilst waiting for endoscopy and in combination with endoscopic techniques. The aim of vasoconstrictor agents is to restrict portal inflow by splanchnic arterial constriction.

- **Terlipressin.** This is the only vasoconstrictor shown to reduce mortality. The dose is 2 mg 6-hourly, reducing to 1 mg 4-hourly after 48 hours if a prolonged dosage regimen is used. It should not be given to patients with ischaemic heart disease. The patient will complain of abdominal colic, will defaecate and have facial pallor owing to the generalized vasoconstriction.
- **Somatostatin.** This drug has few side-effects. An infusion of 250–500 μg/h appears to reduce bleeding, but has no effect on mortality. It should be used if there are contraindications to terlipressin.

**Balloon tamponade**

Balloon tamponade is used mainly to control bleeding if endoscopic therapy or vasoconstrictor therapy has failed or is contraindicated or if there is exsanguinating haemorrhage. The usual balloon tube is a four lumen Sengstaken-Blake more, which should be left in place for no more than 12 hours and removed in the endoscopy room prior to the endoscopic procedure. The tube is passed into the stomach and the gastric balloon is inflated with air and pulled back. It should be positioned in close apposition to the gastro-oesophageal junction to prevent the cephalad variceal blood flow to the bleeding point. The oesophageal balloon should be inflated only if bleeding is not controlled by the gastric balloon alone.

This technique is successful in up to 90% of patients and is very useful in the first few hours of bleeding. However, it can have serious complications such as aspiration pneumonia, oesophageal rupture and mucosal ulceration, which lead to a 5% mortality. The procedure is very unpleasant for the patient. A self-expanding covered metal stent introduced orally and placed over the varices is currently being evaluated, and has the advantage that swallowing is not impaired.

**Additional management of acute episode**

- Measures to prevent encephalopathy. Portosystemic encephalopathy (PSE) can be precipitated by a large
bleed (since blood contains protein). The management is described on page 353.

Nursing. Patients require high-dependency/intensive care nursing. They should be nil by mouth until bleeding has stopped.

Sucralfate. 1 g four times daily is given to reduce oesophageal ulceration following endoscopic therapy.

Management of an acute rebleed
Rebleeding occurs in 20–30% within 5 days after a single session of therapeutic endoscopy. The source of rebleeding should be established by endoscopy. It is sometimes due to a sclerotherapy induced ulcer or slippage of a ligation band. Management starts with repeat endoscopic therapy – once only to control rebleeding (further sessions of sclerotherapy or banding are not advisable).

Transjugular intrahepatic portocaval shunt (TIPS)
TIPS is used when bleeding cannot be stopped after two sessions of endoscopic therapy within 5 days. In this technique, a guidewire is passed from the jugular vein into the liver and an expandable covered metal shunt is placed over it to form a channel between the systemic and portal venous systems. It reduces the hepatic sinusoidal and portal vein pressure by creating a total shunt and does not have the risks of general anaesthesia and major surgery. However there is an increased risk of portal systemic encephalopathy. Recurrent portal hypertension due to stent stenosis or thrombosis is far less frequent with ‘covered’ compared to ‘bare’ stents. Collaterals arising from the splenic or portal veins can be selectively embolized.

Emergency surgery
This is used when other measures fail or if TIPS is not available and, particularly, if the rebleeding is from gastric fundal varices. Oesophageal transection and ligation of the feeding vessels to the bleeding varices is the most common surgical technique. Acute portosystemic shunt surgery (see below) is infrequently performed.

Prevention of recurrent variceal bleeding
Following an episode of variceal bleeding, the risk of recurrence is 60–80% over a 2-year period with an approximate mortality of 20% per episode. These facts justify the use of measures to prevent rebleeding.

Long-term measures
Non-selective beta-blockade. Oral propranolol in a dose sufficient to reduce resting pulse rate by 25% has been shown to decrease portal pressure. Portal inflow is reduced by two mechanisms: by a decrease in cardiac output ($\beta_1$), and by the blockade of $\beta_2$ vasodilator receptors on the splanchic arteries, leaving an unopposed vasoconstrictor effect. This decreases the frequency of rebleeding, and is as effective as sclerotherapy and ligation as it also prevents bleeding from portal hypertensive gastropathy. It is the treatment of first choice, but a substantial number of patients either have contraindications or are intolerant of treatment. Significant reduction of hepatic venous pressure gradient (HVPG, measured by hepatic vein catheterization) is associated with very low rates or absence of rebleeding, particularly if $<12$ mmHg. Assessment of HVPG target reduction has prognostic specificity but poor sensitivity and thus poor clinical applicability.

Endoscopic treatment. The use of repeated courses of banding at 2-weekly intervals leads to obliteration of the varices. This markedly reduces rebleeding, most instances occurring before the varices have been fully obliterated. Between 30% and 40% of varices return per year, so follow-up endoscopy with ablation should be performed. Banding is superior to sclerotherapy.

Although a reduction in bleeding episodes occurs, the effect on survival is controversial and probably small. Complications include oesophageal ulceration, mediastinitis and rarely strictures. Combined medical and endoscopic therapy is often used in practice.

Transjugular portosystemic stent shunts. These reduce rebleeding rates compared to endoscopic techniques, but do not improve survival and increase encephalopathy. They are used if endoscopic or medical therapy fails.

Surgical procedures
Surgical portosystemic shunting is associated with an extremely low risk of rebleeding, and is used if TIPS is not available. Hepatic encephalopathy is a significant complication. Operative mortality is low in patients with Child’s grade A (0–5%) but rises with worsening liver disease. The ‘shunts’ performed are usually an end-to-side portocaval anastomosis or a selective distal splenorenal shunt (Warren shunt), which transiently maintains hepatic blood flow via the superior mesenteric vein.

Devascularization procedures including oesophageal transection do not produce encephalopathy, and can be used when there is splanchic venous thrombosis. Liver transplantation (p. 347) is the best option when there is poor liver function.

Prophylactic measures
Patients with cirrhosis and varices that have not bled should be prescribed non-selective beta-blockers (e.g. propranolol). This reduces the chances of upper GI bleeding, may increase survival and is cost-effective. If there are contraindications or intolerance, variceal banding is an option. Beta-blockers do not prevent development of varices.

Ascites
Ascites is fluid within the peritoneal cavity and is a common complication of cirrhosis. The pathogenesis of ascites in liver disease is secondary to renal sodium and water retention. Several factors are involved.

Sodium and water retention results from peripheral arterial vasodilatation and consequent reduction in the effective blood volume. Nitric oxide and other substances (e.g. atrial natriuretic peptide and prostaglandins) act as vasodilators. The reduction in effective blood volume activates various neurohumoral pressor systems such as the sympathetic nervous system and the renin–angiotensin system, thus promoting salt and water retention (Fig. 12.3).

Portal hypertension exerts a local hydrostatic pressure and leads to increased hepatic and splanchic production of lymph and transudation of fluid into the peritoneal cavity.
Low serum albumin (a consequence of poor synthetic liver function) may further contribute by a reduction in plasma oncotic pressure.

In patients with ascites, urine sodium excretion rarely exceeds 5 mmol in 24 hours. Loss of sodium from extrarenal sites accounts for approximately 30 mmol in 24 hours. The normal daily dietary sodium intake may vary between 120 and 200 mmol, resulting in a positive sodium balance of approximately 90–170 mmol in 24 hours (equivalent to 600–1300 mL of fluid retained).

**Clinical features**

The abdominal swelling associated with ascites develops over many weeks or as rapidly as a few days. Precipitating factors include a high sodium diet or the development of a hepatocellular carcinoma or splanchic vein thrombosis. Mild generalized abdominal pain and discomfort are common but, if more severe, should raise the suspicion of spontaneous bacterial peritonitis (see below). Respiratory distress accompanies tense ascites, and also causes difficulty in eating.

The presence of fluid is confirmed by the demonstration of shifting dullness. Many patients also have peripheral oedema. A pleural effusion (usually on the right side) may infrequently be found and arises from the passage of ascitic fluid through congenital diaphragmatic defects.

**Investigations**

A diagnostic aspiration of 10–20 mL of fluid should be obtained and the following performed:

- **Cell count.** A neutrophil count above 250 cells/mm³ is indicative of an underlying (usually spontaneous) bacterial peritonitis.
- **Gram stain and culture** – for bacteria and acid-fast bacilli.
- **Protein.** A high serum–ascites albumin gradient of >11 g/L suggests portal hypertension, and a low gradient <11 g/L is associated with abnormalities of the peritoneum, e.g. inflammation, infections, neoplasia (Box 7.4).
- **Cytology** – for malignant cells.
- **Amylase** – to exclude pancreatic ascites.

The differential diagnosis of ascites is listed in Table 7.14.

**Management**

The aim is to both reduce sodium intake and increase renal excretion of sodium, producing a net reabsorption of fluid from the ascites into the circulating volume. The maximum rate at which ascites can be mobilized is 500–700 mL in 24 hours (see below). The management is as follows:

- Check serum electrolytes and creatinine at the start and every other day; weigh patient and measure urinary output daily.
- Bed rest alone will lead to a diuresis in a small proportion of people by improving renal perfusion, but in practice is not helpful.
- By dietary sodium restriction it is possible to reduce sodium intake to 40 mmol in 24 hours and still maintain an adequate protein and calorie intake with a palatable diet.
- Drugs: many contain significant amounts of sodium (up to 50 mmol daily). Examples include antacids, antibiotics (particularly the penicillins and cephalosporins) and effervescent tablets. Sodium-retaining drugs (non-steroidals, corticosteroids) should be avoided.
- Fluid restriction is probably not necessary unless the serum sodium is under 128 mmol/L (see below).
- The diuretic of first choice is the aldosterone antagonist spironolactone, starting at 100 mg daily. Chronic administration produces gynaecomastia. Eplerenone 25 mg once daily does not cause gynaecomastia.

The aim of diuretic therapy should be to produce a net loss of fluid approaching 700 mL in 24 hours (0.7 kg weight loss or 1.0 kg if peripheral oedema is present). Although 60% of patients respond with this regimen, diuresis is often poor and
the spironolactone can be increased gradually to 500 mg daily with no hyperkalaemia. A loop diuretic, such as furosemide 20–40 mg or bumetanide 1 mg daily, may be added if response is poor. These loop diuretics have several potential disadvantages, including hyponatraemia, hypokalaemia and volume depletion.

Ascitic fluid is mobilized more slowly than interstitial fluid, and diuretics should be given with great care in those without peripheral oedema.

Diuretics should be temporarily discontinued if a rise in serum creatinine level occurs, representing overdiuresis and hypovolaemia, or if there is hyperkalaemia or the development of precoma. Hyponatraemia occurring during therapy almost always represents haemodilution secondary to a fall in free water (usually a marker of reduced renal perfusion) and should be treated by stopping the diuretics if the sodium level falls below approximately 128 mmol/L as well as introducing water restriction. Vaptans (p. 663), a class of drugs that increase free water clearance by inhibition of vasopressin receptors, are being evaluated in cirrhosis.

**Paracentesis**

This is used to relieve symptomatic tense ascites. It is also used as a means of rapid therapy in patients with ascites and peripheral oedema, thus avoiding prolonged hospital stay. The main complication is hypovolaemia and renal dysfunction (post-paracentesis circulatory dysfunction) as the ascites reaccumulates at the expense of the circulating volume; this is more likely with more than 5 litres removal and worse liver function. In patients with normal renal function and without hyponatraemia, this is overcome by infusing albumin (8 g per litre of ascitic fluid removed). In practice, up to 20 L can be removed over 4–6 hours with albumin infusion.

**Shunts**

A transjugular intrahepatic portosystemic shunt (TIPS) is used for resistant ascites providing there is no spontaneous portosystemic encephalopathy and minimal disturbance of renal function. Frequency of paracentesis and diuretic use is usually reduced. Survival may improve. The use of a peritono-venous shunt has been abandoned in most centres due to a high rate of blockage.

**Spontaneous bacterial peritonitis (SBP)**

This represents a serious complication of ascites with cirrhosis and occurs in approximately 8% of the infecting organisms gain access to the peritoneum by haematogenous spread; most are *Escherichia coli*, *Klebsiella* or enterococci. The condition should be suspected in any patient with ascites who clinically deteriorates. Features such as pain and pyrexia are frequently absent. Diagnostic aspiration should always be performed (see above). A raised neutrophil count in ascites is alone sufficient evidence to start treatment immediately. A third-generation cephalosporin, such as ceftaxime or cefazidime, is used and is modified on the basis of culture results. Mortality is 10–15%. Recurrence is common (70% within a year) and an oral quinolone, e.g. norfloxacin 400 mg daily, is given for prevention, prolonging the survival. Primary prophylaxis of SBP in patients with ascites protein <10 g/L or severe liver disease also improves survival.

SBP is an indication to refer to a liver transplant centre.

**Portosystemic encephalopathy (PSE)**

This is a chronic neuropsychiatric syndrome secondary to cirrhosis. Acute encephalopathy can occur in acute hepatic failure (see p. 342). PSE can occur in portal hypertensive patients due to spontaneous ‘shunting’, or in those with surgical or TIPS shunts. Encephalopathy is potentially reversible.

**Pathogenesis**

The mechanism is unknown but several factors are involved. In cirrhosis, the portal blood bypasses the liver via the collaterals and the “toxic” metabolites pass directly to the brain to produce the encephalopathy.

Many “toxic” substances may be causative factors, including ammonia, free fatty acids, mercaptans and accumulation of false neurotransmitters (octopamine) or activation of the γ-aminobutyric acid (GABA) inhibitory neurotransmitter system. Increased blood levels of aromatic amino acids (tyrosine and phenylalanine) and reduced branched-chain amino acids (valine, leucine and isoleucine) also occur. Ammonia has a major role; ammonia-induced alteration of brain neurotransmitter balance – especially at the astrocyte–neurone interface – is the leading pathophysiological mechanism. Ammonia is produced by intestinal bacteria breaking down protein. The factors precipitating PSE are shown in Table 7.15.

**Clinical features**

An acute onset often has a precipitating factor (Table 7.15). The patient becomes increasingly drowsy and comatose. Chronically, there is a disorder of personality, mood and intellect, with a reversal of normal sleep rhythm. These changes may fluctuate, and a history from a relative must be obtained. The patient is irritable, confused, disorientated and has slow slurred speech. General features include nausea, vomiting and weakness. Coma occurs as the encephalopathy becomes more marked, but there is always hyperreflexia and increased tone. Convulsions are so very rare that other causes must be looked for.

Signs include:

- fetor hepaticus (a sweet smell to the breath)
- a coarse flapping tremor seen when the hands are outstretched and the wrists hyperextended (asterixis)

TIPS, transjugular intrahepatic portocaval shunt
constructional apraxia, with the patient being unable to write or draw, for example, a five-pointed star
• decreased mental function, which can be assessed by using the serial-sevens test (see p. 1189). A trail-making (or connection) test (the ability to join numbers and letters (in chronological order) with a pen within a certain time – a standard psychological test for brain dysfunction) is prolonged.

Diagnosis is clinical. Routine liver biochemistry merely confirms the presence of liver disease, not the presence of encephalopathy.

Additional investigations
• Electroencephalography (EEG) shows a decrease in the frequency of the normal α-waves (8–13 Hz) to δ-waves of 1.5–3 Hz. These changes occur before coma supervenes.
• Visual evoked responses (see p. 1121) also detect subclinical encephalopathy.
• Arterial blood ammonia can be useful for the differential diagnosis of coma and to follow a patient with PSE, but is not readily available.

Management
• Identify and remove the possible precipitating cause, such as drugs with cerebral depressant properties, constipation or electrolyte imbalance due to overdiuresis.
• Give purgation and enemas to empty the bowels of nitrogenous substances. Lactulose (10–30 mL three times daily) is an osmotic purgative that reduces the colonic pH and limits ammonia absorption. Lactitol (β-galactoside sorbitol 30 g daily) is metabolized by colonic bacteria and is comparable in efficacy to lactulose.
• Maintain nutrition with adequate calories, given if necessary via a fine-bore nasogastric tube, and do not restrict protein for more than 48 hours.
• Give antibiotics. Rifaximin is mainly unabsorbed and well tolerated long term. Metronidazole (200 mg four times daily) is also effective in the acute situation. Neomycin should be avoided. Stop or reduce diuretic therapy.
• Give intravenous fluids as necessary (beware of too much sodium).
• Treat any infection.
• Increase protein in the diet to the limit of tolerance as the encephalopathy improves.

Course and prognosis
Acute encephalopathy in acute liver failure has a very poor prognosis as the disease itself has a high mortality. In cirrhosis, chronic PSE is very variable and adversely affects prognosis. Very rarely with chronic portosystemic shunting an organic syndrome with cerebellar signs or choreoathetosis can develop, as well as a myelopathy leading to a spastic paraparesis due to demyelination. Patients should be referred to a liver transplant centre.

Renal failure (hepatorenal syndrome)
The hepatorenal syndrome occurs typically in a patient with advanced cirrhosis, portal hypertension with jaundice and ascites. The urine output is low with a low urinary sodium concentration, a maintained capacity to concentrate urine (i.e. tubular function is intact) and almost normal renal histology. The renal failure is described as ‘functional’. It is sometimes precipitated by overvigorous diuretic therapy, NSAIDs, diarrhoea or paracentesis, and infection, particularly spontaneous bacterial peritonitis.

The mechanism is similar to that producing ascites. The initiating factor is thought to be extreme peripheral vasodilatation, possibly due to nitric oxide, leading to an extreme decrease in the effective blood volume and hypotension (p. 351). This activates the homeostatic mechanisms, causing a rise in plasma renin, aldosterone, norepinephrine (noradrenaline) and vasopressin, leading to vasoconstriction of the renal vasculature. There is an increased preglomerular vascular resistance causing the blood flow to be directed away from the renal cortex. This leads to a reduced glomerular filtration rate and plasma renin remains high. Salt and water retention occur with reabsorption of sodium from the renal tubules.

Other mediators have been incriminated in the pathogenesis of the hepatorenal syndrome, in particular the eicosanoids. This has been supported by the precipitation of the syndrome by inhibitors of prostaglandin synthase such as non-steroidal anti-inflammatory drugs (NSAIDs).

Diuretic therapy should be stopped and intravascular hypovolaemia corrected, preferably with albumin. Terlipresin or noradrenaline with intravenous albumin improves renal function in one-third of patients. Liver transplantation is the best option.

Hepatopulmonary syndrome
This is defined as a hypoaemia occurring in patients with advanced liver disease. It is due to intrapulmonary vascular dilatation with no evidence of primary pulmonary disease. The patients have features of cirrhosis with spider naevi and clubbing as well as cyanosis. Most patients have no respiratory symptoms, but with more severe disease, patients are breathless on standing. Transthoracic ECHO shows intrapulmonary shunting, and arterial blood gases confirm the arterial oxygen desaturation. These changes are improved with liver transplantation.

Porto-pulmonary hypertension
This must be distinguished from the hepatopulmonary syndrome as in this group there is pulmonary hypertension. It occurs in 1–2% of patients with cirrhosis related to portal hypertension. It may respond to medical therapy. Severe pulmonary hypertension is a contraindication for liver transplantation.

Primary hepatocellular carcinoma
This is discussed on page 363.

TYPES OF CIRRHOSIS
Alcoholic cirrhosis
This is discussed in the section on alcoholic liver disease (p. 358).
**Primary biliary cirrhosis**

Primary biliary cirrhosis (PBC) is a chronic disorder in which there is a progressive destruction of bile ducts, eventually leading to cirrhosis. Ninety per cent of those affected are women in the age range 40–50 years. PBC is frequently being diagnosed in its milder forms. The prevalence is approximately 7.5 per 100,000, with a 1–6% increase in first-degree relatives. PBC has been called ‘chronic non-suppurative destructive cholangitis’; this term is more descriptive of the early lesion and emphasizes that true cirrhosis occurs only in the later stages of the disease.

**Aetiology**

The aetiology is unknown, but immunological mechanisms play a part. Serum anti-mitochondrial antibodies (AMA) are found in almost all patients with PBC, and of the mitochondrial proteins involved, the antigen M2 is specific to PBC.

Five M2-specific antigens have been further defined using immunoblot techniques, of which the E2 component of the pyruvate dehydrogenase complex (PDC) is the major M2 autoantigen (72 kDa E2 subunit (PDC,E2)). The presence of AMA in high titre is unrelated to the clinical or histological picture and its role in pathogenesis is unclear. Antibodies against nuclear antigens, e.g. anti gp210, are present in 50% of patients and correlate with progression towards liver failure.

It seems likely that an environmental factor acts on a genetically predisposed host via molecular mimicry initiating autoimmunity. *E. coli* and *N. aromaticivorans* antibodies are present in high titre. Halogenated hydrocarbons mimic the PDC autoepitopes.

Although damage to bile ducts is a feature, antibodies to bile ductules are not specific to PBC. Biliary epithelium from patients with PBC expresses aberrant class II HLAs, but it is not known whether this expression is the cause or result of the inflammatory response. Cell-mediated immunity is impaired (demonstrated both in vitro and by skin testing); cytotoxic DC4+ and CD8+ T lymphocytes directly produce biliary epithelium damage. They recognize the inner lipoyl domain and lipic acid also recognized by AMA. There is an increased synthesis of IgM, thought to be due to a failure of the switch from IgM to IgG antibody synthesis. No specific associated Class 2 MHC loci have been found.

Asymptomatic patients are discovered on routine examination or screening and may have hepatomegaly, a raised serum alkaline phosphatase or autoantibodies.

Pruritus is often the earliest symptom, preceding jaundice by a few years. Fatigue, which is often disabling, may accompany pruritus, particularly in progressive cases. When jaundice appears, hepatomegaly is usually found. In the later stages, patients are pigmented and jaundiced with severe pruritus. Pigmented xanthelasma on eyelids or other deposits of cholesterol in the creases of the hands may be seen.

**Investigations**

- **Mitochondrial antibodies** – measured routinely by ELISA (in titres >1:160) – are present in over 95% of patients; M2 antibody is specific. Other non-specific antibodies (e.g. anti-nuclear factor and smooth muscle) may also be present.
- **High serum alkaline phosphatase** is often the only abnormality in the liver biochemistry.
- **Serum cholesterol** is raised.
- **Serum IgM** may be very high.
- **Ultrasound** can show a diffuse alteration in liver architecture.
- **Liver biopsy** shows characteristic histological features of a portal tract infiltrate, mainly of lymphocytes and plasma cells; approximately 40% have granulomas. Most of the early changes are in zone 1. Later, there is damage to and loss of small bile ducts with ductular proliferation. Portal tract fibrosis and, eventually, cirrhosis is seen.

*Hepatic granulomas* are not specific and are also seen in sarcoidosis, tuberculosis, schistosomiasis, drug reactions, brucellosis, parasitic infestation (e.g. *strongyloidiasis*) and other conditions.

**Differential diagnosis**

The classical picture presents little difficulty with diagnosis (high serum alkaline phosphatase and the presence of AMA); this can be confirmed by the characteristic histological features although this is not necessary except in doubtful cases. There is a group of patients with the histological changes of PBC but the serology of autoimmune hepatitis. This has been given the name of autoimmune cholangitis and responds to steroids and azathioprine.

In the jaundiced patient, extrahepatic biliary obstruction should be excluded by ultrasound and, if there is doubt about the diagnosis, MRCP (or ERCP) should be performed to make sure that the bile ducts are normal.

**Treatment**

Ursodeoxycholic acid (10–15 mg/kg) improves bilirubin and aminotransferase levels. It should be given early in the asymptomatic phase. It is not clear if prognosis is altered. Symptoms are not improved. Steroids improve biochemical and histological disease but may lead to increased osteoporosis and other side-effects and should not be used.

Malabsorption of fat-soluble vitamins (A, D and K) occurs and supplementation is required when deficiency is detected and prophylactically in the jaundiced patient. Bisphosphonates are required for osteoporosis. Despite raised serum lipid concentrations there is no increased risk from cardiovascular disease, although this has been recently disputed by one group.

Pruritus is difficult to control, but colestyramine, one 4 g sachet three times daily, can be helpful, although it is unpalatable. Rifampicin, naltrexone hydrochloride and naltrexone (opioid antagonists) have been shown to be of benefit. Intracanal pruritus can be relieved by plasmapheresis or a molecular absorbent re-circulating system (MARS).

The lack of effective medical therapy has made PBC a major indication for liver transplantation (p. 347).
**Complications**
The complications are those of cirrhosis. In addition, osteoporosis, and rarely osteomalacia and a polyneuropathy can also occur.

**Course and prognosis**
This is very variable. Asymptomatic patients and those presenting with pruritus will survive for more than 20 years. Symptomatic patients with jaundice have a more rapidly progressive course and die of liver failure or bleeding varices in approximately 5 years. Liver transplantation should therefore be offered when the serum bilirubin reaches 100 µmol/L. Transplantation has a 5-year survival of at least 80%.

**Secondary biliary cirrhosis**
Cirrhosis can result from prolonged (for months) large duct biliary obstruction. Causes include bile duct strictures, gallstones and sclerosing cholangitis. An ultrasound examination, followed by ERCP or PTC, is performed to outline the ducts and any remedial cause is dealt with.

**Hereditary haemochromatosis**
(see also p. 394)
Hereditary haemochromatosis (HH) is an inherited disease characterized by excess iron deposition in various organs leading to eventual fibrosis and functional organ failure.

**Prevalence and aetiology**
HH is transmitted by an autosomal recessive gene with a prevalence in Caucasians of homozygotes (affected) of 1 in 400, but very variable phenotypic expression and a heterozygote (carrier) frequency of 1 in 10. It is the most common single gene disorder in Caucasians. The most common form of HH is due to a mutation in a gene, HFE, on the short arm of chromosome 6.

Between 85% and 90% of patients with overt HH are homozygous for the Cys 282 Tyr (C282Y mutation). A second mutation (His 63 Asp (H63D)) occurs in about 25% of the population and is in complete linkage disequilibrium with Cys 282 Tyr. Another form of haemochromatosis occurs in Southern Europe and is associated with TfR2, a transferrin receptor isoform. Rarer types are ferroportin related, and there is also a juvenile form.

Dietary intakes of iron and chelating agents (ascorbic acid) may be relevant. Iron overload may be present in alcoholics, but alcohol excess per se does not cause HH although there is a history of excess alcohol intake in 25% of patients.

**Mechanism of damage.** This is still unclear. The HFE gene protein interacts with the transferrin receptor 1, which is a mediator in intestinal iron absorption (see Fig. 8.8). Iron is taken up by the mucosal cells inappropriately, exceeding the binding capacity of transferrin. Hepatic expression of the hepcidin gene is decreased in HFE haemochromatosis, facilitating liver iron overload. Excess iron is then taken up by the liver and other tissues gradually over a long period. It seems likely that it is the iron itself that precipitates fibrosis.

**Pathology**
In symptomatic patients the total body iron content is 20–40 g, compared with 3–4 g in a normal person. The iron content is particularly increased in the liver and pancreas (50–100 times normal) but is also increased in other organs (e.g. the endocrine glands, heart and skin).

In established cases the liver shows extensive iron deposition and fibrosis. Early in the disease, iron is deposited in the periportal hepatocytes (in pericanalicular lysosomes). Later it is distributed widely throughout all acinar zones, biliary duct epithelium, Kupffer cells and connective tissue. Cirrhosis is a late feature.

**Clinical features**
The course of the disease depends on a number of factors, including sex, dietary iron intake, presence of associated hepatotoxins (especially alcohol) and genotypes. Overt clinical manifestations occur more frequently in men; the reduced incidence in women is probably explained by physiological blood loss and a smaller dietary intake of iron. Most affected individuals present in the fifth decade. The classic triad of bronze skin pigmentation (due to melanin deposition), hepatomegaly and diabetes mellitus is only present in cases of gross iron overload.

Hypogonadism secondary to pituitary dysfunction is the most common endocrine feature. Deficiency of other pituitary hormones is also found, but asymptomatic endocrine deficiencies, such as loss of libido, are very rare. Cardiac manifestations, particularly heart failure and arrhythmias, are common, especially in younger patients. Calcium pyrophosphate is deposited asymmetrically in both large and small joints (chondrocalcinosis) leading to an arthropathy. The exact relationship of chondrocalcinosis to iron deposition is uncertain.

**Complications**
Thirty per cent of patients with cirrhosis will develop primary hepatocellular carcinoma (HCC). HCC has only very rarely been described in non-cirrhotic patients in whom the excess iron stores have been removed. Early diagnosis is vital.

**Investigations**

**Homozygotes**
- **Serum iron** is elevated (>30 µmol/L) in 90% with a reduction in the TIBC and a transferrin saturation of >45%.
- **Serum ferritin** is elevated (usually >500 µg/L or 240 nmol/L).
- **Liver biochemistry** is often normal, even with established cirrhosis.

**Heterozygotes**
Heterozygotes may have normal biochemical tests or modest increases in serum iron transferrin saturation (>45%) or serum ferritin (usually >400 µg/L).

**Genetic testing**
If iron studies are abnormal, genetic testing is performed.

**Liver biopsy**
This is not required for diagnosis, but is useful to assess the extent of tissue damage, assess tissue iron, and measure the hepatic iron concentration (>180 µmol/g dry weight of liver indicates haemochromatosis).

Mild degrees of parenchymal iron deposition in patients with other forms of cirrhosis, particularly due to alcohol, can often cause confusion with true homozygous HH.
Magnetic resonance imaging
MRI shows dramatic reduction in the signal intensity of the liver and pancreas owing to the paramagnetic affect of ferritin and haemosiderin. A highly T2 weighted gradient recalled echo (GRE) technique detects all clinically relevant liver iron overload (>60 µmol/g of liver). In secondary iron overload (haemosiderosis), which involves the reticuloendothelial cells, the pancreas is spared, enabling distinction between these two conditions.

Treatment and management
Venesection
This prolongs life and may reverse tissue damage; the risk of malignancy still remains if cirrhosis is present. All patients should have excess iron removed as rapidly as possible. This is achieved using venesection of 500 mL performed twice-weekly for up to 2 years, i.e. 160 units with 250 mg of iron per unit, equals 40 g removed. During venesection, serum iron and ferritin and the mean corpuscular volume (MCV) should be monitored. These fall only when available iron is depleted. Three or four venesections per year are required to prevent reaccumulation of iron. Serum ferritin should remain within the normal range.

Manifestations of the disease usually improve or disappear, except for diabetes, testicular atrophy and chondrocalcinosis. The requirements for insulin often diminish in diabetic patients. Testosterone replacement is often helpful.

In the rare patient who cannot tolerate venesection (because of severe cardiac disease or anaemia), chelation therapy with desferrioxamine, either intermittently or continuously by infusion, has been successful in removing iron.

Screening
In all cases of HH, all first-degree family members must be screened to detect early and asymptomatic disease. HFE mutation analysis is performed with measurement of transferrin saturation and serum ferritin.

In the general population, the serum iron and transferrin saturation are the best and cheapest tests available.

Wilson’s disease (progressive hepatocellular degeneration)
Dietary copper is normally absorbed from the stomach and upper small intestine. It is transported to the liver loosely bound to albumin. Here it is incorporated into apoceruloplasmin forming ceruloplasmin, a glycoprotein synthesized in the liver, and secreted into the blood. The remaining copper is normally excreted in the bile and excreted in faeces.

Wilson’s disease is a very rare inborn error of copper metabolism that results in copper deposition in various organs, including the liver, the basal ganglia of the brain and the cornea. It is potentially treatable and all young patients with liver disease must be screened for this condition.

Aetiology
It is an autosomal recessive disorder with a molecular defect within a copper-transporting ATPase encoded by a gene (designated ATP7B) located on chromosome 13, affecting between 1 in 30,000 and 1 in 100,000 individuals. Over 300 mutations have been identified, the most frequent being His1069 Gly (H1069Q) found in approximately 50% of Cau-
casian patients, with compound heterozygotes being frequent. This mutation is rare in India and Asia. Wilson’s disease occurs world-wide, particularly in countries where consanguinity is common. There is a failure of both incorporation of copper into procaeruloplasmin, which leads to low serum caeruloplasmin, and biliary excretion of copper. There is a low serum caeruloplasmin in over 80% of patients but this is not the cause of the copper deposition. The precise mechanism for the failure of copper excretion is not known.

Pathology
The liver histology is not diagnostic and varies from that of chronic hepatitis to macronodular cirrhosis. Stains for copper show a periportal distribution but this can be unreliable (see below). The basal ganglia are damaged and show cavitation, the kidneys show tubular degeneration, and erosions are seen in bones.

Clinical features
Children usually present with hepatic problems, whereas young adults have more neurological problems, such as tremor, dysarthria, involuntary movements and eventually dementia. The liver disease varies from episodes of acute hepatitis, especially in children, which can go on to fulminant hepatic failure, to chronic hepatitis or cirrhosis.

Typical signs are of chronic liver disease with neurological signs of basal ganglia involvement (p. 1148). A specific sign is the Kayser–Fleischer ring, which is due to copper deposition in Descemet’s membrane in the cornea. It appears as a greenish brown pigment at the corneoscleral junction and frequently requires slit-lamp examination for identification. It may be absent in young children.

Investigations
- Serum copper and caeruloplasmin are usually reduced but can be normal.
- Urinary copper is usually increased 100–1000 µg in 24 hours (1.6–16 µmol); normal levels <40 µg (0.6 µmol).
- Liver biopsy. The diagnosis depends on measurement of the amount of copper in the liver (>250 µg/g dry weight), although high levels of copper are also found in the liver in chronic cholestasis.
- Haemolysis and anaemia may be present.
- Genetic analysis is limited but selected exons are screened according to population group.

Treatment
Lifetime treatment with penicillamine, 1–1.5 g daily, is effective in chelating copper. If treatment is started early, clinical and biochemical improvement can occur. Urine copper levels should be monitored and the drug dose adjusted downwards after 2–3 years. Serious side-effects of the drug occur in 10% and include skin rashes, leucopenia, skin changes and renal damage. Trientine (1.2–1.8 g/day) and zinc acetate (150 mg/ day) have been used as maintenance therapy and for asymptomatic cases. All siblings and children of patients should be screened (ATP7B mutation analysis is useful) and treatment given even in the asymptomatic if there is evidence of copper accumulation.

Prognosis
Early diagnosis and effective treatment have improved the outlook. Neurological damage is, however, permanent. Ful-
ominant hepatic failure or decompensated cirrhosis should be treated by liver transplantation.

\(\alpha_1\)-Antitrypsin deficiency (see also p. 837)

A deficiency of \(\alpha_1\)-antitrypsin (\(\alpha_1\)AT) is sometimes associated with liver disease and pulmonary emphysema (particularly in smokers). \(\alpha_1\)AT is a glycoprotein, part of a family of serine protease inhibitors, or serpin, superfamily. \(\alpha_1\)AT-deficiency is inherited as an autosomal dominant and 1 in 10 northern Europeans carries an abnormal gene.

The protein is a 394-amino acid 52 kDa acute-phase protein that is synthesized in the liver and constitutes 90% of the serum \(\alpha_1\)-globulin seen on electrophoresis. Its main role is to inhibit the proteolytic enzyme, neutrophil elastase.

The gene is located on chromosome 14. The genetic variants of \(\alpha_1\)AT are characterized by their electrophoretic mobilities as medium (M), slow (S) or very slow (Z). The normal genotype is protease inhibitor inhibitor (PiMM), the homozgyote for Z is PiZZ, and the heterozygotes are PiMZ and PiSZ. S and Z variants are due to a single amino acid replacement of glutamic acid at positions 264 and 342 of the polypeptide, respectively. This results in decreased synthesis and secretion of the protein by the liver as protein–protein interactions occur between the reactive centre loop of one molecule and the \(\beta\)-pleated sheet of a second (loop sheet polymerization).

How this causes liver disease is uncertain. It is postulated that the failure of secretion of the abnormal protein leads to an accumulation in the liver, causing liver damage.

Clinical features

The majority of patients with clinical disease are homozygotes with a PiZZ phenotype. Some may present in childhood and a few require transplantation. Approximately 10–15% of adult patients will develop cirrhosis, usually over the age of 50 years, and 75% will have respiratory problems. Approximately 5% of patients die of their liver disease. Heterozygotes (e.g. PiSZ or PiMZ) may develop liver disease, but the risk is small.

Investigations

- Serum \(\alpha_1\)-antritrypsin is low, at 10% of the normal level in the PiZZ phenotypes, and 60% of normal in the S variant.

Histologically periodic acid–Schiff (PAS)-positive, diastase-resistant globules which contain \(\alpha_1\)AT are seen in periportal hepatocytes. Fibrosis and cirrhosis can be present.

Treatment

There is no treatment apart from dealing with the complications of liver disease. Patients with hepatic decompensation should be considered for liver transplantation. Patients should stop smoking (see p. 830).

Ethanol is metabolized in the liver by two pathways, resulting in an increase in the NADH/NAD ratio. The altered redox potential results in increased hepatic fatty acid synthesis with decreased fatty acid oxidation, both events leading to hepatic accumulation of fatty acid that is then esterified to glycerides. The changes in oxidation–reduction also impair carbohydrate and protein metabolism and are the cause of the centrilobular necrosis of the hepatic acinus typical of alcohol damage.

Acetaldehyde is formed by the oxidation of ethanol, and its effect on hepatic proteins may well be a factor in producing liver cell damage. The exact mechanism of alcoholic hepatitis and cirrhosis is unknown, but since only 10–20% of people who drink heavily will develop cirrhosis, a genetic predisposition is recognized. Immunological mechanisms have also been proposed.

Alcohol can enhance the effects of toxic metabolites of drugs (e.g. paracetamol) on the liver, as it induces microsomal metabolism via the microsomal ethanol oxidizing system (MEOS) (p. 238).

Pathology

Alcohol can produce a wide spectrum of liver disease from fatty change to hepatitis and cirrhosis.

Fatty change

The metabolism of alcohol invariably produces fat in the liver, mainly in zone 3. This is minimal with small amounts of alcohol, but with larger amounts the cells become swollen with fat (steatosis). There is no liver cell damage. The fat disappears on stopping alcohol. Steatosis is also seen in non-alcoholic fatty liver disease.

In some cases collagen is laid down around the central hepatic veins (perivenular fibrosis) and this can sometimes progress to cirrhosis without a preceding hepatitis. Alcohol directly affects stellate cells, transforming them into collagen-producing myofibroblast cells (p. 320).

Alcoholic hepatitis

In addition to fatty change there is infiltration by polymorphonuclear leucocytes and hepatocyte necrosis mainly in zone 3. Dense cytoplasmic inclusions called Mallory bodies are sometimes seen in hepatocytes and giant mitochondria are also a feature. Mallory bodies are suggestive of, but not specific for, alcoholic damage as they can be found in other liver disease, such as Wilson’s disease and PBC. If alcohol consumption continues, alcoholic hepatitis may progress to cirrhosis.

Alcoholic cirrhosis

This is classically of the micronodular type, but a mixed pattern is also seen accompanying fatty change, and evidence of pre-existing alcoholic hepatitis may be present.

Clinical features

Fatty liver

There are often no symptoms or signs. Vague abdominal symptoms of nausea, vomiting and diarrhoea are due to the more general effects of alcohol on the gastrointestinal tract. Hepatomegaly, sometimes huge, can occur together with other features of chronic liver disease.

### ALCHEHOLIC LIVER DISEASE

This section gives the pathology and clinical features of alcoholic liver disease. The amounts needed to produce liver damage, alcohol metabolism, and other clinical effects of alcohol are described on page 239.
Alcoholic hepatitis
The clinical features vary in degree:
- The patient may be well, with few symptoms, the hepatitis only being apparent on the liver biopsy in addition to fatty change.
- Mild to moderate symptoms of ill-health, occasionally with mild jaundice, may occur. Signs include all the features of chronic liver disease. Liver biochemistry is deranged and the diagnosis is made on liver histology.
- In the severe case, usually superimposed on alcoholic cirrhosis, the patient is ill, with jaundice and ascites. Abdominal pain is frequently present, with a high fever associated with the liver necrosis. On examination there is deep jaundice, hepatomegaly, sometimes splenomegaly, and ascites with ankle oedema. The signs of chronic liver disease are also present.

Alcoholic cirrhosis
This represents the final stage of liver disease from alcohol abuse. Nevertheless, patients can be very well with few symptoms. On examination, there are usually signs of chronic liver disease. The diagnosis is confirmed by liver biopsy. Usually the patient presents with one of the complications of cirrhosis. In many cases there are features of alcohol dependency (see p. 1212) as well as evidence of involvement of other systems, such as polyneuropathy.

Investigations
Fatty liver
An elevated MCV often indicates heavy drinking. Liver biochemistry shows mild abnormalities with elevation of both serum aminotransferase enzymes. The γ-GT level is a sensitive test for determining whether the patient is taking alcohol. With severe fatty infiltration, marked changes in all liver biochemical parameters can occur. Ultrasound or CT will demonstrate fatty infiltration, as will liver histology. Elastography can be used to estimate the degree of fibrosis.

Alcoholic hepatitis
Investigations show a leucocytosis with markedly deranged liver biochemistry with elevated:
- serum bilirubin
- serum AST and ALT
- serum alkaline phosphatase
- prothrombin time (PT).

A low serum albumin may also be found. Rarely, hyperlipidaemia with haemolysis (Zieve’s syndrome) may occur.

Liver biopsy, if required, is performed by the transjugular route because of prolonged PT.

Alcoholic cirrhosis
Investigations are as for cirrhosis in general.

Management and prognosis
General management
Patients should be advised to stop drinking. Delirium tremens (a withdrawal symptom) is treated with diazepam. Intravenous thiamin should be given empirically to prevent Wernicke–Korsakoff encephalopathy. Bed rest with a diet high in protein and vitamin supplements is given. Dietary protein rarely needs to be limited because of encephalopathy. Patients need to be advised to participate in alcohol cessa-

tion programmes. The likelihood of abstention is dependent on many factors, particularly social and family ones.

Fatty liver
The patient is advised to stop drinking alcohol; the fat will disappear and the liver biochemistry usually returns to normal. Small amounts of alcohol can be drunk subsequently as long as patients are aware of the problems and can control their consumption.

Alcoholic hepatitis
In severe cases the patient requires admission to hospital. Nutrition must be maintained with enteral feeding if necessary and vitamin supplementation given. Steroid therapy does improve outcome in more severe cases as judged by a discriminant function (DF).

Discriminant function (DF)
DF = [4.6 × prothrombin time above control in seconds] + bilirubin (mg/DL)
Bilirubin umol/L × 17 to convert to mg/DL
Severe = >32

Infection must be excluded or concomitantly treated. Treatment for encephalopathy and ascites is commenced. Antifungal prophylaxis should also be used.

Patients are advised to stop drinking for life, as this is undoubtedly a precirrhotic condition. The prognosis is variable and, despite abstinence, the liver disease is progressive in many patients.

In severe cases the mortality is at least 50%, and with a PT twice the normal, progressive encephalopathy and renal failure, the mortality approaches 90%.

Alcoholic cirrhosis
The management of cirrhosis is described on page 347. Again, all patients are advised to stop drinking for life. Abstinence from alcohol results in an improvement in prognosis, with a 5-year survival of 90%, but with continued drinking this falls to 60%. With advanced disease (i.e. jaundice, ascites and haematemesis) the 5-year survival rate falls to 35%, with most of the deaths occurring in the first year. Liver transplantation results in good survival ~ recurrence of cirrhosis due to recidivism is rare. Patients often sign a contract with their clinicians regarding their abstinence, both before and after transplantation.

A trial of abstinence to establish if liver disease can improve is mandatory, but transplantation should not be denied if the patient continues to deteriorate. Specific follow-up regarding alcohol use is recommended.

Hepatocellular carcinoma is a complication, particularly in men.

BUDD–CHIARI SYNDROME

In this condition there is obstruction to the venous outflow of the liver owing to occlusion of the hepatic vein. In one-third of patients the cause is unknown, but specific causes include hypercoagulability states (e.g. paroxysmal nocturnal haemoglobinuria, polycythaemia vera) or thrombophilia (p. 442), taking the contraceptive pill, or leukaemia. Other causes include occlusion of the hepatic vein owing to posterior abdominal wall sarcomas, renal or adrenal tumours, hepatocellular carcinoma, hepatic infections (e.g. hydatid cyst), congenital venous webs, radiotherapy, or trauma to the liver.
The acute form presents with abdominal pain, nausea, vomiting, tender hepatomegaly and ascites (a fulminant form occurs particularly in pregnant women). In the chronic form there is enlargement of the liver (particularly the caudate lobe), mild jaundice, ascites, a negative hepatojugular reflux, and splenomegaly with portal hypertension.

**Investigations**

Investigations show a high protein content in the ascitic fluid and characteristic liver histology with centrilobular congestion, haemorrhage, fibrosis and cirrhosis. Ultrasound, CT or MRI will demonstrate hepatic vein occlusion with diffuse abnormal parenchyma on contrast enhancement. The caudate lobe is spared because of its independent blood supply and venous drainage. There may be compression of the inferior vena cava. Pulsed Doppler sonography or colour Doppler is useful as they show abnormalities of flow in the hepatic vein. Thrombophilia screening is mandatory. Multiple defects of coagulation are found. Thrombosis of the portal vein is present in 2% of patients.

**Differential diagnosis**

A similar clinical picture can be produced by inferior vena caval obstruction, right-sided cardiac failure or constrictive pericarditis, and appropriate investigations should be performed.

**Treatment**

In the acute situation, thrombolytic therapy can be given. Ascites should be treated, as should any underlying cause (e.g. polycythaemia). Congenital webs should be treated radiologically or resected surgically. A transjugular intrahepatic portosystemic shunt (TIPS) is the first treatment of choice as caval compression does not prejudice the efficacy of TIPS. Surgical porto-caval shunts are reserved for those who fail this treatment providing there is no caval obstruction or severe caval compression when a caval stent can be inserted. Liver transplantation is the treatment of choice for chronic Budd–Chiari syndrome and for the fulminant form. Lifelong anticoagulation is mandatory following TIPS and transplantation.

**Prognosis**

The prognosis depends on the aetiology, but some patients can survive for several years.

**FIBROPOLYCYSTIC DISEASES**

These diseases are usually inherited and lead to the presence of cysts or fibrosis in the liver, kidney and occasionally the pancreas, and other organs.

**Polycystic disease of the liver**

Multiple cysts can occur in the liver as part of autosomal dominant polycystic disease of the kidney (p. 642). These cysts are usually asymptomatic but occasionally cause abdominal pain and distension. Liver function is normal and complications such as oesophageal varices are very rare. The prognosis is excellent and depends on the kidney disease.

**Solitary cysts**

These are usually found by chance during imaging and are mainly asymptomatic.

**Congenital hepatic fibrosis**

In this rare condition the liver architecture is normal but there are broad collagenous fibrous bands extending from the portal tracts. It is often inherited as an autosomal recessive condition but can also occur sporadically. It usually presents in childhood with hepatosplenomegaly, and portal hypertension is common. It may present later in life and can be misdiagnosed as cirrhosis.

A wedge biopsy of the liver may be required to confirm the diagnosis. The outlook is good and the condition should be distinguished from cirrhosis. Patients who bleed do well after endoscopic therapy of varices or a portocaval anastomosis because of their good liver function.

**Congenital intrahepatic biliary dilatation (Caroli’s disease)**

In this rare, non-familial disease there are saccular dilatations of the intrahepatic or extrahepatic ducts. It can present at any age (although usually in childhood) with fever, abdominal pain and recurrent attacks of cholangitis with Gram-negative sepsicaemia. Jaundice and portal hypertension are absent. Diagnosis is by ultrasound, PTC, ERCP or MRCP. There is an increased risk of biliary malignancy.

**VENO-OCLUSION DISEASE**

This is due to injury of the hepatic veins and presents clinically like the Budd–Chiari syndrome. It was originally described in Jamaica, where the ingestion of toxic pyrrolizidine alkaloids in bush tea (made from plants of the genera Senecio, Heliotropium and Crotophalaria) caused damage to the hepatic veins. It can be seen in other parts of the world. It is also seen as a complication of chemotherapy and total body irradiation before allogeneic bone marrow transplantation. The development of veno-occlusive disease after transplantation carries a high mortality. Treatment is supportive with control of ascites and hepatocellular failure. Defibrotide has been tried and TIPS has been used in a few cases.

**LIVER ABSCESS**

**Pyogenic abscess**

These abscesses are uncommon, but may be single or multiple. The most common was a portal pyaemia from intra-abdominal sepsis (e.g. appendicitis or perforations), but now in many cases the aetiology is not known. In the elderly, biliary sepsis is a common cause. Other causes include trauma, bacteraemia and direct extension from, for example, a periphephic abscess.

The organism found most commonly is E. coli, Streptococcus milleri and anaerobic organisms such as Bacteroides are often seen. Other organisms include Enterococcus fae-
Clinical features

Some patients are not acutely ill and present with malaise lasting several days or even months. Others can present with fever, rigors, anorexia, vomiting, weight loss and abdominal pain. In these patients a Gram-negative septicaemia with shock can occur. On examination there may be little to find. Alternatively, the patient may be toxic, febrile and jaundiced. In such patients, the liver is tender and enlarged and there may be signs of a pleural effusion or a pleural rub in the right lower chest.

Investigations

Patients who are not acutely ill are often investigated as a ‘pyrexia of unknown origin’ (PUO) and most investigations will be normal. Often the only clue to the diagnosis is a raised serum alkaline phosphatase.

- **Serum bilirubin** is raised in 25% of cases.
- **Normochromic normocytic anaemia** may occur, usually accompanied by a polymorphonuclear leucocytosis.
- **Serum alkaline phosphatase and ESR** are often raised.
- **Serum B_12** is very high, as vitamin B_12_ is stored in and subsequently released from the liver.
- **Blood cultures** are positive in only 30% of cases.

Imaging

Ultrasound is useful for detecting abscesses. A CT scan may be of value in complex and multiple lesions (Fig. 7.26). A chest X-ray will show elevation of the right hemidiaphragm with a pleural effusion in the severe case. Depending on age, imaging of the colon may be necessary to find the source of the infection.

Management

Aspiration of the abscess should be attempted under ultrasound control. Antibiotics should initially cover Gram-positive, Gram-negative and anaerobic organisms until the causative organism is identified.

Further drainage via a large-bore needle under ultrasound control or surgically may be necessary if resolution is difficult or slow. Any underlying cause must also be treated.

Prognosis

The overall mortality depends on the nature of the underlying pathology and has been reduced to approximately 16% with needle aspiration and antibiotics. A unilocular abscess in the right lobe has the better prognosis. Scattered multiple abscesses have a very high mortality, with only one in five patients surviving.

**Amoebic abscess** (see also p. 161)

This condition occurs world-wide and must be considered in patients travelling from endemic areas. *Entamoeba histolytica* (p. 161) can be carried from the bowel to the liver in the portal venous system. Portal inflammation results, with the development of multiple microabscesses and eventually single or multiple large abscesses.

Clinically the onset is usually gradual but may be sudden. There is fever, anorexia, weight loss and malaise. There is often no history of dysentery. On examination the patient looks ill and has tender hepatomegaly and signs of an effusion or consolidation in the base of the right side of the chest. Jaundice is unusual.

**Investigations**

These are as for pyogenic abscess, plus:

- Serological tests for amoeba (e.g. haemagglutination, amoebic complement fixation test, ELISA). These are always positive, particularly if there are bowel symptoms, and remain positive after a clinical cure and therefore do not indicate current disease. A repeat negative test, however, is good evidence against an amoebic abscess.
- **Diagnostic aspiration of fluid looking like anchovy sauce.**

**Treatment**

Metronidazole 800 mg three times daily is given for 10 days. Aspiration is used in patients failing to respond, in multiple and sometimes large abscesses, and in those with abscesses in the left lobe of the liver or impending rupture.

**Complications**

Complications include rupture, secondary infection and septicaemia.

**Schistosomiasis** (see also p. 168)

*Schistosoma mansoni* and *S. japonicum* affect the liver, but *S. haematobium* rarely does so. During their adult life cycle the ova reach the liver via the venous system and obstruct the portal branches, producing granulomas, fibrosis and inflammation but not cirrhosis.

Clinically there is hepatosplenomegaly and portal hypertension, which is particularly severe with *S. mansoni*. In Egypt there is frequently concomitant chronic hepatitis C infection.

Investigations show a raised serum alkaline phosphatase and ova can be found in the stools (centrifuged deposits) and in rectal and liver biopsies. Skin tests and other immunological tests often have false results and may also be positive because of past infection.

**Treatment** is with praziquantel, but fibrosis still remains with a potential risk of portal hypertension, characteristically pre-sinusoidal due to intense portal fibrosis.

**Hydatid disease** (see also p. 171)

Cysts caused by *Echinococcus granulosus* are single or multiple. They usually occur in the lower part of the right lobe. The cyst has three layers: an outside layer derived from the host, an intermediate laminated layer, and an inner germinal layer that buds off brood capsules to form daughter cysts.

Clinically there may be no symptoms or a dull ache and swelling in the right hypochondrium. Investigations show a
peripheral eosinophilia in 30% of cases and usually a positive hydatid complement fixation test or haemagglutination (85%). Plain abdominal X-ray may show calcification of the outer coat of the cyst. Ultrasound and CT scan demonstrate cysts and may show diagnostic daughter cysts within the parent cyst (Fig. 7.27).

Medical treatment (e.g. with albendazole 10 mg/kg, which penetrates into large cysts) results in cysts becoming smaller. Puncture, aspiration, injection, reaspiration (PAIR) has been used since the 1980s. Fine-needle aspiration is undertaken under ultrasound control with chemotherapeutic cover. Surgery can be performed with removal of the cyst intact if possible after first sterilizing the cyst with alcohol, saline or cetrimide. Chronic calcified cysts can be left. There have been no well-designed clinical trials for any modality.

Complications include rupture into the biliary tree, other organs or intraperitoneally, with spread of infection. The prognosis without any complications is good, although there is always the risk of rupture. Preventative measures include deworming of pet dogs and prevention of pets from eating infected carcasses, as well as veterinary control programmes.

Echinococcus multilocularis causes alveolar echinococcosis and is almost exclusively a hepatic disease, with a high mortality if not treated. Early diagnosis would enable radical surgery and then continued chemosuppression.

Acquired immunodeficiency syndrome (see also p. 187)

The liver is often involved and is a significant cause of morbidity or mortality. HIV itself is probably not the cause of the liver abnormalities. The following are seen:

- pre-existing/coincidental viral hepatitis – the hepatitis progresses more rapidly (HBV, HCV, HDV) and is a leading cause of death
- neoplasia: Kaposi’s sarcoma and non-Hodgkin’s lymphoma – increased risk of HCC
- opportunistic infection (e.g. Mycobacterium tuberculosis, M. avium-intracellulare, Cryptococcus, Candida albicans, toxoplasmosis)
- drug hepatotoxicity
- secondary sclerosing cholangitis (see p. 162)
- non-cirrhotic portal hypertension associated with antiretroviral therapy.

Clinical hepatomegaly is common (60% of patients).

LIVER DISEASE IN PREGNANCY

Liver function is not impaired in pregnancy. Any liver disease from whatever cause can occur incidentally and coincide with pregnancy. For example, viral hepatitis accounts for 40% of all cases of jaundice during pregnancy. Pregnancy does not necessarily exacerbate established liver disease, but it is uncommon for women with advanced liver disease to conceive.

The following changes take place:

- Plasma and blood volumes increase during pregnancy but the hepatic blood flow remains constant.
- The proportion of cardiac output delivered to the liver therefore falls from 35% to 29% in late pregnancy; drug metabolism can thus be affected.
- The size of the liver remains constant.
- Liver biochemistry remains unchanged apart from a rise in serum alkaline phosphatase from the placenta (up to three to four times) and a decrease in total protein owing to increased plasma volume.
- Triglycerides and cholesterol levels rise, and caeruloplasmin, transferrin, α-anititrypsin and fibrinogen levels are elevated owing to increased hepatic synthesis.
- Postpartum there is a tendency to hypercoagulability, and acute Budd–Chiari syndrome can occur.

There are a number of liver diseases that complicate pregnancy.

Hyperemesis gravidarum

Pathological vomiting during pregnancy can be associated with liver dysfunction and jaundice. Liver dysfunction resolves when vomiting subsides.

Intrahepatic cholestasis of pregnancy

This condition of unknown aetiology presents usually with pruritus alone in the third trimester. It has a familial tendency and there is a higher prevalence in Scandinavia, Chile and Bolivia.

Liver biochemistry shows a cholestatic picture with high serum ALP (up to four times normal) and raised aminotransferases which occasionally can be very high. The serum bilirubin is slightly raised with jaundice in 60% of cases. Liver biopsy is not indicated but would show centrilobular cholestasis.

Treatment is symptomatic with ursodeoxycholic acid 15 mg/kg daily. Prognosis is usually excellent for the mother but there is increased fetal loss and the condition resolves after delivery. Recurrent cholestasis may occur during subsequent pregnancies or with the ingestion of oestrogen-containing oral contraceptive pills.

Pre-eclampsia and eclampsia

Pre-eclampsia is characterized by hypertension, proteinuria and oedema occurring in the second or third trimester. Eclampsia is marked by seizures or coma in addition. Hepatic complications include subcapsular haematoma and infarction, and occasionally fulminant hepatic failure. The HELLP
syndrome – a combination of haemolysis, elevated liver enzymes and a low platelet count – can occur in association with severe pre-ecclampsia. In the HELLP syndrome, there is epigastric pain, nausea and vomiting, with jaundice in 5% of patients. Delivery is the best treatment for eclampsia.

**Acute fatty liver of pregnancy (AFLP)**

This is a rare, serious condition of unknown aetiology. There is an association between acute fatty liver and long-chain 3-hydroxylacyl-CoA-dihydroxy (LCHAD) deficiency. The mechanism is unclear, but abnormal fatty acid metabolites produced by the homozygous or heterozygous fetus enter the circulation and overcome maternal hepatic mitochondrial oxidation systems in a heterozygote mother. It presents in the last trimester with symptoms of fulminant hepatitis – jaundice, vomiting, abdominal pain, and occasionally haematemesis and coma.

Investigations show hepatocellular damage, hyperuricaemia, thrombocytopenia, and rarely DIC. CT scanning shows a low density of the liver owing to the high fat content. It can sometimes be difficult to differentiate from the HELLP syndrome and as LCHAD deficiency has also been shown in HELLP there is a view that there is a spectrum of HELLP to AFLP. Liver biopsy shows fine droplets of fat (microvesicular) in hepatocytes with little necrosis, but is not necessary for diagnosis.

Immediate delivery of the child may save both baby and mother. Early diagnosis and treatment has reduced the mortality to less than 20%. Treatment is as for acute liver failure.

**Hepatocellular carcinoma**

Hepatocellular carcinoma (HCC) is the fifth most common cancer world-wide.

**Aetiology**

Carriers of HBV and HCV have an extremely high risk of developing HCC. In areas where HBV is prevalent, 90% of patients with this cancer are positive for the hepatitis B virus. Cirrhosis is present in approximately 80% of these patients. The development of HCC is related to the integration of viral HBV DNA into the genome of the host hepatocyte (see p. 336) and the degree of viral replication (>10 000 copies/mL). The risk of HCC in HCV is higher than in HBV (even higher with both HBV and HCV) despite no viral integration. Unlike HBV infection, cirrhosis is always present. Primary liver cancer is also associated with other forms of cirrhosis, such as alcoholic cirrhosis and haemochromatosis. Non-alcoholic fatty liver disease is associated with HCC, probably secondary to the presence of cirrhosis. Males are affected more than females. Other aetiological factors are aflatoxin (a metabolite of a fungus found in groundnuts) and androgenic steroids, and there is a weak association with the contraceptive pill.

**Pathology**

The tumour is either single or occurs as multiple nodules throughout the liver. Histologically it consists of cells resembling hepatocytes. It can metastasise via the hepatic or portal veins to the lymph nodes, bones and lungs.

**Clinical features**

The clinical features include weight loss, anorexia, fever, an ache in the right hypochondrium and ascites. The rapid development of these features in a cirrhotic patient is suggestive of HCC. On examination, an enlarged, irregular, tender liver may be felt. Increasingly, due to surveillance, HCC is found without symptoms in cirrhotics.

**Investigations**

*Serum α-fetoprotein* may be raised, but is normal in at least a third of patients. *Ultrasound* scans show filling defects in 90% of cases. Enhanced *CT* scans (Fig. 7.28) identify HCC but it is difficult to confirm the diagnosis in lesions <2 cm. An *MRI* can further help to delineate lesions. Tumour *biopsy*, particularly under ultrasonic guidance, may be performed for diagnosis, but is increasingly less used as imaging techniques show characteristic appearances (hypervascularity of the nodule and lack of portal vein wash out) and because seeding along the biopsy tract can occur.

**Treatment and prognosis**

Surgical resection is occasionally possible. Conventional chemotherapy and radiotherapy are unhelpful, but transarterial embolization in selected patients prolongs survival. Radiofrequency ablation is also effective. Antiangiogenic compounds are being evaluated: sorafenib prolongs survival in patients with non-resectable tumours. Liver transplantation is curative in patients with smaller tumours (<3 nodules <3 cm diameter or a single tumour <5 cm).

In advanced cases survival is seldom more than 6 months.

**LIVER TUMOURS**

**Secondary liver tumours**

The most common liver tumour is a secondary (metastatic) tumour, particularly from the gastrointestinal tract (from the distribution of the portal blood supply), breast or bronchus. They are usually multiple.

*Clinical features* are variable but usually include weight loss, malaise, upper abdominal pain and hepatomegaly, with or without jaundice.

**Diagnosis.** Ultrasound is the primary investigation, with CT or MRI to define metastases and look for a primary. The serum alkaline phosphatase is almost invariably raised.

**Treatment.** This will depend on the site of the primary and the burden of liver metastases. The best results are obtained in colorectal cancer in patients with few hepatic metastases. If the primary tumour is removed and hepatic resection is performed, reasonable survival rates are possible. Chemotherapy is used, particularly with breast cancer (p. 488). Radiofrequency ablation of the metastases is an alternative to surgery.

**PRIMARY MALIGNANT TUMOURS**

Primary liver tumours may be benign or malignant, but the most common are malignant.
BENIGN TUMOURS

The most common benign tumour is a haemangioma. It is usually small and single but can be multiple and large. Haemangiomas are usually found incidentally on ultrasound, CT or MRI and have characteristic appearances. They require no treatment.

Hepatic adenomas are associated with oral contraceptives. They can present with abdominal pain or intrahepatic bleeding. Resection is only required for symptomatic patients, those with tumours >5 cm diameter or in those in whom discontinuation of oral contraception does not result in shrinkage of the tumour.

MISCELLANEOUS CONDITIONS OF THE LIVER

Hepatic mitochondrial injury syndromes

These syndromes – in which there is mitochondrial damage with inhibition of β-oxidation of fatty acids – can be categorized as follows:

- Genetic, with abnormalities which include medium-chain acyl-coenzyme A dehydrogenase deficiency leading to microsteatosis.
- Toxins leading to liver failure include aflatoxin and cerulide (produced by Bacillus cereus) which causes food poisoning (see p. 133).
- Drugs (e.g. i.v. tetracycline, valproic acid and nucleoside reverse-transcriptase inhibitors) can produce a fatal microsteatosis.
- Idiopathic, the best known being fatty liver of pregnancy (p. 363) and Reye’s syndrome. The latter, due to inhibition of β-oxidation and uncoupling of oxidative phosphorylation in mitochondria, leads in children to an acute encephalopathy and diffuse microvesicular fatty infiltration of the liver. Aspirin ingestion and viral infections have been implicated as precipitating agents. Mortality is about 50%, usually due to cerebral oedema.

Idiopathic adult ductopenia

This unexplained condition is characterized by pruritus and cholestatic jaundice. Histology of the liver shows a decrease in intrahepatic bile ducts in at least 50% of the portal tracts, together with the features of cholestasis and marked fibrosis or cirrhosis. In most, the disease is progressive and the only treatment is liver transplantation.

Indian childhood cirrhosis

This condition of children is seen in the Indian subcontinent. The cause is unknown. Eventually there is development of a micronodular cirrhosis with excess copper in the liver.

Hepatic porphyrias

These are dealt with on page 1074.

**Prevention**

Persistent HBV infection, usually acquired after perinatal infection, is a high risk factor for HCC in many parts of the world, such as South East Asia. Widespread vaccination against HBV is being used and this has reduced the annual incidence of HCC in Taiwan.

**Cholangiocarcinoma**

Cholangiocarcinomas are increasing in incidence and can be extrahepatic (see p. 374) or intrahepatic. Intrahepatic adenocarcinomas arising from the bile ducts account for approximately 10% of primary tumours. They are not associated with cirrhosis or hepatitis B. In the Far East they may be associated with infestation with Clonorchis sinensis or Opisthorchis viverrini. The clinical features are similar to primary HCC except that jaundice is frequent with hilar tumours, and cholangitis is more frequent.

Surgical resection is rarely possible and patients usually die within 6 months. Transplantation is contraindicated, outside of specialized protocols.

**Fig. 7.28** Hepatocellular carcinoma. (a) CT showing cirrhosis with a hepatocellular carcinoma. (b) T2-weighted MRI of the liver following gadolinium contrast showing a hepatocellular carcinoma.
**Cystic fibrosis** (see also p. 844)

This disease affects mainly the lung and pancreas, but patients can develop fatty liver, cholestasis and cirrhosis. The aetiology of the liver involvement is unclear.

**Coeliac disease** (see also p. 277)

Abnormal liver biochemical tests are common. A tissue transglutaminase should be performed when hepatic causes are not found when investigating abnormal liver biochemistry. These return to normal with a gluten-free diet.

---

## DRUGS AND THE LIVER

### Drug metabolism

The liver is the major site of drug metabolism. Drugs are converted from fat-soluble to water-soluble substances that can be excreted in the urine or bile. This metabolism of drugs is mediated by a group of mixed-function enzymes (p. 925).

### Drug hepatotoxicity

Many drugs impair liver function. When abnormal liver biochemical tests are found, drugs should always be considered as a cause, particularly when other causes have been excluded. Damage to the liver by drugs is usually classified as being either predictable (or dose-related) or non-predictable (not dose-related) (see p. 928). However, there is considerable overlap and at least six mechanisms may be involved in the production of damage:

1. disruption of intracellular calcium homeostasis
2. disruption of bile canalicul transport mechanisms
3. formation of non-functioning adducts (enzyme–drug) which may then
4. present on the surface of the hepatocyte as new immunogens (attacked by T cells)
5. induction of apoptosis
6. inhibition of mitochondrial function, which prevents fatty acid metabolism, and accumulation of both lactate and reactive oxygen species.

The predominant mechanism or combination of mechanisms determines the type of liver injury, i.e. hepatitic, cholestatic or immunological (skin rashes, fever and arthralgia, i.e. serum-sickness syndrome). Eosinophilia and circulating immune complexes and antibodies may occasionally be detected.

When a small amount of hepatotoxic drug whose effect is dose-dependent (e.g. paracetamol) is ingested, a large proportion of it undergoes conjugation with glucuronide and sulphate, whilst the remainder is metabolized by microsomal enzymes to produce toxic derivatives that are immediately detoxified by conjugation with glutathione. If larger doses are ingested, the former pathway becomes saturated and the toxic derivative is produced at a faster rate. Once the hepatic glutathione is depleted, large amounts of the toxic metabolite accumulate and produce damage (p. 947).

The ‘predictability’ of drugs to produce damage can, however, be affected by metabolic events preceding their ingestion. For example, chronic alcohol abusers may become more susceptible to liver damage because of the enzyme-inducing effects of alcohol, or ill or starving patients may become susceptible because of the depletion of hepatic glutathione produced by starvation. Many other factors such as environmental or genetic effects may be involved in determining the ‘susceptibility’ of certain patients to certain drugs.

The incidence of drug hepatotoxicity is 14 per 100 000 population with a 6% mortality. It is the most common cause of acute liver failure in the USA. Liver transplantation is used.

### Hepatic damage

The type of damage produced by various drugs is shown in Table 7.16. The diagnosis of these conditions is usually by exclusion of other causes. Most reactions occur within 3 months of starting the drug. Monitoring liver biochemistry in patients on long-term treatment, such as antituberculosis therapy, is mandatory. If a drug is suspected of causing hepatic damage it should be stopped immediately. Liver biopsy is of limited help in confirming the diagnosis, but occasionally hepatic eosinophilia or granulomas may be seen. Diagnostic challenge with subtherapeutic doses of the drug is sometimes required after the liver biochemistry has returned to normal, to confirm the diagnosis.

### Individual drugs

**Paracetamol.** In high doses paracetamol produces liver cell necrosis (see above). The toxic metabolite binds irreversibly to liver cell membranes. Overdosage is discussed on page 947.

**Halothane and other volatile liquid anaesthetics.** Halothane, which is available in the UK on a named patient basis, produces a hepatitis in patients having repeated exposures. The mechanism is thought to be a hypersensitivity reaction. An unexplained fever occurs approximately 10 days after the second or subsequent halothane anaesthetic and is followed by jaundice, typically with a hepatic picture. Most patients recover spontaneously but there is a high mortality in severe cases. There are no chronic sequelae. Both sevoflurane and isoflurane also cause hepatotoxicity in those sensitized to halogenated anaesthetics but the risk is smaller than with halothane and remote with desflurane.

**Steroid compounds.** Cholestasis is caused by natural and synthetic oestrogens as well as methyltestosterone. These agents interfere with canalicul biliary flow by blocking MRP2 and MDR3 (see Fig. 7.4) and cause a pure cholestasis. Cholestasis is rare with the contraceptive pill because of the low dosage used. However, the contraceptive pill is associated with an increased incidence of gallstones, hepatic adenomas (rarely HCCs), the Budd–Chiari syndrome and peliosis hepatis. The latter condition, which also occurs with anabolic steroids, consists of dilatation of the hepatic sinusoids to form blood-filled lakes.

**Phenothiazines.** Phenothiazines (e.g. chlorpromazine) can produce a cholestatic picture owing to a hypersensitivity reaction. It occurs in 1% of patients, usually within 4 weeks of starting the drug. Typically it is associated with a fever and eosinophilia. Recovery occurs on stopping the drug.

NSAID, non-steroidal anti-inflammatory drug.
NB. Anti-HIV drugs, e.g. maraviroc, cause hepatic dysfunction.

**Antituberculous chemotherapy.** Isoniazid produces elevated aminotransferases in 10–20% of patients. Hepatic necrosis with jaundice occurs in a smaller percentage. The hepatotoxicity of isoniazid is related to its metabolites and is dependent on acetylator status. Rifampicin produces a hepatitis, usually within 3 weeks of starting the drug, particularly in patients on high doses. Pyrazinamide produces abnormal liver biochemical tests and, rarely, liver cell necrosis.

**Amiodarone.** This leads to a steatohepatitis histologically and liver failure if the drug is not stopped in time.

**Sodium valproate.** This causes mitochondrial injury with microvesicular steatosis. Intravenous carnitine should be used as an antidote.

**Drug prescribing for patients with liver disease**

The metabolism of drugs is impaired in severe liver disease (with jaundice and ascites) as the removal of many drugs depends on liver blood flow and the integrity of the hepatocyte. In general, therefore, the effect of drugs is prolonged by liver disease and also by cholestasis. This is further accentuated by portosystemic shunting, which diminishes the first-pass extraction of drugs. With hypoproteinaemia there is decreased protein binding of some drugs, and bilirubin competes with many drugs for the binding sites on serum albumin. In patients with portosystemic encephalopathy, care must be taken in prescribing drugs with a central depressant action, e.g. narcotics, including codeine and anxiolytics. Other common drugs to be avoided in cirrhosis include ACE inhibitors (cause hepatorenal failure) and NSAIDs (bleeding).
The structure, formation and function of bile is discussed on page 321.

GALLSTONES

Prevalence of gallstones
Gallstones may be present at any age but are unusual before the third decade. The prevalence of gallstones is strongly influenced both by age and sex. There is a progressive increase in the prevalence of gallstones with age but the prevalence is two to three times higher in women than in men, although this difference is less marked in the sixth and seventh decade. At this age the prevalence ranges between 25% and 30%. The increase in life expectancy is reflected in an increased burden of symptomatic gallstone disease. There are considerable racial differences, gallstones being more common in Scandinavia, South America and Native North Americans but less common in Asian and African groups.

Types of gallstones
Two principal types of gallstone disease occur. In the western world 80% of gallstones contain cholesterol. The second, less frequent, type of gallstone is ‘pigment stones’, being predominantly composed of calcium bilirubinate or polymer-like complexes with calcium, copper and some cholesterol.

Cholesterol gallstones
The formation of cholesterol stones is the consequence of cholesterol crystallization from gall bladder bile. This is dependent upon three factors:

- cholesterol supersaturation of bile
- crystallization-promoting factors within bile
- motility of the gall bladder.

The majority of cholesterol is derived from hepatic uptake from dietary sources. However, hepatic biosynthesis may account for up to 20%. The rate-limiting step in cholesterol synthesis is β-hydroxy-β-methyl glutaryl Co-A (HMG-CoA) reductase, which catalyses the first step, i.e. the conversion of acetate to mevalonate (see Fig. 7.4). The cholesterol formed is co-secreted with phospholipids into the biliary canaliculus as unilamellar vesicles. Cholesterol will only crystallize into stones when the bile is supersaturated with cholesterol relative to the bile salt and phospholipid content. This can occur as a consequence of excess cholesterol secretion into bile which, in some instances, has been shown to be due to an increase in HMG-CoA reductase activity. Recently, leptin (p. 229) has been shown to increase cholesterol secretion into bile. Elevated levels of leptin during rapid weight loss may account for the increased incidence of cholesterol gallstones. An alternative mechanism of supersaturation is a decreased bile salt content which may occur as a consequence of bile salt loss (e.g. terminal ileal resection or involvement with Crohn’s disease).

The composition of the bile salt pool may also influence the ability to maintain cholesterol in solution. There is evidence that an increased proportion of the secondary hydrophobic bile acid (deoxycholic acid) in the bile acid pool may predispose to cholesterol stone formation. This has been linked with slow colonic transit during which the primary bile acid cholic acid may undergo microbial enzyme metabolism yielding deoxycholic acid which is then absorbed back into the bile salt pool (see Fig. 7.4).

Whilst cholesterol supersaturation of bile is essential for cholesterol stone formation, many individuals in whom such supersaturation occurs will never develop stones. It is the balance between cholesterol crystallizing and solubilizing factors that determines whether cholesterol will crystallize out of solution. A number of lipoproteins have been reported as putative crystallizing factors.

There is increasing evidence from epidemiological, family and twin studies of the importance of genetic factors in gallstone formation. A number of lithogenic genes have been identified which may interact with environmental factors. However, monogenic susceptibility appears uncommon. There are rare cases in which a single mutation leading to ABC (ATP-binding cassette) transporter deficiencies is associated with recurrent intra- and extrahepatic cholelithiasis in young patients.

Gall bladder motility represents a further factor that may influence the cholesterol crystallization from supersaturated bile. There is evidence from animal models that gall bladder stasis leads to cholesterol crystallization mediated by hypersecretion of mucin.

Abnormalities of gall bladder motility have been suggested as factors in such circumstances as pregnancy, multiparity and diabetes as well as octreotide-related gall bladder stones (p. 980). Recognized risk factors for gallstones are shown in Table 7.17.

Bile pigment stones
The pathogenesis of pigment stones is entirely independent of cholesterol gallstones. There are two main types of pigment gallstones, black and brown.

Black pigment gallstones are composed of calcium bilirubinate and a network of mucin glycoproteins that interface with salts such as calcium carbonate and/or calcium phosphate. These stones range in colour from deep black to very dark brown and have a glass-like cross-sectional surface on fracturing. Black pigment stones are seen in 40–60% of patients with haemolytic conditions such as sickle cell disease and hereditary spherocytosis in which there is chronic excess bilirubin production. However, the majority of pigment stones occur without haemolysis. There is recent evidence that bile salt loss into the colon (consequent upon ileal resection or ileal disease) promotes solubilization and colonic reabsorption of bilirubin. This enhances the entero-hepatic circulation and biliary secretion of bilirubin with the formation of gallstones. Pigment stones have also been linked with bacterial colonization of the biliary tree. Some pigment stones have been shown to contain bacteria, many of which produce glucuronidase and phospholipase, factors that are known to facilitate stone formation. It is speculated that this subclinical bacterial colonization of the bile duct is responsible for the pigment stone formation.

Brown stones are usually of a muddy hue and on cross-section seem to have alternating brown and tan layers. These stones are composed of calcium salts of fatty acids as well as calcium bilirubinate. They are almost always found in the presence of bile stasis and/or biliary infection. Brown stones are a common cause of recurrent bile duct stones following cholecystectomy and may also be found in the intrahepatic ducts in circumstances of duct disease such as Caroli’s syndrome and primary sclerosing cholangitis. In the Far East such brown stones are identified within both the intra- and extrahepatic biliary tree and have been linked with chronic parasitic infection.

Clinical presentation of gallstones
(Fig. 7.29)

The majority of gallstones are asymptomatic and remain so during a person’s lifetime. Gallstones are increasingly detected as an incidental finding at the time of either abdominal radiography or ultrasound scanning. Over a 10- to 15-year period approximately 20% of these stones will be the cause of symptoms with 10% having severe complications. Once gallstones have become symptomatic there is a strong trend towards recurrent complications, often of increasing severity. Gallstones do not cause dyspepsia, fat intolerance, constipation or other vague upper abdominal symptoms. The chances of a fair, fat, female of 40 having gallstones are the same as in the general population.

Biliary or gallstone colic

Biliary colic is the term used for the pain associated with the temporary obstruction of the cystic or common bile duct by a stone usually migrating from the gall bladder. Despite the term ‘colic’, the pain of stone-induced ductular obstruction is severe but constant and has a crescendo characteristic. Many sufferers can relate the symptoms to over-indulgence with food, particularly when this has a high fat content. The most common time of day for such an episode is in the mid-evening and lasting until the early hours of the morning.

The initial site of pain is usually in the epigastrium but there may be a right upper quadrant component. Radiation may occur over the right shoulder and right subcapsular region.

Nausea and vomiting frequently accompany the more severe attacks. The cessation of the attack may be spontaneous after a number of hours or terminated by the administration of opiate analgesia. More protracted pain, particularly when associated with fevers and rigors, suggests secondary complications such as cholecystitis, cholangitis or gallstone-related pancreatitis (see below).

Acute cholecystitis

The initial event in acute cholecystitis is obstruction to gall bladder emptying. In 95% of cases a gall bladder stone can be identified as the cause. Such obstruction results in an increase of gall bladder glandular secretion leading to progressive distension which in turn may compromise the vascular supply to the gall bladder.

There is also an inflammatory response secondary to retained bile within the gall bladder. Infection is a secondary phenomenon following the vascular and inflammatory events described above.

The initial clinical features of an episode of cholecystitis are similar to those of biliary colic described above. However, over a number of hours there is progression with severe localized right upper quadrant abdominal pain corresponding to parietal peritoneal involvement in the inflammatory process. The pain is associated with tenderness and muscle guarding or rigidity. Occasionally the gall bladder can become distended by pus (an empyema) and rarely an acute gangrenous cholecystitis develops which can perforate, with generalized peritonitis.

Investigations

Biliary colic as a consequence of a stone in the neck of the gall bladder or cystic duct is unlikely to be associated with significant abnormality of laboratory tests. Acute cholecystitis is usually associated with a moderate leucocytosis and raised inflammatory markers (e.g. C reactive protein).

- The serum bilirubin, alkaline phosphatase andaminotransferase levels may be marginally elevated in the presence of cholecystitis alone, even in the absence of bile duct obstruction. More significant elevation of the
bilirubin and alkaline phosphatase is in keeping with bile duct obstruction.

- **An abdominal ultrasound scan** is the single most useful investigation for the diagnosis of gallstone-related disease (Fig. 7.30). Look for:
  - gallstones within the gall bladder, particularly when these are obstructing the gall bladder neck or cystic duct
  - focal tenderness over the underlying gall bladder
  - thickening of the gall bladder wall. This may also be seen with hypoalbuminaemia, portal hypertension and acute viral hepatitis.

**Gallstones** are a common finding in an ageing population, and in the absence of specific symptoms great care should be taken when determining whether the gallstones are responsible for the symptoms.

- **Biliary scintigraphy using technetium derivatives of iminodiacetate**. These isotopes are taken up by hepatocytes and excreted into bile. They delineate the extrahepatic biliary tree. The absence of cystic duct and gall bladder filling provides evidence towards acute cholecystitis although the findings must be closely correlated with the presenting symptoms.

**Differential diagnosis**

Typical cases of biliary colic are usually suspected by a careful clinical history. The differential diagnosis includes the irritable bowel syndrome (spasm of the hepatic flexure), carcinoma of the right side of the colon, atypical peptic ulcer disease, renal colic and pancreatitis.

The differential diagnosis of acute cholecystitis includes a number of other conditions marked by severe right upper quadrant pain and fever, e.g. acute episodes of pancreatitis, perforated peptic ulceration or an intrahepatic abscess. Conditions above the right diaphragm such as basal pneumonia as well as myocardial infarction may on occasions mimic the clinical picture.

**Fig. 7.30** Ultrasound scan in a patient with acute cholecystitis. There is a stone (casting an acoustic shadow – thin arrow) impacted in the gall bladder neck, with a distended gall bladder (thick arrow) and thickening and oedema of the gall bladder wall.

**MANAGEMENT OF GALL BLADDER STONES**

**Cholecystectomy**

Cholecystectomy is the treatment of choice for virtually all patients with symptomatic gall bladder stones. In patients admitted with specific gallstone-related complications (see below) cholecystectomy should be carried out during the period of that admission to prevent the risk of recurrence. For those presenting with pain alone an elective procedure can be planned but the waiting time should be minimized to avoid the high risk of recurrent symptoms (approximately 30% over 4 months) and the need for hospital admission.

Cholecystectomy should not be performed in the absence of typical symptoms just because stones are found on investigation. There is an ongoing debate as to whether prophylactic cholecystectomy is justified in young patients found to have small stones. Such patients have a long period over which they may develop symptomatic disease and small stones are an independent risk factor for the potentially serious complication of gallstone pancreatitis. Each case should be discussed on an individual risk benefit basis.

The laparotomy approach to cholecystectomy has now been largely replaced by the laparoscopic technique. Postoperative pain is minimized with only a short period of ileus and the early ability to mobilize the patient. Laparoscopic cholecystectomy can be safely carried out on a day-care basis in otherwise fit patients (although in most cases an overnight stay remains the norm). This has considerable cost benefits over open cholecystectomy, which is now reserved for a small proportion of patients with contraindications such as extensive previous upper abdominal surgery, ongoing bile duct obstruction or portal hypertension.

In approximately 5% of cases a laparoscopic cholecystectomy is converted to an open operation because of technical difficulties, in particular adhesions in the right upper quadrant or difficulty in identifying the biliary anatomy.

**Acute cholecystitis.** The initial management is conservative, consisting of nil by mouth, intravenous fluids, opiate analgesia and intravenous antibiotics (dictated by local policy with options including extended spectrum cephalosporins, fluoroquinolones or piperacillin/tazobactam).

Cholecystectomy is usually delayed for a few days to allow the symptoms to settle but can then be carried out quite safely in the majority of cases.

When the clinical situation fails to respond to this conservative management, particularly if there is increasing pain and fever, an empyema or gangrene of the gall bladder may have occurred. Urgent ultrasound is performed and urgent surgery will be required if these complications have developed.

**Specific complications of cholecystectomy** include a biliary leak either from the cystic duct or from the gall bladder bed. Injury to the bile duct itself occurs in up to 0.5% of laparoscopic operations and may have serious long-term sequelae in the form of biliary sepsis and secondary biliary liver injury. There is an overall mortality of 0.2%.

**Stone dissolution and shock wave lithotripsy**

These non-surgical techniques for the management of gall bladder stones are infrequently used but may still have a role in a few highly selected patients who may not be fit for laparoscopic cholecystectomy.
Dissolution. Pure or near-pure cholesterol stones can be solubilized by increasing the bile salt content of bile. Cheno-
deoxycholic acid and ursodeoxycholic acid were used but
now laparoscopic surgery has made this treatment redundant.
in any event, its efficacy was limited and the recurrence
rate of gallstones was high. These limitations have restricted
the application of this approach. Further benefit may be
attained by the addition of an HMG-CoA reductase inhibitor
(e.g., simvastatin) to a regimen of ursodeoxycholic acid. This
will then combine reduced cholesterol content of bile as well
an enhanced bile salt concentration but uses are still
limited.

Extracorporeal shock wave lithotripsy. A shock wave can be
directed either radiologically or by ultrasound on to gall
bladder stones. This technique was highly successful but in
only a restricted patient population.

The post-cholecystectomy syndrome
This refers to right upper quadrant pain, often biliary in type,
which occurs a few months after the cholecystectomy but
may be delayed for a number of years. The patients often
comment that the pain is identical to that for which the origi-
nal operation was carried out. In many cases this syndrome
is related to functional large bowel disease with colonic
spasm at the hepatic flexure (hepatic flexure syndrome). In
a small proportion of patients the pain is a result of a retained
common bile duct stone. In a further minority of patients,
hypertension of the sphincter of Oddi is a potential cause.
This is most likely in patients with abnormal liver biochem-
istry and dilatation of the common bile duct (on ultrasound)
during episodes of pain (and in the absence of a documented
retained stone). The diagnosis is confirmed by pressure mea-
surements of the sphincter of Oddi, and the condition can
be successfully managed by endoscopic sphincterotomy
(see below).

COMMON BILE DUCT STONES
The classical features of common bile duct (CBD) stones are
biliary colic, fever and jaundice (acute cholangitis). This triad
is only present in the minority of patients. Abdominal pain is
the most common symptom and has the typical features of
biliary colic (see above). Jaundice is a variable accompani-
ment and is almost always preceded by abdominal pain. A
patient with bile duct stones may experience sequential epis-
odes of pain, only some of which are accompanied by jaundice.
In contrast to malignant bile duct obstruction, the
level of jaundice associated with CBD stones characteristi-
cally tends to fluctuate.

Fever is only present in a minority of cases but indicates
biliary sepsis and sometimes an associated sepsicaemia.
The presence of such biliary sepsis is a significant adverse prog-
nostic factor.

A minority of patients with bile duct stones are discovered
incidentally during imaging for gall bladder disease. Fifteen
per cent of patients undergoing choledactectomy will have
stones within the bile duct only detected at the time of opera-
tive cholangiography. The frequency of asymptomatic bile
duct stones resulting in complications is not well docu-
mented. It is likely that many such stones will pass into the
duodenum without causing symptoms. However, the poten-
tial for serious complication is well recognized and in most
circumstances incidentally identified bile duct stones are
removed (see below).

Physical examination
If the patient is examined between episodes there may be
no abnormal physical finding. During a symptomatic episode
the patient may be jaundiced with a fever and associated
tachycardia. There is tenderness in the right upper quadrant
varying from mild to extremely severe.

More widespread abdominal tenderness extending from
the epigastrium to the left upper quadrant, associated with
distension, may indicate associated stone-related pancreati-
tis (see below).

Investigations
Laboratory tests
 ■ Full blood count is usually normal in the presence of
uncomplicated bile duct stones.
 ■ An elevated neutrophil count and raised inflammatory
markers (ESR and CRP) are frequent accompaniments of
cholangitis.
 ■ The raised serum bilirubin tends to be mild and
often transient. Very high concentrations of bilirubin
(≥ 200 µmol/L) almost always reflect complete bile
duct obstruction.
 ■ Serum alkaline phosphatase and γ-glutamyl
transpeptidase are similarly elevated in proportion to the
degree of hyperbilirubinaemia.
 ■ Aminotransferase levels are usually mildly elevated but
with complete bile duct obstruction there may be very
marked rises to 10–15 times the normal value. These
high levels may lead to an initial misdiagnosis of an
hepatic process.
 ■ Serum amylase levels are often mildly elevated in the
presence of bile duct obstruction but are markedly so if
stone-related pancreatitis has occurred.
 ■ Prothrombin time may be prolonged if bile duct
obstruction has occurred; this reflects decreased
absorption of vitamin K.

Transabdominal ultrasound
This is the initial imaging technique of choice and in many
cases the only imaging technique required.

Bile duct obstruction is characterized by dilatation of
intrahepatic biliary radicles, which are usually easily detected
by the ultrasound scan. It may, however, not be possible to
identify the cause of obstruction. Stones situated in the distal
common bile duct are poorly visualized by transabdominal
ultrasound and up to 50% are missed. The detection of
stones within the gall bladder is poorly predictive as to the
cause of bile duct obstruction. Asymptomatic gallstones are
common (up to 15%) in patients who are 65 years and older.
Conversely, in 5–10% of patients with bile duct stones, no
calci can be seen within the gall bladder.

Other imaging techniques
Magnetic resonance cholangiography (MRC) delineates
the fluid column within the biliary tree and is a sensitive tech-
nique for the detection of common bile duct stones in the
presence of a dilated duct. The technique may be less accu-
rate in the absence of duct dilatation (see the role of endo-
scopic ultrasound, below) (Fig. 7.31).
Spiral CT scanning is an alternative way to detect bile duct dilatation. Opaque stones are more readily identifiable within the bile duct than radiolucent cholesterol stones. CT scanning also provides a means of excluding other causes of bile duct obstruction such as carcinoma of the head of the pancreas.

Endoscopic ultrasound scanning (Fig. 7.32) has enabled high-resolution imaging of the common bile duct, gall bladder and pancreas, although unlike the preceding imaging techniques it is an invasive procedure. The endoscopic ultrasound probe in the duodenum is in close proximity with the distal common bile duct and hence can identify the majority of stones at this level.

This technique may be particularly useful for identifying small calculi (microcalculi), particularly in a non-dilated common bile duct.

Endoscopic retrograde cholangiography (ERC)
The endoscopic technique of ERC (p. 327) enables good visualization of the common bile duct. In experienced hands this will be successful in 98% of cases, providing good documentation of bile duct stones (Fig. 7.33).

However, microcalculi can still be missed. ERC gives the therapeutic opportunity for sphincterotomy and stone extraction (see below).

Differential diagnosis
Cholangitis may occur independently of gallstones in conditions such as primary sclerosing cholangitis and Caroli’s syndrome. On occasions cholangitis may accompany malignant bile duct obstruction. Jaundice may also be a feature of acute cholecystitis in the absence of bile duct stones. A stone impacted in the cystic duct may compress and obstruct the bile duct (Mirizzi’s syndrome). Common bile duct stones may produce pain, but in the absence of jaundice, the differential diagnosis is that of biliary colic (see above).

Management
Acute cholangitis has a high morbidity and mortality, particularly in the elderly. Successful management depends on
intravenous antibiotics (see as for acute cholecystitis), and urgent bile duct drainage by an endoscopic retrograde approach (Fig. 7.33). Access to the bile duct is achieved by sphincterotomy, and thereafter the stones can be removed either by balloon or basket catheters. In the severely ill patient a piece of plastic tubing (termed a stent) can be inserted into the bile duct to maintain bile drainage without the need to remove the stones, hence minimizing the time period to complete the procedure. The residual stones can then be removed endoscopically when the patient has recovered from the episode. In the presence of acute cholangitis surgical drainage has been associated with a high mortality and is now limited to those very few cases which cannot be managed by the endoscopic approach.

Urgent endoscopic bile duct clearance is also indicated in some patients with acute gallstone pancreatitis (see below). Patients who have retained common bile duct stones after a previous cholecystectomy are also optimally managed by endoscopic clearance. Patients shown to have common bile duct stones as well as gall bladder stones may be treated by two different approaches:

- **Laparoscopic cholecystectomy** which can also include exploration of the CBD via the cystic duct or by direct choledochotomy. By using these techniques the laparoscopist can extract stones from the common bile duct. This, however, prolongs the procedure, particularly in the presence of large stones or biliary sepsis.
- **Endoscopic approach** either immediately before or after the cholecystectomy. Removal of CBD stones by this method is the preferred way in the UK.

### COMPLICATIONS OF GALLSTONES

- Acute cholecystitis and acute cholangitis have been discussed (p. 368).
- Gallstone-related pancreatitis is discussed on page 379.
- Gallstones can occasionally erode through the wall of the gall bladder into the intestine giving rise to a biliary enteric fistula. Passage of a gallstone through into the small bowel can give rise to an ileus or true obstruction.
- There is little evidence that gallstones are associated with an increased risk of adenocarcinoma of the gall bladder (p. 374).

### MISCELLANEOUS CONDITIONS OF THE BILIARY TRACT

#### GALL BLADDER

There are a number of non-calculous conditions of the gall bladder, some of which have been associated with symptoms.

**Non-calculous cholecystitis**

Almost 10% of gall bladders removed for biliary symptoms are shown to have chronic inflammation within the wall but an absence of gallstones. Such cases are described as non-calculous cholecystitis. In many instances the gall bladder inflammation is minor and of doubtful significance. In a minority of cases non-calculous cholecystitis is characterized by severe inflammation frequently associated with gall bladder perforation. This condition is characteristically found in an elderly and critically ill group of patients. Chemical inflammation of the gall bladder may also occur from reflux of pancreatic enzymes back into the biliary tree, usually through the common channel at the ampulla of Vater. Bacterial infection of the gall bladder has occasionally been recognized as a cause of chronic inflammation.

The decision to carry out cholecystectomy in the absence of defined gall bladder stones should be guided by the specific features of the history and whether there is evidence of a diseased gall bladder wall on ultrasound scanning.

#### Chronic cholecystitis

There are no symptoms or signs that can conclusively be shown to be due to chronic cholecystitis. Symptoms attributed to this condition are vague, such as indigestion, upper abdominal discomfort or distension. There is no doubt that gall bladders studied histologically can show signs of chronic inflammation, and occasionally a small, shrunken gall bladder is found either radiologically or on ultrasound examination. However, these findings can be seen in asymptomatic people and therefore this clinical diagnosis should not be made. Most patients with chronic right hypochondrial pain suffer from functional bowel disease (p. 309).

#### Primary sclerosing cholangitis

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease characterized by fibrosing inflammatory destruction of both the intra- and extrahepatic bile ducts. In 75% of
patients PSC is associated with inflammatory bowel disease (usually ulcerative colitis) and it is not unusual for the PSC to predate the onset of the inflammatory bowel disease. The causes are unknown but genetic susceptibility to PSC is associated with the HLA A1-B8-DR3 haplotype. The autoantibody pANCA (anti-neutrophil cytoplasmic antibody) is found in the serum of 60% of cases. Seventy per cent of patients are men and the average age of onset is approximately 40 years. Secondary PSC is seen in patients with HIV and cryptosporidium (p. 162).

**Clinical features**

With increasing screening of patients with inflammatory bowel disease PSC is detected at an asymptomatic phase with abnormal liver biochemistry, usually a raised serum alkaline phosphatase. Symptomatic presentation is usually with fluctuating pruritus, jaundice and cholangitis.

**Diagnosis**

The typical biliary changes associated with PSC may be identified by MRC scanning. This technique may fail to identify minor, but still clinically significant, intrahepatic duct abnormalities and this may require endoscopic retrograde cholangiography (ERC). The cholangiogram characteristically shows irregularity of calibre of both intra- and extrahepatic ducts, although either may be involved alone (see Fig. 7.34).

**Management**

Confirmation of the diagnosis comes from liver histology, which shows inflammation of the intrahepatic biliary radicles with associated scar tissue classically described as being onion skin in appearance. The histological changes may range from minor inflammatory infiltrates to the level of established cirrhosis. The presence of cirrhosis has prognostic implications.

PSC is a slowly progressive lesion (symptoms and biochemical tests may fluctuate), ultimately leading to liver cirrhosis and associated decompensation. Cholangiocarcinoma occurs in up to 15% of patients.

The only proven treatment is liver transplantation. The bile acid ursodeoxycholic acid has been evaluated extensively in the treatment of PSC, with well-documented improvement in liver function tests but no conclusive evidence of symptomatic, histological or survival benefit. There is some evidence that high dose therapy (30 mg/kg) may offer some benefit. In a small minority of patients with PSC the dominant lesion is of the extrahepatic ducts. Such lesions may be amenable to endoscopic biliary intervention with balloon dilatation and temporary stent placement.

**Choledochal cyst**

Congenital cystic disease of the bile ducts may occur at all levels of the biliary tree, although most cysts are extrahepatic. The dilatation may be saccular, diverticular or of fusiform configuration. In many cases there is associated pancreatobiliary malunion with the pancreatic duct draining directly into the common bile duct. The majority of asymptomatic cases present in childhood with features of choangiitis. The formation of stones and sludge within the cystic segment may predispose to acute relapsing pancreatitis. In adult life choledochal cysts may be a differential diagnosis in patients presenting with symptoms suggestive of bile duct stones. The cyst must be fully resected to avoid the recurrent biliary complications as well as averting the risk (approximately 15%) of subsequent cholangiocarcinoma.

**Haemobilia**

Haemobilia is the term used to describe bleeding into the biliary tree. This may be as a consequence of liver trauma or as a complication of liver surgery. Biopsy of the liver is also a well-recognized cause. The end result is a fistula between a branch of the hepatic artery and an intrahepatic bile duct.

Haemobilia may be a cause of significant gastrointestinal blood loss and should be suspected when melaena is accompanied by right-sided upper abdominal pain and jaundice. However, the bleeding may occur without any overt biliary symptoms. If the diagnosis is suspected, bleeding may be managed by occlusion of the feeding artery by thrombosis performed radiologically.

Some patients will require surgery to control the bleeding point.

**TUMOURS OF THE BILIARY TRACT**

**Gall bladder polyps**

Polyps of the gall bladder are a common finding, being seen in approximately 4% of all patients referred for hepatobiliary ultrasonography. The vast majority of these are small (less than 5 mm), are non-neoplastic and are inflammatory in origin or composed of cholesterol deposits (see above). Adenomas are the most common benign neoplasm of the gall bladder. Only a proportion of these have a cancerous potential. The only reliable means of defining those at risk is polyp size. Cholecystectomy is recommended for any polyp approximating to 1 cm in diameter or larger.
Primary cancer of the gall bladder

Adenocarcinoma of the gall bladder represents 1% of all cancers. The mean age of occurrence is in the early sixties with a ratio of 3 women to 1 man. Gallstones have been suggested as an aetiological factor but this relationship remains unproven. Diffuse calcification of the gall bladder (porcelain gall bladder), considered to be the end stage of chronic cholecystitis, has also been associated with cancer of the gall bladder and is an indication for cholecystectomy. Adenomatous polyps of the gall bladder in excess of 1 cm in diameter are also recognized as premalignant lesions (see above).

Carcinoma of the gall bladder is often detected at the time of planned cholecystectomy for gallstones and in such circumstances resection of an early lesion may be curative. Early lymphatic spread to the liver and adjacent biliary tract precludes curative resection in more advanced lesions. There are no proven chemotherapeutic agents for carcinoma of the gall bladder. A small proportion of cases are sensitive to radiotherapy but the overall 5-year survival is less than 5%.

Cholangiocarcinoma (see also p. 364)

Cancer of the biliary tree may be intra- or extrahepatic. These malignancies represent approximately 1% of all cancers. A number of associations have been identified such as that with choledochal cyst (see above), and chronic infection of the biliary tree with, for example, Clonorchis sinensis. There are also associations with autoimmune disease processes such as primary sclerosing cholangitis. The bile duct malignancy usually presents with jaundice and may be suspected by imaging, initially ultrasound and thereafter spiral CT and in particular magnetic resonance cholangiopancreatography (MRCP). The disease spread is usually by local lymphatics or local extension. Cholangiocarcinoma of the common bile duct may be resectable at presentation but local extension precludes such management in the majority of more proximal lesions. Localized disease justifies an aggressive surgical approach including partial hepatic resection. Chemoradiation has been used to treat localized small hilar cholangiocarcinoma and in a few cases has facilitated successful liver transplantation, but the carcinoma recurs.

Secondary malignant involvement of the biliary tree

Carcinoma of the head of the pancreas frequently presents with common bile duct obstruction and jaundice. Metastases to the bile ducts from distant cancers are uncommon. Melanoma is the most frequent neoplasm to do so.

Other carcinomas that have caused bile duct metastases, in order of frequency, are those arising in the lung, breast and colon as well as those from the pancreas (metastatic as compared to direct infiltration). Infiltration of the bile duct is not uncommon in disseminated lymphomatous disease.

Palliation of malignant bile duct obstruction

A small proportion of cholangiocarcinomas are surgically resectable, more commonly those in the distal bile duct as compared to the hilar region. All patients must be fully screened for operability using the imaging techniques described above. However, in the greater proportion of patients the treatment is palliative. Relief of bile duct obstruction has been shown to improve quality of life considerably and with pain control is the major end point of palliation. In recent years endoscopic techniques have allowed the insertion of stents into the biliary tree to re-establish bile flow. The initial use of plastic stents has largely been replaced by self-expanding metal stents which have considerably longer periods of patency (Fig. 7.35). In the small proportion of patients in whom bile duct drainage is not possible

![Fig. 7.35 Stents](image-url)
scopically, the percutaneous route offers an alternative method of stent placement. There is some evidence of benefit from the use of photodynamic therapy in those patients in whom biliary drainage has been achieved. This technique involves the use of a porphyrin derivative to sensitize the malignant cells prior to activation by an endoscopically placed laser probe. The aim is to provide local tumour destruction and maintain bile duct patency.

### THE PANCREAS

### STRUCTURE AND FUNCTION

#### Structure

The pancreas extends retroperitoneally across the posterior abdominal wall from the second part of the duodenum to the spleen. The head is encircled by the duodenum; the body, which forms the main bulk of the organ, ends in a tail that lies in contact with the spleen. The pancreas consists of exocrine and endocrine cells, the former making up 98% of the human pancreas.

The pancreatic acinar cells are grouped into lobules, forming the ductal system which eventually joins into the main pancreatic duct.

The main pancreatic duct has many tributary ductules and gradually tapers towards the tail of the pancreas. The main pancreatic duct itself usually joins the common bile duct to enter the duodenum as a short single duct at the ampulla of Vater.

#### Exocrine function

The pancreatic acinar cells are responsible for production of digestive enzymes. These include amylase, lipase, colipase, phospholipase and the proteases (trypsinogen and chymotrypsinogen). These enzymes are stored within the acinar cells in secretory granules and are released by exocytosis (Fig. 7.36).

After ingestion of a meal, pancreatic exocrine secretion is regulated by cephalic, gastric and intestinal stimuli. The cephalic phase is mediated by the central nervous system and is stimulated by behavioural cues related to the sight and smell of food. With ingestion of food, the gastric phase commences and in response to distension of the stomach a neural pathway involving the central nervous system stimulates pancreatic secretion. Both these phases are under vagal control. Finally, the presence of protein, fat and gastric acid within the small intestine further augments pancreatic secretion by both hormonal and neurotransmitter activity which produces local enteropancreatic control of secretion. Feedback regulatory events eventually terminate pancreatic secretion.

Cholecystokinin (CCK) is produced in specialized gut endocrine cells (l cells) of the mucosa of the small intestine and is secreted in response to intraluminal food. In animals, it exerts its biological activity by binding to specific G-protein-coupled receptors on target cells in the pancreas. Activated G-proteins lead to the activation of phospholipases. This in turn leads to calcium release from intracellular stores, which in turn results in the fusion of the digestive enzyme granules to the apical plasma membrane and enzyme release. There are no CCK receptors in pancreatic cells in humans, and CCK acts via receptors on vagal afferent fibres to stimulate pancreatic secretion. Of the enzymes produced by the pancreatic acinar cells, the proteases and colipase are secreted as inactive precursors and require duodenal enterokinase to initiate activity.

Secretin is also released from specialized enteroendocrine cells of the small intestine during a meal and in particular during duodenal acidification. Secretin has a direct effect on the pancreatic acinar cells as well as the ductal cells. There is also a vagal-mediated secretory response. Secretin action is mediated via G-coupled receptors and calcium-mediated enzyme release. Secretin results in a bicarbonate-rich pancreatic secretion.

Completion of the postprandial secretory phase involves both neural and hormonal control.

Central neuronal inhibition of pancreatic secretion acts through dopamine and somatostatin receptors mediated by noradrenergic nerves.

Pancreatic polypeptide from the islet cells is released from the pancreas in response to a meal and has an inhibitory effect upon acinar enzyme secretion both by a local effect and via central receptors.

The endocrine pancreas

This consists of hormone-producing cells arranged in nests or islets (islets of Langerhans). The hormones produced are secreted directly into the circulation and there is no access to the pancreatic ductular system. There are five main types of islet cell corresponding to different secretory components. The beta cells are the most common and are responsible for insulin production. The alpha cells produce glucagon. The D cells produce somatostatin, PP cells produce pancreatic polypeptide and enterochromaffin cells produce serotonin.

A number of other hormones have been identified within the endocrine pancreas including gastrin-releasing peptide, neuropeptide Y and galanin. These are believed to be neurotransmitters active in the neuro-gastrointestinal axis.

INVESTIGATION OF THE PANCREAS

Assessment of exocrine function

The assessment of pancreatic exocrine function is used in the investigation of patients with possible chronic pancreatic disease. Clinically evident fat malabsorption does not occur until there has been an 85–90% reduction in pancreatic lipase and is therefore a very late manifestation of pancreatic disease.

Direct tests of pancreatic function

These tests rely upon the analysis of a duodenal aspirate following pancreatic stimulation.

The original test involved the oral administration of a specified meal (Lundh meal). Pancreatic stimulation is now achieved by intravenous secretin and cholecystokinin.

The aspirate is assessed for pancreatic enzymes and bicarbonate production. The procedure is time-consuming and requires a meticulous technique. There is a good correlation with moderate to severe pancreatic function loss, but not for mild damage. These tests are not widely available.

The measurement of peak bicarbonate secretion following secretin stimulation has recently been described using an endoscopic technique for aspirate collection. This method offers similar levels of predictive accuracy as seen with the secretin–cholecystokinin stimulation test but does require a 30 minute endoscopic intubation.

Non-invasive indirect tests of pancreatic function

Faecal tests

- Faecal fat estimation (see p. 277).
- Faecal chymotrypsin. The test is not useful until severe impairment of pancreatic function is present.
- Faecal elastase. This pancreatic specific enzyme is not degraded in the intestine and has high concentrations within the faeces. Diminished levels may be detected in moderate as well as severe pancreatic insufficiency. This has replaced the faecal chymotrypsin test.

Oral pancreatic function tests

- PABA test. Oral N-benzoyl-l-tyrosyl-p-aminobenzoic acid is hydrolysed by chymotrypsin to release p- aminobenzoic acid (PABA), which is then absorbed, conjugated and excreted in the urine where it can be measured. The test is time-consuming but is specific for pancreatic insufficiency, with a 65–80% sensitivity.
- Fluorescein dilaurate test. Oral fluorescein dilaurate is digested by pancreatic esterase to release the fluorescein which is then absorbed and excreted in the urine. This test is relatively inexpensive and commercially available as the ‘Pancreolauryl test’. This is highly sensitive and specific in severe pancreatic insufficiency but has only a 50% sensitivity in mild to moderate disease.

Clinical application of pancreatic function tests

Whilst the invasive duodenal aspiration tests represent the most sensitive and specific means of assessing pancreatic function, these are very rarely used outside specialized centres. The Pancreolauryl and PABA tests are non-invasive and are widely available but are only highly sensitive in the detection of severe pancreatic insufficiency. The faecal elastase test (in a commercially available form) provides similar sensitivity and specificity and is the test of choice as a screening tool for pancreatic insufficiency, but again detection of mild disease is problematic.

Pancreatic imaging (see p. 325)

Imaging has a pivotal role in the investigation and management of pancreatic disease, which covers the spectrum of acute, chronic and malignant conditions.

- A plain abdominal radiograph may show the calcification associated with chronic pancreatitis, particularly when alcohol is the aetiology.
- Ultrasound of the pancreas is a useful screening investigation for inflammation and neoplasia. Views may be limited by overlying bowel gas.
- Spiral CT scan with contrast enhancement and following a specific pancreatic protocol remains the gold standard imaging technique for the investigation of pancreatic disease.
- MRI scanning represents an alternative to CT. Magnetic resonance cholangiopancreatography (MRCP) gives clear definition of the pancreatic duct as well as the biliary tree. Gallstones (including microcalculi) may also be identified in the biliary tree using MRI/MRCP.
- Endoscopic ultrasound is very useful for identifying distal common bile duct stones which may be the
Endoscopic ultrasound can identify the early changes of chronic pancreatitis before these are evident on other imaging methods. There is also an increasing role for this technique to stage the operability of pancreatic adenocarcinoma, particularly with respect to vascular invasion. Endoscopic ultrasound is now considered the imaging technique of choice for investigating cystic lesions of the pancreas (see below). The technique allows fine-needle aspiration and histological sampling as well as the therapeutic option of cyst drainage.

Endoscopic ultrasound is a sensitive means of detecting small pancreatic tumours, particularly those of neuroendocrine origin.

Endoscopic retrograde cholangiopancreatography (ERCP) was considered the gold standard for diagnosing pancreatic disease. However, with the advent of MRCP and endoscopic ultrasound, ERCP is restricted to therapeutic intervention.

Summary. An initial transabdominal ultrasound supplemented by spiral CT provides sufficient diagnostic information for most inflammatory and neoplastic conditions of the pancreas. MRI and MRCP are now widely available and provide additional information, particularly with respect to pancreatic ductal and biliary anatomy. Endoscopic ultrasound is now widely available and has become a useful tool in the investigation of possible pancreatic malignancy, particularly for preoperative assessment.

## PANCREATITIS

### Classification

Pancreatitis is divided into acute and chronic. By definition acute pancreatitis is a process that occurs on the background of a previously normal pancreas and can return to normal after resolution of the episode. In chronic pancreatitis there is continuing inflammation with irreversible structural changes.

In practice the differentiation between acute and chronic pancreatitis may be extremely difficult. Any of the causes of acute pancreatitis if untreated may result in recurrent episodes classified as acute relapsing pancreatitis. In other cases the recurrent episodes of recurrent pancreatitis may represent exacerbations of an underlying chronic process.

### Acute pancreatitis

The causes of acute pancreatitis are listed in Table 7.18. In the western world, gallstones and alcohol account for the vast majority of episodes. Alcohol also causes chronic pancreatitis (see below). The severity of the pancreatitis may range from mild and self-limiting to extremely severe with extensive pancreatic and peripancreatic necrosis as well as haemorrhage. In the most severe form of pancreatitis the mortality rises to between 40% and 50%.

### Pathogenesis

Mechanisms by which pancreatic necrosis occurs remain speculative. Any theory must take into account how a very diverse group of aetiological factors can produce the same end point. There is some suggestion that the final common pathway is a marked elevation of intracellular calcium which in turn leads to activation of intracellular proteases. It is these activated enzymes which are responsible for cellular necrosis. In the case of gallstone-related pancreatitis it is believed that stones occlude the pancreatic drainage at the level of the ampulla leading to pancreatic ductular hypertension. Such ductular hypertension has been shown in animal models to increase cytosolic free ionized calcium. There is also evidence that alcohol interferes with calcium homeostasis in pancreatic acinar cells.

### Clinical features

Acute pancreatitis is a differential diagnosis in any patient with upper abdominal pain. The pain usually begins in the epigastrium accompanied by nausea and vomiting. As inflammation spreads throughout the peritoneal cavity the pain becomes more intense. Involvement of the retroperitoneum frequently leads to back pain.

The patient may give a history of previous similar episodes or be known to have gallstones. An attack may follow an alcoholic binge. However, in many cases there are no obvious aetiological factors.

Physical examination at the time of presentation may show little more than a patient in pain with some upper abdominal tenderness but no systemic abnormalities. In more severe disease the patient may have a tachycardia, hypotension and be oliguric. Abdominal examination may show widespread tenderness with guarding as well as reduced or absent bowel sounds. Specific clinical signs that support a diagnosis of severe necrotizing pancreatitis include periumbilical (Cullen’s sign) and flank bruising (Grey Turner’s sign). In patients with a gallstone aetiology the clinical picture may also include the features of jaundice or cholangitis.

### Diagnosis

#### Blood tests

- **Serum amylase** is an extremely sensitive test if it is 3 times the upper limit of normal when measured within 24 hours of the onset of pain. A number of other conditions may occasionally cause a very elevated amylase (Table 7.19). Amylase levels gradually fall back towards normal over the next 3–5 days. With a late presentation the serum amylase level may give a false-negative result.

- **Urinary amylase** levels may be diagnostic as these remain elevated over a longer period of time.

- Serum lipase levels are also raised in acute pancreatitis and these remain elevated for a longer period of time than those of amylase. However, overall, the accuracy of serum lipase is not significantly greater than amylase and it is technically more difficult to measure.
- C reactive protein level is useful in assessing disease severity and prognosis.
- Other baseline investigations include a full blood count, urea and electrolytes, blood glucose, liver biochemistry, plasma calcium and arterial blood gases. These are documented at presentation and then repeated at 24 and 48 hours and provide a basis for assessing the severity of an attack (see below).

**Radiology**

- An erect chest X-ray is mandatory to exclude gastroduodenal perforation, which also raises the serum amylase (see Table 7.19). A supine abdominal film may show gallstones or pancreatic calcification.
- An abdominal ultrasound scan is used as a screening test to identify a possible biliary (gallstone) cause of pancreatitis. Gallstones are difficult to detect in the distal common bile duct but dilated intrahepatic ducts may be present in the presence of bile duct obstruction. Stones within the gall bladder are not sufficient to justify a diagnosis of gallstone-related pancreatitis. The ultrasound may also demonstrate pancreatic swelling and necrosis as well as peripancreatic fluid collections if present. In severe pancreatitis the pancreas may be difficult to visualize because of gas-filled loops of bowel.
- Contrast-enhanced spiral CT scanning is essential in all but the most mild attacks of pancreatitis (Fig. 7.37). It should be performed after 72 hours to assess the extent of pancreatic necrosis. CT provides very valuable prognostic information. Later, repeated CT scans can detect other complications including fluid collections, abscess formation and pseudocyst development.
- MRI (MRCP) assesses the degree of pancreatic damage and identifies gallstones within the biliary tree. MRI is particularly useful to differentiate between fluid and solid inflammatory masses.
- ERCP is used as a treatment measure to remove bile duct stones in the presence of gallstone-related pancreatitis (see below).

**Assessment of disease severity**

The majority of cases of acute pancreatitis are mild but approximately 25% run a more complicated course which may result in haemodynamic instability and multiple organ failure. The early prediction of such a severe attack allows appropriate monitoring and intensive care to be in place.

Early clinical assessment has been shown to have poor sensitivity for predicting a severe attack. Similarly, individual laboratory tests have very limited value. Elevations of CRP of >200 mg/L in the first 4 days have an 80% predictive value of a severe attack. Multiple factors are also used to develop scoring systems (Table 7.20). The Ranson and Glasgow scoring systems are based on such parameters and have been shown to have an 80% sensitivity for predicting a severe attack, although only after 48 hours following presentation. The acute physiology and chronic health evaluation (APACHE) score has been extensively adopted as a means of assessing the severity of a wide spectrum of illness. The APACHE scoring system is based on common physiological and laboratory values and adjusted for age as well as the presence or absence of a number of other chronic health problems (see Table 7.21). This scoring system appears to have a high sensitivity as early as 24 hours after onset of symptoms. There is evidence that obesity predicts the outcome from an episode of pancreatitis as the excessive adipose tissue is a substrate for activated enzyme activity. This will in turn generate an extensive inflammatory reaction. Even modest obesity (body mass index (BMI) between 25 and 30) has an adverse effect. This is incorporated as an adverse factor in the APACHE score (p. 920) for acute pancreatitis, and other variables have also been added.

Adjust for age and severe organ insufficiency or for immunocompromised. BMI is an additional parameter

Treatment

The initial management of acute pancreatitis is similar, whatever the cause. A multiple factor scoring system (ideally APACHE II with a modification for obesity) should be used at the end of the first 24 hours after presentation to allow identification of the 25% of patients with a predicted severe attack. This should be repeated at 48 hours to identify a further subgroup who appear to be moving into the severe category. These patients should then be managed on a high-dependency or intensive care unit. Even patients outside the severe category may require considerable supportive care.

Early fluid losses in acute pancreatitis may be large, requiring well-maintained intravenous access as well as a central line and urinary catheter to monitor circulating volume and renal function.

- **Nasogastric suction** prevents abdominal distention and vomiting and hence the risk of aspiration pneumonia.
- **Baseline arterial blood gases** determine the need for continuous oxygen administration.
- **Prophylactic antibiotics**. Broad-spectrum antibiotics, e.g. cefuroxime, or aztreonam, along with an agent active against Gram-positive cocci, reduce the risk of infective complications and are given from the outset.
- **Analgesia requirements**. Pethidine and tramadol are the drugs of choice for immediate post-presentation pain control. Unless there is prompt resolution of pain, a patient-controlled system of administration is indicated to provide continuous and adequate pain relief. Fentanyl has been used widely for this application. There is a theoretical risk that morphine and diamorphine might exacerbate pancreatic ductular hypertension by causing sphincter of Oddi contraction and they are best avoided in acute pancreatitis.

- **Feeding**. In patients with a severe episode there is little likelihood of oral nutrition for a number of weeks. Total parenteral nutrition has been associated with a high risk of infection and has been replaced by enteral nutrition. In the absence of gastroparesis most patients will tolerate nasogastric administration of feed without exacerbation of pain. In those with gastroparesis or poorly tolerated nasogastric feeding (exacerbation of pain or precipitation of nausea and vomiting), postpyloric feeding should be instituted by the endoscopic placement of a nasojejunal tube.

- **Anticoagulation** with a low molecular weight heparin for DVT prophylaxis.

In a small proportion of patients, multigorgan failure will develop in the first few days after presentation, reflecting the extent of pancreatic necrosis. Such patients will require positive-pressure ventilation and often renal support. The mortality in this group is extremely high (in excess of 80%).

**Gallstone-related pancreatitis**

In patients with gallstone-related pancreatitis and associated bile duct obstruction (particularly when complicated by cholangitis), endoscopic intervention with sphincterotomy and stone extraction is the treatment of choice. In the absence of bile duct obstruction, sphincterotomy and stone extraction is only of proven benefit when the episode of pancreatitis is predicted as severe. In less severe cases of gallstone-related pancreatitis the presence of residual bile duct stones can be assessed by MRCP or endoscopic ultrasound after recovery from the episode of pancreatitis (usually a 6 week period is allowed) and, if present, removed at the time of ERCP. To prevent a recurrent episode of pancreatitis cholecystectomy should be carried out at a similar time interval.

**Late complications of acute pancreatitis**

Within the first 7 days the morbidity and mortality of acute pancreatitis reflect the systemic inflammatory response, which in turn results in multiple organ failure. After this initial period the prognosis thereafter is most closely related to the extent of pancreatic necrosis. This can be most accurately assessed by contrast-enhanced CT, which should be carried out in all patients with severe disease after the first week. Extensive necrosis (greater than 50% of the pancreas) is associated with high risk of further complicated disease, frequently requiring surgical intervention.

It is infection of the necrotic pancreas which is of most concern and which may rapidly lead to overwhelming sepsis. Prophylactic antibiotics have been used to prevent this but do not reliably do so. If there is evidence of incipient infection, monitored by a rising neutrophil count and CRP level, an aspirate of the necrotic pancreas is taken under ultrasound control and cultured. The vast majority of patients with a positive culture should be considered for surgical resection of the necrotic pancreas. In the most severe cases multiple operations are required to fully ressect the areas of necrosis.

**Peripancreatic fluid collections** are common in the early stages of acute pancreatitis; the vast majority will resolve spontaneously. Some fluid collections will be surrounded by granulation tissue producing the so-called ‘pseudocyst’. These by definition are not fully formed until 6 weeks after the onset of the illness. The smaller pseudocysts (less than 6 cm in diameter) frequently resolve on their own but others may persist in the long term, giving rise to potential complications such as infection, intraperitoneal bleeding and gastric outlet obstruction. Larger pseudocysts persisting for longer than 6 weeks are usually actively managed by endoscopic drainage under endoscopic ultrasound guidance. Surgical drainage may be indicated in cases in which the cyst anatomy is not compatible with endoscopic drainage.

**Long-term outcome**

The vast majority of patients with a mild to moderate episode of acute pancreatitis will make a full recovery with no long-term sequelae. Recurrent episodes of pancreatitis may occur, particularly if there has been any long-term pancreatic ductal damage. Patients with more severe acute pancreatitis may become pancreatic insufficient both with respect to exocrine (malabsorption) and endocrine function (diabetes).
Chronic pancreatitis

Aetiology

In developed countries by far the most common cause of chronic pancreatitis is alcohol, accounting for 60–80% of cases (see Table 7.18).

Tropical chronic pancreatitis is commonly found in children and young adults. The aetiology is unknown but there is some evidence of a genetic susceptibility with increased prevalence of mutations of the trypsin inhibitor gene SPINK1. There is a strong likelihood of an interaction between genetic susceptibility and environmental triggers.

Hereditary chronic pancreatitis is an autosomal dominant condition with variable penetrance. The gene mutations have been mapped to a cluster of trypsinogen genes situated on the long arm of chromosome 7.

Autoimmune chronic pancreatitis also occurs. This is seen predominantly in middle-aged men and associated with raised titres of anti-nuclear factor and particularly raised levels of IgG. As well as pancreatic-related complications these patients often have other autoimmune phenomena such as a cholangiopathy, Sjögren’s syndrome and renal disease.

Cystic fibrosis (p. 844). Almost all patients have established chronic pancreatitis, usually from birth. Cystic fibrosis gene mutations have also been identified in patients with chronic pancreatitis but in whom there were no other manifestations of cystic fibrosis.

Obstruction of the pancreatic duct because of either a benign or malignant process may result in chronic pancreatitis. Congenital abnormalities of the pancreatic duct, in particular pancreas divisum, have been implicated.

Pathogenesis

A possible common pathway for pancreatic damage is the inappropriate activation of enzymes within the pancreas. This has been well demonstrated in the case of hereditary pancreatitis where genetic abnormalities of cationic trypsinogen and its inhibitory proteins have led to unopposed trypsin activity within the pancreas itself.

Chronic alcohol intake is also believed to increase the level of trypsinogen relative to its inhibitor. Human trypsinogen has a propensity to autoactivate, and any relative impairment or deficiency of inhibitor proteins will lead to unopposed enzyme activity and possible pancreatic damage (Fig. 7.38).

It is believed that the intrapancreatic enzyme activity leads to the precipitation of proteins within the duct lumen in the form of plugs. These then form a nidus for calcification but are also the cause of ductal obstruction leading to ductal hypertension and further pancreatic damage. Cytokine activation and oxygen stress are thought to play a role in perpetuating this process.

Clinical features

Pain is the most common presentation of chronic pancreatitis. It is usually epigastric and often radiates through into the back. The pattern of pain may be episodic, with short periods of severe pain, or chronic unremitting. Exacerbations of the pain may follow further alcohol excess although this is not a uniform relationship.

During periods of abdominal pain anorexia is common and weight loss may be severe. This is particularly so in those patients with chronic unremitting symptoms. Exocrine and endocrine insufficiency may develop at any time, and occasionally malabsorption or diabetes is the presenting feature in the absence of abdominal pain. Jaundice secondary to obstruction of the common bile duct during its course through the fibroded head of pancreas may also occur and may be a presenting feature in a small proportion of patients.

Investigations

The extent to which investigations are required is dependent upon the clinical setting. In a patient with known alcohol abuse and typical pain, few confirmatory tests are required.

- Serum amylase and lipase levels are rarely significantly elevated in established chronic pancreatitis.
- Faecal elastase level will be abnormal in the majority of patients with moderate to severe pancreatic disease.
- PABA and Pancreolaurylest tests (see p. 376).
- Transabdominal ultrasound is used for initial assessment.
- Contrast-enhanced spiral CT scan provides a more detailed assessment. In the presence of pancreatic calcification and a dilated pancreatic duct the diagnosis of chronic pancreatitis can be easily established (Fig. 7.39). This may be much more difficult when these features are not present and in particular with an atypical presentation such as with steatorrhoea alone.
- MRI with MRCP is increasingly utilized to define more subtle abnormalities of the pancreatic duct which may be seen in non-dilated chronic pancreatitis.
- Endoscopic ultrasound is used in a small proportion of patients in whom the diagnosis is not confirmed with the above imaging or specifically for assessing complications of chronic pancreatitis including pseudocyst formation.
- Diagnostic ERCP has been replaced by MRCP.

Differential diagnosis

The differential diagnosis is that of pancreatic malignancy. Carcinoma of the pancreas can reproduce many of the symptoms and imaging abnormalities that are commonly seen with chronic pancreatitis. The diagnosis of malignancy...
should be considered in patients with a short history and in whom there is a localized ductal abnormality. Considerable difficulties may arise when a malignancy develops on the background of established chronic pancreatitis (the latter being a recognized premalignant lesion).

High-quality imaging is able to define malignant features with a localized mass lesion, local invasion and lymph node enlargement. Endoscopic ultrasound may provide the most accurate assessment of a potential mass lesion.

**Treatment**

In patients with alcohol-related chronic pancreatitis long-term abstinence is likely to be of benefit although this has been difficult to prove.

**Abdominal pain.** For short-term flare-ups of pain a combination of a non-steroidal anti-inflammatory drug and an opiate (tramadol) is usually sufficient for symptomatic relief. In patients with chronic unremitting pain this may be inadequate and also risks opiate addiction.

Tricyclic antidepressants (e.g. amitriptyline) are used for chronic pain and reduce the need for opiates. Antioxidants are not of proven benefit. Coeliac axis nerve block may produce good pain relief but is unreliable in its extent and duration of action. In the majority of patients some spontaneous improvement in pain control occurs with time. After a 6- to 10-year period some 60% of patients will become pain-free. For patients with recurrent severe or debilitating chronic pain, both endoscopic and surgical intervention has been used but with limited success. The endoscopic approach has centred upon improving duct drainage by removing intraductal stones and repeated stenting to maintain duct patency. Extracorporeal shock wave lithotripsy has been used to fragment stones within the head of pancreas. Surgical intervention usually involves a duct drainage procedure combined with partial resection of the diseased head of pancreas. There is recent evidence suggesting improved symptom control following surgical intervention as compared to the endoscopic approach. However, it is reasonable to attempt endoscopic therapy as a first measure.

**Steatorrhea.** The steatorrhea associated with pancreatic insufficiency may be high, with up to 30 mmol of fat lost per 24 hours. This will usually improve with pancreatic enzymes supplements. Current preparations are presented in the form of microspheres which reduce the problems of acid degradation in the stomach. An acid suppressor (H₂-receptor antagonist or proton pump inhibitor) is also given. Despite this, a proportion of patients continue to malabsorb, usually reflecting the inadequate mixing of the pancreatic supplements with the food as well as the low pH in the duodenum secondary to inadequate pancreatic bicarbonate production. There is no justification to reduce fat intake below the recommended levels of a normal diet as this may contribute to malnutrition seen in patients with chronic pancreatitis.

**Diabetes** associated with pancreatic endocrine failure may be difficult to control, with a rapid progression from oral hypoglycaemic agents to an insulin requirement. Brittle control is a common problem secondary to inadequate glucagon production from the damaged pancreas.

**Complications**

The most common structural complication of chronic pancreatitis is a pancreatic pseudocyst, a fluid collection surrounded by granulation tissue (see p. 379). These usually occur in relationship to a period of enhanced inflammatory activity within the pancreas giving abdominal pain but may develop silently during what would appear to be a stable phase. Intra- or retroperitoneal rupture, bleeding or cyst infection may occur. The larger cysts may occlude nearby structures including the duodenum and the bile duct. In pseudocysts less than 6 cm in diameter, spontaneous resolution can be anticipated. In larger cysts that have been present for a period in excess of 6 weeks, resolution is less common and a long-term complication rate of approximately 30% can be anticipated. Many pseudocysts are closely apposed to the posterior wall of the stomach or duodenum and can be successfully drained endoscopically using endoscopic ultrasound to identify the optimum drainage site. A direct fistula is created between the pseudocyst lumen and the gastric or duodenal lumen which is then kept patent by the insertion of plastic stents. This approach will be successful in approximately 75% of cases. Surgical drainage is required for failures of endoscopic therapy or in circumstances in which the pseudocyst anatomy does not allow endoscopic access.

Ascites and occasionally pleural effusions can be a direct consequence of chronic pancreatitis when there has been disruption of the main pancreatic duct. A high ascites or pleural fluid amylase will confirm the aetiology. Such disruptions of the main pancreatic duct require surgical intervention.

**Cystic fibrosis** (see pp. 46 and 844)

This common cause of pancreatic disease in childhood is inherited as an autosomal recessive. A specific gene mutation ΔF508 is present in 70% of cases. The gene(s) code for a membrane protein in epithelial cells which regulates chloride transport (the cystic fibrosis transmembrane regulator, CFTR). Defective chloride channel transport secondarily leads to a failure to hydrate pancreatic secretion. The increased viscosity of such secretions then leads to ductular obstruction and secondary pancreatic damage. Eighty-five per cent of patients with cystic fibrosis will have pancreatic failure, and in the majority of these this will develop in utero and be present from the perinatal period. It has recently been...
recognized that a small proportion of patients with chronic pancreatitis of unknown aetiology (idiopathic) are homozygous for cystic fibrosis genes but have no other overt manifestation of cystic fibrosis. Furthermore there is accumulating evidence of patients with idiopathic pancreatitis who carry a single CF gene mutation. It is likely that other environmental or genetic factors combine with the single CF gene mutation to result in a diseased pancreas.

Clinical features and diagnosis
Clinical features and diagnostic tests are described on page 845; pancreatic function tests and imaging are described on page 376.

Treatment of cystic fibrosis
In the vast majority of patients with cystic fibrosis, pulmonary complications dominate the clinical picture. However, the management of pancreatic insufficiency is necessary to optimize the growth and overall nutrition. Pancreatic supplements are closely titrated against the level of steatorrhoea. Fat intake should be maintained to avoid nutritional deficit and enzyme intake adjusted to deal with this intake. To obtain optimal enzyme mixing with food, the supplements are taken throughout the meal. These are most commonly administered in an enteric-coated form to minimize degradation within the acid milieu of the stomach. A daily lipase intake of up to 10,000 units/kg bodyweight may be required. High-dose enteric-coated preparations are available but have been implicated in right-sided colon stricture formation in children with cystic fibrosis. The exact mechanism by which this occurred has not been fully defined but these preparations are no longer recommended in children.

Despite appropriate enzyme dosage, up to 20% of patients continue to have significant fat malabsorption. In many cases this is secondary to poor compliance. Other mechanisms include acid degradation of the enzyme preparations, and this can be ameliorated by acid suppression, either with H$_2$-receptor antagonists or proton pump inhibitors. There is documented evidence of an age-related deterioration in glucose tolerance in patients with cystic fibrosis. Ten per cent of patients will develop clinically significant diabetes mellitus. This must be detected at the earliest opportunity to prevent the adverse nutritional effects. In the large proportion of cases, management will be insulin dependent.

CARCINOMA OF THE PANCREAS

Incidence of pancreatic cancer in the West has been estimated at approximately 10 cases per 100,000 with no increase over the last 20 years. Pancreatic cancer is now the fifth most common cause of cancer death in the western world. The incidence increases with age and the majority of cases occur in patients over the age of 60. Approximately 60% of patients with this condition are male. Ninety-six per cent of pancreatic cancers are adenocarcinoma in type and the large majority are of ductal origin.

Risk factors. Smoking is associated with a twofold increase. Other possible environmental factors include the petroleum product, naphthalamine. Chronic pancreatitis is precancerous, particularly in patients with inherited trypsinogen gene mutations who have a 100 fold increased risk of malignancy.

There is increasing evidence that pancreatic cancer is a genetic disorder caused by germline and acquired somatic mutations associated with cancer development. Subtle changes in an oncogene and both mutations and deletions of tumour suppressor genes are the most common forms of genetic alteration. The best known among the oncogenes is K-ras, which is present in 90% of human ductal adenocarcinomas. Other oncogenes include β-catenin and tumour suppressor genes – p16, p53 and DPC4 (or SMAD4). The latter is a key transcription factor in growth regulation and is inactivated in over 50% of cases.

The accumulation of genetic precursors for pancreatic cancer is associated with progressive premalignant ductal histological changes. These are described as pancreatic intraepithelial neoplasias (PanINs). The changes are classified as 1A, 1B, -2 and -3, reflecting the progression from premalignancy to invasive cancer (Fig. 7.40).

A small percentage of pancreatic adenocarcinomas arise from cystic lesions including intraductal papillary mucinous tumours (IPMT) and mucinous cystic neoplasia (see below). There is evidence that these cystic neoplasms demonstrate a similar multistep genetic and histological progression to invasive adenocarcinoma.

Clinical picture
Pancreatic adenocarcinoma may be viewed clinically as two diseases – the lesions of the head and lesions of the body and tail.

![Fig. 7.40 Genetic model for the development of pancreatic ductal adenocarcinoma.](image-url)
Carcinoma of the head of the pancreas. A diagrammatic representation of the close relationship of a carcinoma of the head of pancreas to the surrounding structures.

**Symptoms**

Carcinoma of the head of pancreas or the ampulla of Vater tends to present earlier with obstruction to the bile duct as this passes through the head of pancreas giving jaundice (Fig. 7.41). These more localized lesions are usually painless, although pain may become a feature with tumour progression.

Carcinoma localized to the body or tail of the pancreas is much more likely to present with abdominal pain as well as non-specific symptoms such as anorexia and weight loss. The pain is often dull in character with radiation through into the back. A characteristic feature is partial relief of pain by sitting forward. Bile duct obstruction and jaundice may infrequently be late phenomena.

**Physical signs**

With carcinoma of the head of pancreas the patient is jaundiced with the characteristic scratch mark secondary to cholestasis. In a proportion of cases the gall bladder will be palpable (Courvoisier’s sign). A central abdominal mass may be palpable as well as hepatomegaly if metastatic disease is present. With carcinoma of the body and tail, there are often no physical signs.

Other presenting physical signs include thrombo-embolic phenomena, polyarthitis and skin nodules. The latter are secondary to localized fat necrosis and associated inflammation. These manifestations, distant to the tumour itself, have not been fully explained but may preceede the overt presentation of pancreatic cancer by months to years.

**Investigations**

- **Transabdominal ultrasound** is the initial investigation in the majority of patients. In the presence of bile duct obstruction this will confirm dilated intrahepatic bile ducts as well as a mass in the head of the pancreas. Ultrasound is less reliable when the cancer is found in the body and tail of the pancreas because of overlying bowel gas, with a sensitivity of detection of 60%.

- **Contrast-enhanced spiral CT scan** should confirm the presence of a mass lesion (Fig. 7.42). It is also necessary prior to possible surgical resection with contrast providing vascular definition to exclude tumour invasion as well as local lymph node involvement and distant metastases.

- **Laparoscopy** is also used for preoperative assessment.

- **ERCP** is usually restricted to palliative treatment but may provide a source of cytology to confirm the diagnosis when this is in question.

- **Percutaneous needle biopsy** is discouraged in potentially operable cases as this may be a source of tumour cell spread within the peritoneum. If palliative chemotherapy is considered, a histological diagnosis is essential prior to treatment.

- **MRI scanning and endoscopic ultrasound** are techniques that are useful in a small proportion of patients in whom the tumour has not been adequately defined.

- **Several tumour markers** have been evaluated for the diagnosis and monitoring of pancreatic cancer. The CA19-9 has a high sensitivity (80%) but a high false-positive rate. In individual patients single values of these tumour markers may be of little help but a progressive elevation over time is often diagnostic, and in such circumstances tumour marker levels can be used to monitor response to treatment.

**Differential diagnosis**

The diagnosis should not be difficult in the presence of painless jaundice or epigastric pain radiating into the back with progressive weight loss. Unfortunately many patients present with very minor symptoms including pain, change in bowel habit and weight loss. Imaging, particularly abdominal CT, should be performed if pancreatic cancer is suspected. Pancreatic cancer may rarely present with recurrent episodes of typical acute pancreatitis.

**Management**

The 5-year survival rate for carcinoma of the pancreas is approximately 2–5%, with surgical intervention representing the only chance of long-term survival. Approximately 20% of all cases have a localized tumour suitable for resection but in an elderly population many of these have co-morbid factors that preclude such major surgery. To optimize the percentage of patients undergoing possible surgical resec-
tion it is necessary to review each case in a multidisciplinary meeting. This approach also allows formulation of treatment strategies for those considered unsuitable for surgery.

In the majority of cases the management is palliative. Jaundice is a debilitating complication, often associated with severe pruritus but also the cause of non-specific malaise, lethargy and anorexia. Endoscopic placement of endoprostheses (stents) offers excellent palliation with a low associated procedural morbidity and mortality.

Palliative surgery has a role in duodenal obstruction (a complication seen in 10% of cases) but in advanced disease self-expanding metal stents can be placed across the duodenal obstruction with excellent short-term results.

The results of radiotherapy have been disappointing but there is now increasing evidence of benefit from a number of chemotherapeutic agents. 5-Fluorouracil and gemcitabine have been shown to improve short-term survival in advanced disease and have also demonstrated survival benefit as an adjuvant therapy to pancreatic resection.

With disease progression, abdominal pain is a frequent complicating factor which may prove extremely difficult to treat. This is best managed by experienced palliative care teams which offer a multidisciplinary approach. Endocrine and exocrine pancreatic failure occur and are managed as described on page 381.

### CYSTIC TUMOURS OF THE PANCREAS

Cystic lesions of the pancreas are not uncommon. Seventy-five per cent of these lesions will be pseudocysts (see above) but of the remainder the majority are true cystic neoplasms.

**Serous cyst adenomatosis** are composed of multiple small cystic cavities lined by cuboidal glycogen-rich, mucin-poor cells. These lesions tend to occur in an elderly age group and are often an asymptomatic finding. Malignant transformation in a serous cystadenoma is extremely rare. Larger serous cystadenomas may cause local compressive complications (when over approximately 5 cm).

**Mucinous cyst adenomatosis** are almost exclusively found in women in the fifth and sixth decades and are sited in the pancreatic body and tail. Multilocular cysts are lined by tall mucin-synthesizing cells. Twenty per cent of these lesions are malignant at the time of presentation and the majority appear to have a malignant potential. As a consequence they are much more likely to produce symptoms.

**Intraductal papillary mucinous tumour (IPMT)** is a pancreatic cystic neoplasm that can arise from either the side branches or the main duct. The majority are found in men between the ages of 60 and 70. The presentation is usually with pancreatic pain but may be an incidental finding. The lesion is slowly progressive with a significant malignant potential; this appears to be more so when the main duct is the site of origin.

There is a high risk of malignancy in cystic lesions and therefore resection is desirable. The differentiation between pseudocysts and true cystic neoplasms is difficult, even with multiple imaging techniques. Patients with pseudocysts may have a history of pancreatitis. Endoscopic ultrasound scanning and fine-needle aspiration can be helpful in the differentiation. The measurement of cyst fluid CEA and CA19-9 may help to identify malignant change.

### NEUROENDOCRINE TUMOURS OF THE PANCREAS

The islets of Langerhans (p. 376) have the capacity to synthesize more than one hormone. They also synthesize ectopic hormones that are not usually found in the pancreas such as gastrin, adrenocorticotrophin, vasoactive intestinal peptide and growth hormone. Whilst many pancreatic endocrine tumours are multihormonal, one peptide tends to predominate and is responsible for the clinical syndrome. Other tumours, whilst containing peptide hormone, are functionally inactive.

These tumours are rare with an incidence of less than 1 in 100 000 of the population. Insulinomas are the commonest variant (50%), gastrinomas account for 20% and the rarer functioning tumours 5%. The remaining 25% are non-functioning tumours. Approximately 25% of islet cell tumours are associated with a multiple endocrine syndrome (type I) (see p. 1026). The majority of the endocrine pancreatic tumours are malignant in their behaviour.

**Presentation** of pancreatic neuroendocrine tumours is most commonly related to the actions of ectopic hormone secretion. Identification of the primary and possibly metastatic lesions may be difficult despite multiple imaging techniques. Endoscopic ultrasound may be the most sensitive means of detecting small tumours. Many of these tumours have somatostatin receptors, and radiolabelled somatostatin analogue (such as octreotide) scanning provides a means of tumour localization.

**Treatment** options for pancreatic neuroendocrine tumours require a multidisciplinary approach and depend upon the presence or absence of metastatic (usually hepatic) disease. **Surgical resection** of the pancreatic lesion is the only potential curative approach. Aggressive surgical intervention including a resection of the primary lesion as well as liver resection for metastasis has been used in selected cases. Somatostatin analogues such as octreotide and lanreotide have been used specifically for the control of symptoms secondary to the hormonal secretion.

There is some evidence that the somatostatin analogues combined with interferon-alfa also control tumour proliferation. The chemotherapeutic agents streptozotocin, 5-fluorouracil and doxorubicin produce partial remission in approximately 40% of cases. Pancreatic neuroendocrine tumours show a very high degree of vascularization as well as abundant production and secretion of growth factors. There is preliminary evidence of benefit from antiangiogenesis therapy utilizing vascular endothelial growth factor (VEGF) antagonists. Antagonists to a number of oncogenic growth factors are currently under investigation.

In patients with extensive liver metastasis, occlusion of the arterial blood flow by hepatic arterial embolization may control hormone-related symptoms. In most cases the tumours are slowly progressive and may allow a reasonable quality of life for many years.
Clinical syndromes

Insulinoma is described on page 1059.

A gastrinoma accounts for approximately 1 in 1000 cases of duodenal ulcer disease. This results from hypersecretion of gastric acid secondary to ectopic gastrin secretion within the endocrine pancreas (Zollinger–Ellison syndrome). Recurrent severe duodenal ulceration occurs with only a partial response to acid suppression. The diagnosis is confirmed by an elevated gastrin level. High-dose proton pump inhibitors are used to suppress symptoms.

A VIPoma is an endocrine pancreatic tumour producing vasoactive intestinal polypeptide (VIP). This causes a severe secretory diarrhoea secondary to the stimulation of adenyl cyclase within the enterocyte (Verner–Morrison syndrome). The clinical syndrome is one of profuse watery diarrhoea, hypokalaemia and a metabolic acidosis. To produce the syndrome, the tumours are usually in excess of 3 cm in diameter. The clinical syndrome can be controlled by glucocorticoids, long-acting octreotide or lanreotide.

Glucagonomas are rare alpha-cell tumours which are responsible for the syndrome of migratory necrolytic dermatitis, weight loss, diabetes mellitus, deep vein thrombosis, anaemia and hypoalbuminaemia. The diagnosis is made by measuring pancreatic glucagon in the serum. Metastases are common at presentation but if the tumour is localized, pancreatic resection may be curative.

Somatostatinomas are rare malignant D cell tumours of the pancreas and 30% occur in the duodenum and small bowel. These tumours cause diabetes mellitus, gallstones and diarrhoea/steatorrhoea. They can be diagnosed by high serum somatostatin levels, CT/MR scans or octreotide scintiscans. Treatment is by resection, where possible, and octreotide therapy.

Non-functioning neuroendocrine tumours usually present by the local mass effect with pain, weight loss and the occasional bile duct obstruction. At the time of presentation the tumours are frequently large with distant metastases. Curative resection is possible in only a small proportion. Palliative surgery may be indicated to alleviate mass-related symptoms.

INTRODUCTION AND GENERAL ASPECTS

Blood consists of:

- red cells
- white cells
- platelets
- plasma, in which the above elements are suspended.

Plasma is the liquid component of blood, which contains soluble fibrinogen. Serum is what remains after the formation of the fibrin clot.

The formation of blood cells (haemopoiesis)

The haemopoietic system includes the bone marrow, liver, spleen, lymph nodes and thymus. There is an enormous turnover of cells with the red cells surviving 120 days, platelets around 7 days but granulocytes only 7 hours. The production of as many as \(10^{13}\) new myeloid cells (all blood cells except for lymphocytes) per day in the normal healthy state obviously requires to be tightly regulated according to the needs of the body.

Blood islands are formed in the yolk sac in the third week of gestation and produce primitive blood cells, which migrate to the liver and spleen. These organs are the chief sites of haemopoiesis from 6 weeks to 7 months, when the bone marrow becomes the main source of blood cells. However in childhood and adult life, the bone marrow is the only source of blood cells in a normal person.

At birth, haemopoiesis is present in the marrow of nearly every bone. As the child grows the active red marrow is gradually replaced by fat (yellow marrow) so that haemopoiesis in the adult becomes confined to the central skeleton and the proximal ends (trabecular area) of the long bones. Only if the demand for blood cells increases and persists do the areas of red marrow extend. Pathological processes interfering with normal haemopoiesis may result in resumption of haemopoietic activity in the liver and spleen, which is referred to as extramedullary haemopoiesis.

All blood cells are derived from pluripotent stem cells. These stem cells are supported by stromal cells (see below), which also influence haemopoiesis. The stem cell has two
properties – the first is self-renewal, i.e. the production of more stem cells, and the second is its proliferation and differentiation into progenitor cells, committed to one specific cell line.

There are two major ancestral cell lines derived from the pluripotential stem cell: lymphocytic and myeloid (non-lymphocytic) cells (Fig. 8.1). The former gives rise to T and B cells. The myeloid stem cell gives rise to the progenitor CFU-GEMM (colony-forming unit, granulocyte–erythrocyte–monocyte–megakaryocyte). The progenitor cells such as CFU-GEMM cannot be recognized in bone marrow biopsies but are recognized by their ability to form colonies when haemopoietic cells are immortalized in a soft gel matrix. The CFU-GEMM can go on to form CFU-GM, CFU-Eo, and CFU-Meg, each of which can produce a particular cell type (e.g. neutrophils, eosinophils and platelets) under appropriate growth conditions. Haemopoiesis is under the control of growth factors and inhibitors, and the microenvironment of the bone marrow also plays a role in its regulation.

Haemopoietic growth factors

Haemopoietic growth factors are glycoproteins, which regulate the differentiation and proliferation of haemopoietic progenitor cells and the function of mature blood cells. They act on the cytokine-receptor superfamily expressed on haemopoietic cells at various stages of development to maintain the haemopoietic progenitor cells and to stimulate increased production of one or more cell lines in response to stresses such as blood loss and infection (Fig. 8.1).

These haemopoietic growth factors including erythropoietin, interleukin 3 (IL-3), IL-6, -7, -11, -12, β-catenin, stem cell factor (SCF, Steel factor or C-kit ligand) and Flt3-tyrosine kinase 3 (Flt3) act via their specific receptor on cell surfaces to stimulate the cytoplasmic Janus kinase (JAK) (see p. 24). This major signal transducer activates tyrosine kinase causing gene activation in the cell nucleus. Colony-stimulating factors (CSFs, the prefix indicating the cell type, see Fig. 8.1), as well as…

![Diagram of haemopoietic growth factors](image-url)

**Fig. 8.1 Role of growth factors in normal haemopoiesis.** Some of the multiple growth factors acting on stem cells and early progenitor cells are shown. baso, basophil; BFU, burst-forming unit; CFU, colony-forming unit; CSF, colony-stimulating factor; E, erythroid; Eo, eosinophil; EPO, erythropoietin; G, granulocyte; GEMM, mixed granulocyte, erythroid, monocyte, megakaryocyte; GM, granulocyte, monocyte; IL, interleukin; M, monocyte; Meg, megakaryocyte; SCF, stem cell (Steel) factor or C-kit ligand; TNF, tumour necrosis factor; TPO, thrombopoietin.
as interleukins and erythropoietin (EPO) regulate the lineage committed progenitor cells.

Thrombopoietin (TPO, which, like erythropoietin, is produced in the kidneys and the liver) controls platelet production, along with IL-6 and IL-11. In addition to these factors stimulating haemopoiesis, other factors inhibit the process and include tumour necrosis factor (TNF) and transforming growth factor β (TGF-β). Many of the growth factors are produced by activated T cells, monocytes and bone marrow stromal cells such as fibroblasts, endothelial cells and macrophages; these cells are also involved in inflammatory responses. Bone marrow stem cells can differentiate into other organ cell types, e.g. heart, liver, nerves, and this is called stem cell plasticity.

Uses in treatment
Many growth factors have been produced by recombinant DNA techniques and are being used clinically. Examples include granulocyte-colony-stimulating factor (G-CSF), which is used to accelerate haemopoietic recovery after chemotherapy and haemopoietic cell transplantation, and erythropoietin, which is used to treat anaemia in patients with chronic renal failure. Thrombopoietin is undergoing clinical trials in patients with immune thrombocytopenic purpura.

Stem cell diseases
The clonal proliferation of stem cells leads to diseases, e.g. leukaemia (see p. 467), polycythaemia vera (see p. 419), myelofibrosis (see p. 421), paroxysmal nocturnal haemoglobinuria (see p. 418). Failure of stem cell growth leads to aplastic anaemia (see p. 402). Viral infections, e.g. hepatitis, and chemotherapy damage stem cells leading to marrow failure.

Peripheral blood
Automated cell counters are used to measure the level of haemoglobin (Hb) and the number and size of red cells, white cells and platelets (Table 8.1). Other indices can be derived from these values. A carefully evaluated blood film is still an essential adjunct to the above, as definitive abnormalities of cells can be seen.

ESR, erythrocyte sedimentation rate; Hb, haemoglobin; MCH, mean corpuscular haemoglobin; MCHC, mean corpuscular haemoglobin concentration; MCV, mean corpuscular volume of red cells; PCV, packed cell volume; RCC, red cell count; RDW, red blood cell distribution width; WBC, white blood count.

The mean corpuscular volume (MCV) of red cells is the most useful of the indices and is used to classify anaemia (see p. 392).

The red cell distribution width (RDW) is calculated by dividing the standard deviation of the red cell width by the mean cell width × 100. An elevated RDW suggests variation in red cell size, i.e. anisocytosis, and this is seen in iron deficiency. In β thalassaemia trait, the RDW is usually normal.

The white cell count (WCC, or WBC, white blood count) gives the total number of circulating leucocytes, and many automated cell counters produce differential counts as well.

Reticulocytes normally are less than 2% of the red cells (see p. 390). The reticulocyte count gives a guide to the erythroid activity in the bone marrow. An increased count is seen with increased marrow maturity, e.g. following haemorrhage or haemolysis, and during the response to treatment with a specific haematinic. A low count in the presence of anaemia indicates an inappropriate response by the bone marrow and may be seen in bone marrow failure (from whatever cause) or where there is a deficiency of a haematinic.

Erythrocyte sedimentation rate (ESR) is the rate of fall of red cells in a column of blood and is a measure of the acute-phase response. The pathological process may be immunological, infective, ischaemic, malignant or traumatic. A raised ESR reflects an increase in the plasma concentration of large proteins, such as fibrinogen and immunoglobulins. These proteins cause rouleaux formation, with red cells clumping together and therefore falling more rapidly. The ESR increases with age, and is higher in females than in males. It is low in polycythaemia vera, owing to the high red cell concentration, and increased in patients with severe anaemia.

Plasma viscosity is a measurement used instead of the ESR in some laboratories. It is also dependent on the concentration of large molecules such as fibrinogen and immunoglobulins. It is not affected by the level of Hb.

C-reactive protein (CRP) is a pentraxin, one of the proteins produced in the acute-phase response. It is synthesized exclusively in the liver and rises within 6 hours of an acute event. It rises with fever (possibly triggered by IL-1, IL-6 and TNF-α and other cytokines), in inflammatory conditions and after trauma. It follows the clinical state of the patient much more rapidly than the ESR and is unaffected by the level of Hb, but it is less helpful than the ESR or plasma viscosity in monitoring chronic inflammatory diseases. The measurement of CRP is easy and quick to perform using an immunoassay that can be automated. High-sensitivity assays have shown that increased levels may predict future cardiovascular disease (see p. 747).

THE RED CELL

Erythropoiesis

Red cell precursors pass through several stages in the bone marrow. The earliest morphologically recognizable cells are pronormoblasts. Smaller normoblasts result from cell
divisions, and precursors at each stage progressively contain less RNA and more Hb in the cytoplasm. The nucleus becomes more condensed and is eventually lost from the late normoblast in the bone marrow, when the cell becomes a reticulocyte.

- **Reticulocytes** contain residual ribosomal RNA and are still able to synthesize Hb. They remain in the marrow for about 1–2 days and are released into the circulation, where they lose their RNA and become mature red cells (erythrocytes) after another 1–2 days. Mature red cells are non-nucleated biconcave discs.
- Nucleated red cells (*normoblasts*) are not normally present in peripheral blood, but are present if there is extramedullary haemopoiesis and in some marrow disorders (see leucocythroblastic anaemia, p. 430).
- About 10% of erythroblasts die in the bone marrow even during normal erythropoiesis. Such ineffective erythropoiesis is substantially increased in some anaemias such as thalassaemia major and megaloblastic anaemia.
- **Erythropoietin** is a hormone which controls erythropoiesis. The gene for erythropoietin is on chromosome 7 and codes for a heavily glycosylated polypeptide of 165 amino acids. Erythropoietin has a molecular weight of 30,400 and is produced in the peritubular cells in the kidneys (90%) and in the liver (10%). Its production is regulated mainly by tissue oxygen tension. Production is increased if there is hypoxia from whatever cause – for example, anaemia, or cardiac or pulmonary disease. The erythropoietin gene is one of a number of genes that is regulated by the hypoxic sensor pathway. The 3'-flanking region of the erythropoietin gene has a hypoxic response element, which is necessary for the induction of transcription of the gene in hypoxic cells. Hypoxia-inducible factor 1 (HIF-1) is a transcription factor, which binds to the hypoxia response element and acts as a master regulator of several genes that are responsive to hypoxia. Erythropoietin stimulates an increase in the proportion of bone marrow precursor cells committed to erythropoiesis, and CFU-E are stimulated to proliferate and differentiate. Increased ‘inappropriate’ production of erythropoietin is also seen in patients with renal disease and neoplasms in other sites, which result in polycythaemia (see Table 8.16).

**Haemoglobin synthesis**

Haemoglobin performs the main functions of red cells – carrying O₂ to the tissues and returning CO₂ from the tissues to the lungs. Each normal adult Hb molecule (Hb A) has a molecular weight of 68,000 and consists of two α and two β globin polypeptide chains (α₂β₂) which have 141 and 146 amino acids, respectively. Hb A comprises about 97% of the Hb in adults. Two other types, Hb A₂ (α₂δ₂) and Hb F (ε₂ζ₂), are found in adults in small amounts (1.5–3.2% and <1%, respectively) (see p. 406).

Haemoglobin synthesis occurs in the mitochondria of the developing red cell (Fig. 8.2). The major rate-limiting step is the conversion of glycine and succinic acid to δ-aminolaevulinic acid (ALA) by ALA synthase. Vitamin B₆ is a coenzyme for this reaction, which is inhibited by haem and stimulated by erythropoietin. Two molecules of δ-ALA condense to form a pyrrole ring (porphobilinogen). These rings are then grouped in fours to produce protoporphyrins. Finally, iron is inserted to form haem. Haem is then inserted into the globin chains to form Hb. The structure of Hb is shown in Figure 8.3.

**Fig. 8.2 Haemoglobin synthesis.** Transferrin attaches to a surface receptor on developing red cells. Iron is released and transported to the mitochondria, where it combines with protoporphyrin to form haem. Protoporphyrin itself is manufactured from glycine and succinyl-CoA. Haem combines with α and β chains (formed on ribosomes) to make haemoglobin.

**Fig. 8.3 Model of the haemoglobin molecule showing α (pink) and β (blue) chains.** 2,3-BPG (bisphosphoglycerate) or diphosphoglycerate (DGP) binds in the centre of the molecule and stabilizes the deoxygenated form by cross-linking the β chains (also see Fig. 8.4). M, methyl; P, propionic acid; V, vinyl.
**Fig. 8.4 Oxygenated and deoxygenated haemoglobin molecule.** The haemoglobin molecule is predominantly stabilized by α–β chain bonds rather than α–α and β–β chain bonds. The structure of the molecule changes during O₂ uptake and release. When O₂ is released, the β chains rotate on the αβα and αββ contacts, allowing the entry of 2,3-BPG which causes a lower affinity of haemoglobin for O₂ and improved delivery of O₂ to the tissues. From Hoffbrand AV, Pettit JE. *Essential Haematology*, 3rd edn. Oxford: Blackwell Scientific Publications, 1993, with permission.

**Haemoglobin function**

The biconcave shape of red cells provides a large surface area for the uptake and release of oxygen and carbon dioxide. Haemoglobin becomes saturated with oxygen in the pulmonary capillaries where the partial pressure of oxygen is high and Hb has a high affinity for oxygen. Oxygen is released in the tissues where the partial pressure of oxygen is low and Hb has a low affinity for oxygen.

In adult haemoglobin (Hb A), a haem group is bound to each of the four globin chains; the haem group has a porphyrin ring with a ferrous atom which can reversibly bind one oxygen molecule. The haemoglobin molecule exists in two conformations, R and T. The T (taut) conformation of deoxyhaemoglobin is characterized by the globin units being held tightly together by electrostatic bonds (Fig. 8.4). These bonds are broken when oxygen binds to haemoglobin, resulting in the R (relaxed) conformation in which the remaining oxygen-binding sites are more exposed and have a much higher affinity for oxygen than in the T conformation. The binding of one oxygen molecule to deoxyhaemoglobin increases the oxygen affinity of the remaining binding sites – this property is known as ‘cooperativity’ and is the reason for the sigmoid shape of the oxygen dissociation curve. Haemoglobin is, therefore, an example of an allosteric protein. The binding of oxygen can be influenced by secondary effectors – hydrogen ions, carbon dioxide and red-cell 2,3-bisphosphoglycerate (2,3-BPG). Hydrogen ions and carbon dioxide added to blood cause a reduction in the oxygen-binding affinity of haemoglobin (the Bohr effect). Oxygenation of haemoglobin reduces its affinity for carbon dioxide (the Haldane effect). These effects help the exchange of carbon dioxide and oxygen in the tissues.

Red cell metabolism produces 2,3-BPG from glycolysis. 2,3-BPG accumulates because it is sequestered by binding to deoxyhaemoglobin. The binding of 2,3-BPG stabilizes the T conformation and reduces its affinity for oxygen. The P₅₀ is the partial pressure of oxygen at which the haemoglobin is 50% saturated with oxygen. P₅₀ increases with 2,3-BPG concentrations, which increase when oxygen availability is reduced in conditions such as hypoxia or anaemia. P₅₀ also rises with increasing body temperature, which may be beneficial during prolonged exercise. Haemoglobin regulates oxygen transport as shown in the oxyhaemoglobin dissociation curve. When the primary limitation to oxygen transport is in the periphery, e.g. heavy exercise, anaemia, the P₅₀ is increased to enhance oxygen unloading. When the primary limitation is in the lungs, e.g. lung disease, high altitude exposure, the P₅₀ is reduced to enhance oxygen loading.

A summary of normal red cell production and destruction is given in Figure 8.5.
ANAEMIA

Anaemia is present when there is a decrease in the level of haemoglobin in the blood below the reference level for the age and sex of the individual (Table 8.1). Alterations in the level of Hb may occur as a result of changes in the plasma volume, as shown in Figure 8.6. A reduction in the plasma volume will lead to a spuriously high Hb – this is seen with dehydration and in the clinical condition of apparent polycythaemia (see p. 421). A raised plasma volume produces a spurious anaemia, even when combined with a small increase in red cell volume as occurs in pregnancy.

The various types of anaemia, classified by MCV, are shown in Figure 8.7. There are three major types:

- Hypochromic microcytic with a low MCV
- Normochromic normocytic with a normal MCV
- Macrocytic with a high MCV.

Clinical features

Patients with anaemia may be asymptomatic. A slowly falling level of Hb allows for haemodynamic compensation and enhancement of the oxygen-carrying capacity of the blood. A rise in 2,3-BPG causes a shift of the oxygen dissociation curve to the right, so that oxygen is more readily given up to the tissues. Where blood loss is rapid, more severe symptoms will occur, particularly in elderly people.

Symptoms (all non-specific)

- Fatigue, headaches and faintness are all very common in the general population
- Breathlessness
- Angina
- Intermittent claudication
- Palpitations.

A common problem is that anaemia exacerbates cardio-respiratory problems especially in the elderly. For example, angina or intermittent claudication may be precipitated by anaemia. A good way to assess the effects of anaemia is to ask about breathlessness in relation to different levels of exercise (e.g. walking on the flat or climbing one flight of stairs).

Signs

- Pallor
- Tachycardia
- Systolic flow murmur
- Cardiac failure.

Specific signs seen in the different types of anaemia will be discussed in the appropriate sections. Examples include:

- Koilonychia – spoon-shaped nails seen in iron deficiency anaemia
- Jaundice – found in haemolytic anaemia
- Bone deformities – found in thalassaemia major

Fig. 8.6 Alterations of haemoglobin in relation to plasma.

Fig. 8.7 Classification of anaemia. MCV, mean corpuscular volume.
leg ulcers – occur in association with sickle cell disease.

It must be emphasized that anaemia is not a diagnosis, and a cause must be found.

**Investigations**

**Peripheral blood**

A low haemoglobin should always be considered in relation to:

- the white blood cell (WBC) count
- the platelet count
- the reticulocyte count (as this indicates marrow activity)
- the blood film, as abnormal red cell morphology (Fig. 8.9) may indicate the diagnosis. Where two populations of red cells are seen, the blood film is said to be dimorphic. This may, for example, be seen in patients with ‘double deficiencies’ (e.g. combined iron and folate deficiency in coeliac disease, or following treatment of anaemic patients with the appropriate haematinic).

**Bone marrow**

Examination of the bone marrow is performed to further investigate abnormalities found in the peripheral blood (Practical Box 8.1). Aspiration provides a film which can be examined by microscopy for the morphology of the developing haemopoietic cells. The trephine provides a core of bone which is processed as a histological specimen and allows an overall view of the bone marrow architecture, cellularity and presence/absence of abnormal infiltrates.

The following are assessed:

- cellularity of the marrow
- type of erythropoiesis (e.g. normoblastic or megaloblastic)
- cellularity of the various cell lines
- infiltration of the marrow
- iron stores.

Special tests may be performed for further diagnosis: cyto- genetic, immunological, cytochemical markers, biochemical analyses (e.g. deoxyuridine suppression test), microbiological culture.

---

**MICROCYTIC ANAEMIA**

Iron deficiency is the most common cause of anaemia in the world, affecting 30% of the world’s population equivalent to 500 million people. This is because of the body’s limited ability to absorb iron and the frequent loss of iron owing to haemorrhage. Although iron is abundant, most is in the insoluble ferric (Fe\(^{3+}\)) form, which has poor bioavailability. Ferrous (Fe\(^{2+}\)) is more readily absorbed. Free iron is toxic, and it is bound to various proteins for transport and storage.

The other causes of a microcytic hypochromic anaemia are anaemia of chronic disease, sideroblastic anaemia and thalassaemia. In thalassaemia (see p. 407) there is a defect in globin synthesis, in contrast to the other three causes of microcytic anaemia where the defect is in the synthesis of haem.

**Iron**

**Dietary intake**

The average daily diet in the UK contains 15–20 mg of iron, although normally only 10% of this is absorbed. Absorption may be increased to 20–30% in iron deficiency and pregnancy.

Non-haem iron is mainly derived from cereals, which are commonly fortified with iron; it forms the main part of dietary iron. Haem iron is derived from haemoglobin and myoglobin in red or organ meats. Haem iron is better absorbed than non-haem iron, whose availability is more affected by other dietary constituents.

**Absorption** (Fig. 8.8a, b)

Factors influencing iron and haem iron absorption are shown in Table 8.2

**Dietary haem iron** is more rapidly absorbed than non-haem iron derived from vegetables and grain. Most haem is absorbed in the proximal intestine, with absorptive capacity decreasing distally. The intestinal haem transporter HCPI (haem carrier protein 1) has been identified and found to be highly expressed in the duodenum. It is upregulated by hypoxia and iron deficiency. Some haem iron may be reabsorbed intact into circulation via the cell by two exporter proteins – BCRP (breast cancer resistant protein) and FLVCR (feline leukaemia virus subgroup C).

**Non-haem iron absorption** occurs primarily in the duodenum. Non-haem iron is dissolved in the low pH of the stomach and reduced from the ferric to the ferrous form by a brush border ferrireductase. Cells in duodenal crypts are able to sense the body’s iron requirements and retain this
Fig. 8.8 (a) Regulation of the absorption of intestinal iron. The iron-absorbing cells of the duodenal epithelium originate in the intestinal crypts and migrate toward the tip of the villus as they differentiate (maturation axis). Absorption of intestinal iron is regulated by at least three independent mechanisms. First, iron absorption is influenced by recent dietary iron intake (dietary regulator). After a large dietary bolus, absorptive cells are resistant to iron uptake for several days. Second, iron absorption can be modulated considerably in response to body iron stores (stores regulator). Third, a signal communicates the state of bone marrow erythropoiesis to the intestine (erythroid regulator).

(b) Duodenal crypt cells sense body iron status through the binding of transferrin to the HFE/B2M/MFR1 complex. Cytosolic enzymes change the oxidative state of iron from ferric (Fe\(^{3+}\)) to ferrous (Fe\(^{2+}\)). A decrease in crypt cell iron concentration upregulates the divalent metal transporter (DMT1). This increases as crypt cells migrate up the villus and become mature absorptive cells.

(c) Apical cell. Dietary iron is reduced from the ferric to the ferrous state by the brush border ferrireductase. DMT1 facilitates iron absorption from the intestinal lumen. The export proteins, e.g. ferroportin 1 (Ireg1) and hephaestin, transfer iron from the enterocyte into the circulation. BCRP, breast cancer resistant protein; B2M, β₂-microglobulin; FLVCR, feline leukemia virus subgroup C; HCP-1, Haem carrier protein-1; HFE, hereditary haemochromatosis gene.

Table 8.2 Factors influencing iron absorption

| Haem iron is absorbed better than non-haem iron |
| Ferrous iron is absorbed better than ferric iron |
| Gastric acidity helps to keep iron in the ferrous state and soluble in the upper gut |
| Formation of insoluble complexes with phytate or phosphate decreases iron absorption |
| Iron absorption is increased with low iron stores and increased erythropoietic activity, e.g. bleeding, haemolysis, high altitude |
| There is a decreased absorption in iron overload, except in hereditary haemochromatosis, where it is increased |

Fig. 8.9 Hypochromic microcytic cells (arrow) on a blood film. Polikilocytosis and anisocytosis are seen.

information as they mature into cells capable of absorbing iron at the tips of the villus. A protein, divalent metal transporter 1 (DMT1) or natural resistance-associated macrophage protein (NRAMP2), transports iron (and other metals) across the apical (luminal) surface of the mucosal cells in the small intestine. Haem iron is absorbed in a separate less-well-characterized process.

Once inside the mucosal cell, iron may be transferred across the cell to reach the plasma, or be stored as ferritin; the body’s iron status at the time the absorptive cell developed from the crypt cell is probably the crucial
deciding factor. Iron stored as ferritin will be lost into the gut lumen when the mucosal cells are shed; this regulates iron balance. The mechanism of transport of iron across the basolateral surface of mucosal cells involves a transporter protein, ferroportin 1 (Ireg1). This transporter protein requires an accessory, multicopper protein, hephaestin (Fig. 8.8c).

The body iron content is closely regulated by the control of iron absorption but there is no physiological mechanism for eliminating excess iron from the body. The key molecule regulating iron absorption is hepcidin, a 25 amino acid peptide synthesized in the liver. Hepcidin acts by regulating the activity of the iron exporting protein ferroportin by binding to ferroportin causing its internalization and degradation, thereby decreasing iron efflux from iron exporting tissues into plasma. Therefore, high levels of hepcidin will destroy ferroportin and limit iron absorption, and vice versa low levels of hepcidin will encourage iron absorption. However, the importance of hepcidin goes further than its role in physiologic iron absorption. For example, most forms of haemochromatosis result from dysregulation of hepcidin or defects of hepcidin or ferroportin themselves.

A longstanding mystery is why anaemias characterized by ineffective erythropoiesis such as thalassaemia are associated with excessive and inappropriate iron absorption. Preliminary evidence again suggests that the increased iron absorption in beta-thalassaemia is mediated by downregulation of hepcidin and upregulation of ferroportin.

Transport in the blood

The normal serum iron level is about 13–32 μmol/L; there is a diurnal rhythm with higher levels in the morning. Iron is transported in the plasma bound to transferrin, a β-globulin that is synthesized in the liver. Each transferrin molecule binds two atoms of ferric iron and is normally one-third saturated. Most of the iron bound to transferrin comes from macrophages in the reticuloendothelial system and not from iron absorbed by the intestine. Transferrin-bound iron becomes attached by specific receptors to erythroblasts and reticulocytes in the marrow and the iron is removed (Fig. 8.2).

In an average adult male, 20 mg of iron, chiefly obtained from red cell breakdown in the macrophages of the reticuloendothelial system, is incorporated into Hb every day.

Iron stores

About two-thirds of the total body iron is in the circulation as haemoglobin (2.5–3 g in a normal adult man). Iron is stored in reticuloendothelial cells, hepatocytes and skeletal muscle cells (500–1500 mg). About two-thirds of this is stored as ferritin and one-third as haemosiderin in normal individuals. Small amounts of iron are also found in plasma (about 4 mg bound to transferrin), with some in myoglobin and enzymes.

Ferritin is a water-soluble complex of iron and protein. It is more easily mobilized than haemosiderin for Hb formation. It is present in small amounts in plasma.

Haemosiderin is an insoluble iron–protein complex found in macrophages in the bone marrow, liver and spleen. Unlike ferritin, it is visible by light microscopy in tissue sections and bone marrow films after staining by Perls’ reaction.

Requirements

Each day 0.5–1.0 mg of iron is lost in the faeces, urine and sweat. Menstruating women lose 30–40 mL of blood per month, an average of about 0.5–0.7 mg of iron per day. Blood loss through menstruation in excess of 100 mL will usually result in iron deficiency as increased iron absorption from the gut cannot compensate for such losses of iron. The demand for iron also increases during growth (about 0.6 mg per day) and pregnancy (1–2 mg per day). In the normal adult the iron content of the body remains relatively fixed. Increases in the body iron content (haemochromatosis) are classified into:

- Hereditary haemochromatosis (see p. 356), where a mutation in the HFE gene causes increased iron absorption.
- Secondary haemochromatosis (transfusion siderosis; see p. 408). This is due to iron overload in conditions where repeated transfusion is the only therapy.

Iron deficiency

Iron deficiency anaemia develops when there is inadequate iron for haemoglobin synthesis. A normal level of Hb is maintained for as long as possible after the iron stores are depleted; latent iron deficiency is said to be present during this period.

- blood loss
- increased demands such as growth and pregnancy
- decreased absorption (e.g. postgastrectomy)
- poor intake.

Most iron deficiency is due to blood loss, usually from the uterus or gastrointestinal tract. Premenopausal women are in a state of precarious iron balance owing to menstruation. Iron deficiency affects more than a quarter of the world’s population, but isolated nutritional iron deficiency is rare in developed countries. The most common cause of iron deficiency world-wide is blood loss from the gastrointestinal tract resulting from hookworm infestation. The poor quality of the diet, predominantly containing vegetables, also contributes to the high prevalence of iron deficiency in developing countries. Even in developed countries, iron deficiency is not uncommon in infancy where iron intake is insufficient for the demands of growth. It is more prevalent in infants born prematurely or where the introduction of mixed feeding is delayed.

Clinical features

The symptoms of anaemia are described on page 392. Other clinical features occur as a result of tissue iron deficiency. These are mainly epithelial changes induced by the effect of inadequate iron in the cells:

- brittle nails
- spoon-shaped nails (koilonychia)
- atrophy of the papillae of the tongue
- angular stomatitis
- brittle hair
- a syndrome of dysphagia and glossitis (Plummer–Vinson or Paterson–Brown–Kelly syndrome; see p. 255).

The diagnosis of iron deficiency anaemia relies on a clinical history with questions about dietary intake, regular self-
medication with non-steroidal anti-inflammatory drugs (which may give rise to gastrointestinal bleeding), and the presence of blood in the faeces (which may be a sign of haemorrhoids or carcinoma of the lower bowel). In women, a careful enquiry about the duration of periods, the occurrence of clots and the number of sanitary towels or tampons (normal 3–5/day) used should be made.

Investigations

■ **Blood count and film.** A characteristic blood film is shown in Figure 8.9. The red cells are microcytic (MCV < 80 fL) and hypochromic (MCH (mean corpuscular haemoglobin) < 27 pg). There is poikilocytosis (variation in shape) and anisocytosis (variation in size). Target cells are seen.

■ **Serum iron and iron-binding capacity.** The serum iron falls and the total iron-binding capacity (TIBC) rises in iron deficiency compared with normal. Iron deficiency is regularly present when the transferrin saturation (i.e. serum iron divided by TIBC) falls below 19% (Table 8.3).

■ **Serum ferritin.** The level of serum ferritin reflects the amount of stored iron. The normal values for serum ferritin are 30–300 µg/L (11.6–144 nmol/L) in males and 15–200 µg/L (5.8–96 nmol/L) in females. In simple iron deficiency, a low serum ferritin confirms the diagnosis. However, ferritin is an acute-phase reactant, and levels increase in the presence of inflammatory or malignant diseases. In these cases, measurement of serum iron/ TIBC, serum ferritin and soluble transferrin receptors is used.

■ **Serum soluble transferrin receptors.** The number of transferrin receptors increases in iron deficiency. The results of this immunoaassay compare well with results from bone marrow aspiration at estimating iron stores. This assay can help to distinguish between iron deficiency and anaemia of chronic disease (Table 8.3), and may avoid the need for bone marrow examination even in complex cases.

■ **Bone marrow.** Erythroid hyperplasia with ragged normoblasts is seen in the marrow in iron deficiency. Staining using Perl’s reaction (acid ferricyanide) does not show the characteristic Prussian-blue granules of stainable iron in the bone marrow fragments or in the erythroblasts. Examination of the bone marrow is not essential for the diagnosis of iron deficiency but it may be helpful in the investigation of complicated cases of anaemia, e.g. to determine if iron deficiency is present in a patient with anaemia of chronic disease.

■ **Other investigations.** These will be indicated by the clinical history and examination. Investigations of the gastrointestinal tract are often required to determine the cause of the iron deficiency (see p. 270).

### Differential diagnosis

The presence of anaemia with microcytosis and hypochromia does not necessarily indicate iron deficiency. The most common other causes are thalassaemia, sideroblastic anaemia and anaemia of chronic disease, and in these disorders the iron stores are normal or increased. The differential diagnosis of microcytic anaemia is shown in Table 8.3.

### Treatment

Iron deficiency is not a diagnosis per se. The correct management of iron deficiency is to find and treat the underlying cause, and to give iron to correct the anaemia and replace iron stores. The response to iron therapy can be monitored using the reticulocyte count and Hb level, with an expected rise in haemoglobin of 1 g/dL per week.

Oral iron is all that is required in most cases. The best preparation is ferrous sulphate (200 mg three times daily, a total of 180 mg ferrous iron), which is absorbed best when the patient is fasting. If the patient has side-effects such as nausea, diarrhoea or constipation, taking the tablets with food or reducing the dose using a preparation with less iron such as ferrous gluconate (300 mg twice daily, only 70 mg ferrous iron) is all that is usually required to reduce the symptoms. The use of expensive iron compounds, particularly the slow-release ones, which release iron beyond its main sites of absorption, is unnecessary.

In developing countries, distribution of iron tablets and fortification of food are the main approaches for the alleviation of iron deficiency. However, iron supplementation programmes have been ineffective, probably mainly because of poor compliance.

Oral iron should be given for long enough to correct the Hb level and to replenish the iron stores. This can take 6 months. The commonest causes of failure of response to oral iron are:

- lack of compliance
- continuing haemorrhage
- incorrect diagnosis, e.g. thalassaemia trait.

| Table 8.3 Microcytic anaemia: the differential diagnosis |
|-----------------------------------|------------------|-----------------|------------------|
| **Iron deficiency**               | **Anaemia of chronic disease** | **Thalassaemia trait (α or β)** | **Sideroblastic anaemia** |
| **MCV**                           | Reduced          | Low normal or normal | Very low for degree of anaemia | Low in inherited type but often raised in acquired type |

TIBC, total iron binding capacity.
These possibilities should be considered before parenteral iron is used. However, parenteral iron is required by occasional patients, e.g. intolerant to oral preparation, severe malabsorption, chronic disease (e.g. inflammatory bowel disease). Iron stores are replaced much faster with parenteral iron than with oral iron, but the haematological response is no quicker. Parenteral iron can be given as repeated deep intramuscular injections of iron–sorbitol (1.5 mg of iron per kg bodyweight) or by intravenous infusion of low molecular weight iron dextran (test dose required) or iron sucrose.

**Anaemia of chronic disease**

One of the most common types of anaemia, particularly in hospital patients, is the anaemia of chronic disease, occurring in patients with chronic infections such as tuberculosis or chronic inflammatory disease such as Crohn’s disease, rheumatoid arthritis, systemic lupus erythematosus (SLE), polymyalgia rheumatica and malignant disease. There is decreased release of iron from the bone marrow to developing erythroblasts, an inadequate erythropoietin response to the anaemia, and decreased red cell survival.

The exact mechanisms responsible for these effects are not clear but it now seems likely that high levels of hepcidin expression play a key role (see iron absorption).

The serum iron and the TIBC are low, and the serum ferritin is normal or raised because of the inflammatory process. The serum soluble transferrin receptor level is normal (Table 8.3). Stainable iron is present in the bone marrow, but iron is not seen in the developing erythroblasts. Patients do not respond to iron therapy, and treatment is, in general, that of the underlying disorder. Recombinant erythropoietin therapy is used in the anaemia of renal disease (see p. 633), and occasionally in inflammatory disease (rheumatoid arthritis, inflammatory bowel disease).

**Sideroblastic anaemia**

Sideroblastic anaemias are inherited or acquired disorders characterized by a refractory anaemia, a variable number of hypochromic cells in the peripheral blood, and excess iron and ring sideroblasts in the bone marrow. The presence of ring sideroblasts is the diagnostic feature of sideroblastic anaemia. There is accumulation of iron in the mitochondria of erythroblasts owing to disordered haem synthesis forming a ring of iron granules around the nucleus that can be seen with Perls’ reaction. The blood film is often dimorphic; ineffective haem synthesis is responsible for the microcytic hypochromic cells. Sideroblastic anaemias are classified as shown in Table 8.4. A structural defect in δ-aminolaevulinic acid (ALA) synthase, the pyridoxine-dependent enzyme responsible for the first step in haem synthesis (Fig. 8.2), has been identified in one form of inherited sideroblastic anaemia. Primary acquired sideroblastic anaemia is one of the myelodysplastic syndromes (see p. 422). Lead toxicity is described on page 944.

**Treatment**

Some patients respond when drugs or alcohol are withdrawn, if these are the causative agents. In occasional cases, there is a response to pyridoxine. Treatment with folic acid may be required to treat accompanying folate deficiency.

**NORMOCYTIC ANAEMIA**

Normocytic, normochromic anaemia is seen in anaemia of chronic disease, in some endocrine disorders (e.g. hypopituitarism, hypothyroidism and hypoadrenalism) and in some haematological disorders (e.g. aplastic anaemia and some haemolytic anaemias) (Fig. 8.7). In addition, this type of anaemia is seen acutely following blood loss.

---

**MACROCYTIC ANAEMIAS**

These can be divided into megaloblastic and non-megaloblastic types, depending on bone marrow findings.

**MEGALOBLASTIC ANAEMIA**

Megaloblastic anaemia is characterized by the presence in the bone marrow of erythroblasts with delayed nuclear maturation because of defective DNA synthesis (megaloblasts). Megaloblasts are large and have large immature nuclei. The nuclear chromatin is more finely dispersed than normal and has an open stippled appearance (Fig. 8.10). In addition, giant metamyelocytes are frequently seen in megaloblastic anaemia. These cells are about twice the size of normal cells and often have twisted nuclei. Megaloblastic changes occur in:

- vitamin B₁₂ deficiency or abnormal vitamin B₁₂ metabolism
- folic acid deficiency or abnormal folate metabolism
- other defects of DNA synthesis, such as congenital enzyme deficiencies in DNA synthesis (e.g. orotic aciduria), or resulting from therapy with drugs interfering with DNA synthesis (e.g. hydroxycarbamide (hydroxyurea), azathiprine, zidovudine – AZT)
- meylodysplasia due to dyserythropoiesis.

---

**Fig. 8.10** Megaloblasts (arrowed) in the bone marrow.
**Haematological findings**

- Anaemia may be present. The MCV is characteristically >96 fl unless there is a coexisting cause of microcytosis when there may be a dimorphic picture with a normal/low average MCV.
- The peripheral blood film shows oval macrocytes with hypersegmented polymorphs with six or more lobes in the nucleus (Fig. 8.11).
- If severe, there may be leucopenia and thrombocytopenia.

**Biochemical basis of megaloblastic anaemia**

The key biochemical problem common to both vitamin B₁₂ and folate deficiency is a block in DNA synthesis owing to an inability to methylate deoxyuridine monophosphate to deoxythymidine monophosphate, which is then used to build DNA (Fig. 8.12). The methyl group is supplied by the folate coenzyme, methylene tetrahydrofolate.

Deficiency of folate reduces the supply of this coenzyme; deficiency of vitamin B₁₂ also reduces its supply by slowing the demethylation of methylenetetrahydrofolate (methyl THF) and preventing cells receiving tetrahydrofolate for synthesis of methylene tetrahydrofolate polyglutamate.

Other congenital and acquired forms of megaloblastic anaemia are due to interference with purine or pyrimidine synthesis causing an inhibition in DNA synthesis.

**Deoxyuridine suppression test**

This is a useful method for rapidly determining the nature and severity of the vitamin B₁₂ or folate deficiency in severe or complex cases of megaloblastic anaemia.

Tritiated thymidine is added to the patient’s bone marrow in vitro. In a normoblastic marrow, the thymidine requirement is supplied by the methylation of deoxyuridine and this ‘suppresses’ the requirement for preformed tritiated thymidine to less than 5%. In a megaloblastic marrow, however, much more tritiated thymidine is used (5–50%). If the addition of B₁₂ corrects the abnormality, it suggests that B₁₂ is the cause of the deficiency. The addition of folate corrects the abnormality in both vitamin B₁₂ and folate deficiency.

**Vitamin B₁₂**

Vitamin B₁₂ is synthesized by certain microorganisms, and humans are ultimately dependent on animal sources. It is found in meat, fish, eggs and milk, but not in plants. Vitamin B₁₂ is not usually destroyed by cooking. The average daily diet contains 5–30 μg of vitamin B₁₂, of which 2–3 μg is absorbed. The average adult stores some 2–3 mg, mainly in the liver, and it may take 2 years or more after absorptive failure before B₁₂ deficiency develops, as the daily losses are small (1–2 μg).

**Structure and function**

Cobalamins consist of a planar group with a central cobalt atom (corrin ring) and a nucleotide set at right-angles (Fig. 8.13). Vitamin B₁₂ was first crystallized as cyanocobalamin, but the main natural cobalamins have deoxyadenosyl-, methyl- and hydroxocobalamin groups attached to the cobalt atom.

![Fig. 8.11](image1) Macrocytes and a hypersegmented neutrophil (arrowed) on a peripheral blood film.

![Fig. 8.12](image2) Biochemical basis of megaloblastic anaemia. The metabolic relationship between vitamin B₁₂ and folate and their role in DNA synthesis. THF, tetrahydrofolate.

![Fig. 8.13](image3) Methylcobalamin structure. This is the main form of vitamin B₁₂ in the plasma.
The main function of B₁₂ is the methylation of homocysteine to methionine with the demethylation of methyl THF polyglutamate to THF. THF is a substrate for folate polyglutamate synthesis.

Deoxyadenosylcobalamin is a coenzyme for the conversion of methylmalonyl CoA to succinyl CoA. Measurement of methylmalonic acid in urine was used as a test for vitamin B₁₂ deficiency but it is no longer carried out routinely.

**Absorption and transport**

Vitamin B₁₂ is liberated from protein complexes in food by gastric enzymes and then binds to a vitamin B₁₂-binding protein (‘R’ binder) which is related to plasma transcobalamin I (TCI) and is derived from saliva. Vitamin B₁₂ is released from the ‘R’ binder by pancreatic enzymes and then becomes bound to intrinsic factor.

Intrinsic factor is a glycoprotein with a molecular weight of 45000. It is secreted by gastric parietal cells along with H⁺ ions. It combines with vitamin B₁₂ and carries it to specific receptors on the surface of the mucosa of the ileum. Vitamin B₁₂ enters the ileal cells and intrinsic factor remains in the lumen and is excreted. Vitamin B₁₂ is transported from the enterocytes to the bone marrow and other tissues by the glycoprotein transcobalamin II (TCII). Although TCII is the essential carrier protein for vitamin B₁₂, the amount of B₁₂ on TCII is low. However, it has a rapid clearance and is able to deliver cobalamin to all cells of the body. Vitamin B₁₂ in plasma is mainly bound to TCII (70–90%), but the functional role of this protein is unknown. About 1% of an oral dose of B₁₂ is absorbed ‘passively’ without the need for intrinsic factor.

**Vitamin B₁₂ deficiency**

There are a number of causes of B₁₂ deficiency and abnormal B₁₂ metabolism (Table 8.5). The most common cause of vitamin B₁₂ deficiency in adults is pernicious anaemia. Malabsorption of vitamin B₁₂ because of pancreatitis, coeliac disease or treatment with metformin is mild and does not usually result in significant vitamin B₁₂ deficiency.

### Pernicious anaemia

Pernicious anaemia (PA) is an autoimmune disorder in which there is atrophic gastritis with loss of parietal cells in the gastric mucosa with consequent failure of intrinsic factor production and vitamin B₁₂ malabsorption.

**Pathogenesis of pernicious anaemia**

This disease is common in the elderly, with 1 in 8000 of the population aged over 60 years being affected in the UK. It can be seen in all races, but occurs more frequently in fair-haired and blue-eyed individuals, and those who have the blood group A. It is more common in females than males.

There is an association with other autoimmune diseases, particularly thyroid disease, Addison’s disease and vitiligo. Approximately one-half of all patients with PA have thyroid antibodies. There is a higher incidence of gastric carcinoma with PA (1–3%) than in the general population.

Parietal cell antibodies are present in the serum in 90% of patients with PA – and also in many older patients with gastric atrophy. Conversely, intrinsic factor antibodies, although found in only 50% of patients with PA, are specific for this diagnosis. Two types of intrinsic factor antibodies are found: a blocking antibody, which inhibits binding of intrinsic factor to B₁₂, and a precipitating antibody, which inhibits the binding of the B₁₂–intrinsic factor complex to its receptor site in the ileum.

B₁₂ deficiency may rarely occur in children from a congenital deficiency or abnormality of intrinsic factor, or as a result of early onset of the adult autoimmune type.

**Pathology**

Autoimmune gastritis (see p. 263) affecting the fundus is present with plasma cell and lymphoid infiltration. The parietal and chief cells are replaced by mucin-secreting cells. There is achlorhydria and absent secretion of intrinsic factor. The histological abnormality can be improved by corticosteroid therapy, which supports an autoimmune basis for the disease.

**Clinical features**

The onset of PA is insidious, with progressively increasing symptoms of anaemia. Patients are sometimes said to have a lemon-yellow colour owing to a combination of pallor and mild jaundice caused by excess breakdown of haemoglobin. A red sore tongue (glossitis) and angular stomatitis are sometimes present.

The neurological changes, if left untreated for a long time, can be irreversible. These neurological abnormalities occur only with very low levels of serum B₁₂ (less than 60 ng/L or 50 pmol/L) and occasionally occur in patients who are not clinically anaemic. The classical neurological features are those of a polyneuropathy progressively involving the peripheral nerves and the posterior and eventually the lateral columns of the spinal cord (subacute combined degeneration; see p. 1175). Patients present with symmetrical paraesthesiae in the fingers and toes, early loss of vibration sense and proprioception, and progressive weakness and ataxia. Paraplegia may result. Dementia, psychiatric problems, hallucinations, delusions, and optic atrophy may occur from vitamin B₁₂ deficiency.

**Investigations**

- **Haematological findings** show the features of a megaloblastic anaemia as described on page 398.
- **Bone marrow** shows the typical features of megaloblastic erythropoiesis (Fig. 8.10), although

</table>
it is frequently not performed in cases of straightforward macrocytic anaemia and a low serum vitamin B₁₂.

- **Serum bilirubin** may be raised as a result of ineffective erythropoiesis. Normally a minor fraction of serum bilirubin results from premature breakdown of newly formed red cells in the bone marrow. In many megaloblastic anaemias, where the destruction of developing red cells is much increased, the serum bilirubin can be increased. LDH can also be raised due to haemolysis.

- **Serum methylmalonic acid (MMA) and homocysteine (HC)** are raised in B₁₂ deficiency. They are only useful in cases where the B₁₂ and folate levels are not conclusive with only HC raised in folate deficiency.

- **Serum vitamin B₁₂** is usually well below 160 ng/L, which is the lower end of the normal range. Serum vitamin B₁₂ can be assayed using radioisotope dilution or immunological assays.

- **Serum folate level** is normal or high, and the red cell folate is normal or reduced owing to inhibition of normal folate synthesis.

**Absorption tests**

Vitamin B₁₂ absorption tests are performed only occasionally when the underlying cause of the B₁₂ deficiency is not obvious. They cannot be performed in the UK as radioactive B₁₂ is not available. However, the principle of the absorption test is useful.

**Schilling test.** Radioactive B₁₂ is given orally followed by an i.m. injection of non-radioactive B₁₂ to saturate B₁₂ binding proteins and to flush out Ba-Co-B₁₂. The urine is collected for 24 hours and >10% of the oral dose would be excreted in a normal person. If this is abnormal, the test is repeated with the addition of oral intrinsic factor capsules. If the excretion is now normal, the diagnosis is pernicious anaemia or gastrectomy. If the excretion is still abnormal, the lesion must be in the terminal ileum or there may be bacterial overgrowth. The latter could be confirmed by repeating the test after a course of antibiotics.

**Gastrointestinal investigations**

In PA there is achlorhydria. Intubation studies can be performed to confirm this but are rarely carried out in routine practice. Endoscopy or barium meal examination of the stomach is performed only if gastric symptoms are present.

**Differential diagnosis**

Vitamin B₁₂ deficiency must be differentiated from other causes of megaloblastic anaemia, principally folate deficiency, but usually this is quite clear from the blood level of these two vitamins.

Pernicious anaemia should be distinguished from other causes of vitamin B₁₂ deficiency (Table 8.5). Any disease involving the terminal ileum or bacterial overgrowth in the small bowel can produce vitamin B₁₂ deficiency (see p. 280). Gastrorectomy can lead, in the long term, to vitamin B₁₂ deficiency. Vegans are strict vegetarians and eat no meat or animal products and prophylactic B₁₂ should be given.

**Treatment**

See page 401.

---

**Folic acid**

Folic acid monoglutamate is not itself present in nature but occurs as polyglutamates (extra glutamic acid residues). Folates are present in food as polyglutamates in the reduced dihydrofolate or tetrahydrofolate (THF) forms (Fig. 8.14), with methyl (CH₃), formyl (CHO) or methylene (CH₂) groups attached to the pteridine part of the molecule. Polyglutamates are broken down to monoglutamates in the upper gastrointestinal tract, and during the absorptive process these are converted to methyl THF monoglutamate, which is the main form in the serum. The methylation of homocysteine to methionine requires both methylcobalamin and methyl THF as coenzymes. This reaction is the first step in which methyl THF entering cells from the plasma is converted into folate polyglutamates. Intracellular polyglutamates are the active forms of folate and act as coenzymes in the transfer of single carbon units in amino acid metabolism and DNA synthesis (Fig. 8.12).

**Dietary intake**

Folate is found in green vegetables such as spinach and broccoli, and offal, such as liver and kidney. Cooking causes a loss of 60–90% of the folate. The minimal daily requirement is about 100 μg.

**Folate deficiency**

The causes of folate deficiency are shown in Table 8.6. The main cause is poor intake, which may occur alone or in combination with excessive utilization or malabsorption. The

**Pathological**

Haematological disease with excess red cell production, e.g. haemolytic Malignant disease with increased cell turnover Inflammatory disease Metabolic disease, e.g. homocystinuria Haemodialysis or peritoneal dialysis

**Malabsorption**

Occurs in small bowel disease, but the effect is minor compared with that of anorexia.
body’s reserves of folate, unlike vitamin B₁₂, are low (about 10 mg). On a deficient diet, folate deficiency develops over the course of about 4 months, but folate deficiency may develop rapidly in patients who have both a poor intake and excess utilization of folate (e.g., patients in intensive care units).

There is no simple relationship between maternal folate status and fetal abnormalities but folic acid supplements at the time of conception and in the first 12 weeks of pregnancy reduce the incidence of neural tube defects. Despite worldwide public health campaigns recommending periconceptional daily supplementation of synthetic folic acid to reduce the risk of neural tube defects, many women are not following these recommendations. In the USA and Canada mandatory fortification of grain products, e.g., bread, flour and rice, has substantially improved folate status and has been associated with a significant fall in neural tube defects.

**Clinical features**

Patients with folate deficiency may be asymptomatic or present with symptoms of anaemia or of the underlying cause. Glossitis can occur. Unlike with B₁₂ deficiency, neuropathy does not occur.

**Investigations**

The haematological findings are those of a megaloblastic anaemia as discussed on page 398.

**Blood measurements**

Serum and red cell folate are assayed by radioisotope dilution or immunological methods. Normal levels of serum folate are 4–18 μg/L (5–63 nmol/L). The amount of folate in the red cells is a better measure of tissue folate; the normal range is 160–640 μg/mL.

**Further investigations**

In many cases of folate deficiency the cause is not obvious from the clinical picture or dietary history. Occult gastrointestinal disease should then be suspected and appropriate investigations, such as small bowel biopsy, should be performed.

**Treatment and prevention of megaloblastic anaemia**

Treatment depends on the type of deficiency. Blood transfusion is not indicated in chronic anaemia; indeed, it is dangerous to transfuse elderly patients, as heart failure may be precipitated. Folic acid may produce a haematological response in vitamin B₁₂ deficiency but may aggravate the neuropathy. Large doses of folic acid alone should not be used to treat megaloblastic anaemia unless the serum vitamin B₁₂ level is known to be normal. In severely ill patients, it may be necessary to treat with both folic acid and vitamin B₁₂ while awaiting serum levels.

**Treatment of vitamin B₁₂ deficiency**

Hydroxocobalamin 1000 μg can be given intramuscularly to a total of 5–6 mg over the course of 3 weeks; 1000 μg is then necessary every 3 months for the rest of the patient’s life. Alternatively, it is now recommended that oral B₁₂ 2 mg per day is given, as 1–2% of an oral dose is absorbed by diffusion and therefore does not require intrinsic factor.

Compliance with an oral daily regimen may be a problem, particularly in elderly patients. The use of sublingual nuggets of B₁₂ (2 × 1000 μg daily) has been suggested to be an effective and more convenient option.

Clinical improvement may occur within 48 hours and a reticulocyte count seen some 2–3 days after starting therapy, peaking at 5–7 days. Improvement of the polyneuropathy may occur over 6–12 months, but longstanding spinal cord damage is irreversible. Hypokalaemia can occur and, if severe, supplements should be given. Iron deficiency often develops in the first few weeks of therapy. Hyperuricaemia also occurs but clinical gout is uncommon. In patients who have had a total gastrectomy or an ileal resection, vitamin B₁₂ should be monitored; if low levels occur, prophylactic vitamin B₁₂ should be given.

**Treatment of folate deficiency**

Folate deficiency can be corrected by giving 5 mg of folic acid daily; the same haematological response occurs as seen after treatment of vitamin B₁₂ deficiency. Treatment should be given for about 4 months to replace body stores. Any underlying cause, e.g., coeliac disease, should be treated.

Prophylactic folic acid (400 μg daily) is recommended for all women planning a pregnancy to reduce neural tube defects. Many authorities also recommend prophylactic administration of folate throughout pregnancy. Whether this can be achieved by increased consumption of foods with a high folate content or whether women should take folate supplements is under debate.

Women who have had a child with a neural tube defect should take 5 mg folic acid daily before and during a subsequent pregnancy.

Prophylactic folic acid is also given in chronic haematological disorders where there is rapid cell turnover. A dose of 5 mg each week is probably sufficient.

**MACROCYTOSIS WITHOUT MEGALOBLASTIC CHANGES**

A raised MCV with macrocytosis on the peripheral blood film can occur with a normoblastic rather than a megaloblastic bone marrow.

A common physiological cause of macrocytosis is pregnancy. Macrocytosis may also occur in the newborn.

Common pathological causes are:

- alcohol excess
- liver disease
- reticulocytosis
- hypothyroidism
- some haematological disorders (e.g., aplastic anaemia, sideroblastic anaemia, pure red cell aplasia)
- drugs (e.g., cytotoxics – azathioprine)
- spurious (agglutinated red cells measured on red cell counters)
- cold agglutinins due to autoagglutination of red cells (see p. 416) (the MCV decreases to normal with warming of the sample to 37°C).

In all these conditions, normal serum levels of vitamin B₁₂ and folate will be found. The exact mechanisms in each case are uncertain, but in some there is increased lipid deposition in the red cell membrane.

An increased number of reticulocytes leads to a raised MCV because they are large cells.
Alcohol is a frequent cause of a raised MCV in an otherwise normal individual. A megaloblastic anaemia can also occur in people who abuse alcohol; this is due to a toxic effect of alcohol on erythropoiesis or to dietary folate deficiency.

**ANAEMIA DUE TO MARROW FAILURE (APLASTIC ANAEMIA)**

Aplastic anaemia is defined as pancytopenia with hypocellularity (aplasia) of the bone marrow; there are no leukaemic, cancerous or other abnormal cells in the peripheral blood or bone marrow. It is an uncommon but serious condition that may be inherited but is more commonly acquired.

Aplastic anaemia is due to a reduction in the number of pluripotential stem cells (Fig. 8.1) together with a fault in those remaining or an immune reaction against them so that they are unable to repopulate the bone marrow. Failure of only one cell line may also occur, resulting in isolated deficiencies such as the absence of red cell precursors in pure red cell aplasia. Evolution to myelodysplasia, paroxysmal nocturnal haemoglobinuria (PNH) or acute myeloblastic leukaemia occurs in some cases, probably owing to the emergence of an abnormal clone of haemopoietic cells.

**Causes**

A list of causes of aplasia is given in Table 8.7. Immune mechanisms are probably responsible for most cases of idiopathic acquired aplastic anaemia and play a part in at least the persistence of many secondary cases. Activated cytotoxic T cells in blood and bone marrow are responsible for the bone marrow failure.

Many drugs may cause marrow aplasia, including cytotoxic drugs such as busulfan and doxorubicin, which are expected to cause transient aplasia as a consequence of their therapeutic use. However, some individuals develop aplasia due to sensitivity to non-cytotoxic drugs such as chloramphenicol, gold, carbimazole, chlorpromazine, phenytoin, ribovirin, tolbutamide, non-steroidal anti-inflammatory agents, and many others which have been reported to cause occasional cases of aplasia.

Congenital aplastic anaemias are rare. Gene mutations are being identified, e.g. the telomerase RNA component, and have been seen in one-third of aplastic anaemias. Fanconi’s anaemia is inherited as an autosomal recessive and is associated with skeletal, renal and central nervous system abnormalities. It usually presents between the ages of 5 and 10 years.

**Clinical features**

The clinical manifestations of marrow failure from any cause are anaemia, bleeding and infection. Bleeding is often the predominant initial presentation of aplastic anaemia with bruising with minimal trauma or blood blisters in the mouth. Physical findings include ecchymoses, bleeding gums and epistaxis. Mouth infections are common. Lymphadenopathy and hepatosplenomegaly are rare in aplastic anaemia.

**Investigations**

- Pancytopenia
- The virtual absence of reticulocytes
- A hypocellular or aplastic bone marrow with increased fat spaces (Fig. 8.15).

**Differential diagnosis**

This is from other causes of pancytopenia (Table 8.8). A bone marrow trephine is essential for assessment of the bone marrow cellularity.

**Fig. 8.15** Bone marrow trephine biopsies in low-power view. (a) Normal cellularity. (b) Hypocellularity in aplastic anaemia.
Treatment and prognosis
The treatment of aplastic anaemia depends on providing supportive care while awaiting bone marrow recovery and specific treatment to accelerate marrow recovery.

The main danger is infection and stringent measures should be undertaken to avoid this (see also p. 461). Any suspicion of infection in a severely neutropenic patient should lead to immediate institution of broad-spectrum parenteral antibiotics. Supportive care including transfusions of red cells and platelets should be given as necessary. The cause of the aplastic anaemia must be eliminated if possible.

The course of aplastic anaemia can be variable, ranging from a rapid spontaneous remission to a persistent increasingly severe pancytopenia, which may lead to death through haemorrhage or infection. The most reliable determinants for the prognosis are the number of neutrophils, reticulocytes, platelets, and the cellularity of the bone marrow.

A bad prognosis (i.e. severe aplastic anaemia) is associated with the presence of two of the following three features:

- neutrophil count of <0.5 × 10⁹/L
- platelet count of <20 × 10⁹/L
- reticulocyte count of <40 × 10⁹/L.

In severe aplastic anaemia, there is a very poor outcome without treatment.

Bone marrow transplantation is the treatment of choice for some patients. For the patients under the age of 40 who fail to respond to immunosuppression, bone marrow transplantation using unrelated donors is an option, but the results are poor (5-year survival of only 30%) owing to a high incidence of graft rejection, graft-versus-host disease and viral infections. For those with an HLA-identical sibling donor, it gives a 75–90% chance of long-term survival and restoring the blood count to normal. Patients over the age of 40 are not eligible for bone marrow transplantation whether an HLA-identical donor is available or not, because of the high risk of graft-versus-host disease as a complication of bone marrow transplantation. Immunosuppressive therapy is used for patients without HLA-matched sibling donors and those over the age of 40 years; antilymphocyte globulin (ALG) and ciclosporin in combination give a response rate of 60–80%.

Levels of haemopoietic growth factors (Fig. 8.1) are normal or increased in most patients with aplastic anaemia, and are ineffective as primary treatment.

Androgens (e.g. oxymetholone) are sometimes useful in patients not responding to immunosuppression and in patients with moderately severe aplastic anaemia.

Steroids have little activity in severe aplastic anaemia but are used for serum sickness due to ALG. They are also used to treat children with congenital pure red cell aplasia (Diamond–Blackfan syndrome). Adult pure red cell aplasia is associated with a thymoma in 30% of cases and thymectomy may induce a remission. It may also be associated with autoimmune disease or be idiopathic. Steroids and ciclosporin are effective treatment in some cases.

HAEMOLYTIC ANAEMIAS: AN INTRODUCTION

Haemolytic anaemias are caused by increased destruction of red cells. The red cell normally survives about 120 days, but in haemolytic anaemias the red cell survival times are considerably shortened.

Breakdown of normal red cells occurs in the macrophages of the bone marrow, liver and spleen (Fig. 8.5).

Consequences of haemolysis (Fig. 8.16)
Shortening of red cell survival does not always cause anaemia as there is a compensatory increase in red cell production by the bone marrow. If the red cell loss can be contained within the marrow’s capacity for increased output, then a haemolytic state can exist without anaemia (compensated haemolytic disease). The bone marrow can increase its output by six to eight times by increasing the proportion of cells committed to erythropoiesis (erythroid hyperplasia) and by expanding the volume of active marrow. In addition, immature red cells (reticulocytes) are released prematurely. These cells are larger than mature cells and stain with a light blue tinge on a peripheral blood film (the description of this appearance on the blood film is polychromasia). Reticulocytes may be counted accurately as a percentage of all red cells on a blood film using a supravital stain for residual RNA (e.g. new methylene blue).

Sites of haemolysis
Extravascular haemolysis
In most haemolytic conditions red cell destruction is extravascular. The red cells are removed from the circulation by macrophages in the reticuloendothelial system, particularly the spleen.

Intravascular haemolysis
When red cells are rapidly destroyed within the circulation, haemoglobin is liberated (Fig. 8.17). This is initially bound to plasma haptoglobins but these soon become saturated.

Excess free plasma Hb is filtered by the renal glomerulus and enters the urine, although small amounts are reabsorbed by the renal tubules. In the renal tubular cell, Hb is broken down and becomes deposited in the cells as haemosiderin. This can be detected in the spun sediment of urine using Perl’s reaction. Some of the free plasma Hb is oxidized to methaemoglobin, which dissociates into ferrithion and globin. Plasma haemopexin binds ferrithion; but if its binding capacity is exceeded, ferrithion becomes attached to albumin, forming methaemalbumin. On spectrophotometry of the plasma, methaemalbumin forms a characteristic band; this is the basis of Schummm’s test.

The liver plays a major role in removing Hb bound to haptoglobin and haemopexin and any remaining free Hb.

Evidence for haemolysis
Increased red cell breakdown is accompanied by increased red cell production. This is shown in Figure 8.16.

Demonstration of shortened red cell lifespan
Red cell survival can be estimated from ⁵¹Cr-labelled red cells given intravenously but is rarely performed.

Intravascular haemolysis
This is suggested by raised levels of plasma Hb, haemosida-erinuria, very low or absent haptoglobins, and the presence of methaemalbumin (positive Schummm’s test).
Various laboratory studies will be necessary to determine the exact type of haemolytic anaemia present. The causes of haemolytic anaemias are shown in Table 8.9.

**INHERITED HAEMOLYTIC ANAEMIA**

**RED CELL MEMBRANE DEFECTS**

The normal red cell membrane consists of a lipid bilayer crossed by integral proteins with an underlying lattice of proteins (or cytoskeleton), including spectrin, actin, ankyrin and protein 4.1, attached to the integral proteins (Fig. 8.18).

**Hereditary spherocytosis (HS)**

HS is the most common inherited haemolytic anaemia in northern Europeans, affecting 1 in 5000. It is inherited in an autosomal dominant manner, but in 25% of patients neither parent is affected and it is presumed that HS has occurred by spontaneous mutation. HS is due to defects in the red cell membrane, resulting in the cells losing part of the cell membrane as they pass through the spleen, possibly because the lipid bilayer is inadequately supported by the membrane.
skeleton. The best-characterized defect is a deficiency in the structural protein spectrin, but quantitative defects in other membrane proteins have been identified (Fig. 8.18), with ankyrin defects being the most common. The abnormal red cell membrane in HS is associated functionally with an increased permeability to sodium, and this requires an increased rate of active transport of sodium out of the cells which is dependent on ATP produced by glycolysis. The surface-to-volume ratio decreases, and the cells become spherocytic. Spherocytes are more rigid and less deformable than normal red cells. They are unable to pass through the splenic microcirculation so they have a shortened lifespan.

Clinical features
The condition may present with jaundice at birth. However, the onset of jaundice can be delayed for many years and some patients may go through life with no symptoms and are detected only during family studies. The patient may eventually develop anaemia, splenomegaly and ulcers on the leg. As in many haemolytic anaemias, the course of the disease may be interrupted by aplastic, haemolytic and megaloblastic crises. Aplastic anaemia usually occurs after infections, particularly with erythro-parvo-virus, whereas megaloblastic anaemia is the result of folate depletion owing to the hyperactivity of the bone marrow. Chronic haemolysis leads to the formation of pigment gallstones (see p. 367).

Investigations
- **Anaemia.** This is usually mild, but occasionally can be severe.
- **Blood film.** This shows spherocytes (Fig. 8.19) and reticulocytes.
- **Haemolysis** is evident (e.g. the serum bilirubin and urinary urobilinogen will be raised).
- **Osmotic fragility.** When red cells are placed in solutions of increasing hypotonicity, they take in water, swell, and eventually lyse. Spherocytes tolerate hypotonic solutions less well than do normal biconcave red cells. Osmotic fragility tests are infrequently carried out in routine practice, but may be useful to confirm a suspicion of spherocytosis on a blood film.
- **Direct antiglobulin (Coombs’)** test is negative in hereditary spherocytosis, virtually ruling out autoimmune haemolytic anaemia where spherocytes are also commonly present.

![Fig. 8.19 Spherocytes (arrowed). This blood film also shows reticulocytes, polychromasia and a nucleated erythroblast.](image)

![Fig. 8.18 Hereditary spherocytosis (HS) and hereditary elliptocytosis (HE): red cell membrane showing the sites (purple) of the principal defects. Vertical interactions producing HS: (a) ankyrin mutation, HS (Ank+) producing deficiency (45% of cases); (b) HS band 3 deficiency (20%); (c) β spectrin deficiency, HS (Sp+) (<20%); (d) abnormal spectrin/protein 4.1 binding, HS (Sp–4.1); (e) protein 4.2 (pallidin) deficiency (Japanese). These produce various autosomal dominant and recessive forms of the disease. Horizontal interactions producing HE: α spectrin (80%), protein 4.1 (15%), β spectrin (5%).](image)
Treatment

The spleen, which is the site of cell destruction, should be removed in all but the mildest cases. The decision about splenectomy in symptomless patients is difficult, but a raised bilirubin and especially the presence of gallstones should encourage splenectomy.

It is best to postpone splenectomy until after childhood, as sudden overwhelming fatal infections, usually due to encapsulated organisms such as pneumococci, may occur (see p. 423). Splenectomy should be preceded by appropriate immunization and followed by lifelong penicillin prophylaxis (see Box 8.3).

Following splenectomy, the spherocytes persist but the Hb level usually returns to normal as the red cells are no longer destroyed.

Folate deficiency often occurs in chronic haemolysis with rapid cell turnover. Folate levels should be monitored, or folic acid can be given prophylactically.

Hereditary elliptocytosis

This disorder of the red cell membrane is inherited in an autosomal dominant manner and has a prevalence of 1 in 2500 in Caucasians. The red cells are elliptical due to deficiencies of protein 4.1 or the spectrin/actin/4.1 complex which leads to weakness of the horizontal protein interaction and to the membrane defect (Fig. 8.18). Clinically it is a similar condition to HS but milder. Only a minority of patients have anaemia and only occasional patients require splenectomy.

Rarely, hereditary spherocytosis or elliptocytosis may be inherited in a homozygous fashion giving rise to a severe haemolytic anaemia sometimes necessitating splenectomy in early childhood.

Hereditary stomatocytosis

Stomatocytes are red cells in which the pale central area appears slit-like. Their presence in large numbers may occur in a hereditary haemolytic anaemia associated with a membrane defect, but excess alcohol intake is also a common cause. Although these hereditary conditions are very rare, a correct diagnosis is required since splenectomy is surprisingly contraindicated as it may result in fatal thromboembolic events.

HAEMOGLOBIN ABNORMALITIES

In early embryonic life, haemoglobins Gower 1, Gower 2 and Portland predominate (Fig. 8.20). Later, fetal haemoglobin (Hb F), which has two α and two γ chains, is produced. There is increasing synthesis of β chains from 13 weeks of gestation and at term there is 80% Hb F and 20% Hb A. The switch from Hb F to Hb A occurs after birth when the genes for γ chain production are further suppressed and there is rapid increase in the synthesis of β chains. The exact mechanism responsible for the switch remains unknown. There is little Hb F produced (normally less than 1%) from 6 months after birth. The α chain is synthesized just before birth and Hb A2 (α2β2) remains at a level of about 2% throughout adult life (Table 8.10).

Globin chains are synthesized in the same way as any protein (see p. 31). Four globin chain genes are required to control α-chain production (Fig. 8.20). Two are present on each haploid genome (genes derived from one parent). These are situated close together on chromosome 16. The genes controlling the production of ε, γ, δ and β chains are close together on chromosome 11. The globin genes are arranged on chromosomes 16 and 11 in the order in which they are expressed and combine to give different haemoglobins. Normal haemoglobin synthesis is discussed on page 390.

Abnormal haemoglobins

Abnormalities occur in:

- globin chain production (e.g. thalassaemia)
- structure of the globin chain (e.g. sickle cell disease)
- combined defects of globin chain production and structure, e.g. sickle cell β-thalassaemia.

![Fig. 8.20 Loci of genes on chromosomes 16 and 11 and the combination of various chains to produce different haemoglobins. HS-40 (for α genes) and locus control region (LCR) HS1–5 (for β genes) are regulatory control elements.](image-url)

Genetic defects in haemoglobin are the most common of all genetic disorders.

THE THALASSAEMIAS

The thalassaemias affect people throughout the world (Fig. 8.21). Normally there is balanced (1:1) production of α and β chains. The defective synthesis of globin chains in thalassaemia leads to ‘imbalanced’ globin chain production, leading to precipitation of globin chains within the red cell precursors and resulting in ineffective erythropoiesis. Precipitation of globin chains in mature red cells leads to haemolysis.

β-Thalassaemia

In homozygous β-thalassaemia, either no normal β chains are produced (β0), or β-chain production is very reduced (β+). There is an excess of α chains, which precipitate in erythroblasts and red cells causing ineffective erythropoiesis and haemolysis. The excess α chains combine with whatever β, δ and γ chains are produced, resulting in increased quantities of Hb A2 and Hb F and, at best, small amounts of Hb A. In heterozygous β-thalassaemia there is usually symptomless microcytosis with or without mild anaemia. Table 8.11 shows the findings in the homozygote and heterozygote for the common types of β-thalassaemia.

Molecular genetics

The molecular errors accounting for over 200 genetic defects leading to β-thalassaemia have been characterized. Unlike in α-thalassaemia, the defects are mainly point mutations rather than gene deletions. The mutations result in defects in transcription, RNA splicing and modification, translation via frame shifts and nonsense codons producing highly unstable β-globin which cannot be utilized.

Clinical syndromes

Clinically, β-thalassaemia can be divided into the following:

- thalassaemia minor (or trait), the symptomless heterozygous carrier state
- thalassaemia intermedia, with moderate anaemia, rarely requiring transfusions

Thalassaemia minor (trait)

This common carrier state (heterozygous β-thalassaemia) is asymptomatic. Anaemia is mild or absent. The red cells are hypochromic and microcytic with a low MCV and MCH, and it may be confused with iron deficiency. However, the two are easily distinguished, as in thalassaemia trait the serum ferritin and the iron stores are normal (Table 8.3). The RDW is usually normal (see p. 389). Hb electrophoresis usually shows a raised Hb A2 and often a raised Hb F (Fig. 8.22). Iron should not be given to these patients unless they have proven coincidental iron deficiency.

Thalassaemia intermedia

Thalassaemia intermedia includes patients who are symptomatic with moderate anaemia (Hb 7–10 g/dL) and who do not require regular transfusions. Thalassaemia intermedia may be due to a combination of homozygous mild β+ and α-thalassaemia, where there is reduced α-chain precipitation and less ineffective erythropoi-
Thalassaemia major (Cooley’s anaemia)

Most children affected by homozygous β-thalassaemia present during the first year of life with:

- failure to thrive and recurrent bacterial infections
- severe anaemia from 3 to 6 months when the switch from γ- to β-chain production should normally occur
- extramedullary haemopoiesis that soon leads to hepatosplenomegaly and bone expansion, giving rise to the classical thalassaemic facies (Fig. 8.23a).

Skull X-rays in these children show the characteristic ‘hair on end’ appearance of bony trabeculation as a result of expansion of the bone marrow into cortical bone (Fig. 8.23b). The expansion of the bone marrow is also shown in an X-ray of the hand (Fig. 8.23c).

The classic features of untreated thalassaemia major are generally only observed in patients from countries without good blood transfusion support.

Management

The aims of treatment are to suppress ineffective erythropoiesis, prevent bony deformities and allow normal activity and development.

- **Long-term folic acid supplements** are required.
- **Regular transfusions** should be given to keep the Hb above 10 g/dL. Blood transfusions may be required every 4–6 weeks.

- If **transfusion requirements** increase, splenectomy may help, although this is usually delayed until after the age of 6 years because of the risk of infection. Prophylaxis against infection is required for patients undergoing splenectomy (see p. 423).

- **Iron overload** caused by repeated transfusions (transfusion haemosiderosis) may lead to damage to the endocrine glands, liver, pancreas and the myocardium by the time patients reach adolescence. Magnetic resonance imaging (myocardial T2- relaxation time) is useful for monitoring iron overload in thalassaemia, both the heart and the liver can be monitored. The standard iron-chelating agent remains deferasirox, although it has to be administered parenterally. Deferiprone is given as an overnight subcutaneous infusion on 5–7 nights each week. Ascorbic acid 200 mg daily is given, as it increases the urinary excretion of iron in response to deferasirox. Often young children have a very high standard of chelation as it is organized by their parents. However, when the children become adults and take on this role themselves they often rebel and chelation with deferasirox may become problematic. Preliminary results on a new once-daily oral iron chelator, deferasirox, indicate that it is safe, similar in effectiveness to deferasirox and well tolerated. Deferiprone, an oral iron chelator, is also now available.

- **Intensive treatment** with deferasirox has been reported to reverse damage to the heart in patients with severe iron overload, but excessive doses of deferasirox may cause cataracts, retinal damage and nerve deafness. Infection with *Yersinia enterocolitica* occurs in iron-loaded patients treated with deferasirox. Iron overload should be periodically assessed by measuring the serum ferritin and by assessment of hepatic iron stores by MRI.

- **Bone marrow transplantation** has been used in young patients with HLA-matched siblings. It has been successful in patients in good clinical condition with a 3-year mortality of less than 5%, but there is a high
morality (>50%) in patients in poor condition with iron overload and liver dysfunction.

- **Prenatal diagnosis and gene therapy** are discussed on page 45.
- **Patients’ partners should be tested.** If both partners have β-thalassaemia trait, there is a 1 in 4 chance of such pregnancy resulting in a child having β-thalassaemia major. Therefore, couples in this situation must be offered prenatal diagnosis.

### α-Thalassaemia

**Molecular genetics**

In contrast to β-thalassaemia, α-thalassaemia is often caused by gene deletions, although mutations of the alpha globin genes may also occur. The gene for α globin chains is duplicated on both chromosomes 16, i.e. a normal person has a total of four alpha globin genes. Deletion of one α-chain gene (α+) or both α-chain genes (α0) on each chromosome 16 may occur (Table 8.12). The former is the most common of these abnormalities.

- **Four-gene deletion** (deletion of both genes on both chromosomes); there is no α-chain synthesis and only Hb Bart's (HbF) is present. Hb Bart's cannot carry oxygen and is incompatible with life (Tables 8.10 and 8.12). Infants are either stillborn at 28–40 weeks or die very shortly after birth. They are pale, oedematous and have enormous livers and spleens – a condition called hydrops fetalis.

- **Three-gene deletion;** there is moderate anaemia (Hb 7–10 g/dL) and splenomegaly (Hb H disease). The patients are not usually transfusion-dependent. Hb A, Hb Barts and Hb H (Hb F) are present. Hb A2 is normal or reduced.

- **Two-gene deletion** (α-thalassaemia trait); there is microcytosis with or without mild anaemia. Hb H bodies may be seen on staining a blood film with brilliant cresyl blue.

- **One-gene deletion;** the blood picture is usually normal.

Globin chain synthesis studies for the detection of a reduced ratio of α to β chains may be necessary for the definitive diagnosis of α-thalassaemia trait.

Less commonly, α-thalassaemia may result from genetic defects other than deletions, for example mutations in the stop codon producing an α-chain with many extra amino acids (Hb Constant Spring).

### SICKLE SYNDROMES

Sickle cell haemoglobin (Hb S) results from a single-base mutation of adenine to thymine which produces a substitution of valine for glutamic acid at the sixth codon of the β-globin chain (ααββ<sup>6Glut→Val</sup>). In the homozygous state (sickle cell anaemia) both genes are abnormal (Hb SS), whereas in the heterozygous state (sickle cell trait, Hb AS) only one chromosome carries the gene. As the synthesis of Hb F is normal, the disease usually does not manifest itself until the Hb F decreases to adult levels at about 6 months of age.

The sickle gene is commonest in Africans (up to 25% gene frequency in some populations) but is also found in India, the Middle East and Southern Europe.

### Pathogenesis

Deoxygenated Hb S molecules are insoluble and polymerize. The flexibility of the cells is decreased and they become rigid and take up their characteristic sickle appearance (Fig. 8.24). This process is initially reversible but, with repeated sickling, the cells eventually lose their membrane flexibility and become irreversibly sickled. This is due to dehydration, partly caused by potassium leaving the red cells via calcium activated potassium channels called the Gados channel. These irreversibly sickled cells are dehydrated and dense and will not return to normal when oxygenated. Sickling can produce:

- a shortened red cell survival
- impaired passage of cells through the microcirculation, leading to obstruction of small vessels and tissue infarction.

Sickling is precipitated by infection, dehydration, cold, acidosis or hypoxia. In many cases the cause is unknown, but adhesion proteins on activated endothelial cells (VCAM-1) may play a causal role, particularly in vaso-occlusion when rigid cells are trapped, facilitating polymerization. Hb S releases its oxygen to the tissues more easily than does normal Hb, and patients therefore feel well despite being anaemic (except of course during crises or complications).

Depending on the type of haemoglobin chain combinations, three clinical syndromes occur:

- homozygous Hb SS have the most severe disease
- combined heterozygosity (Hb SC) for Hb S and C (see below) who suffer intermediate symptoms
- heterozygous Hb AS (sickle cell trait) have no symptoms (see p. 411).

### Sickle cell anaemia

#### Clinical features

**Vaso-occlusive crises**

The earliest presentation in the first few years of life is acute pain in the hands and feet (dactyliitis) owing to vaso-
occlusion of the small vessels. Severe pain in other bones, e.g. femur, humerus, vertebrae, ribs, pelvis, occurs in older children/adults. These attacks vary in frequency from daily to perhaps only once a year. Fever often accompanies the pain.

**Anaemia**
Chronic haemolysis produces a stable haemoglobin level, usually in the 6–8 g/dL range but an acute fall in the haemoglobin level can occur owing to:
- splenic sequestration
- bone marrow aplasia
- further haemolysis.

**Splenic sequestration**
Vaso-occlusion produces an acute painful enlargement of the spleen. There is splenic pooling of red cells and hypovolaemia, leading in some to circulatory collapse and death. The condition occurs in childhood before multiple infarctions have occurred. The latter eventually leads to a fibrotic non-functioning spleen. Liver sequestration can also occur.

**Bone marrow aplasia**
This most commonly occurs following infection with erythrovirus B19, which invades proliferating erythroid progenitors. There is a rapid fall in haemoglobin with no reticulocytes in the peripheral blood, because of the failure of erythropoiesis in the marrow.

Haemolysis due to drugs, acute infection or associated G6PD deficiency also occurs. Anaemia can also result from folate deficiency.

**Long-term problems**
In adults, nearly every organ is involved eventually, as patients survive longer with better treatment.

**Growth and development.** Young children are short but regain their height by adulthood. However, they remain below the normal weight. There is often delayed sexual maturation which may require hormone therapy.

**Bones** are a common site for vaso-occlusive episodes, leading to chronic infarcts. Avascular necrosis of hips, shoulders, compression of vertebrae and shortening of bones in the hands and feet occur. These episodes are the common cause for the painful crisis. Osteomyelitis is common in sickle cell disease and is caused by *Staphylococcus aureus, Staph. pneumoniae* and salmonella (see p. 541). Occasionally hip joint replacement may be required.

**Infections** are common in tissues susceptible to vaso-occlusion, e.g. bones, lungs, kidneys.

**Respiratory.** The acute chest syndrome occurs in up to 30%, and pulmonary hypertension and chronic lung disease are the commonest cause of death in adults with sickle cell disease. The acute chest syndrome is caused by infection, fat embolism from necrotic bone marrow or pulmonary infarction due to sequestration of sickle cells. It comprises shortness of breath, chest pain, hypoxia, and new chest X-ray changes due to consolidation. The presentation may be gradual or very rapid, leading to death in a few hours. Initial management is with pain relief, inspired oxygen, antibiotics and exchange transfusion to reduce the amount of Hb S to <20%; occasionally ventilation may be necessary. Infections can be due to chlamydia and mycoplasma, as well as *Streptococcus pneumoniae*.

**Leg ulcers** occur spontaneously (vaso-occlusive episodes) or following trauma and are usually over the medial or lateral malleol. They often become infected and are quite resistant to treatment, sometimes blood transfusion may facilitate ulcer healing.

**Cardiac** problems occur, with cardiomegaly, arrhythmias and iron overload cardiomyopathy. Myocardial infarctions occur due to thrombotic episodes which are not secondary to atheroma.

**Neurological** complications occur in 25% of patients, with transient ischaemic attacks, fits, cerebral infarction, cerebral haemorrhage and coma. Strokes occur in about 11% of patients under 20 years of age. The most common finding is obstruction of a distal intracranial internal carotid artery or a proximal middle cerebral artery. 10% of children without neurological signs or symptoms have abnormal blood-flow velocity indicative of clinically significant arterial stenosis; such patients have very high risk of stroke. It has now been demonstrated that if children with stenotic cranial artery lesions, as demonstrated on transcranial Doppler ultrasonography, are maintained on a regular programme of transfusion that is designed to suppress erythropoiesis so that no more than 30% of the circulating red cells are their own, about 90% of strokes in such children could be prevented.

**Cholelithiasis.** Pigment stones occur as a result of chronic haemolysis.

**Liver.** Chronic hepatomegaly and liver dysfunction are caused by trapping of sickle cells.

**Renal.** Chronic tubulo-interstitial nephritis are caused by trapping of sickle cells.

**Priapism.** An unwanted painful erection occurs from vaso-occlusion and can be recurrent. This may result in impotence. Treatment is with an α-adrenergic blocking drug, analgesia and hydration.

**Eye.** Background retinopathy, proliferative retinopathy, vitreous haemorrhages and retinal detachments all occur. Regular yearly eye checks are required.

**Pregnancy.** Impaired placental blood flow causes spontaneous abortion, intrauterine growth retardation, pre-eclampsia and fetal death. Painful episodes, infections and severe anaemia occur in the mother. Prophylactic transfusion does not improve fetal outcome. Oral contraceptives with low-dose oestrogens are safe.

**Investigations**
- **Blood count.** The level of Hb is in the range 6–8 g/dL with a high reticulocyte count (10–20%).
- **Blood films** can show features of hyposplenism (see Fig. 8.29) and sickling (Fig. 8.24).
- **Sickle solubility test.** A mixture of Hb S in a reducing solution such as sodium dithionite gives a turbid appearance because of precipitation of Hb S, whereas normal Hb gives a clear solution. A number of commercial kits such as Sickledex are available for rapid screening for the presence of Hb S, for example before surgery in appropriate ethnic groups and in the A&E department.
- **Hb electrophoresis** (Fig. 8.22) is always needed to confirm the diagnosis. There is no Hb A, 80–95% Hb SS and 2–20% Hb F.
- **The parents** of the affected child will show features of sickle cell trait.
Management
Precipitating factors (see above) should be avoided or treated quickly. The complications requiring inpatient management are shown in Table 8.13.

Acute painful attacks require supportive therapy with intravenous fluids, and adequate analgesia. Oxygen and antibiotics are only given if specifically indicated. Crises can be extremely painful and require strong, usually narcotic, analgesia. Morphine is the drug of choice. Milder pain can sometimes be relieved by codeine, paracetamol and NSAIDs (Box 8.1).

Prophylaxis is with penicillin 500 mg daily and vaccination with polyvalent pneumococcal and Haemophilus influenzae type B vaccine (see p. 423). Folic acid is given to all patients with haemolysis.

Anaemia
Blood transfusions should only be given for clear indications. Patients with steady state anaemia, those having minor surgery or having painful episodes without complications should not be transfused. Transfusions should be given for heart failure, TIAs, strokes, acute chest syndrome, acute splenic sequestration and aplastic crises. Before elective operations and during pregnancy, repeated transfusions may be used to reduce the proportion of circulating Hb S to less than 20% to prevent sickling. Exchange transfusions may be necessary in patients with severe or recurrent crises, or before emergency surgery. Transfusion and splenectomy may be life-saving for young children with splenic sequestration. A full blood crossmatching compatibility screen should always be performed.

Hydroxyurea (hydroxyurea) is the first drug which has been widely used as therapy for sickle cell anaemia. It acts, at least in part, by increasing Hb F concentrations. Hydroxyurea has been shown in trials to reduce the episodes of pain, the acute chest syndrome, and the need for blood transfusions.

Inhaled nitric oxide inhibits platelet function, reduces vascular adhesion of red cells and is also a vasodilator. It has been shown to reduce opiate requirements in acute painful episodes.

Bone marrow transplantation has been used to treat sickle cell anaemia although in fewer numbers than for thalassaemia. Children and adolescents younger than 16 years of age who have severe complications (strokes, recurrent chest syndrome or refractory pain) and have an HLA-matched donor are the best candidates for transplantation.

Table 8.13 Complications requiring inpatient management
| Pain – uncontrolled by non-opiate analgesia |
| Swollen painful joints |
| Acute sickle chest syndrome or pneumonia |
| Mesenteric sickling and bowel ischaemia |

| Central nervous system deficit |
| Cholecytitis (pigment stones) |
| Cardiac arrhythmias |
| Renal papillary necrosis resulting in colic or severe haematuria |
| Hyphema and retinal detachment |
| Priapism |

Box 8.1 Management of acute painful crisis in opioid naïve adults with sickle cell disease. Higher doses may be required for patients who have previously received opioids.

Morphine/diamorphine
- 0.1 mg/kg i.v./s.c. every 20 min until pain controlled, then
- 0.05–0.1 mg/kg i.v./s.c. (or oral morphine) every 2–4 hours
- Patient controlled analgesia (PCA) when pain controlled

Patient controlled analgesia (PCA) (example for adults >50 kg)

Diamorphine
- Continuous infusion: 0–10 mg/h
- PCA bolus dose: 2–10 mg
- Dose duration: 1 min
- Lockout time: 20–30 min

Adjuvant oral analgesia
- Paracetamol 1 g 6 hourly
- +/- Ibuprofen* 400 mg 8 hourly
- Or diclofenac* 50 mg 8 hourly

Laxatives (all patients)
For example:
- Lactulose 10 ml × 2 daily
- Senna 2–4 tablets daily
- Sodium docusate 100 mg × 2 daily
- Macrogol 1 sachet daily
- Lubiprostone

Other adjuvants

Anti-pruritics
- Hydroxyzine 25 mg × 2 as required

Antiemetics
- Prochlorperazine 5–10 mg × 3 as required
- Cyclizine 50 mg × 3 as required

Anxiolytic
- Haloperidol 1–3 mg oral/i.m. × 2 as required

*Caution advised with NSAIDs in renal impairment.

Counselling
A multidisciplinary team should be involved, with regular clinic appointments to build up relationships. Adolescents require careful counselling over psychosocial issues, drug and birth control.

Prognosis
Some patients with Hb SS die in the first few years of life from either infection or episodes of sequestration. However, there is marked individual variation in the severity of the disease and some patients have a relatively normal lifespan with few complications.

Sickle cell trait
These individuals have no symptoms unless extreme circumstances cause anoxia, such as flying in non-pressurized aircraft. Sickle cell trait gives some protection against Plasmodium falciparum malaria (see p. 154), and consequently the sickle gene has been seen as an example of a
balanced polymorphism (where the advantage of the malaria protection in the heterozygote is balanced by the mortality of the homozygous condition). Typically there is 60% Hb A and 40% Hb S. It should be emphasized that unlike thalassaemia trait, the blood count and film of a person with sickle cell trait are normal. The diagnosis is made by a positive sickle test or by Hb electrophoresis (Fig. 8.22).

Other structural globin chain defects

There are many Hb variants (e.g. Hb C, D), many of which are not associated with clinical manifestations.

Hb C (α2β2δγ) disease may be associated with Hb S (Hb SC disease). The clinical course is similar to that with Hb SS, but there is an increased likelihood of thrombosis, which may lead to life-threatening episodes of thrombosis in pregnancy, and retinopathy.

Combined defects of globin chain production and structure

Abnormalities of Hb structure (e.g. Hb S, C) can occur in combination with thalassaemia. The combination of β-thalassaemia trait and sickle cell trait (sickle cell β-thalassaemia) resembles sickle cell anaemia (Hb SS) clinically.

Hb E (α2β26glu–lyc) is the most common Hb variant in South East Asia, and the second most prevalent haemoglobin variant world-wide. Hb E heterozygotes are asymptomatic; the haemoglobin level is normal, but red cells are microcytic. Homozygous Hb E causes a mild microcytic anaemia, but the combination of heterozygosity for Hb E and β-thalassaemia produces a variable anaemia, which can be as severe as β-thalassaemia major.

Prenatal screening and diagnosis of severe haemoglobin abnormalities

Of the offspring of parents who both have either β-thalassaemia or sickle cell trait, 25% will have β-thalassaemia major or sickle cell anaemia, respectively. Recognition of these heterozygous states in parents and family counselling provide a basis for antenatal screening and diagnosis.

Prognosis

Pregnant women with either sickle cell trait or thalassaemia trait must be identified at antenatal booking either by selective screening of high-risk groups on the basis of ethnic origin or by universal screening of all pregnant women. β-Thalassaemia trait can always be detected by a low MCV and MCH and confirmed by haemoglobin electrophoresis. However, sickle cell trait is undetectable from a blood count and the laboratory need a specific request to screen for sickle cell trait.

If a pregnant woman is found to have a haemoglobin defect, her partner should be tested. Antenatal diagnosis is offered if both are affected as there is a risk of a severe fetal Hb defect, particularly β-thalassaemia major. Fetal DNA analysis can be carried out using amniotic fluid, chorionic villus or fetal blood samples. Abortion is offered if the fetus is found to be severely affected. Chorionic villus biopsy has the advantage that it can be carried out in the first trimester, thus avoiding the need for second trimester abortions.

Gene therapy would be the ultimate corrective therapy for severe Hb abnormalities. Normal Hb genes could be inserted into the patient’s haemopoietic cells in vitro and these cells could be transplanted back into the patient after ablative bone marrow treatment.

Red cell metabolism

The mature red cell has no nucleus, mitochondria or ribosomes and is therefore unable to synthesize proteins. Red cells have only limited enzyme systems but they maintain the viability and function of the cells. In particular, energy is required in the form of ATP for the maintenance of the flexibility of the membrane and the biconcave shape of the cells to allow passage through small vessels, and for regulation of the sodium and potassium pumps to ensure osmotic equilibrium. In addition, it is essential that Hb be maintained in the reduced state.

The enzyme systems responsible for producing energy and reducing power are (Fig. 8.25):

- the glycolytic (Embden–Meyerhof) pathway, in which glucose is metabolized to pyruvate and lactic acid with production of ATP
- the hexose monophosphate (pentose phosphate) pathway, which provides reducing power for the red cell in the form of NADPH.

About 90% of glucose is metabolized by the former and 10% by the latter. The hexose monophosphate shunt maintains glutathione (GSH) in a reduced state. Glutathione is necessary to combat oxidative stress to the red cell, and failure of this mechanism may result in:

- rigidity due to cross-linking of spectrin, which decreases membrane flexibility (see Fig. 8.18) and causes ‘leakiness’ of the red cell membrane
- oxidation of the Hb molecule, producing methaemoglobin and precipitation of globin chains as Heinz bodies localized on the inside of the membrane; these bodies are removed from circulating red cells by the spleen.

2,3-BPG is formed from a side-arm of the glycolytic pathway (Fig. 8.25). It binds to the central part of the Hb tetramer, fixing it in the low-affinity state (Fig. 8.4). A decreased affinity with a shift in the oxygen dissociation curve to the right enables more oxygen to be delivered to the tissues.

In addition to the G6PD, pyruvate kinase and pyrimidine 5’ nucleotidase deficiencies described below, there are a number of rare enzyme deficiencies that need specialist investigation.

Glucose-6-phosphate dehydrogenase (G6PD) deficiency

The enzyme G6PD holds a vital position in the hexose mono-phosphate shunt (Fig. 8.25), oxidizing glucose-6-phosphate to 6-phosphoglycerate with the reduction of NADP to NADPH. The reaction is necessary in red cells where it is the only source of NADPH, which is used via glutathione to protect the red cell from oxidative damage. G6PD deficiency is a common condition that presents with a haemolytic anaemia and affects millions of people throughout the world, particu-
Fig. 8.25 Glucose metabolism pathways in red cells. The enzymes in green boxes indicate documented hereditary deficiency diseases. larly in Africa, around the Mediterranean, the Middle East (around 20%) and southeast Asia (up to 40% in some regions).

The gene for G6PD is localized to chromosome Xq28 near the factor VIII gene. The deficiency is more common in males than in females. However, female heterozygotes can also have clinical problems due to lyonization, whereby because of random X-chromosome inactivation female heterozygotes have two populations of red cells – a normal one and a G6PD-deficient one.

There are over 400 structural types of G6PD, and mutations are mostly single amino acid substitutions (missense point mutations). WHO has classified variants by the degree of enzyme deficiency and severity of haemolysis. The most common types with normal activity are called type B+, which is present in almost all Caucasians and about 70% of black Africans, and type A+, which is present in about 20% of black Africans. There are many variants with reduced activity but only two are common. In the African, or A− type, the degree of deficiency is mild and more marked in older cells. Haemolysis is self-limiting as the young red cells newly produced by the bone marrow have nearly normal enzyme activity. However, in the Mediterranean type, both young and old red cells have very low enzyme activity. After an oxidant shock the Hb level may fall precipitously; death may follow unless the condition is recognized and the patient is transfused urgently.

Clinical syndromes
- Acute drug-induced haemolysis (Table 8.14) – usually dose related
- Favism (ingestion of fava beans)
- Chronic haemolytic anaemia
- Neonatal jaundice
- Infections and acute illnesses will also precipitate haemolysis in patients with G6PD deficiency.

Pyruvate kinase deficiency

This is the most common defect of red cell metabolism after G6PD deficiency, affecting thousands rather than millions of people. The site of the defect is shown in Figure 8.25. There is reduced production of ATP, causing rigid red cells. Homozygotes have haemolytic anaemia and splenomegaly. It is inherited as an autosomal recessive.

Investigations

- **Anaemia** of variable severity is present (Hb 5–10 g/dl).
  - The oxygen dissociation curve is shifted to the right as a result of the rise in intracellular 2,3-BPG, and this reduces the severity of symptoms due to anaemia.
- **Blood film** shows distorted (‘prickle’) cells and a reticulocytosis.
- **Pyruvate kinase activity** is low (affected homozygotes have levels of 5–20%).

Treatment

Blood transfusions may be necessary during infections and pregnancy. Splenectomy may improve the clinical condition and is usually advised for patients requiring frequent transfusions.

Pyrimidine 5’ nucleotidase deficiency

This autosomal disorder produces a haemolytic anaemia with basophilic stippling of the red cells. The enzyme degrades pyrimidine nucleotides to cytidine and uridine (pentose phosphate shunt), which in turn lead to the degradation of RNA in the reticulocytes. Lack of the enzyme results in accumulation of partially degraded RNA, which shows as basophilic stippling in mature red cells. The enzyme is also inhibited by lead (see p. 945) and thus basophilic stippling is seen in lead poisoning. The hereditary form can be diagnosed by measuring the enzyme in erythrocytes. A screening test using the ultraviolet absorption spectrum of red cells is available.

ACQUIRED HAEMOLYTIC ANAEMIA

These anaemias may be divided into those due to immune, non-immune, or other causes (Table 8.9)

Causess of immune destruction of red cells

- Autoantibodies
- Drug-induced antibodies
- Alloantibodies.

Causess of non-immune destruction of red cells

- Acquired membrane defects (e.g. paroxysmal nocturnal haemoglobinuria; see p. 418).
- Mechanical factors (e.g. prosthetic heart valves, or microangiopathic haemolytic anaemia; see p. 419).
- Secondary to systemic disease (e.g. renal and liver disease).
Autoimmune haemolytic anaemias

Autoimmune haemolytic anaemias (AIHA) are acquired disorders resulting from increased red cell destruction due to red cell autoantibodies. These anaemias are characterized by the presence of a positive direct antiglobulin (Coombs’) test, which detects the autoantibody on the surface of the patient’s red cells (Fig. 8.27).

AIHA is divided into ‘warm’ and ‘cold’ types, depending on whether the antibody attaches better to the red cells at body temperature (37°C) or at lower temperatures. The major features and the causes of these two forms of AIHA are shown in Table 8.15. In warm AIHA, IgG antibodies predominate and the direct antiglobulin test is positive with IgG alone, IgG and complement, or complement only. In cold AIHA, the antibodies are usually IgM. They easily elute off red cells, leaving complement which is detected as C3d.

**Immune destruction of red cells**

IgM or IgG red cell antibodies which fully activate the complement cascade cause lysis of red cells in the circulation (intravascular haemolysis).

IgG antibodies frequently do not activate complement and the coated red cells undergo extravascular haemolysis (Fig. 8.28). They are either completely phagocytosed in the spleen through an interaction with Fc receptors on

**Miscellaneous causes**

- Various toxic substances can disrupt the red cell membrane and cause haemolysis (e.g. arsenic, and products of *Clostridium welchii*).
- Malaria frequently causes anaemia owing to a combination of a reduction in red cell survival and reduced production of red cells.
- Hypersplenism (see p. 423) results in a reduced red cell survival, which may also contribute to the anaemia seen in malaria.
- Extensive burns result in denaturation of red cell membrane proteins and reduced red cell survival.
- Some drugs (e.g. dapsone, sulphasalazine) cause oxidative haemolysis with Heinz bodies.
- Some ingested chemicals (e.g. weedkillers such as sodium chlorate) can cause severe oxidative haemolysis leading to acute renal failure.

**Fig. 8.27 Antiglobulin (Coombs’) tests.** The anti-human globulin forms bridges between the sensitized cells causing visible agglutination. The direct test detects patients’ cells sensitized in vivo. The indirect test detects normal cells sensitized in vitro. HDN, haemolytic disease of newborn.
macrophages, or they lose part of the cell membrane through partial phagocytosis and circulate as spherocytes until they become sequestered in the spleen. Some IgG antibodies partially activate complement, leading to deposition of C3b on the red cell surface, and this may enhance phagocytosis as macrophages also have receptors for C3b.

Non-complement-binding IgM antibodies are rare and have little or no effect on red cell survival. IgM antibodies which partially rather than fully activate complement cause adherence of red cells to C3b receptors on macrophages, particularly in the liver, although this is an ineffective mechanism of haemolysis. Most of the red cells are released from the macrophages when C3b is cleaved to C3d and then circulate with C3d on their surface.

**‘Warm’ autoimmune haemolytic anaemias**

**Clinical features**

These anaemias may occur at all ages and in both sexes, although they are most frequent in middle-aged females. They can present as a short episode of anaemia and jaundice but they often remit and relapse and may progress to an intermittent chronic pattern. The spleen is often palpable. Infections or folate deficiency may provoke a profound fall in the haemoglobin level.

In more than 30% of cases, the cause remains unknown. These anaemias may be associated with lymphoid malignancies or diseases such as rheumatoid arthritis and SLE or drugs (Table 8.15).

**Investigations**

- **Haemolytic anaemia** is evident (see p. 403).
- **Spherocytosis** is present as a result of red cell damage.

- **Direct antiglobulin test** is positive, with either IgG alone (67%), IgG and complement (20%), or complement alone (13%) being found on the surface of the red cells.
- **Autoantibodies** may have specificity for the Rh blood group system (e.g. for the e antigen).
- **Autoimmune thrombocytopenia** and/or neutropenia may also be present (Evans’ syndrome).

**Treatment and prognosis**

Corticosteroids (e.g. prednisolone in doses of 1 mg/kg daily) are effective in inducing a remission in about 80% of patients. Steroids reduce both the production of the red cell autoantibody and destruction of antibody-coated cells. Splenectomy may be necessary if there is no response to steroids or if the remission is not maintained when the dose of prednisolone is reduced. Other immunosuppressive drugs, such as azathioprine and rituximab, may be effective in patients who fail to respond to steroids and splenectomy. Blood transfusion may be necessary if there is severe anaemia; compatibility testing is complicated by the presence of red cell autoantibodies.

**‘Cold’ autoimmune haemolytic anaemias**

Normally, low titres of IgM cold agglutinins reacting at 4°C are present in plasma and are harmless. At low temperatures these antibodies can attach to red cells and cause their agglutination in the cold peripheries of the body. In addition, activation of complement may cause intravascular haemolysis when the cells return to the higher temperatures in the core of the body.

After certain infections (such as *Mycoplasma*, cytomegalovirus, Epstein–Barr virus (EBV)) there is increased synthesis...
of polyclonal cold agglutinins producing a mild to moderate transient haemolysis.

**Chronic cold haemagglutinin disease (CHAD)**

This usually occurs in the elderly with a gradual onset of haemolytic anaemia owing to the production of monoclonal IgM cold agglutinins. After exposure to cold, the patient develops an acrocyanosis similar to Raynaud’s as a result of red cell autoagglutination.

**Investigations**

- **Red cells** agglutinate in the cold or at room temperature. Agglutination is sometimes seen in the sample tube after cooling but is more easily seen on the peripheral blood film made at room temperature. The agglutination is reversible after warming the sample. The agglutination may cause a spurious increase in the MCV (see p. 392).
- **Direct antiglobulin test** is positive with complement (C3d) alone.
- **Monoclonal IgM antibodies** with specificity for the i blood group system, usually for the I antigen but occasionally for the i antigen.

**Treatment**

The underlying cause should be treated, if possible. Patients should avoid exposure to cold. Steroids, alkylating agents and splenectomy are usually ineffective. Treatment with anti-CD20 (rituximab) has been successful in some cases. Blood transfusion may be necessary, and if so, the patient should be in a warm environment; compatibility testing may be difficult due to the cold agglutinin.

**Paroxysmal cold haemoglobinuria (PCH)**

This is a rare condition associated with common childhood infections, such as measles, mumps and chickenpox. Intravascular haemolysis is associated with polyclonal IgG complement-fixing antibodies. These antibodies are biphasic, reacting with red cells in the cold in the peripheral circulation, with lysis occurring due to complement activation when the cells return to the central circulation. The antibodies have specificity for the P red cell antigen. The lytic reaction is demonstrated in vitro by incubating the patient’s red cells and serum at 4°C and then warming the mixture to 37°C (Donath–Landsteiner test). Haemolysis is self-limiting but red cell transfusions may be necessary.

---

**DRUG-INDUCED IMMUNE HAEMLYTIC ANAEMIA**

Drug-induced haemolytic anaemias are rare, although over 100 drugs have been reported to cause immune haemolytic anaemia. The interaction between a drug and red cell membrane may produce three types of antibodies:

- **Antibodies to the drug only**, e.g. quinidine, rifampicin. Immune complexes attach to red cells, and may cause acute and severe intravascular haemolysis, sometimes associated with renal failure. The haemolysis usually resolves quickly once the drug is withdrawn.
- **Antibodies to the cell membrane only**, e.g. methyldopa, fludarabine. There is extravascular haemolysis and the clinical course tends to be more protracted.
- **Antibodies to part-drug, part-cell membrane**, e.g. penicillin. This develops only in patients receiving large doses of penicillin. The haemolysis typically develops over 7–10 days, and recovery is gradual after drug withdrawal.

Confirmation of the diagnosis requires a temporal association between administration of a drug and haemolytic anaemia, and recovery after withdrawal of the drug. In addition, the direct antiglobulin test should be positive, and drug-dependent red cell antibodies are detectable in the first and third mechanisms described above. In the second, the antibodies are not drug-dependent and are indistinguishable from autoantibodies.

**ALLOIMMUNE HAEMLYTIC ANAEMIA**

Antibodies produced in one individual react with the red cells of another. This situation occurs in haemolytic disease of the newborn, haemolytic transfusion reactions (see p. 427) and after allogeneic bone marrow, renal, liver or cardiac transplantation when donor lymphocytes transferred in the allograft (“passenger lymphocytes”) may produce red cell antibodies against the recipient and cause haemolytic anaemia.

**Haemolytic disease of the newborn (HDN)**

HDN is due to fetomaternal incompatibility for red cell antigens. Maternal alloantibodies against fetal red cell antigens pass from the maternal circulation via the placenta into the fetus, where they destroy the fetal red cells. Only IgG antibodies are capable of transplacental passage from mother to fetus.

The most common type of HDN is that due to ABO incompatibility, where the mother is usually group O and the fetus group A.

HDN due to ABO incompatibility is usually mild and exchange transfusion is rarely needed. HDN due to RhD incompatibility has become much less common in developed countries following the introduction of anti-D prophylaxis (see below). HDN may be caused by antibodies against antigens in many blood group systems (e.g. other Rh antigens such as c and E, and Kell, Duffy and Kidd; see p. 424).

Sensitization occurs as a result of passage of fetal red cells into the maternal circulation (which most readily occurs at the time of delivery), so that first pregnancies are rarely affected. However, sensitization may occur at other times, for example after a miscarriage, ectopic pregnancy or blood transfusion, or due to episodes during pregnancy which cause transplacental bleeding such as amniocentesis, chorionic villus sampling and threatened miscarriage.

**Clinical features**

These vary from a mild haemolytic anaemia of the newborn to intrauterine death from 18 weeks’ gestation with the characteristic appearance of hydrops fetalis (hepatosplenomegaly, oedema and cardiac failure).

Kernicterus occurs owing to severe jaundice in the neonatal period, where the unconjugated (lipid-soluble) bilirubin...
exceeds 250 µmol/L and bile pigment deposition occurs in the basal ganglia. This can result in permanent brain damage, choreothetosis and spasticity. In mild cases it may present as deafness.

**Investigations**

**Routine antenatal serology**

All mothers should have their ABO and RhD groups determined and tested for atypical antibodies after attending the antenatal booking clinic. These tests should be repeated at 28 weeks’ gestation.

If an antibody is detected, its blood group specificity should be determined and the mother should be retested at least monthly. A rising antibody titre of IgG antibodies or a history of HDN in a previous pregnancy is an indication for referral to a fetal medicine unit.

**Antenatal assessment and treatment**

If a clinically significant antibody capable of causing HDN, e.g. anti-D, anti-c or anti-K, is detected, the father’s phenotype provides useful information to predict the likelihood of the fetus carrying the relevant red cell antigen. If the father is heterozygous, the genotype of the fetus can be determined from fetal DNA obtained by amniocentesis, chorionic villous sampling or fetal blood sampling. Soluble fetal DNA in maternal plasma can also be used for RhD typing, avoiding an invasive procedure.

The severity of anaemia is assessed by Doppler flow velocity of the fetal middle cerebral artery; measurement of bile pigments in the amniotic fluid is no longer routinely used.

If the infant appears to have severe anaemia by non-invasive monitoring, ultrasound-guided fetal blood sampling is used to confirm this directly, and if necessary, an intravascular fetal transfusion of red cells is given.

**At the birth of an affected infant**

A sample of cord blood is obtained. This shows:

- anaemia with a high reticulocyte count
- a direct positive antoglobulin test
- a raised serum bilirubin.

**Postnatal management**

In mild cases, phototherapy may be used to convert bilirubin to water-soluble biliverdin. Biliverdin can be excreted by the kidneys and this therefore reduces the chance of kernicterus.

In more severely affected cases, exchange transfusion may be necessary to replace the infant’s red cells and to remove bilirubin. Indications for exchange transfusion include:

- a cord Hb of <12 g/dL (normal cord Hb is 13.6–19.6 g/dL)
- a cord bilirubin of >60 µmol/L
- a later serum bilirubin of >300 µmol/L
- a rapidly rising serum bilirubin level.

Further exchange transfusions may be necessary to remove the unconjugated bilirubin.

The blood used for exchange transfusions should be ABO-compatible with the mother and infant, lack the antigen against which the maternal antibody is directed, be fresh (no more than 5 days from the day of collection) and be CMV- and herpes virus seronegative to prevent transmission of cytomegalovirus.

**Prevention of RhD immunization in the mother**

Anti-D should be given after delivery when all of the following are present:

- the mother is RhD negative
- the fetus is RhD positive
- there is no maternal anti-D detectable in the mother's serum; i.e. the mother is not already immunized.

The dose is 500 i.u. of IgG anti-D intramuscularly within 72 hours of delivery. The Kleihauer test is used to assess the number of fetal cells in the maternal circulation. A blood film prepared from maternal blood is treated with acid, which elutes Hb A. Hb F is resistant to this treatment and can be seen when the film is stained with eosin. If large numbers of fetal red cells are present in the maternal circulation, a higher or additional dose of anti-D will be necessary.

It may be necessary to give prophylaxis to RhD-negative women at other times when sensitization may occur, for example after an ectopic pregnancy, threatened miscarriage or termination of pregnancy. The dose of anti-D is 250 i.u. before 20 weeks’ gestation and 500 i.u. after 20 weeks. A Kleihauer test should be carried out after 20 weeks to determine if more anti-D is required.

Of previously non-immunized RhD-negative women carrying RhD-positive fetuses, 1–2% became immunized by the time of delivery. Antenatal prophylaxis with administration of 500 i.u. anti-D to RhD-negative women at both 28 and 34 weeks’ gestation has been shown to reduce the incidence of immunization, and its routine use is being implemented in the UK. Monoclonal anti-D could in principle replace polyclonal anti-D, which is collected from RhD-negative women immunized in pregnancy and deliberately immunized RhD-negative males, but it is likely to be some years before trials have been completed to confirm its safety and effectiveness.

**NON-IMMUNE HAEMOLYTIC ANAEMIA**

**Paroxysmal nocturnal haemoglobinuria (PNH)**

Paroxysmal nocturnal haemoglobinuria is a rare form of haemolytic anaemia which results from the clonal expression of haematopoietic stem cells that have mutations in the X-linked gene PIG-A. These mutations result in an impaired synthesis of glycosylphosphatidylinositol (GPI), which anchors many proteins to the cell surface such as decay accelerating factor (DAF; CD55) and membrane inhibitor of reactive lysis (MIRL; CD59) to cell membranes. CD55 and CD59 and other proteins are involved in complement degradation (at the C3 and C5 levels), and in their absence the haemolytic action of complement continues.

**Clinical features**

The major clinical signs are intravascular haemolysis, venous thrombosis and haemoglobinuria. Haemolysis may be precipitated by infection, iron therapy or surgery. Characteristically only the urine voided at night and in the morning on waking is dark in colour, although the reason for this phenomenon is not clear. In severe cases all urine samples are dark. Urinary iron loss may be sufficient to cause iron deficiency.

Some patients present insidiously with signs of anaemia and recurrent abdominal pains.
Venous thrombotic episodes are very common in unusual places and severe thromboses may occur, for example in hepatic (Budd–Chiari syndrome), mesenteric or cerebral veins. The cause of the increased predisposition to thrombosis is not known, but may be due to complement-mediated activation of platelets deficient in CD55 and CD59. Another suggestion is that intravascular haemolysis, which releases haemoglobin in the plasma, lowers plasma nitric oxide, which causes the symptoms and venous thrombosis.

**Investigations**
- Intravascular haemolysis is evident (see p. 403).
- Flow cytometric analysis of red cells with anti-CD55 and anti-CD59 has replaced the Ham’s test.
- Bone marrow is sometimes hypoplastic (or even aplastic) despite haemolysis.

**Treatment and prognosis**
PNH is a chronic disorder requiring supportive measures such as blood transfusions, which are necessary for patients with severe anaemia. Leucocyte-depleted blood should be used in order to prevent transfusion reactions resulting in complement activation and acceleration of the haemolysis. Treatment is with eculizumab, a recombinant humanized monoclonal antibody that prevents the cleavage of C5 (and therefore the formation of the membrane attack complex). It reduces intravascular haemolysis, haemoglobinuria, the need for transfusion and gives an improved quality of life.

Long-term anticoagulation may be necessary for patients with recurrent thrombotic episodes. In patients with bone marrow failure, treatment options include immunosuppression with antilymphocyte globulin, ciclosporin or bone marrow transplantation. Bone marrow transplantation has been successfully carried out using either HLA-matched sibling donors in patients under the age of 50 or matched unrelated donors in patients under the age of 25.

The course of PNH is variable. PNH may transform into aplastic anaemia or acute leukaemia, but it may remain stable for many years and the PNH clone may even disappear, which must be taken into account if considering potentially dangerous treatments such as bone marrow transplantation. The median survival is 10–15 years.

Gene therapy will perhaps be possible in the future.

**POLYCYTHAEMIA**

Polycythaemia (or erythrocytosis) is defined as an increase in haemoglobin, PCV and red cell count. PCV is a more reliable indicator of polycythaemia than is Hb, which may be disproportionately low in iron deficiency. Polycythaemia can be divided into absolute erythrocytosis where there is a true increase in red cell volume, or relative erythrocytosis where the red cell volume is normal but there is a decrease in the plasma volume (Fig. 8.6).

Absolute erythrocytosis is due to primary polycythaemia (PV) or secondary polycythaemia. Secondary polycythaemia is due to either an appropriate increase in red cells in response to anoxia, or an inappropriate increase associated with tumours, such as a renal carcinoma. The causes of polycythaemia are given in Table 8.16.

**Primary polycythaemia: polycythaemia vera (PV)**

PV is a clonal stem cell disorder in which there is an alteration in the pluripotent progenitor cell leading to excessive prolif-
eration of erythroid, myeloid and megakaryocytic progenitor cells. Over 95% of patients with PV have acquired mutations of the gene Janus Kinase 2 (JAK2). There is a V617F mutation which causes the substitution of phenylalanine for valine at position 617. JAK2 is a cytoplasmic tyrosine kinase that transduces signals, especially those triggered by haemato-
opietic growth factors such as erythropoietin, in normal and neoplastic cells. The significance of the discovery is twofold: first of immediate significance is the clinical utility of the detection of JAK2 mutations for the diagnosis of PV and second is the prospect of the development of new treat-
ments for the myeloproliferative disorders based on targeting JAK2 activity.

Clinical features
The onset is insidious. It usually presents in patients aged over 60 years with tiredness, depression, vertigo, tinnitus and visual disturbance. It should be noted that these symptoms are also common in the normal population over the age of 60 and consequently PV is easily missed. These features, together with hypertension, angina, intermittent claudication and a tendency to bleed, are suggestive of PV.

Severe itching after a hot bath or when the patient is warm is common. Gout due to increased cell turnover may be a feature, and peptic ulceration occurs in a minority of patients. Thrombosis and haemorrhage are the major com-
lications of PV.

The patient is usually plethoric and has a deep dusky cyanosis. Injection of the conjunctivae is commonly seen. The spleen is palpable in 70% and is useful in distinguishing PV from secondary polycythaemia. The liver is enlarged in 50% of patients.

Diagnosis
Box 8.2 shows the revised WHO criteria for diagnosis in adults. The measurement of red cell and plasma volume are not necessary. There may be a raised serum uric acid, leu-
cocyte alkaline phosphatase and a raised serum vitamin B_{12} and vitamin B_{12} binding protein (transcobalamin 1).

Course and management
Treatment is designed to maintain a normal blood count and to prevent the complications of the disease, particularly thromboses and haemorrhage. Treatment is aimed at keeping the PCV below 0.45 L/L and the platelet count below 400 × 10^{12}/L. There are three types of specific treatment:

■ Venesection. The removal of 400–500 mL weekly will successfully relieve many of the symptoms of PV. Iron deficiency limits erythropoiesis. Venesection is often used as the sole treatment and other therapy is reserved to control the thrombocytosis. The aim is to maintain a packed cell volume (PVC) of <0.45 L/L.

■ Chemotherapy. Continuous or intermittent treatment with hydroxyurea (hydroxyurea) is used frequently because of the ease of controlling thrombocytosis and general safety in comparison to the alkylating agents such as busulfan, which carry an increased risk of acute leukemia. Low-dose intermittent busulfan may be more convenient for elderly people, and this must be weighed against the potential risk of long-term complications.

■ Low dose aspirin 100 mg daily with the above treatments is used for patients with recurrent thrombotic episodes.

### Box 8.2 Modified from proposed revised WHO criteria for polycythaemia vera (PV)

</tbody>
</table>

*EEC. This is not routinely available but colony formation in the absence of exogenous erythropoietin in vitro is 100% specific and sensitive in patients without previous treatment. This research was originally published in Blood. Tefteri A, Thiele J, Orazi A et al. Proposals and rationale for revision of the World Health Organization diagnostic criteria for polycythaemia vera, essential thrombocytopenia, and primary myelofibrosis: recommendations from an ad hoc international expert panel. Blood 2007; 110: 1092–1097. © American Society of Hematology.

■ Anagrelide inhibits megakaryocyte differentiation and is useful for thrombolysis.

General treatment
Radioactive {superscript}32P is only given to patients over 70 years because of the increased risk of transformation to acute leukaemia. Allopurinol is given to block uric acid production. The pruritus is lessened by avoiding very hot baths. H1-receptor antagonists have largely proved unsuccessful in relieving distressing pruritus, but H2-receptor antagonists such as cimetidine are occasionally effective.

Surgery. Polycythaemia should be controlled before surgery. Patients with uncontrolled PV have a high operative risk; 75% of patients have severe haemorrhage following surgery and 30% of these patients die. In an emergency, reduction of the haematocrit by venesection and appropriate fluid replacement must be carried out.

Prognosis
PV develops into myelofibrosis in 30% of cases and into acute myeloblastic leukaemia in 5% as part of the natural history of the disease.

Secondary polycythaemias
Many high-oxygen affinity haemoglobin mutants (HOAHM) have been described which lead to increased oxygen affinity but decreased oxygen delivery to the tissues, resulting in compensatory polycythaemia. A congenital autosomal recessive disorder (Chuvasch polycythaemia) is due to a defect in the oxygen-sensing erythropoietin production pathway caused by a mutation of the von Hippel–Lindau (VHL) gene, resulting in an increased production of erythropoietin.

The causes of secondary polycythaemias are shown in Table 8.16.
Serum erythropoietin (EPO) levels are normal or raised in secondary polycythaemia. Rarely the discovery of a high EPO level may be the clue to the presence of an EPO-secret- ing tumour.

The treatment is that of the precipitating factor; for example, renal or posterior fossa tumours need to be resected. The commonest cause is heavy smoking, which can produce as much as 10% carboxyhaemoglobin and this can produce polycythaemia because of a reduction in the oxygen-carrying capacity of the blood. Heavy smokers also often have respiratory disease.

Complications of secondary polycythaemia are similar to those seen in PV, including thrombosis, haemorrhage and cardiac failure, but the complications due to myeloproliferative disease such as progression to myelofibrosis or acute leukaemia do not develop. Venection may be symptomatically helpful in the hypoxic patient, particularly if the PCV is above 0.55 L/L.

‘Relative’ or ‘apparent’ polycythaemia (Gaisböck’s syndrome)
This condition was originally thought to be stress-induced. The red cell volume is normal, but as the result of a decreased plasma volume, there is a relative polycythaemia. ‘Relative’ polycythaemia is more common than PV and occurs in middle-aged men, particularly in smokers who are obese and hypertensive. The condition may present with cardiovascular problems such as myocardial or cerebral ischaemia. For this reason, it may be justifiable to venesect the patient. Smoking should be stopped.

Essential thrombocythaemia (ET)
Essential thrombocythaemia (ET) is a myeloproliferative dis- order closely related to PV. Patients have normal Hb levels and WBC but elevated platelet counts. At diagnosis the platelet count will usually be >600 × 10^9/L, and may be as high as 2000 × 10^9/L or rarely even higher. ET presents either symptomatically with thromboembolic or less commonly bleeding problems or incidentally (e.g. at a routine medical check).

The diagnosis of ET is not straightforward as there is no global gold standard test. The JAK2 mutation tests (see PV) are useful in that the gene is mutated in about half of all cases of ET, confirming a myeloproliferative disorder. For the remaining 50% of patient with a normal JAK2 gene, clinical assessment and observation over a period of time are required. As a generalization a person with a very high plate- let count (>1000 × 10^9/L) who is clinically normal with good health will most likely prove to have ET. In a patient with a lower platelet count, e.g. 600 × 10^9/L, and in poor health the diagnosis can be more difficult. Other disorders which may give rise to reactive high platelet counts include autoimmune rheumatic disorders and malignancy. Individuals who have been splenectomized (for any reason, including trauma) sometimes have high platelet counts.

Treatment
Treatment is with hydroxyurea (hydroxyurea), anagrelide or busulfan to control the platelet count to less than 400 × 10^9/L.

α-interferon is also effective; it is administered by subcu- taneous injection. ET may eventually transform into PV, myelofibrosis or acute leukaemia, but the disease may not progress for many years.

MYELOFIBROSIS (MELOSCLEROSIS)

The terms myelosclerosis and myelofibrosis are interchange- able. There is clonal proliferation of stem cells and myeloid metaplasia in the liver, spleen and other organs. Increased fibrosis in the bone marrow is caused by hyperplasia of abnormal megakaryocytes which release fibroblast-stimulat- ing factors such as platelet-derived growth factor. In about 25% of cases there is a preceding history of PV and 50% have the JAK2 mutation seen in PV.

Clinical features
The disease presents insidiously with lethargy, weakness and weight loss. Patients often complain of a ‘fullness’ in the upper abdomen due to splenomegaly. Severe pain related to respiration may indicate perisplenitis secondary to splenic infarction, and bone pain and attacks of gout can complicate the illness. Bruising and bleeding occur because of thrombocyto- penia or abnormal platelet function. Other physical signs include anaemia, fever and massive splenomegaly (for other causes, see p. 423).

Investigations
- Anaemia with leucoerythroblastic features is present (see p. 430). Poikilocytes and red cells with characteristic tear-drop forms are seen. The WBC count may be over 100 × 10^9/L, and the differential WBC count may be very similar to that seen in chronic myeloid leukaemia (CML); later leucopenia may develop.
- The platelet count may be very high, but in later stages, thrombocytopenia occurs.
- Bone marrow aspiration is often unsuccessful and this gives a clue to the presence of the condition. A bone marrow trephine is necessary to show the markedly increased fibrosis. Increased numbers of megakaryocytes may be seen.
- The Philadelphia chromosome is absent; this helps to distinguish myelofibrosis from most cases of CML.
- The leucocyte alkaline phosphatase (LAP) score is normal or high.
- A high serum urate is present.
- Low serum folate levels may occur owing to the increased haemopoietic activity.

Differential diagnosis
The major diagnostic difficulty is the differentiation of myelo- fibrosis from CML as in both conditions there may be marked splenomegaly and a raised WBC count with many granulo- cyte precursors seen in the peripheral blood. The main dis- tinguishing features are the appearance of the bone marrow and the absence of the Philadelphia chromosome in myelofibrosis.

Fibrosis of the marrow, often with a leucoerythroblastic anaemia, can also occur secondarily to leukaemia or lymphoma, tuberculosis or malignant infiltration with metastatic carcinoma, or to irradiation.

Treatment
This consists of general supportive measures such as blood transfusion, folic acid, analgesics and allopurinol. Drugs such as hydroxyurea (hydroxyurea) and busulfan are used to reduce metabolic activity and high WBC count and platelet levels. Chemotherapy and radiotherapy are used to reduce splenic size. If the spleen becomes very large and painful,
and transfusion requirements are high, it may be advisable to perform splenectomy. Splenectomy may also result in relief of severe thrombocytopenia.

**Prognosis**

Patients may survive for 10 years or more; median survival is 3 years. Death may occur in 10–20% of cases from transformation to acute myeloblastic leukaemia. The most common causes of death are cardiovascular disease, infection and gastrointestinal bleeding.

**MYELODYSPLASIA (MDS)**

Myelodysplasia (MDS) describes a group of acquired bone marrow disorders that are due to a defect in stem cells. They are characterized by increasing bone marrow failure with quantitative and qualitative abnormalities of all three myeloid cell lines (red cells, granulocyte/monocytes and platelets). The natural history of MDS is variable, but there is a high morbidity and mortality owing to bone marrow failure, and transformation into acute myeloblastic leukaemia occurs in about 30% of cases. A classification of the myelodysplastic syndrome is shown in Table 8.17.

**Clinical and laboratory features**

MDS occurs mainly in the elderly, and presents with symptoms of anaemia, infection or bleeding due to pancytopenia. Serial blood counts show evidence of increasing bone marrow failure with anaemia, neutropenia, monocytosis and thrombocytopenia, either alone or in combination. By contrast, in chronic myelomonocytic leukaemias (CMML), monocytosis are >1 × 10⁹/L and the WBC count may be >100 × 10⁹/L.

The bone marrow usually shows increased cellularity despite the pancytopenia. Dyserythropoiesis is present, and granulocyte precursors and megakaryocytes also have abnormal morphology. Ring sideroblasts are present in all types. In refractory anaemia with excess blasts (RAEB) and refractory anaemia with excess blasts in transformation (RAEB-t), the number of blasts in the bone marrow is increased, and the prognosis is worse than in those types with a low number of blast cells (<5%).

**Management**

Patients with <5% blasts in the bone marrow are usually managed conservatively with red cell and platelet transfusions and antibiotics for infections, as they are needed. Haemopoietic growth factors (e.g. erythropoietin, G-CSF) may be useful in some patients.

Patients with >5% blasts have a less favourable prognosis, and a number of treatment options are available:

- **Supportive care** only is suitable for elderly patients with other medical problems.
- **‘Gentle’ chemotherapy** (low-dose or single-agent, e.g. azacytidine) may be useful in patients with high WBC counts.
- **Intensive chemotherapy** schedules used for acute myeloblastic leukaemia (see p. 469) may be tried in patients under the age of 60, but the remission rate is less, and prolonged pancytopenia may occur owing to poor haemopoietic regeneration because of the defect in stem cells.
- **Lenalidomide** (a thalidomide analogue) has been proven to be remarkably successful in the treatment of early stage myelodysplasia with a chromosome 5q deletion (the 5q– syndrome). Avoid use in women of child-bearing age.
- **Bone marrow transplantation** offers the hope of cure in the small proportion of MDS patients who are under the age of 50 and who have an HLA-identical sibling or an unrelated HLA-matched donor.

In all categories, monocytes in the peripheral blood < 1.0 × 10⁹/L. RS, ring sideroblasts; RAEB-t (in transformation) also includes the 5q syndrome (deletion of 5q) – usually elderly females but with good prognosis.

**THE SPLEEN**

The spleen is the largest lymphoid organ in the body and is situated in the left hypochondrium. There are two anatomical components:

- the red pulp, consisting of sinuses lined by endothelial macrophages and cords (spaces)
- the white pulp, which has a structure similar to lymphoid follicles.

Blood enters via the splenic artery and is delivered to the red and white pulp. During the flow the blood is ‘skimmed’, with leucocytes and plasma preferentially passing to white pulp. Some red cells pass rapidly through into the venous system while others are held up in the red pulp.

**Functions**

**Sequestration and phagocytosis.** Normal red cells, which are flexible, pass through the red pulp into the venous system without difficulty. Old or abnormal cells are damaged by the hypoxia, low glucose and low pH found in the sinuses of the red pulp and are therefore removed by phagocytosis along with other circulating foreign matter. Howell–Jolly and Heinz bodies and sideroblastic granules have their particles removed by ‘pitting’ and are then returned to the circulation. IgG-coated red cells are removed through their Fc receptors by macrophages.

**Extramedullary haemopoiesis.** Pluripotent stem cells are present in the spleen and proliferate during severe haematological stress, such as in haemolytic anaemia or thalassaemia major.
**Immunological function.** About 25% of the body’s T lymphocytes and 15% of B lymphocytes are present in the spleen. The spleen shares the function of production of antibodies with other lymphoid tissues.

**Blood pooling.** Up to one-third of the platelets are sequestered in the spleen and can be rapidly mobilized. Enlarged spleens pool a significant percentage (up to 40%) of the red cell mass.

### SPLENOMEGALY

**Causes**

A clinically palpable spleen can have many causes.

- Infection:
  - (a) acute, e.g. septic shock, infective endocarditis, typhoid, infectious mononucleosis
  - (b) chronic, e.g. tuberculosis and brucellosis
  - (c) parasitic, e.g. malaria, kala-azar and schistosomiasis.

- Inflammation: rheumatoid arthritis, sarcoidosis, SLE.

- Haematological: haemolytic anaemia, haemoglobinopathies and the leukaemias, lymphomas and myeloproliferative disorders.

- Portal hypertension: liver disease.

- Miscellaneous: storage diseases, amyloid, primary and secondary neoplasias, tropical splenomegaly.

**Massive splenomegaly.** This is seen in myelofibrosis, chronic myeloid leukaemia, chronic malaria, kala-azar or, rarely, Gaucher’s disease.

### Hypersplenism

This can result from splenomegaly due to any cause. It is commonly seen with splenomegaly due to haematological disorders, portal hypertension, rheumatoid arthritis (Felty’s syndrome) and lymphoma. Hypersplenism produces:

- pancytopenia

- haemolysis due to sequestration and destruction of red cells in the spleen

- increased plasma volume.

**Treatment.** This is often dependent on the underlying cause, but splenectomy is sometimes required for severe anaemia or thrombocytopenia.

### Splenectomy

Splenectomy is performed mainly for:

- trauma

- immune thrombocytopenic purpura (see p. 436)

- haemolytic anaemias (see p. 408)

- hypersplenism.

**Problems after splenectomy**

An immediate problem is an increased platelet count (usually 600–1000 × 10^9/L) for 2–3 weeks. Thrombo-embolic phenomena may occur. In the longer term there is an increased risk of overwhelming infections, particularly pneumococcal infections.

---

**Box 8.3 Prophylaxis against infection after splenectomy or splenic dysfunction**

Vaccinate 2–3 weeks before elective splenectomy.

- A 23-valent unconjugated pneumococcal polysaccharide vaccine repeated every 5 years

- Meningococcal group C conjugate vaccine

- Annual influenza vaccine

- *Haemophilus influenzae* type b (Hib) vaccine

- Long-term penicillin V 500 mg 12-hourly (if sensitive, use erythromycin)

- Meningococcal polysaccharide vaccine (ACWY) for travellers to Africa/Saudi Arabia, e.g. during Haj and Umrah pilgrimages

**Fig. 8.29** Postsplenectomy film with Howell–Jolly bodies (arrowed), target cells and irregularly contracted cells.

**Prophylaxis against infection after splenectomy or splenic dysfunction** (Box 8.3)

All patients should be educated about the risk of infection and the importance of its early recognition and treatment. They should be given an information leaflet and should carry a card or bracelet to alert health professionals to their risk of overwhelming infection.

**Postsplenectomy haematological features**

- **Thrombocytosis** persists in about 30% of cases.

- **The WBC count** is usually normal but there may be a mild lymphocytosis and monocytosis.

- **Abnormalities in red cell morphology** are the most prominent changes and include Howell–Jolly bodies (contain basophilic nuclear remnants), Pappenheimer bodies (contain sideroblastic granules), target cells and irregular contracted red cells (Fig. 8.29). Pitted red cells can be counted.

**Splenic atrophy**

This is seen in sickle cell disease due to infarction. It is also seen in coeliac disease, dermatitis herpetiformis, and occasionally in ulcerative colitis and essential thrombocytopenia. Postsplenectomy haematological features are seen.

---

**Blood transfusion**

The cells and proteins in the blood express antigens which are controlled by polymorphic genes; that is, a specific antigen may be present in some individuals but not in others. A blood transfusion may immunize the recipient against donor antigens that the recipient lacks (alloimmunization), and repeated transfusions increase the risk of the occurrence...
of alloimmunization. Similarly, the transplacental passage of fetal blood cells during pregnancy may alloimmunize the mother against fetal antigens inherited from the father. Antibodies stimulated by blood transfusion or pregnancy, such as Rh antibodies, are termed immune antibodies and are usually IgG, in contrast to naturally occurring antibodies, such as ABO antibodies, which are made in response to environmental antigens present in food and bacteria and which are usually IgM.

**BLOOD GROUPS**

The blood groups are determined by antigens on the surface of red cells; more than 280 blood groups are recognized. The ABO and Rh systems are the two major blood groups, but incompatibilities involving many other blood groups (e.g., Kell, Duffy, Kidd) may cause haemolytic transfusion reactions and/or haemolytic disease of the newborn (HDN).

**ABO system**

This blood group system involves naturally occurring IgM anti-A and anti-B antibodies which are capable of producing rapid and severe intravascular haemolysis of incompatible red cells.

The ABO system is under the control of a pair of allelic genes, H and h, and also three allelic genes, A, B, and O, producing the genotypes and phenotypes shown in Table 8.18. The A, B and H antigens are very similar in structure; differences in the terminal sugars determine their specificity. The H gene codes for enzyme H, which attaches fucose to the basic glycoprotein backbone to form H substance, which is the precursor for A and B antigens (Fig. 8.30).

The A and B genes control specific enzymes responsible for the addition to H substance of N-acetylgalactosamine for Group A and d-galactose for Group B. The O gene is amorphic and does not transform H substance and therefore O is not antigenic. The A, B and H antigens are present on most body cells. These antigens are also found in soluble form in tissue fluids such as saliva and gastric juice in the 80% of the population who possess secretor genes.

**Rh system**

There is a high frequency of development of IgG RhD antibodies in RhD-negative individuals after exposure to RhD-positive red cells. The antibodies formed cause HDN and haemolytic transfusion reactions.

This system is coded by allelic genes, C, c, E and e, D and no d, which is signified as c; they are inherited as triplets on each chromosome 1, one from each pair of genes (i.e. CDE/cde). RhD-negative individuals have no D protein in the red cell membrane which explains why it is so immunogenic. In Caucasians, the RhD-negative phenotype almost always results from a complete deletion of the RhD gene; in black Africans, it can also result from an inactive gene containing stop codons in the reading frame.

**PROCEDURE FOR BLOOD TRANSFUSION**

The safety of blood transfusion depends on meticulous attention to detail at each stage leading to and during the transfusion. Avoidance of simple errors involving patient and blood sample identification at the time of collection of the sample for compatibility testing and at the time of transfusion would avoid most serious haemolytic transfusion reactions, almost all of which involve the ABO system.

**Pretransfusion compatibility testing**

**Blood grouping**

The ABO and RhD groups of the patient are determined.

**Antibody screening**

The patient’s serum or plasma is screened for atypical antibodies that may cause a significant reduction in the survival of the transfused red cells. The patient’s serum or plasma is
tested against red cells from at least two group O donors, expressing a wide range of red cell antigens, for detection of IgM red cell alloantibodies (using a direct agglutination test of cells suspended in saline) and IgG antibodies (using an indirect antiglobulin test, see p. 415). About 10% of patients have a positive antibody screening result; in which case, further testing is carried out using a comprehensive panel of typed red cells to determine the blood group specificity of the antibody (clinically significant red cell antibodies are detected in about 20% of patients with positive antibody screens).

Selection of donor blood and crossmatching

Donor blood of the same ABO and RhD group as the patient is selected. Matching for additional blood groups is carried out for patients with clinically significant red cell antibodies (see below), for patients who are likely to be multitransfused and at high risk of developing antibodies, e.g. sickle cell disease, and many centres routinely provide c-negative and Kell-negative blood for women of child-bearing age to minimize the risk of alloimmunization and subsequent HDN.

Crossmatching procedures

Patients without atypical red cell antibodies. The full crossmatch involves testing the patient’s serum or plasma against the donor red cells suspended in saline in a direct agglutination test, and also using an indirect antiglobulin test. In many hospitals this serological crossmatch has been omitted as the negative antibody screen makes it highly unlikely that there will be any incompatibility with the donor units. A greater risk is that of a transfusion error involving the collection of the patient sample or a mix-up of samples in the laboratory. Laboratories can use their information system to check the records of the patient and authorize the release of the donor units if a number of criteria are met (computer or electronic crossmatching), including:

- The system is automated for ABO and RhD grouping and antibody screening including positive sample identification and electronic transfer of results.
- The antibody screening procedure conforms to national recommendations.
- The patient’s serum or plasma does not contain clinically significant red cell antibodies.
- The release of ABO incompatible blood must be prevented by conformation of laboratory computer software to the following requirements:
  (a) the issue of blood is not allowed if the patient has only been grouped once
  (b) the issue of blood is not allowed if the current group does not match the historical record
  (c) the system must not allow the reservation and release of units which are ABO incompatible with the patient.
- The laboratory must assure the validity of the ABO and RhD group of the donor blood either by written verification from the Blood Service supplying the donor units or confirmatory testing in the laboratory; the UK Blood Transfusion Services guarantee that the blood group information is correct.

Alternatively, the crossmatch can be shortened to an ‘immediate spin crossmatch’ where the patient’s serum or plasma is briefly incubated with the donor red cells, followed by centrifugation and examination for agglutination; this rapid crossmatch is an acceptable method of excluding ABO incompatibility in patients known to have a negative antibody screen.

Patients with atypical red cell antibodies. Donor blood should be selected that lacks the relevant red cell antigen(s), as well as being the same ABO and RhD group as the patient. A full crossmatch should always be carried out.

Several other systems for blood grouping, antibody screening and crossmatching are available to hospital transfusion laboratories. They do not depend on agglutination of red cells in suspension, but rather on the differential passage of agglutinated and unagglutinated red cells through a column of dextran gel matrix (e.g. DiaMed and Ortho Biouva systems), or on the capture of antibodies by red cells immobilized on the surface of a microplate well (e.g. Capture-R solid phase system).

Blood ordering

Elective surgery

Many hospitals have guidelines for the ordering of blood for elective surgery (maximum surgical blood ordering schedules). These are aimed at reducing unnecessary crossmatching and the amount of blood that eventually becomes outdated. Many operations in which blood is required only occasionally for unexpectedly high blood loss can be classified as ‘group and save’; this means that, where the antibody screen is negative, blood is not reserved in advance but can be made available quickly if necessary, i.e. in a few minutes, using the immediate spin or electronic crossmatch procedures. If a patient has atypical antibodies, compatible blood should always be reserved in advance; this may take several days if the patient has multiple or unusual antibodies.

Emergencies

There may be insufficient time for full pretransfusion testing. The options include:

- Blood required immediately – use of 2 units of O RhD negative blood (‘emergency stock’), to allow additional time for the laboratory to group the patient.
- Blood required in 10–15 minutes – use of blood of the same ABO and RhD groups as the patient (‘group compatible blood’).
- Blood required in 45 minutes – most laboratories will be able to provide fully crossmatched blood within this time.

COMPLICATIONS OF BLOOD TRANSFUSION (Table 8.19)

In the USA, it has been mandatory to report transfusion-associated deaths to the Food and Drug Administration since 1975; such reports have provided useful data which have contributed to efforts to improve the safety of blood transfusion. Similar reporting schemes under the term ‘haemovigilance’ have been set up in other countries, including the Serious Hazards of Transfusion (SHOT) scheme which produced its first report in the UK in 1997. Figure 8.31 shows the reports to SHOT up to 2005, indicating that ‘incorrect blood component transfused’ is the most frequent type of
serious incident. Errors at the time of collection of blood from the fridge and/or the administration of blood (53%) were the commonest source of error in 2005, followed by laboratory errors (43%) and mistakes in the collection of blood samples for compatibility testing (5%). Death or serious morbidity can also be attributed to other complications of blood transfusion including transfusion-associated lung injury (TRALI), transfusion-associated graft-versus-host disease (TA-GvHD) and bacterial infection of blood components.

Prevention

The serious consequences of such failures emphasize the need for meticulous checks at all stages in the procedure of blood transfusion. Written procedures and good training of staff is essential. Regular audit to ensure compliance with these procedures is also required. New approaches are also being used including the use of barcode patient identification and new technology at the bedside. Handheld devices can be used to prompt staff through the key steps and check that the barcode on the patient’s wristband matches the barcode on the unit of blood (Fig. 8.32).

Immunological complications

Alloimmunization

Blood transfusion carries a risk of alloimmunization to the many ‘foreign’ antigens present on red cells, leucocytes, platelets and plasma proteins. Alloimmunization also occurs during pregnancy – to fetal antigens inherited from the father and not shared by the mother (see p. 417).

Alloimmunization does not usually cause clinical problems with the first transfusion but these may occur with
subsequent transfusions. There may also be delayed consequences of alloimmunization, such as HDN and rejection of tissue transplants.

Incompatibility
